Total T_4 (Reference Range 55–150 nmol/L) and T_3 (Reference Range 1.5–3.5 nmol/L) Total T_4 and T_3 levels are measured by radioimmunoassay and measure both the free and bound components of the hormones. Total T_4 levels reflect the output from the thyroid gland, whereas T_3 levels in the nonstimulated thyroid gland are more indicative of peripheral thyroid hormone metabolism, and are, therefore, not generally suitable as a general screening test. Total T_4 levels are increased not only in hyperthyroid patients, but also in those with elevated Tg levels secondary to pregnancy, estrogen/progesterone use, or congenital diseases. Similarly, total T_4 levels decrease in hypothyroidism and in patients with decreased Tg levels due to anabolic steroid use and protein-losing disorders like nephrotic syndrome. Individuals with these latter disorders may be euthyroid if their free T_4 levels are normal. Measurement of total T_3 levels is important in clinically hyperthyroid patients with normal T_4 levels, who may have T_3 thyrotoxicosis. As discussed previously in Thyroid Hormone Synthesis, Secretion, and Transport, total T_3 levels often are increased in early hypothyroidism.

Free T_4 (Reference Range 12–28 pmol/L) and Free T_3 (3–9 pmol/L) These radioimmunoassay-based tests are a sensitive and accurate measurement of biologically active thyroid hormone. Free T_4 estimates are not performed as a routine screening tool in thyroid disease. Use of this test is confined to cases of early hyperthyroidism in which total T_4 levels may be normal but free T_4 levels are raised. In patients with end-organ resistance to T_4 (Refetoff's syndrome), T_4 levels are increased, but TSH levels usually are normal. Free T_3 is most useful in confirming the diagnosis of early hyperthyroidism, in which levels of free T_4 and free T_3 rise before total T_4 and T_3. Free T_4 levels may also be measured indirectly using the T_3-resin uptake test. If free T_4 levels are increased, fewer hormone binding sites are available for binding radiolabeled T_3 that has been added to the patient's serum. Therefore, more T_3 binds with an ion-exchange resin, and the T_3-resin uptake is increased.

Thyrotropin-Releasing Hormone This test is useful to evaluate pituitary TSH secretory function and is performed by administering 500 μg of TRH intravenously and measuring TSH levels after 30 and 60 minutes. In a normal individual, TSH levels should increase at least 6 μIU/mL from the baseline. This test also was previously used to assess patients with borderline hyperthyroidism but has largely been replaced by sensitive TSH assays for this purpose.

Thyroid Antibodies Thyroid antibodies include anti-Tg, antimicrosomal, or anti-TPO and thyroid-stimulating immunoglobulin (TSI). Anti-Tg and anti-TPO antibody levels do not determine thyroid function, but rather indicate the underlying disorder, usually an autoimmune thyroiditis. About 80% of patients with Hashimoto's thyroiditis have elevated thyroid antibody levels; however, levels may also be increased in patients with Graves' disease, multinodular goiter, and occasionally, thyroid neoplasms.

Serum Thyroglobulin Tg is only made by normal or abnormal thyroid tissue. It normally is not released into the circulation in large amounts but increases dramatically in destructive processes of the thyroid gland, such as thyroiditis, or overactive states such as Graves' disease and toxic multinodular goiter. The most important use for serum Tg levels is in monitoring patients with differentiated thyroid cancer for recurrence, particularly after total thyroidectomy and RAI ablation. Elevated anti-Tg antibodies can interfere with the accuracy of serum Tg levels and should always be measured when interpreting Tg levels.

Serum Calcitonin (0–4 pg/mL Basal) This 32-amino-acid polypeptide is secreted by the C cells and functions to lower serum calcium levels, although in humans, it has only minimal physiologic effects. It is also a sensitive marker of MTC.

Thyroid Imaging

Radionuclide Imaging Both iodine-123 (^{123}I) and iodine-131 (^{131}I) are used to image the thyroid gland. The former emits low-dose radiation, has a half-life of 12 to 14 hours, and is used to image lingual thyroids or goiters. In contrast, ^{131}I has a half-life of 8 to 10 days and leads to higher-dose radiation exposure. Therefore, this isotope is used to screen and treat patients with differentiated thyroid cancers for metastatic disease. The images

Figure 38-10. Radioactive iodine scan of the thyroid, with the *arrow* showing an area of decreased uptake, a cold nodule.

obtained by these studies provide information not only about the size and shape of the gland, but also the distribution of functional activity. Areas that trap less radioactivity than the surrounding gland are termed *cold* (Fig. 38-10), whereas areas that demonstrate increased activity are termed *hot*. The risk of malignancy is higher in "cold" lesions (20%) compared to "hot" or "warm" lesions (<5%). Technetium Tc 99m pertechnetate (^{99m}Tc) is taken up by the thyroid gland and is increasingly being used for thyroid evaluation. This isotope is taken up by the mitochondria, but is not organified. It also has the advantage of having a shorter half-life and minimizes radiation exposure. It is particularly sensitive for nodal metastases. More recently, ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) combined with computed tomography (CT) is being increasingly used to screen for metastases in patients with thyroid cancer in whom other imaging studies are negative. PET scans are not routinely used in the evaluation of thyroid nodules; however, they may show clinically occult thyroid lesions. There are several recent reports of rates of malignancy in these lesions ranging from 14% to 63%. These incidentally discovered nodules should be worked up by ultrasound and fine-needle aspiration biopsy (FNAB).

Ultrasound Ultrasound is an excellent noninvasive and portable imaging study of the thyroid gland with the added advantage of no radiation exposure. It is helpful in the evaluation of thyroid nodules, distinguishing solid from cystic ones, and providing information about size and multicentricity. In addition, characteristics such as echotexture, shape, borders and presence of calcifications, and vascularity can provide useful information regarding risk of malignancy. Ultrasound is also especially helpful for assessing cervical lymphadenopathy (Fig. 38-11) and to guide FNAB. An experienced ultrasonographer is necessary for the best results.

Computed Tomography/Magnetic Resonance Imaging Scan CT and magnetic resonance imaging (MRI) studies provide excellent imaging of the thyroid gland and adjacent nodes and are particularly useful in evaluating the extent of large, fixed, or substernal goiters (which cannot be evaluated by ultrasound) and their relationship to the airway and vascular structures. Noncontrast CT scans should be obtained for patients who are likely to require subsequent RAI therapy. If contrast is necessary, therapy needs to be delayed by several months. Combined PET-CT scans are increasingly being used for Tg-positive, RAI-negative tumors.

Benign Thyroid Disorders

Hyperthyroidism. The clinical manifestations of hyperthyroidism result from an excess of circulating thyroid hormone. Hyperthyroidism may arise from a number of conditions that are listed in Table 38-1. It is important to distinguish disorders such as Graves' disease and toxic nodular goiters that result from increased production of thyroid hormone from those disorders that lead to a release of stored hormone from injury to the thyroid gland (thyroiditis) or from other nonthyroid gland–related conditions. The former disorders lead to an increase in RAI uptake (RAIU), whereas the latter group is characterized by low RAIU. Of these disorders, Graves' disease, toxic multinodular goiter, and solitary toxic nodule are most relevant to the surgeon.

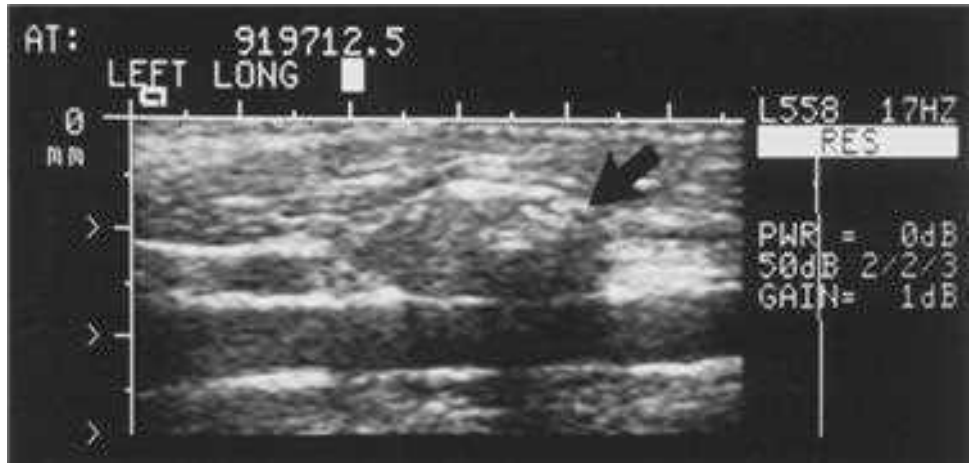

Figure 38-11. Thyroid ultrasound showing a lymph node (*arrow*) along the carotid artery.

Table 38-1

Differential diagnosis of hyperthyroidism

INCREASED HORMONE SYNTHESIS (INCREASED RAIU)	RELEASE OF PREFORMED HORMONE (DECREASED RAIU)
Graves' disease (diffuse toxic goiter)	Thyroiditis—acute phase of Hashimoto's thyroiditis, subacute thyroiditis
Toxic multinodular goiter	Factitious (iatrogenic) thyrotoxicosis
Toxic adenoma	"Hamburger thyrotoxicosis"
Drug induced—amiodarone, iodine	
Thyroid cancer	
Struma ovarii	
Hydatidiform mole	
TSH-secreting pituitary adenoma	

RAIU = radioactive iodine uptake; TSH = thyroid-stimulating hormone.

Diffuse Toxic Goiter (Graves' Disease) Although originally described by the Welsh physician Caleb Parry in a posthumous article in 1825, this disorder is known as Graves' disease after Robert Graves, an Irish physician who described three patients in 1835. Graves' disease is by far the most common cause of hyperthyroidism in North America, accounting for 60% to 80% of cases. It is an autoimmune disease with a strong familial predisposition, female preponderance (5:1), and peak incidence between the ages of 40 and 60 years. Graves' disease is characterized by thyrotoxicosis, diffuse goiter, and extrathyroidal conditions including ophthalmopathy, dermopathy (pretibial myxedema), thyroid acropachy, gynecomastia, and other manifestations.

Etiology, Pathogenesis, and Pathology. The exact etiology of the initiation of the autoimmune process in Graves' disease is not known. However, conditions such as the postpartum state, iodine excess, lithium therapy, and bacterial and viral infections have been suggested as possible triggers. Genetic factors also play a role, as haplotyping studies indicate that Graves' disease is associated with certain human leukocyte antigen (HLA) haplotypes, including HLA-B8, HLA-DR3, and HLADQA1*0501 in Caucasian patients, whereas HLA-DRB1*0701 is protective against it. Polymorphisms of the cytotoxic T-lymphocyte antigen 4 (*CTLA-4*) gene also have been associated with Graves' disease development.[3] Once initiated, the process causes sensitized T-helper lymphocytes to stimulate B lymphocytes, which produce antibodies directed against the thyroid hormone receptor. TSIs or antibodies that stimulate the TSH-R, as well as TSH-binding inhibiting immunoglobulins or antibodies, have been described. The thyroid-stimulating antibodies stimulate the thyrocytes to grow and synthesize excess thyroid hormone, which is a hallmark of Graves' disease. Graves' disease also is associated with other autoimmune conditions such as type 1 diabetes mellitus, Addison's disease, pernicious anemia, and myasthenia gravis.

Macroscopically, the thyroid gland in patients with Graves' disease is diffusely and smoothly enlarged, with a concomitant increase in vascularity. Microscopically, the gland is hyperplastic, and the epithelium is columnar with minimal colloid present. The nuclei exhibit mitosis, and papillary projections of hyperplastic epithelium are common. There may be aggregates of lymphoid tissue, and vascularity is markedly increased.

Clinical Features. The clinical manifestations of Graves' disease can be divided into those related to hyperthyroidism and those specific to Graves' disease. Hyperthyroid symptoms include heat intolerance, increased sweating and thirst, and weight loss despite adequate caloric intake. Symptoms of increased adrenergic stimulation include palpitations, nervousness, fatigue, emotional lability, hyperkinesis, and tremors. The most common GI symptoms include increased frequency of bowel movements and diarrhea. Female patients often develop amenorrhea, decreased fertility, and an increased incidence of miscarriages. Children experience rapid growth with early bone maturation, whereas older patients may present with cardiovascular complications such as atrial fibrillation and congestive heart failure.

On physical examination, weight loss and facial flushing may be evident. The skin is warm and moist, and African American patients often note darkening of their skin. Tachycardia or atrial fibrillation is present, with cutaneous vasodilation leading to a widening of the pulse pressure and a rapid falloff in the transmitted pulse wave (collapsing pulse). A fine tremor, muscle wasting, and proximal muscle group weakness with hyperactive tendon reflexes often are present.

Approximately 50% of patients with Graves' disease also develop clinically evident ophthalmopathy, and dermopathy occurs in 1% to 2% of patients. It is characterized by deposition of glycosaminoglycans, leading to thickened skin in the pretibial region and dorsum of the foot (Fig. 38-12). Eye symptoms include lid lag (von Graefe's sign), spasm of the upper eyelid revealing the sclera above the corneoscleral limbus (Dalrymple's sign), and a prominent stare, due to catecholamine excess. True infiltrative eye disease results in periorbital edema, conjunctival swelling and congestion (chemosis), proptosis, limitation of upward and lateral gaze (from involvement of the inferior and medial rectus muscles, respectively), keratitis, and even blindness due to optic nerve involvement. The etiology of Graves' ophthalmopathy is not completely known; however, orbital fibroblasts and muscles are thought to share a common antigen, the TSH-R. Ophthalmopathy is thought to result from inflammation caused by cytokines released from sensitized killer T lymphocytes and cytotoxic antibodies. Gynecomastia is common in young men. Rare bony involvement leads to subperiosteal bone formation and swelling in the metacarpals (thyroid acropachy). Onycholysis, or separation of fingernails from their beds, is a commonly observed finding. On physical examination, the thyroid usually is diffusely and symmetrically enlarged, as evidenced by an enlarged pyramidal lobe. There may be an overlying bruit or thrill over the thyroid gland and a loud venous hum in the supraclavicular space.

Diagnostic Tests. The diagnosis of hyperthyroidism is made by a suppressed TSH with or without an elevated free T_4 or T_3 level. If eye signs are present, other tests are generally not needed. However, in the absence of eye findings, an ^{123}I uptake and scan should be performed. An elevated uptake, with a diffusely enlarged gland, confirms the diagnosis of Graves' disease and helps to differentiate it from other causes of hyperthyroidism. Technetium scintigraphy (using pertechnetate, which is trapped by the thyroid, but not organified) can also be used to determine etiology. While technetium scans results in low range of normal uptake and high background activity,

A

B

Figure 38-12. **A.** Graves' ophthalmopathy and (**B**) pretibial myxedema. This patient demonstrates exophthalmos, proptosis, periorbital swelling, congestion, and edema of the conjunctiva.

total-body radiation exposure is less than that of ^{123}I scans. If free T_4 levels are normal, free T_3 levels should be determined, as they often are elevated in early Graves' disease or toxic nodules (T_3 toxicosis). Anti-Tg and anti-TPO antibodies are elevated in up to 75% of patients but are not specific. Elevated TSH-R or thyroid-stimulating antibodies (TSAb) are diagnostic of Graves' disease and are increased in about 90% of patients. MRI scans of the orbits are useful in evaluating Graves' ophthalmopathy.

Treatment. Graves' disease may be treated by any of three treatment modalities: antithyroid drugs, thyroid ablation with radioactive ^{131}I, and thyroidectomy. The choice of treatment depends on several factors, as discussed in the following sections.

Antithyroid Drugs. Antithyroid medications generally are administered in preparation for RAI ablation or surgery. The drugs commonly used are propylthiouracil (PTU, 100 to 300 mg three times daily) and methimazole (10 to 30 mg three times daily, then once daily). Methimazole has a longer half-life and can be dosed once daily. Both drugs reduce thyroid hormone production by inhibiting the organic binding of iodine and the coupling of iodotyrosines (mediated by TPO). In addition, PTU also inhibits the peripheral conversion of T_4 to T_3, making it useful for the treatment of thyroid storm. Both drugs can cross the placenta, inhibiting fetal thyroid function, and are excreted in breast milk, although PTU has a lower risk of transplacental transfer. Methimazole also has been associated with congenital aplasia; therefore, PTU is preferred in pregnant and breastfeeding women. Side effects of treatment include reversible granulocytopenia, skin rashes, fever, peripheral neuritis, polyarteritis, vasculitis, hepatitis, and, rarely, agranulocytosis and aplastic anemia. Patients should be monitored for these possible complications and should always be warned to stop PTU or methimazole immediately and seek medical advice should they develop a sore throat or fever. Treatment of agranulocytosis involves admission to the hospital, discontinuation of the drug, and broad-spectrum antibiotic therapy. Surgery should be postponed until the granulocyte count reaches 1000 cells/mm^3.

The dose of antithyroid medication is titrated as needed in accordance with TSH and T_4 levels. Most patients have improved symptoms in 2 weeks and become euthyroid in about 6 weeks. Some physicians use the block-replace regimen, by adding T_4 (0.05 to 0.10 mg) to prevent hypothyroidism and suppress TSH secretion, because some, but not all, studies suggest that this reduces recurrence rates. The length of therapy is debated. Treatment with antithyroid medications is associated with a high relapse rate when these drugs are discontinued, with 40% to 80% of patients developing recurrent disease after a 1- to 2-year course. Patients with small glands are less likely to recur so that treatment for curative intent is reserved for patients with (a) small, nontoxic goiters less than 40 g; (b) mildly elevated thyroid hormone levels; (c) negative or low or titers of thyroid hormone receptor antibodies; and (d) rapid decrease in gland size with antithyroid medications. The catecholamine response of thyrotoxicosis can be alleviated by administering β-blocking agents. β-Blockade should be considered in all patients with symptomatic thyrotoxicosis and is recommended for elderly patients, those with coexistent cardiac disease, and patients with resting heart rates >90 bpm. These drugs have the added effect of decreasing the peripheral conversion of T_4 to T_3. Propranolol is the most commonly prescribed medication in doses of about 20 to 40 mg four times daily. Higher doses are sometimes required due to increased clearance of the medication. Caution should be exercised in patients with asthma. Calcium channel blockers are useful for rate control in patients in whom β-blockers are contraindicated.

Radioactive Iodine Therapy (^{131}I). RAI forms the mainstay of Graves' disease treatment in North America. The major advantages of this treatment are the avoidance of a surgical procedure and its concomitant risks, reduced overall treatment costs, and ease of treatment. Antithyroid drugs are given until the patient

is euthyroid and then discontinued to maximize drug uptake. The ^{131}I dose is calculated after a preliminary scan and usually consists of 8 to 12 mCi administered orally. After standard treatment with RAI, most patients become euthyroid within 2 months. However, only about 50% of patients treated with RAI are euthyroid 6 months after treatment, and the remaining are still hyperthyroid or already hypothyroid.[4] After 1 year, about 2.5% of patients develop hypothyroidism each year. RAI also has been documented to lead to progression of Graves' ophthalmopathy (33% after RAI compared to 16% after surgery), and ophthalmopathy is more common in smokers. Although there is no evidence of long-term problems with infertility, and overall cancer incidence rates are unchanged, there is a small increased risk of nodular goiter, thyroid cancer,[5] and hyperparathyroidism (HPT)[6] in patients who have been treated with RAI. Patients treated with RAI have an unexplained increase in their overall and cardiovascular mortality rates when compared to the general population.

RAI therapy is therefore most often used in older patients with small or moderate-sized goiters, those who have relapsed after medical or surgical therapy, and those in whom antithyroid drugs or surgery are contraindicated. Absolute contraindications to RAI include women who are pregnant (or planning pregnancy within 6 months of treatment) or breastfeeding. Relative contraindications include young patients (i.e., especially children and adolescents), those with thyroid nodules, and those with ophthalmopathy. Lack of access to a high-volume thyroid surgeon is also a consideration. The higher the initial dose of ^{131}I, the earlier the onset and the higher the incidence of hypothyroidism.

Surgical Treatment. In North America, surgery is recommended when RAI is contraindicated as in patients who (a) have confirmed cancer or suspicious thyroid nodules, (b) are young, (c) desire to conceive soon (<6 months) after treatment, (d) have had severe reactions to antithyroid medications, (e) have large goiters (>80 g) causing compressive symptoms, and (f) are reluctant to undergo RAI therapy. Relative indications for thyroidectomy include patients, particularly smokers, with moderate to severe Graves' ophthalmopathy, those desiring rapid control of hyperthyroidism with a chance of being euthyroid, and those demonstrating poor compliance to antithyroid medications. Pregnancy is also a relative contraindication, and surgery should be used only when rapid control is needed and antithyroid medications cannot be used. Surgery is best performed in the second trimester. The goal of thyroidectomy for Graves' disease should be the complete and permanent control of the disease with minimal morbidity. Patients should be rendered euthyroid before operation with antithyroid drugs that should be continued up to the day of surgery. Lugol's iodide solution or saturated potassium iodide generally is administered beginning 7 to 10 days preoperatively (three drops twice daily) to reduce vascularity of the gland and decrease the risk of precipitating thyroid storm. The major action of iodine in this situation is to inhibit release of thyroid hormone. If it is not possible to render the patient euthyroid prior to surgery (if the surgery is urgent or the patient is allergic to antithyroid medications), the patient can be prepared with β-blockade and potassium iodide alone. Steroids can be a useful adjunct in this situation.

The extent of thyroidectomy to be performed used to be determined by the desired outcome (risk of recurrence vs. euthyroidism) and surgeon experience. In patients with coexistent thyroid cancer and those who refused RAI therapy or had severe ophthalmopathy or life-threatening reactions to antithyroid medications (vasculitis, agranulocytosis, or liver failure), total or near-total thyroidectomy was recommended. Ophthalmopathy has been demonstrated to stabilize or improve in most patients after total thyroidectomy, presumably from removal of the antigenic stimulus. A subtotal thyroidectomy, leaving a 4- to 7-g remnant, was recommended for all remaining patients. During subtotal thyroidectomy, remnant tissue may be left on each side (bilateral subtotal thyroidectomy), or a total lobectomy can be performed on one side with a subtotal thyroidectomy on the other side (Hartley-Dunhill procedure). Results were similar with either procedure,[7] but the latter procedure was theoretically associated with fewer complications and requires re-entering only one side of the neck should recurrence require reoperation. Most studies, however, show no difference in the rates of complications with either approach, although patients undergoing a total resection had higher rates of temporary hypoparathyroidism. However, patients treated with subtotal thyroidectomy are prone to recurrence, the rates of which are dependent on remnant size. Based on the current evidence, recently published guidelines from the American Thyroid Association (ATA) and the American Association of Clinical Endocrinologists (AACE) recommend total or near-total thyroidectomy as the procedure of choice for the surgical management of Graves' disease.[8] Recurrent thyrotoxicosis usually is managed by radioiodine treatment.

1▶

Toxic Multinodular Goiter Toxic multinodular goiters usually occur in older individuals, who often have a prior history of a nontoxic multinodular goiter. Over several years, enough thyroid nodules become autonomous to cause hyperthyroidism. The presentation often is insidious in that hyperthyroidism may only become apparent when patients are placed on low doses of thyroid hormone suppression for the goiter. Some patients have T_3 toxicosis, whereas others may present only with atrial fibrillation or congestive heart failure. Hyperthyroidism also can be precipitated by iodide-containing drugs such as contrast media and the antiarrhythmic agent amiodarone (Jod-Basedow hyperthyroidism). Symptoms and signs of hyperthyroidism are similar to Graves' disease, but extrathyroidal manifestations are absent.

Diagnostic Studies. Blood tests are similar to Graves' disease with a suppressed TSH level and elevated free T_4 or T_3 levels. RAI uptake also is increased, showing multiple nodules with increased uptake and suppression of the remaining gland.

Treatment. Hyperthyroidism must be adequately controlled. Both RAI and surgical resection may be used for treatment. When surgery is performed, near-total or total thyroidectomy is recommended to avoid recurrence and the consequent increased complication rates with repeat surgery. Care must be taken in identifying the RLN, which may be found laterally on the thyroid (rather than posterior) or stretched anteriorly over a nodule. RAI therapy is reserved for elderly patients who represent very poor operative risks, provided there is no airway compression from the goiter and thyroid cancer is not a concern. However, because uptake is less than in Graves' disease, larger doses of RAI often are needed to treat the hyperthyroidism. Furthermore, RAI-induced thyroiditis has the potential to cause swelling and acute airway compromise and leaves the goiter intact, with the possibility of recurrent hyperthyroidism.

Toxic Adenoma Hyperthyroidism from a single hyperfunctioning nodule typically occurs in younger patients who note recent growth of a long-standing nodule along with the symptoms of hyperthyroidism. Toxic adenomas are characterized by somatic mutations in the TSH-R gene, although G-protein–stimulating

gene (*gsp*) mutations may occur also.[9] Most hyperfunctioning or autonomous thyroid nodules have attained a size of at least 3 cm before hyperthyroidism occurs. Physical examination usually reveals a solitary thyroid nodule without palpable thyroid tissue on the contralateral side. RAI scanning shows a "hot" nodule with suppression of the rest of the thyroid gland. These nodules are rarely malignant. Smaller nodules may be managed with antithyroid medications and RAI. Larger nodules can require higher doses, which can lead to hypothyroidism. Surgery (lobectomy and isthmusectomy) is preferred to treat young patients and those with larger nodules. Percutaneous ethanol injection (PEI) has been reported to have reasonable success rates but has not been directly compared with surgery.

Thyroid Storm Thyroid storm is a condition of hyperthyroidism accompanied by fever, central nervous system agitation or depression, and cardiovascular and GI dysfunction, including hepatic failure. The condition may be precipitated by abrupt cessation of antithyroid medications, infection, thyroid or nonthyroid surgery, and trauma in patients with untreated thyrotoxicosis. Occasionally, thyroid storm may result from amiodarone administration or exposure to iodinated contrast agents or following RAI therapy. This condition was previously associated with high mortality rates but can be appropriately managed in an intensive care unit setting. β-Blockers are given to reduce peripheral T_4 to T_3 conversion and decrease the hyperthyroid symptoms. Oxygen supplementation and hemodynamic support should be instituted. Nonaspirin compounds can be used to treat pyrexia, and Lugol's iodine or sodium ipodate (intravenously) should be administered to decrease iodine uptake and thyroid hormone secretion. PTU therapy blocks the formation of new thyroid hormone and reduces peripheral conversion of T_4 to T_3. Corticosteroids often are helpful to prevent adrenal exhaustion and block hepatic thyroid hormone conversion.

Hypothyroidism. Deficiency in circulating levels of thyroid hormone leads to hypothyroidism and, in neonates, to cretinism, which is characterized by neurologic impairment and mental retardation. Hypothyroidism also may occur in Pendred's syndrome (associated with deafness) and Turner's syndrome. Conditions that cause hypothyroidism are listed in Table 38-2.

Clinical Features Failure of thyroid gland development or function in utero leads to cretinism and characteristic facies similar to those of children with Down syndrome and dwarfism. Failure to thrive and severe mental retardation often are present. Immediate testing and treatment with thyroid hormone at birth can lessen the neurologic and intellectual deficits. Hypothyroidism developing in childhood or adolescence results in delayed development and may also lead to abdominal distention, umbilical hernia, and rectal prolapse. In adults, symptoms in general are nonspecific, including tiredness, weight gain, cold intolerance, constipation, and menorrhagia. Patients with severe hypothyroidism or myxedema develop characteristic facial features due to the deposition of glycosaminoglycans in the subcutaneous tissues, leading to facial and periorbital puffiness. The skin becomes rough and dry and often develops a yellowish hue from reduced conversion of carotene to vitamin A. Hair becomes dry and brittle, and severe hair loss may occur. There is also a characteristic loss of the outer two thirds of the eyebrows. An enlarged tongue may impair speech, which is already slowed, in keeping with the impairment of mental processes. Patients may also have nonspecific abdominal pain accompanied by distention and constipation. Libido and fertility are impaired in both sexes. Cardiovascular changes in hypothyroidism include bradycardia, cardiomegaly, pericardial effusion, reduced cardiac output, and pulmonary effusions. When hypothyroidism occurs as a result of pituitary failure, other features of hypopituitarism, such as pale, waxy skin; loss of body hair; and atrophic genitalia, may be present.

Laboratory Findings Hypothyroidism is characterized by low circulating levels of T_4 and T_3. Raised TSH levels are found in primary thyroid failure, whereas secondary hypothyroidism is characterized by low TSH levels that do not increase following TRH stimulation. Thyroid autoantibodies are highest in patients with autoimmune disease (Hashimoto's thyroiditis, Graves' disease) and may also be elevated in patients with nodular goiter and thyroid neoplasms. An electrocardiogram demonstrates decreased voltage with flattening or inversion of T waves.

Treatment T_4 is the treatment of choice and is administered in dosages varying from 50 to 200 μg per day, depending on the patient's size and condition. Starting doses of 100 μg of T_4 daily are well tolerated; however, elderly patients and those with coexisting heart disease and profound hypothyroidism should be started on a considerably lower dose such as 25 to 50 μg daily because of associated hypercholesterolemia and atherosclerosis. The dose can be slowly increased over weeks to months to attain a euthyroid state. A baseline electrocardiogram should always be obtained in patients with severe hypothyroidism before treatment. T_4 dosage is titrated against clinical response

Table 38-2

Causes of hypothyroidism

PRIMARY (INCREASED TSH LEVELS)	SECONDARY (DECREASED TSH LEVELS)	TERTIARY
Hashimoto's thyroiditis	Pituitary tumor	Hypothalamic insufficiency
RAI therapy for Graves' disease	Pituitary resection or ablation	Resistance to thyroid hormone
Postthyroidectomy		
Excessive iodine intake		
Subacute thyroiditis		
Medications: antithyroid drugs, lithium		
Rare: iodine deficiency, dyshormogenesis		

RAI = radioactive iodine; TSH = thyroid-stimulating hormone.

and TSH levels, which should return to normal. The management of patients with subclinical hypothyroidism (normal T_4, slightly raised TSH) is controversial. Some evidence suggests that patients with subclinical hypothyroidism and increased antithyroid antibody levels should be treated, because they will subsequently develop hypothyroidism. Patients who present with myxedema coma may require initial emergency treatment with large doses of IV T_4 (300 to 400 μg), with careful monitoring in an intensive care unit setting.

Thyroiditis. Thyroiditis usually is classified into acute, subacute, and chronic forms, each associated with a distinct clinical presentation and histology.

Acute (Suppurative) Thyroiditis The thyroid gland is inherently resistant to infection due to its extensive blood and lymphatic supply, high iodide content, and fibrous capsule. However, infectious agents can seed it (a) via the hematogenous or lymphatic route, (b) via direct spread from persistent pyriform sinus fistulae or thyroglossal duct cysts, (c) as a result of penetrating trauma to the thyroid gland, or (d) due to immunosuppression. *Streptococcus* and anaerobes account for about 70% of cases; however, other species also have been cultured.[10] Acute suppurative thyroiditis is more common in children and often is preceded by an upper respiratory tract infection or otitis media. It is characterized by severe neck pain radiating to the jaws or ear, fever, chills, odynophagia, and dysphonia. Complications such as systemic sepsis, tracheal or esophageal rupture, jugular vein thrombosis, laryngeal chondritis, and perichondritis or sympathetic trunk paralysis may also occur.

The diagnosis is established by leukocytosis on blood tests and FNAB for Gram's stain, culture, and cytology. CT scans may help to delineate the extent of infection and identify abscesses. A persistent pyriform sinus fistula should always be suspected in children with recurrent acute thyroiditis. The sensitivity of identification of fistulae in the acute setting is lowest for barium esophagography (50%) and best for direct endoscopy (100%), with CT scans being intermediate (80%). Both barium esophagogram and CT scans have improved sensitivity once the acute inflammation has resolved (100% and 83%, respectively), with CT being better at defining the accurate anatomic pathway and its relationship to the thyroid gland.[11] Treatment consists of parenteral antibiotics and drainage of abscesses. Thyroidectomy may be needed for persistent abscesses or failure of open drainage. Patients with pyriform sinus fistulae require complete resection of the sinus tract, including the area of the thyroid where the tract terminates, to prevent recurrence. Transnasal flexible fiberoptic laryngoscopy is being increasingly used to identify the internal opening of the pyriform sinus tract and may also allow electrocauterization of the tract, and success rates similar to open surgery have been reported.

Subacute Thyroiditis Subacute thyroiditis can occur in the painful or painless forms. Although the exact etiology is not known, painful thyroiditis is thought to be viral in origin or result from a postviral inflammatory response. Genetic predisposition may also play a role, as manifested by its strong association with the HLA-B35 haplotype. One model of pathogenesis suggests that viral or thyroid antigens, when presented by macrophages in the context of HLA-B35, stimulate cytotoxic T lymphocytes and damage thyroid follicular cells.

Painful thyroiditis most commonly occurs in 30- to 40-year-old women and is characterized by the sudden or gradual onset of neck pain, which may radiate toward the mandible or ear. History of a preceding upper respiratory tract infection often can be elicited. The gland is enlarged, exquisitely tender, and firm. The disorder classically progresses through four stages. An initial hyperthyroid phase, due to release of thyroid hormone, is followed by a second, euthyroid phase. The third phase, hypothyroidism, occurs in about 20% to 30% of patients and is followed by resolution and return to the euthyroid state in >90% of patients. A few patients develop recurrent disease.

In the early stages of the disease, TSH is decreased, and Tg, T_4, and T_3 levels are elevated due to the release of preformed thyroid hormone from destroyed follicles. The erythrocyte sedimentation rate is typically >100 mm/h. RAIU also is decreased (<2% at 24 hours), even in euthyroid patients, due to the release of thyroid hormones from destruction of the thyroid parenchyma. Painful thyroiditis is self-limited, and therefore, treatment is primarily symptomatic. Aspirin and other nonsteroidal anti-inflammatory drugs are used for pain relief, but steroids may be indicated in more severe cases. Short-term thyroid replacement may be needed and may shorten the duration of symptoms. Thyroidectomy is reserved for the rare patient who has a prolonged course not responsive to medical measures or for recurrent disease.

Painless thyroiditis is considered to be autoimmune in origin and may occur sporadically or in the postpartum period; the latter typically occurs at about 6 weeks after delivery in women with high TPO antibody titers in early pregnancy. This timing is thought to coincide with a decrease in the normal immune tolerance of pregnancy and consequent rebound elevation of antibody titers.

Painless thyroiditis also is more common in women and usually occurs between 30 and 60 years of age. Physical examination demonstrates a normal sized or minimally enlarged, slightly firm, nontender gland. Laboratory tests and RAIU are similar to those in painful thyroiditis, except for a normal erythrocyte sedimentation rate. The clinical course also parallels painful thyroiditis. Patients with symptoms may require β-blockers and thyroid hormone replacement. Thyroidectomy or RAI ablation is only indicated for the rare patient with recurrent, disabling episodes of thyroiditis.

Chronic Thyroiditis

Lymphocytic (Hashimoto's) Thyroiditis. Lymphocytic thyroiditis was first described by Hashimoto in 1912 as *struma lymphomatosa*—a transformation of thyroid tissue to lymphoid tissue. It is the most common inflammatory disorder of the thyroid and the leading cause of hypothyroidism.

Etiology, Pathogenesis, and Pathology. Hashimoto's thyroiditis is an autoimmune process that is thought to be initiated by the activation of $CD4^+$ T (helper) lymphocytes with specificity for thyroid antigens. Once activated, T cells can recruit cytotoxic $CD8^+$ T cells to the thyroid. Hypothyroidism results not only from the destruction of thyrocytes by cytotoxic T cells but also by autoantibodies, which lead to complement fixation and killing by natural killer cells or block the TSH-R. Antibodies are directed against three main antigens—Tg (60%), TPO (95%), and TSH-R (60%)—and, less commonly, the sodium/iodine symporter (25%). Apoptosis (programmed cell death) also has been implicated in the pathogenesis of Hashimoto's thyroiditis. Chronic thyroiditis also has been associated with increased intake of iodine and administration of medications such as interferon-α, lithium, and amiodarone. Support for an inherited predisposition includes an increased incidence of thyroid

autoantibodies in first-degree relatives of patients with Hashimoto's thyroiditis compared to controls and the occurrence of the autoantibodies and hypothyroidism in patients with specific chromosomal abnormalities such as Turner's syndrome and Down syndrome. Associations with HLA-B8, DR3, and DR5 haplotypes of the major histocompatibility complex also have been described.

On gross examination, the thyroid gland is usually mildly enlarged throughout and has a pale, gray-tan cut surface that is granular, nodular, and firm. On microscopic examination, the gland is diffusely infiltrated by small lymphocytes and plasma cells and occasionally shows well-developed germinal centers. Thyroid follicles are smaller than normal with reduced amounts of colloid and increased interstitial connective tissue. The follicles are lined by Hürthle or Askanazy cells, which are characterized by abundant eosinophilic, granular cytoplasm.

Clinical Presentation. Hashimoto's thyroiditis is also more common in women (male:female ratio 1:10 to 20) between the ages of 30 and 50 years old. The most common presentation is that of a minimally or moderately enlarged firm granular gland discovered on routine physical examination or the awareness of a painless anterior neck mass, although 20% of patients present with hypothyroidism, and 5% present with hyperthyroidism (Hashitoxicosis). In classic goitrous Hashimoto's thyroiditis, physical examination reveals a diffusely enlarged, firm gland, which also is lobulated. An enlarged pyramidal lobe often is palpable.

Diagnostic Studies. When Hashimoto's thyroiditis is suspected clinically, an elevated TSH and the presence of thyroid autoantibodies usually confirm the diagnosis. FNAB with ultrasound guidance is indicated in patients who present with a solitary suspicious nodule or a rapidly enlarging goiter. Thyroid lymphoma is a rare but well-recognized, ominous complication of chronic autoimmune thyroiditis and has a prevalence 80 times higher than expected frequency in this population than in a control population without thyroiditis. Recent studies of clonal similarity indicate that lymphoma may, in fact, evolve from Hashimoto's thyroiditis.[12]

Treatment. Thyroid hormone replacement therapy is indicated in overtly hypothyroid patients, with a goal of maintaining normal TSH levels. The management of patients with subclinical hypothyroidism (normal T_4 and elevated TSH) is controversial. A systematic review of cohort studies showed that in age- and sex-adjusted analyses, subclinical hypothyroidism is associated with a hazard ratio (HR) for coronary heart disease events of 1.89 (95% confidence interval [CI], 1.28 to 2.80; P <.001) and coronary heart disease mortality of 1.58 (95% CI, 1.10 to 2.27; P = .005) for a TSH level of 10 to 19.9 mIU/L.[13] The data for TSH levels of 5 to 10 mIU/L were less convincing. An evaluation of the 12 randomized controlled trials in this area only showed a trend toward improvement of some lipid parameters, and none of the included trials evaluated overall mortality or cardiac morbidity. Given the above, levothyroxine is recommended for all patients with TSH levels >10 µIU/mL and patients with levels of 5 to 10 µIU/mL in the presence of a goiter or anti-TPO antibodies. Treatment is also advised especially for middle-aged patients with cardiovascular risk factors such as hyperlipidemia or hypertension and in pregnant patients. Surgery may occasionally be indicated for suspicion of malignancy or for goiters causing compressive symptoms or cosmetic deformity.

Riedel's Thyroiditis Riedel's thyroiditis is a rare variant of thyroiditis also known as *Riedel's struma* or *invasive fibrous thyroiditis* that is characterized by the replacement of all or part of the thyroid parenchyma by fibrous tissue, which also invades into adjacent tissues. The etiology of this disorder is controversial, and it has been reported to occur in patients with other autoimmune diseases. This association, coupled with the presence of lymphoid infiltration and response to steroid therapy, suggests a primary autoimmune etiology. Riedel's thyroiditis also is associated with other focal sclerosing syndromes including mediastinal, retroperitoneal, periorbital, and retro-orbital fibrosis and sclerosing cholangitis, suggesting that it may, in fact, be a primary fibrotic disorder. The disease occurs predominantly in women between the ages of 30 and 60 years old. It typically presents as a painless, hard anterior neck mass, which progresses over weeks to years to produce symptoms of compression, including dysphagia, dyspnea, choking, and hoarseness. Patients may present with symptoms of hypothyroidism and hypoparathyroidism as the gland is replaced by fibrous tissue. Physical examination reveals a hard, "woody" thyroid gland with fixation to surrounding tissues. The diagnosis needs to be confirmed by open thyroid biopsy, because the firm and fibrous nature of the gland renders FNAB inadequate.

Surgery is the mainstay of the treatment. The chief goal of operation is to decompress the trachea by wedge excision of the thyroid isthmus and to make a tissue diagnosis. More extensive resections are not advised due to the infiltrative nature of the fibrotic process that obscures usual landmarks and structures. Hypothyroid patients are treated with thyroid hormone replacement. Some patients who remain symptomatic have been reported to experience dramatic improvement after treatment with corticosteroids and tamoxifen. More recently mycophenolate mofetil has been used to attenuate the inflammatory process and led to dramatic symptom improvements in some patients.[14]

Goiter. Any enlargement of the thyroid gland is referred to as a goiter. The causes of nontoxic goiters are listed in Table 38-3. Goiters may be diffuse, uninodular, or multinodular. Most nontoxic goiters are thought to result from TSH stimulation secondary to inadequate thyroid hormone synthesis and other paracrine growth factors.[15] Elevated TSH levels induce diffuse thyroid hyperplasia, followed by focal hyperplasia, resulting in nodules that may or may not concentrate iodine, colloid nodules, or microfollicular nodules. The TSH-dependent nodules progress to become autonomous. Familial goiters resulting from inherited deficiencies in enzymes necessary for thyroid hormone synthesis may be complete or partial. The term *endemic goiter*

Table 38-3

Etiology of nontoxic goiter

CLASSIFICATION	SPECIFIC ETIOLOGY
Endemic	Iodine deficiency, dietary goitrogens (cassava, cabbage)
Medications	Iodide, amiodarone, lithium
Thyroiditis	Subacute, chronic (Hashimoto's)
Familial	Impaired hormone synthesis from enzyme defects
Neoplasm	Adenoma, carcinoma
Resistance to thyroid hormone	—

refers to the occurrence of a goiter in a significant proportion of individuals in a particular geographic region. In the past, dietary iodine deficiency was the most common cause of endemic goiter. This condition has largely disappeared in North America due to routine use of iodized salt and iodination of fertilizers, animal feeds, and preservatives. However, in areas of iodine deficiency, such as Central Asia, South America, and Indonesia, up to 90% of the population have goiters. Other dietary goitrogens that may participate in endemic goiter formation include kelp, cassava, and cabbage. In many sporadic goiters, no obvious cause can be identified.

Clinical Features Most patients with nontoxic goiters are asymptomatic, although patients often complain of a pressure sensation in the neck. As the goiters become very large, compressive symptoms such as dyspnea and dysphagia ensue. Patients also describe having to clear their throats frequently (catarrh). Dysphonia from RLN injury is rare, except when malignancy is present. Obstruction of venous return at the thoracic inlet from a substernal goiter results in a positive Pemberton's sign—facial flushing and dilatation of cervical veins upon raising the arms above the head (Fig. 38-13A). Sudden enlargement of nodules or cysts due to hemorrhage may cause acute pain. Physical examination may reveal a soft, diffusely enlarged gland (simple goiter) or nodules of various size and consistency in case of a multinodular goiter. Deviation or compression of the trachea may be apparent.

Diagnostic Tests Patients usually are euthyroid with normal TSH and low-normal or normal free T_4 levels. If some nodules develop autonomy, patients have suppressed TSH levels or become hyperthyroid. RAI uptake often shows patchy uptake with areas of hot and cold nodules. FNAB is recommended in patients who have a dominant nodule or one that is painful or enlarging, as carcinomas have been reported in 5% to 10% of multinodular goiters. CT scans are helpful to evaluate the extent of retrosternal extension and airway compression (Fig. 38-13B).

Treatment Most euthyroid patients with small, diffuse goiters do not require treatment. Some physicians give patients with large goiters exogenous thyroid hormone to reduce the TSH stimulation of gland growth; this treatment may result in decrease and/or stabilization of goiter size and is most effective for small diffuse goiters. Endemic goiters are treated by iodine administration. Surgical resection is reserved for goiters that (a) continue to increase despite T_4 suppression, (b) cause obstructive symptoms, (c) have substernal extension, (d) have malignancy suspected or proven by FNAB, and (e) are cosmetically unacceptable. Near-total or total thyroidectomy is the treatment of choice, and patients require lifelong T_4 therapy.

Solitary Thyroid Nodule

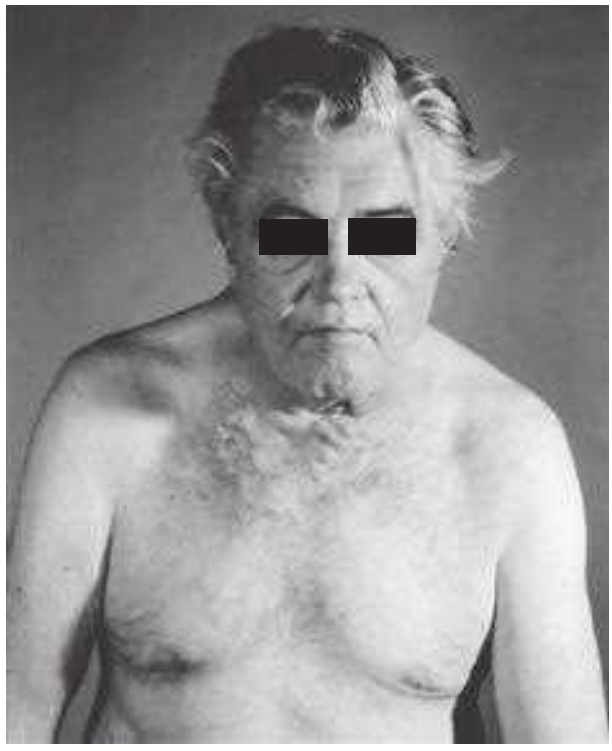
Solitary thyroid nodules are present in approximately 4% of individuals in the United States, whereas thyroid cancer has a much lower incidence of 40 new cases per 1 million. Therefore, it is of utmost importance to determine which patients with solitary thyroid nodule would benefit from surgery.

History. Details regarding the nodule, such as time of onset, change in size, and associated symptoms such as pain, dysphagia, dyspnea, or choking, should be elicited. Pain is an unusual symptom and, when present, should raise suspicion for intrathyroidal hemorrhage in a benign nodule, thyroiditis, or malignancy. Patients with MTC may complain of a dull, aching sensation. A history of hoarseness is worrisome, as it may be secondary to malignant involvement of the RLNs. Most importantly, patients should be questioned regarding risk factors for malignancy, such as exposure to ionizing radiation and family history of thyroid and other malignancies associated with thyroid cancer.

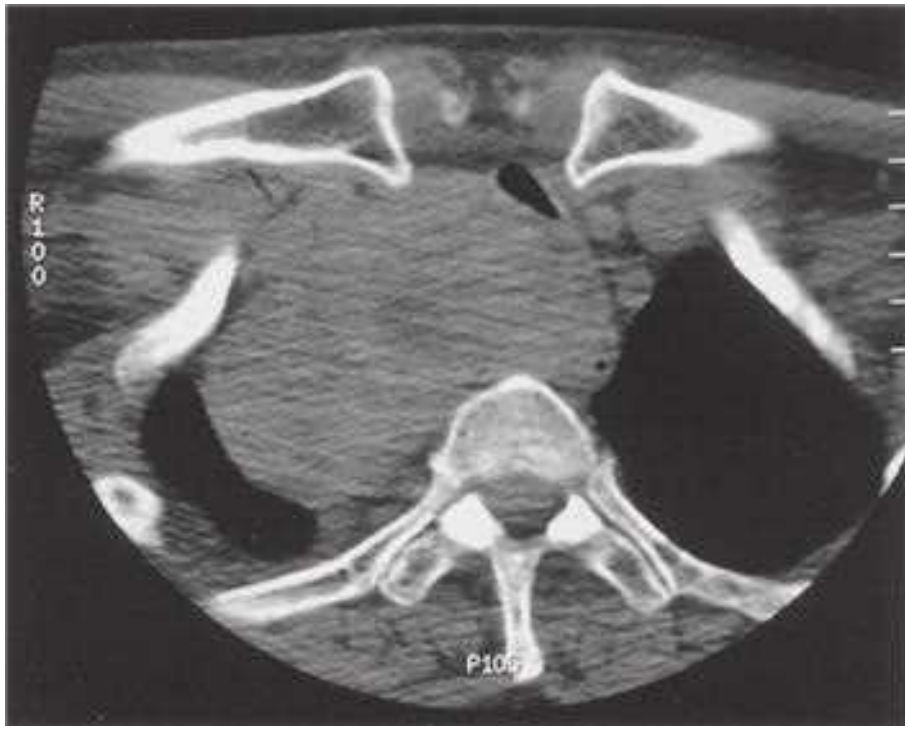
External-Beam Radiation Low-dose therapeutic radiation has been used to treat conditions such as tinea capitis (6.5 cGy), thymic enlargement (100 to 400 cGy), enlarged tonsils and adenoids (750 cGy), acne vulgaris (200 to 1500 cGy), and other conditions such as hemangioma and scrofula. Radiation (approximately 4000 cGy) is also an integral part of the management of patients with Hodgkin's disease. It is now known that a history of exposure to low-dose ionizing radiation to the thyroid gland places the patient at increased risk for developing thyroid cancer. The risk increases linearly from 6.5 to 2000 cGy, beyond which the incidence declines as the radiation causes destruction of the thyroid tissue. The risk is maximum 20 to 30 years after exposure, but these patients require lifelong monitoring. During the nuclear fallout from Chernobyl in 1986, ^{131}I release was accompanied by a marked increase in the incidence of both benign and malignant thyroid lesions noted within 4 years of exposure, particularly in children.[16] Most thyroid carcinomas following radiation exposure are papillary, and some of these cancers with a solid type of histology and presence of *RET/PTC* translocations appear to be more aggressive. In general, there is a 40% chance that patients presenting with a thyroid nodule and a history of radiation have thyroid cancer. Of those patients who have thyroid cancer, the cancer is located in the dominant nodule in 60% of patients, but in the remaining 40% of patients, the cancer is in another nodule in the thyroid gland.

Family History A family history of thyroid cancer is a risk factor for the development of both medullary and nonmedullary thyroid cancer. Familial MTCs occur in isolation or in association with other tumors as part of multiple endocrine neoplasia type 2 (MEN2) syndromes. Nonmedullary thyroid cancers can occur in association with other known familial cancer syndromes such as Cowden's syndrome, Werner's syndrome (adult progeroid syndrome), and familial adenomatous polyposis (Table 38-4). Nonmedullary thyroid cancers can also occur independently of these syndromes as the predominant tumors in the families. The definition of familial nonmedullary thyroid cancer (FNMTC) is variable across the literature; however, in most studies, it is defined by the presence of two or more first-degree relatives with follicular cell–derived cancers. FNMTC is now recognized as a distinct clinical entity associated with a high incidence of multifocal tumors and benign thyroid nodules. 2▶ Some studies report that these patients have higher locoregional recurrence rates and consequent shorter disease-free survival. Several candidate loci that predispose to these tumors have been identified, including MNG1 (14q32), thyroid carcinoma with oxphilia (TCO, on 19p13.2), fPTC/papillary renal neoplasia (PRN, on 1q21), NMTC (2q21), FTEN (8p23.1-p22), and the telomere-telomerase complex.[17]

Physical Examination. The thyroid gland is best palpated from behind the patient and with the neck in mild extension. The cricoid cartilage is an important landmark, as the isthmus is situated just below it. Nodules that are hard, gritty, or fixed to surrounding structures such as the trachea or strap muscles are more likely to be malignant. The cervical chain of lymph nodes should be assessed as well as the nodes in the posterior triangle.



A



B

Figure 38-13. **A.** Retrosternal extension of a large goiter may result in impeded flow in the superior vena cava, leading to dilated veins over the chest wall. This may become more prominent when patients raise their arms above the head—Pemberton's sign. **B.** Computed tomography scan demonstrating retrosternal extension and consequent tracheal deviation and compression from a large goiter.

Diagnostic Investigations. An algorithm for the workup of a solitary thyroid nodule is shown in Fig. 38-14.

Fine-Needle Aspiration Biopsy FNAB has become the single most important test in the evaluation of thyroid masses and can be performed with or without ultrasound guidance.[18] Ultrasound guidance is recommended for nodules that are difficult to palpate, for cystic or solid-cystic nodules that recur after the initial aspiration, and for multinodular goiters. A 23-gauge needle is inserted into the thyroid mass, and several passes are made while aspirating the syringe. After releasing the suction on the syringe, the needle is withdrawn and the cells are immediately placed on

Table 38-4

Familial cancer syndromes involving nonmedullary thyroid cancer

SYNDROME	GENE	MANIFESTATION	THYROID TUMOR
Cowden's syndrome	*PTEN*	Intestinal hamartomas, benign and malignant breast tumors	FTC, rarely PTC and Hürthle cell tumors
FAP	*APC*	Colon polyps and cancer, duodenal neoplasms, desmoids	PTC cribriform growth pattern
Werner's syndrome	*WRN*	Adult progeroid syndrome	PTC, FTC, anaplastic cancer
Carney complex type 1	*PRKAR1α*	Cutaneous and cardiac myxomas, breast and adrenal tumors	PTC, FTC
McCune-Albright syndrome	*GNAS1*	Polyostotic fibrous dysplasia, endocrine abnormalities, café-au-lait spots	PTC clear cell

FAP = familial adenomatous polyposis; FTC = follicular thyroid cancer; PTC = papillary thyroid cancer.

prelabeled dry glass slides; some are immersed in a 70% alcohol solution while others are air dried. A sample of the aspirate is also placed in a 90% alcohol solution for cytospin or cell pellet. The slides are stained by Papanicolaou's or Wright's stains and examined under the microscope. If a bloody aspirate is obtained, the patient should be repositioned in a more upright position and the biopsy repeated with a finer (25- to 30-gauge) needle.

After FNAB, the majority of nodules can be classified into several categories that determine further management. To address the issue of variability in the terminology of fine-needle aspiration (FNA), the National Cancer Institute (NCI) hosted the "NCI Thyroid Fine Needle Aspiration State of the Science Conference," which then defined the Bethesda criteria for thyroid FNA.[19] Accordingly, optimum cytology specimens should have at least six follicles each containing at least 10 to 15 cells from at least two aspirates.

3▶

The FNA is classified as "nondiagnostic or unsatisfactory" in 2% to 20% of cases and typically results from a virtually acellular specimen, cyst fluid, or the presence of blood or clotting artifact. The risk of malignancy in this setting ranges from 1% to 4%, and reaspiration under ultrasound guidance is recommended. A "benign" result is obtained in 60% to 70% of thyroid FNAs. The most common lesion in this setting is a follicular nodule (includes adenomatoid nodule, colloid nodule, and follicular adenoma). Other diagnoses include lymphocytic (Hashimoto's) thyroiditis and granulomatous thyroiditis. False-negative results

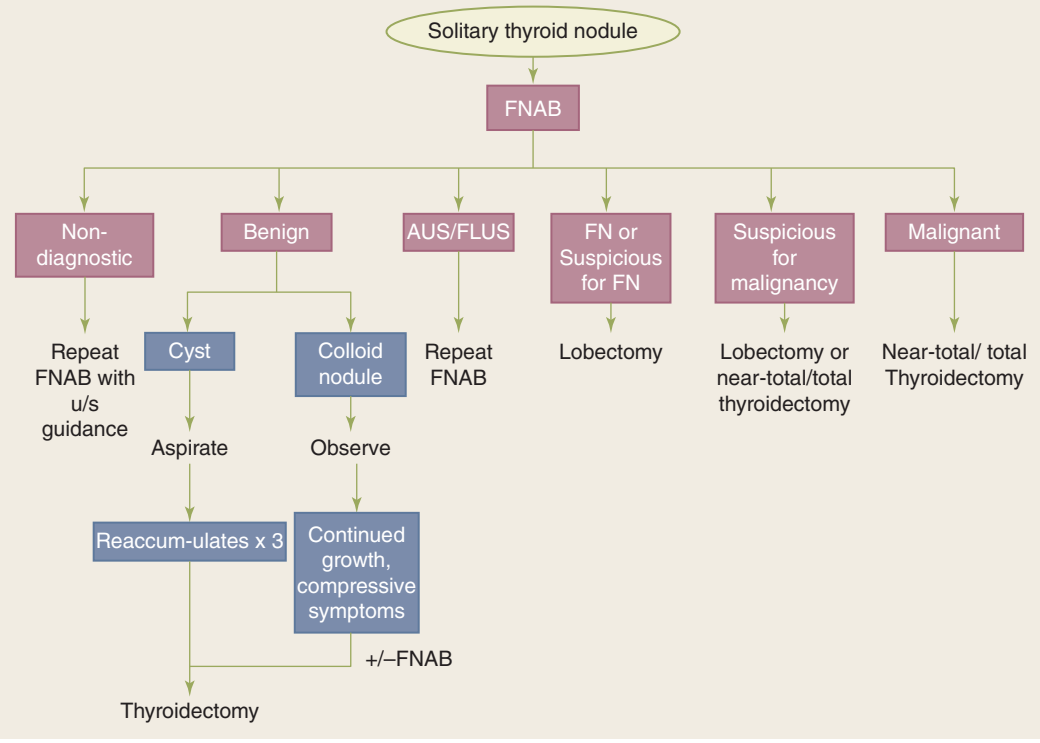


Figure 38-14. Management of a solitary thyroid nodule based on Bethesda criteria. a = except in patients with a history of external radiation exposure or a family history of thyroid cancer; FNAB = fine-needle aspiration biopsy; AUS = atypia of unknown significance; FLUS = follicular lesion of unknown significance; FN = follicular neoplasm.

are reported in up to 3% of cases, and follow-up is recommended. A result of "atypia of unknown significance (AUS) or follicular lesion of unknown significance (FLUS)" is obtained in 3% to 6% of biopsies. The risk of malignancy in this scenario is difficult to determine; however, it is thought to be in the range of 10% to 35% for FLUS and 60% to 75% for AUS. Clinical correlation and a repeat FNA are recommended for AUS lesions (which often results in a more definitive interpretation), although clinical observation or surgery may be appropriate because of worrisome clinical or ultrasound findings. The category of "follicular neoplasm" is intended to identify nodules that might be follicular carcinomas. The term *suspicious for a follicular neoplasm* is preferred by some laboratories for this category because up to 35% of cases turn out not to be neoplasms but hyperplastic proliferations of follicular cells, most commonly those of multinodular goiter. Lobectomy is the preferred treatment for this result, and approximately 15% to 35% of lesions placed in this category prove to be malignant. Hürthle cell neoplasms are also included in this category. Most papillary and other carcinomas can be diagnosed by FNA, but the features are subtle at times, such as in follicular variant of papillary carcinomas. If the diagnosis is uncertain, the lesions are classified as "suspicious for malignancy." Lobectomy or near-total thyroidectomy is recommended because more than 60% turn out to be malignant. This category also includes lesions suspicious for medullary carcinoma and lymphoma, and ancillary testing such as immunohistochemical analysis and flow cytometry may be helpful. The risk of malignancy in lesions classified as "malignant" by FNA is 97% to 99%, and near-total/total thyroidectomy is recommended.

Laboratory Studies Most patients with thyroid nodules are euthyroid. Determining the blood TSH level is helpful. If a patient with a nodule is found to be hyperthyroid, the risk of malignancy is approximately 1%. Serum Tg levels cannot differentiate benign from malignant thyroid nodules unless the levels are extremely high, in which case metastatic thyroid cancer should be suspected. Tg levels are, however, useful in following patients who have undergone total thyroidectomy for thyroid cancer and also for serial evaluation of patients undergoing nonoperative management of thyroid nodules. Serum calcitonin levels should be obtained in patients with MTC or a family history of MTC or MEN2. There is insufficient evidence to recommend routine calcitonin testing for all nodules. All patients with MTC should be tested for *RET* oncogene mutations and have a 24-hour urine collection with measurement of levels of vanillylmandelic acid (VMA), metanephrine, and catecholamine levels to rule out a coexisting pheochromocytoma. About 10% of patients with familial MTC and MEN2A have de novo *RET* mutations, so that their children are at risk for thyroid cancer.

Imaging Ultrasound is helpful for detecting nonpalpable thyroid nodules, differentiating solid from cystic nodules, and identifying adjacent lymphadenopathy. Ultrasound evaluation can identify features of a nodule that increase the a priori risk of malignancy, such as fine stippled calcification and enlarged regional nodes; however, a tissue diagnosis is strongly recommended before thyroidectomy.[20] Ultrasound also provides a noninvasive and inexpensive method of following the size of suspected benign nodules diagnosed by FNAB and for identifying enlarged lymph nodes. Ultrasound elastography is used to evaluate tissue stiffness noninvasively. This technique takes advantage of the fact that malignant nodules tend to be harder than benign nodules and thus deform less compared with the surrounding normal thyroid parenchyma.[21] Larger studies are warranted before elastography can be routinely included in the evaluation of thyroid nodules. CT and MRI are unnecessary in the routine evaluation of thyroid tumors except for large, fixed, or substernal lesions. Scanning the thyroid with ^{123}I or ^{99m}Tc is rarely necessary, and thyroid scanning currently is recommended in the assessment of thyroid nodules only in patients who have follicular thyroid nodules on FNAB and a suppressed TSH. PET scanning does not play a major role in the primary evaluation of thyroid nodules.

Management. Malignant tumors are treated by thyroidectomy, as discussed earlier and later in this chapter in Surgical Treatment under Malignant Thyroid Disease. Simple thyroid cysts resolve with aspiration in about 75% of cases, although some require a second or third aspiration. If the cyst persists after three attempts at aspiration, unilateral thyroid lobectomy is recommended. Lobectomy also is recommended for cysts >4 cm in diameter or complex cysts with solid and cystic components, as the latter have a higher incidence of malignancy (15%). When FNAB is used in complex nodules, the solid portion should be sampled. If a colloid nodule is diagnosed by FNAB, patients should still be observed with serial ultrasound and Tg measurements. If the nodule enlarges, repeat FNAB often is indicated. Although controversial, levothyroxine in doses sufficient to maintain a serum TSH level between 0.1 and 1.0 μU/mL may also be administered. In areas with a high prevalence of iodine deficiency, this can decrease nodule size and potentially prevent the growth of new nodules. In iodine-sufficient populations, the data are less impressive. Randomized controlled trial analyses have shown that less than 25% of benign nodules shrink more than 50% with TSH suppression in iodine-replete populations. Thyroidectomy should be performed if a nodule enlarges on TSH suppression or causes compressive symptoms, or for cosmetic reasons. An exception to this general rule is the patient who has had previous irradiation of the thyroid gland or has a family history of thyroid cancer. In these patients, total or near-total thyroidectomy is recommended because of the high incidence of thyroid cancer and decreased reliability of FNAB in this setting.

Malignant Thyroid Disease

In the United States, thyroid cancer accounts for <1% of all malignancies (2% of women and 0.5% of men) and is the most rapidly increasing cancer in women. Thyroid cancer is responsible for six deaths per million persons annually. Most patients present with a palpable swelling in the neck, which initiates assessment through a combination of history, physical examination, and FNAB.

Molecular Genetics of Thyroid Tumorigenesis. Several oncogenes and tumor suppressor genes are involved in thyroid tumorigenesis,[22] as depicted in Table 38-5. The *RET* proto-oncogene (Fig. 38-15) plays a significant role in the pathogenesis of thyroid cancers. It is located on chromosome 10 and encodes a receptor tyrosine kinase, which binds several growth factors such as glial-derived neurotrophic factor and neurturin. The RET protein is expressed in tissues derived from the embryonic nervous and excretory systems. Therefore, *RET* disruption can lead to developmental abnormalities in organs derived from these systems, such as the enteric nervous system (Hirschsprung's disease) and kidney. Germline mutations in the *RET* proto-oncogene are known to predispose to

Table 38-5

Oncogenes, tumor suppressor genes, and other genetic alterations implicated in thyroid tumorigenesis

GENE	FUNCTION	TUMOR
Oncogenes		
RET	Membrane receptor with tyrosine kinase activity	Sporadic and familial MTC, PTC (RET/PTC rearrangements)
MET	Same	Overexpressed in PTC
TRK1	Same	Activated in some PTC
TSH-R	Linked to heterotrimeric G protein	Hyperfunctioning adenoma
Gsα (gsp)	Signal transduction molecule (GTP binding)	Hyperfunctioning adenoma, follicular adenoma
Ras	Signal transduction protein	Follicular adenoma and carcinoma, PTC
PAX8/PPARγ1	Oncoprotein	Follicular adenoma, follicular carcinoma
B-Raf (BRAF)	Signal transduction	PTC, tall cell and poorly differentiated, anaplastic
CTNNB1 (β-catenin)	Signal transduction	Upregulated in poorly differentiated and anaplastic cancers
Tumor suppressors		
p53	Cell cycle regulator, arrests cells in G_1, induces apoptosis	Dedifferentiated PTC, FTC, anaplastic cancers
p16	Cell cycle regulator, inhibits cyclin-dependent kinase	Thyroid cancer cell lines
PTEN	Protein tyrosine phosphatase	Follicular adenoma and carcinoma
Other genetic alterations		
microRNA	Small, noncoding RNA	Specific types upregulated in papillary and some follicular carcinomas

FTC = follicular thyroid cancer; GTP = guanosine triphosphate; MTC = medullary thyroid cancer; PTC = papillary thyroid cancer.

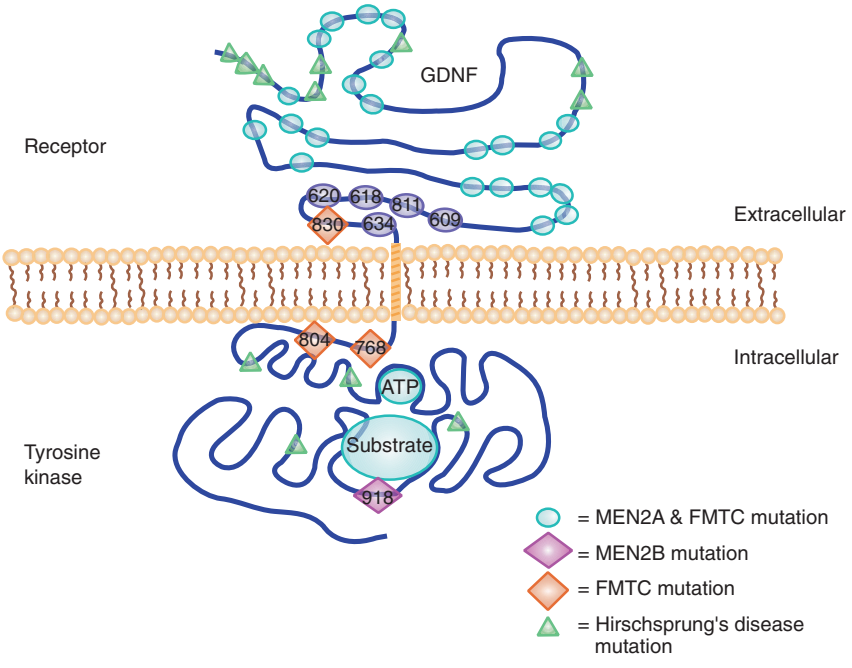

Figure 38-15. Structure of the *RET* tyrosine kinase receptor. Multiple endocrine neoplasia type 2A (MEN2A) and type 2B (MEN2B), familial medullary thyroid cancer (FMTC), and Hirschsprung's disease result from germline mutations in the *RET* proto-oncogene. The extracellular domain binds the ligand glial-derived neurotrophic factor (GDNF) and contains 28 cysteine residues. Mutations in cysteine residues at codons 609, 611, 618, 620, and 634, which are in the juxtamembrane region of the receptor, are associated with MEN2A and FMTC. The ATP-binding site is located intracellularly near the site, which binds the substrate for the tyrosine kinase catalytic domain. Mutations at codon 918 (Met to Thr) alter the substrate binding pocket located in the intracellular region and cause MEN2B. FMTC is associated with mutations at codons 768 and 804. ATP = adenosine triphosphate. *(Reproduced with permission from Wells S, Franz C. Medullary carcinoma of the thyroid.* World J Surg. *2000;24:954. With kind permission of Springer Science + Business Media.)*

MEN2A, MEN2B, and familial MTCs, and somatic mutations have been demonstrated in tumors derived from the neural crest, such as MTCs (30%) and pheochromocytomas. The tyrosine kinase domain of *RET* can fuse with other genes by rearrangement. These fusion products also function as oncogenes and have been implicated in the pathogenesis of PTCs. At least 15 *RET*/*PTC* rearrangements have been described and appear to be early events in tumorigenesis. Young age and radiation exposure seem to be independent risk factors for the development of *RET*/*PTC* rearrangements. Up to 70% of papillary cancers in children exposed to the radiation fallout from the 1986 Chernobyl disaster carry *RET*/*PTC* rearrangements, the most common being *RET*/*PTC1* and *RET*/*PTC3*. These rearrangements confer constitutive activation of the receptor tyrosine kinases. *RET*/*PTC3* is associated with a solid type of PTC that appears to present at a higher stage and to be more aggressive. It has now been established that *RET*/*PTC* signaling involves the mitogen-activated protein kinase (MAPK) pathway via other signaling molecules such as *Ras*, Raf, and MEK. In normal cells, physiologic activation of Raf kinases occurs via direct interaction with guanosine triphosphate (GTP)–bound Ras, a membrane-bound small G protein. Activated Raf, a serine-threonine kinase, in turn phosphorylates MEK, another serine-threonine kinase. This leads to phosphorylation of ERK/MAPK, which phosphorylates regulatory molecules in the nucleus, thereby altering gene expression. Aberrant activation of the MAPK pathway leads to tumorigenesis. Aside from *RET*/*PTC* alterations, mutations in the *Ras* genes can also activate the MAPK pathway. Mutated *RAS* oncogenes have been identified in up to 20% to 40% of thyroid follicular adenomas and carcinomas, multinodular goiters, and papillary and anaplastic carcinomas. There are three Raf kinases, A-Raf, B-Raf (*BRAF*), and C-Raf. Mutations in *BRAF* also have been implicated in aberrant MAPK pathway activation and tumorigenesis. Of the various identified *BRAF* mutations, T1799A (V600E amino acid substitution) is the most common and occurs frequently in thyroid cancers. Interestingly, *BRAF* mutations occur in papillary and anaplastic tumors (average prevalence of 44% and 22%, respectively),[15] but not in follicular thyroid cancers, suggesting a role in the pathogenesis of these malignancies. Studies also show that *BRAF* mutations are associated with more aggressive clinicopathologic features, including larger tumor size, invasion, and lymphadenopathy, and may have a role as prognostic markers.

The *p53* gene is a tumor suppressor gene encoding a transcriptional regulator, which causes cell cycle arrest allowing repair of damaged DNA, thus helping to maintain genomic integrity. Mutations of *p53* are rare in PTCs but common in undifferentiated thyroid cancers and thyroid cancer cell lines. Other cell cycle regulators and tumor suppressors such as *p15* and *p16* are mutated more commonly in thyroid cancer cell lines than in primary tumors. An oncogene resulting from the fusion of the DNA binding domain of the thyroid-transcription factor *PAX8* gene to the peroxisome proliferator-activated receptor gamma 1 (*PPARγ1*) has been noted to play an important role in the development of follicular neoplasms, including follicular cancers. Thyroid cancer stem cells have also been identified; however, their role in thyroid carcinogenesis remains to be determined.[24]

Specific Tumor Types

Papillary Carcinoma Papillary carcinoma accounts for 80% of all thyroid malignancies in iodine-sufficient areas and is the predominant thyroid cancer in children and individuals exposed to external radiation. Papillary carcinoma occurs more often in women, with a 2:1 female-to-male ratio, and the mean age at presentation is 30 to 40 years. Most patients are euthyroid and present with a slow-growing painless mass in the neck. Dysphagia, dyspnea, and dysphonia usually are associated with locally advanced invasive disease. Lymph node metastases are common, especially in children and young adults, and may be the presenting complaint. "Lateral aberrant thyroid" almost always denotes a cervical lymph node that has been invaded by metastatic cancer. Suspicion of thyroid cancer often originates through physical examination of patients and a review of their history. Diagnosis is established by FNAB of the thyroid mass or lymph node. Once thyroid cancer is diagnosed on FNAB, a complete neck ultrasound is strongly recommended to evaluate the contralateral lobe and for lymph node metastases in the central and lateral neck compartments. Distant metastases are uncommon at initial presentation, but may ultimately develop in up to 20% of patients. The most common sites are lungs, followed by bone, liver, and brain.

Pathology. On gross examination, PTCs generally are hard and whitish and remain flat on sectioning with a blade, in contrast to normal tissue or benign nodular lesions that tend to bulge. Macroscopic calcification, necrosis, or cystic change may be apparent. Histologically, papillary carcinomas may exhibit papillary projections (Fig. 38-16A), a mixed pattern of papillary and follicular structures, or a pure follicular pattern (follicular variant). The diagnosis is established by characteristic nuclear cellular features. Cells are cuboidal with pale, abundant cytoplasm, crowded nuclei that may demonstrate "grooving," and intranuclear cytoplasmic inclusions (leading to the designation of *Orphan Annie* nuclei [Fig. 38-16B]), which allow diagnosis by FNAB. Psammoma bodies, which are microscopic, calcified deposits representing clumps of sloughed cells, also may be present. Mixed papillary-follicular tumors and follicular variants of papillary carcinoma are classified as papillary carcinomas because they behave biologically as papillary carcinomas. Multifocality is common in papillary carcinoma and may be present in up to 85% of cases on microscopic examination. Multifocality is associated with an increased risk of cervical nodal metastases, and these tumors may rarely invade adjacent structures such as the trachea, esophagus, and RLNs. Other variants of papillary carcinoma include tall cell, insular, columnar, diffuse sclerosing, clear cell, trabecular, and poorly differentiated types. These variants account for about 1% of all papillary carcinomas and are generally associated with a worse prognosis.

Minimal or occult/microcarcinoma refers to tumors of 1 cm or less in size with no evidence of local invasiveness through the thyroid capsule or angioinvasion, and that are not associated with lymph node metastases. They are nonpalpable and usually are incidental findings at operative, histologic, or autopsy examination. Studies have demonstrated occult PTC to be present in 2% to 36% of thyroid glands removed at autopsy. These tumors are also being identified more frequently due to the widespread use of ultrasound. These occult tumors are generally associated with a better prognosis than larger tumors, but they may be more aggressive than previously appreciated. About 25% of patients with these tumors have associated occult lymph node metastases.

Prognostic Indicators. In general, patients with PTC have an excellent prognosis with a >95% 10-year survival rate. Several prognostic indicators have been incorporated into various staging

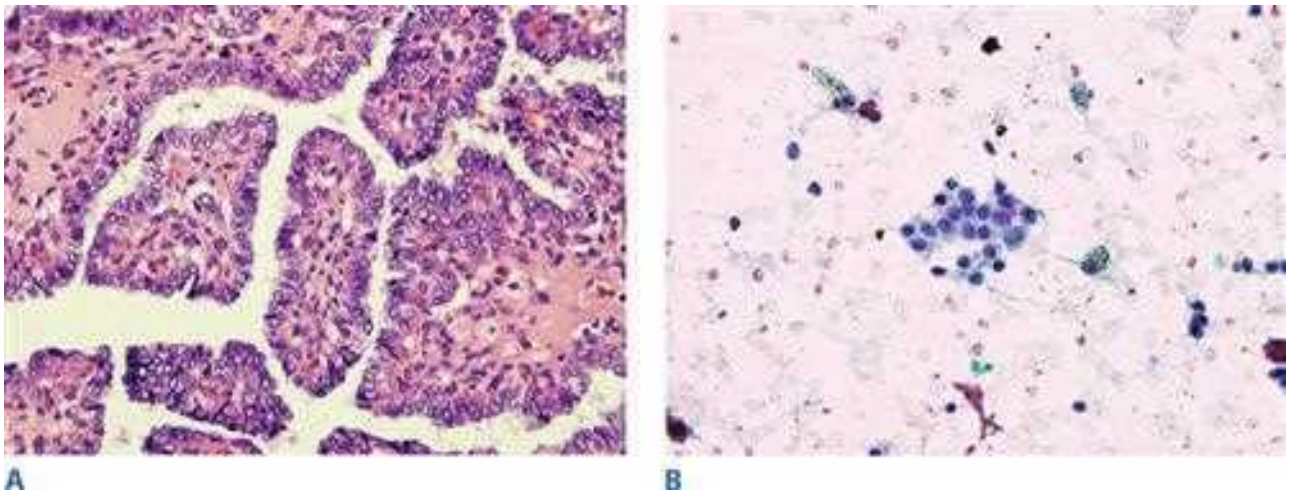

Figure 38-16. A. Histomicrograph of a papillary thyroid cancer (hematoxylin-eosin stain). **B.** Fine-needle aspiration biopsy specimen from a papillary thyroid cancer showing typical intranuclear cytoplasmic inclusions in the center of the slide.

systems, which enable patients to be stratified into low-risk and high-risk groups. Unfortunately, all of these classification systems rely on data that are not available preoperatively.

In 1987, Hay and colleagues[25] at the Mayo Clinic proposed the *AGES* scoring system, which incorporates *A*ge, histologic *G*rade, *E*xtrathyroidal invasion, and metastases and tumor *S*ize to predict the risk of dying from papillary cancer. Low-risk patients are young, with well-differentiated tumors, no metastases, and small primary lesions, whereas high-risk patients are older, with poorly differentiated tumors, local invasion, distant metastases, and large primary lesions. The *MACIS* scale is a postoperative system modified from the AGES scale. This scale incorporates distant *M*etastases, *A*ge at presentation (<40 or >40 years old), *C*ompleteness of original surgical resection, extrathyroidal *I*nvasion, and *S*ize of original lesion (in centimeters) and classifies patients into four risk groups based on their scores. Cady proposed the *AMES* system[26] to classify differentiated thyroid tumors into low- and high-risk groups using *A*ge (men <40 years old, women <50 years old), *M*etastases, *E*xtrathyroidal spread, and *S*ize of tumors (< or >5 cm). Another classification system is the TNM system (*T*umor, *N*odal status, *M*etastases; Table 38-6), which used by most medical centers in North America.[27] A simplified system by DeGroot and associates[28] uses four groups—class I (intrathyroidal), class II (cervical nodal metastases), class III (extrathyroidal invasion), and class IV (distant metastases)—to determine prognosis.

Several molecular and genetic markers such as tumor DNA aneuploidy, decreased cyclic adenosine monophosphate response to TSH, increased epidermal growth factor binding, presence of N-*ras* and *gsp* mutations, overexpression of c-*myc*, and presence of *p53* mutations also have been associated with a worse prognosis. The presence of *BRAF* V600E mutation, as previously mentioned, is associated with aggressive tumor characteristics, including extrathyroidal extension, older age at presentation, and lymph node and distant metastases. This mutation also appears to be an independent predictor of both tumor recurrence (even for early-stage disease) and tumor-related mortality. Some studies propose that *BRAF* mutation status on FNAB can be used to tailor initial management including more extensive initial surgical excision, high-dose postoperative RAI therapy, increased TSH suppression, and closer follow up.[29] The correlation of *RET/PTC* rearrangements and *Ras* mutations with prognosis is less clear.

Surgical Treatment. Most authors agree that patients with high-risk tumors (judged by any of the classification systems discussed earlier in Prognostic Indicators) or bilateral tumors should undergo total or near-total thyroidectomy. The optimal surgical strategy in the majority of patients with low-risk (small, unilateral) cancers was controversial for many years, with the focus of the debate centering around outcome data and risks associated with extent of thyroidectomy in this group of patients.

Proponents of total thyroidectomy indicate that it enables the use of RAI to effectively detect and treat residual thyroid tissue or metastatic disease and makes serum Tg level a more sensitive marker of recurrent or persistent disease. It is also known that a significant proportion (33% to 50%) of patients who develop a recurrence die from their disease,[30] and even though the data are retrospective, long-term, follow-up studies suggest that recurrence rates are lowered and that survival is improved in patients undergoing near-total or total thyroidectomy[28, 30-34] (Fig. 38-17). In addition, diminished survival is noted in patients with low-risk disease (mortality rates of 5% at 10 to 20 years), and it is not possible to accurately risk stratify patients preoperatively. More recently, a large study of >50,000 patients with papillary cancer demonstrated that, in multivariate analyses, total thyroidectomy led to a significantly improved recurrence and survival for tumors >1 cm. Furthermore, the authors also showed that patients with tumors 1 to 2 cm in diameter who were treated with lobectomy had a 24% higher risk of recurrence and a 49% higher risk of thyroid cancer mortality.[35]

4▶ Based on the above, current guidelines for the evidence-based management of thyroid cancers recommend a near-total or total thyroidectomy for primary cancers >1 cm unless there are contraindications to the surgery.[36]

When PTC is diagnosed by FNAB, the definitive operation can be done without confirming the diagnosis by frozen section during the operation. Patients with a nodule that is suspicious for papillary cancer should be treated by thyroid lobectomy, isthmusectomy, and removal of any pyramidal lobe or adjacent lymph nodes. If intraoperative frozen-section examination of a lymph node or primary tumor confirms carcinoma, completion total or near-total thyroidectomy is performed. If a definitive diagnosis cannot be made or the surgeon is concerned about the viability of the parathyroid glands or the status of the RLN, the operation is terminated. When final histology confirms carcinoma,

Definitions:
Primary tumor (T)
TX = Primary tumor cannot be assessed
T0 = No evidence of primary tumor
T1 = Tumor ≤2 cm in diameter, limited to thyroid
T2 = Tumor >2 cm but <4 cm in diameter, limited to thyroid
T3 = Tumor >4 cm in diameter, limited to thyroid, or any tumor with minimal extrathyroidal invasion
T4a = Any size tumor extending beyond capsule to invade subcutaneous soft tissue, larynx, trachea, esophagus, or recurrent laryngeal nerve, or intrathyroidal anaplastic cancer
T4b = Tumor invading prevertebral fascia, or encasing carotid artery or mediastinal vessels; or extrathyroidal anaplastic cancer
Regional lymph nodes (N)—include central, lateral cervical, and upper mediastinal nodes
NX = Regional lymph nodes cannot be assessed
N0 = No regional lymph node metastasis
N1 = Regional lymph node metastasis
N1a = Metastases to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)
N1b = Metastases to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes
Distant metastasis (M)
MX = Distant metastases cannot be assessed
M1 = No distant metastasis

completion thyroidectomy usually is performed. Thyroid lobectomy alone is considered sufficient treatment for small (<1 cm), incidentally discovered, low-risk, unifocal, intrathyroidal papillary carcinomas in the absence of prior head and neck irradiation or radiologically or clinically involved cervical nodal metastases.

During thyroidectomy, enlarged or obviously involved central neck nodes should be removed (therapeutic central-compartment, level VI), along with nodes with known lateral neck metastases. Some investigators recommend routine bilateral central neck dissection due to the high incidence of microscopic metastases and data showing improved rates of recurrence and survival (compared to historic controls). However, these risks need to be balanced with the increased risk of hypoparathyroidism with routine central neck dissection and the fact that some studies do not show any difference in recurrence rates or rates of low or undetectable Tg levels. The 2009 ATA guidelines for thyroid cancer management suggest that prophylactic (ipsilateral or bilateral) dissection may be performed in patients with advanced (T3 or T4) papillary thyroid carcinoma, whereas the procedure is not needed for small (T1 and T2) tumors that are clinically node negative.[36] Further prospective studies are needed before definitive recommendations can be made in this regard.

Biopsy-proven lymph node metastases detected clinically or by imaging in the lateral neck in patients with papillary carcinoma are managed with modified radical or functional neck dissection,[36] as described later in this chapter in Thyroid Surgery. Dissection of the posterior triangle and suprahyoid dissection usually are not necessary unless there is extensive metastatic disease in levels 2, 3, and 4, but should be performed when appropriate. Prophylactic lateral neck node dissection is not necessary in patients with PTC, because these cancers do not appear to metastasize systemically from lymph nodes, and micrometastases often can be ablated with RAI therapy.

Follicular Carcinoma Follicular carcinomas account for 10% of thyroid cancers and occur more commonly in iodine-deficient areas. The overall incidence of this tumor is declining in the United States, probably due to iodine supplementation and improved histologic classification. Women have a higher incidence of follicular cancer, with a female-to-male ratio of 3:1, and a mean age at presentation of 50 years old. Follicular cancers usually present as solitary thyroid nodules, occasionally with a history of rapid size increase, and long-standing goiter. Pain is uncommon, unless hemorrhage into the nodule has occurred. Unlike papillary cancers, cervical lymphadenopathy is uncommon at initial presentation (about 5%), although distant metastases may be present. In <1% of cases, follicular cancers may be hyperfunctioning, leading patients to present with signs and symptoms of thyrotoxicosis. FNAB is unable to distinguish benign follicular lesions from follicular carcinomas. Therefore, preoperative clinical diagnosis of cancer is difficult unless distant metastases are present. Large follicular tumors (>4 cm) in older men are more likely to be malignant.

Due to the limitations inherent in the FNAB diagnosis, a number of studies have focused on identifying molecular markers to distinguish benign from malignant follicular lesions. Many of these genetic changes can be identified using tissue obtained during FNAB. While no single marker has met the ideal characteristics of being simple to use, reproducible, and cost-effective, several studies have explored combinations of markers that appear to be useful in differentiating benign from malignant lesions. Nikiforov and colleagues demonstrated

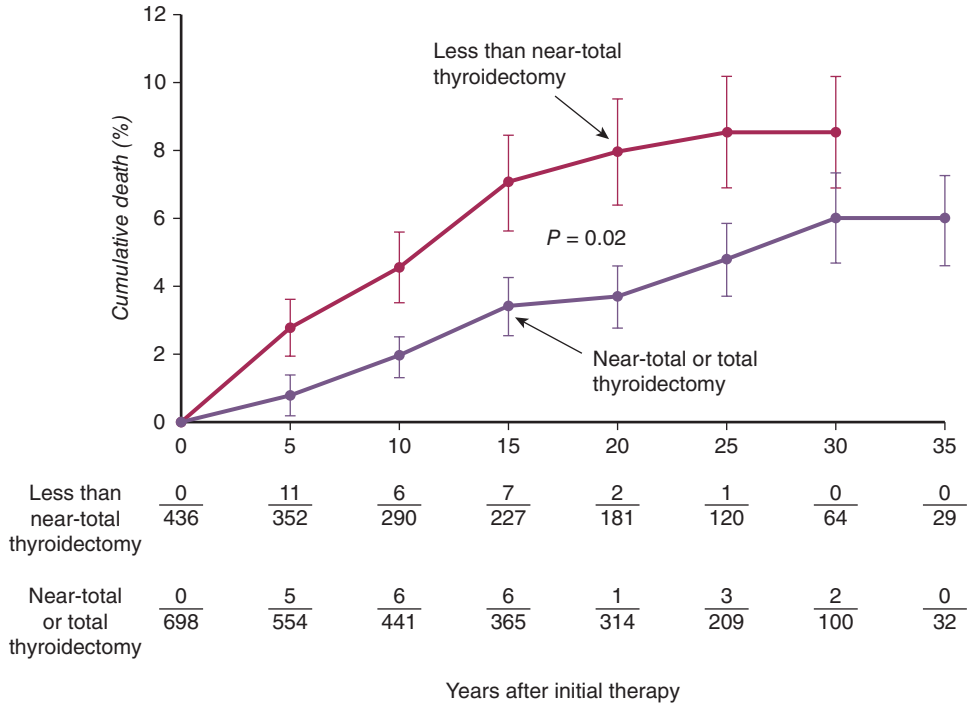

Figure 38-17. Improved survival in patients with papillary or follicular thyroid cancer following total or near-total thyroidectomy compared to those who underwent less than near-total thyroidectomy. *(Reproduced with permission from Mazzaferri E, Jhiang S. Long-term impact of initial surgical and medical therapy on papillary and follicular thyroid cancer.* Am J Med. *1994;97:424. Copyright Elsevier.)*

the utility of examining a combination of DNA-based markers including *BRAF*, *RAS*, *RET/PTC*, and *PAX/PPARγ* abnormalities in the diagnosis of indeterminate nodules. In their study, the presence of any mutation in an FNAB sample was a strong indicator of cancer.[37,38] Expression arrays also have been used to investigate the role of microRNAs, which are a new class of small, noncoding RNAs that have been implicated in carcinogenesis. The specific microRNAs miR-197 and miR-346 are upregulated in follicular thyroid cancers[39] and have the potential to be used as diagnostic markers. Additional studies have also demonstrated the feasibility of studying a panel of microRNAs in a small number of FNA samples. Peripheral blood measurement of TSH-R mRNA levels was able to predict malignancy with a sensitivity of 90% and specificity of 80%; however, its widespread application requires further study.[40] A recently published prospective, multicenter study validated a novel diagnostic test that measures the expression of 167 genes (Veracyte). The gene expression classifier correctly classified 78 of 85 indeterminate nodules as suspicious with a sensitivity of 92%. Additional studies are needed to assess its utility in the broader clinical setting.[41]

Pathology. Follicular carcinomas usually are solitary lesions, and the majority are surrounded by a capsule. Histologically, follicles are present, but the lumen may be devoid of colloid. Architectural patterns depend on the degree of differentiation demonstrated by the tumor. Malignancy is defined by the presence of capsular and vascular invasion (Fig. 38-18). In general, minimally invasive tumors appear grossly encapsulated and have microscopic invasion through the tumor capsule without extension into the parenchyma and/or invasion into small- to medium-sized vessels (venous caliber) in or immediately outside the capsule, but not within the tumor. On the other hand, widely invasive tumors demonstrate evidence of large vessel invasion and/or broad areas of tumor invasion through the capsule. They may, in fact, be unencapsulated. It is important to note that there is a wide variation of opinion among clinicians and pathologists with respect to the above definitions. Tumor infiltration and invasion, as well as tumor thrombus within the middle thyroid or jugular veins, may be apparent at operation.

Surgical Treatment and Prognosis. Patients diagnosed by FNAB as having a follicular lesion should undergo thyroid lobectomy because at least 80% of these patients will have benign adenomas. Total thyroidectomy is recommended by some surgeons in older patients with follicular lesions >4 cm because of the higher risk of cancer in this setting (50%) and certainly should be performed in patients with atypia on FNA, a family history

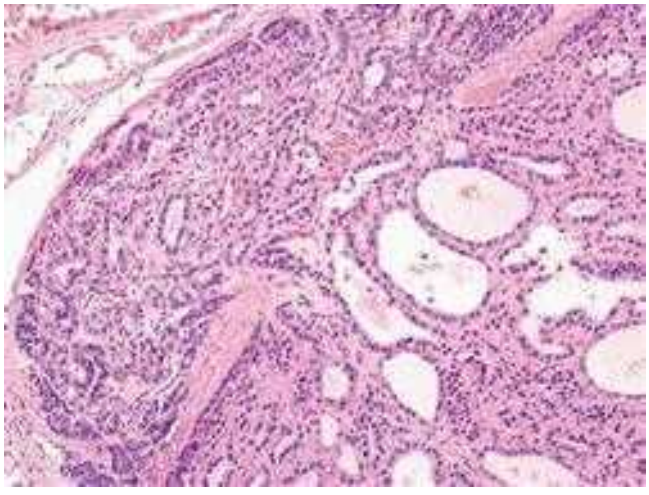

Figure 38-18. Hematoxylin-eosin–stained section from follicular thyroid carcinoma showing capsular invasion.

of thyroid cancer, or a history of radiation exposure. Intraoperative frozen-section examination usually is not helpful, but should be performed when there is evidence of capsular or vascular invasion or when adjacent lymphadenopathy is present. Total thyroidectomy should be performed when thyroid cancer is diagnosed. There is debate among experts about whether patients with minimally invasive follicular cancers should undergo completion thyroidectomy because the prognosis is so good in these patients. A diagnosis of frankly invasive carcinoma or follicular carcinoma with angioinvasion, with or without capsular invasion, necessitates completion of total thyroidectomy primarily so that ^{131}I can be used to detect and ablate metastatic disease. Prophylactic nodal dissection is not needed because nodal involvement is infrequent, but in the unusual patient with nodal metastases, therapeutic neck dissection is recommended. Prophylactic central neck dissection may be considered in patients with large tumors. The cumulative mortality from follicular thyroid cancer is approximately 15% at 10 years and 30% at 20 years. Poor long-term prognosis is predicted by age over 50 years old at presentation, tumor size >4 cm, higher tumor grade, marked vascular invasion, extrathyroidal invasion, and distant metastases at the time of diagnosis.

Hürthle Cell Carcinoma Hürthle cell carcinomas account for approximately 3% of all thyroid malignancies and, under the World Health Organization classification, are considered to be a subtype of follicular thyroid cancer. Hürthle cell cancers also are characterized by vascular or capsular invasion and, therefore, cannot be diagnosed by FNAB. Tumors contain sheets of eosinophilic cells packed with mitochondria, which are derived from the oxyphilic cells of the thyroid gland. Hürthle cell tumors differ from follicular carcinomas in that they are more often multifocal and bilateral (about 30%), usually do not take up RAI (about 5%), are more likely to metastasize to local nodes (25%) and distant sites, and are associated with a higher mortality rate (about 20% at 10 years). Hence, they are considered to be a separate class of tumors by some groups.

Management is similar to that of follicular neoplasms, with lobectomy and isthmusectomy being sufficient surgical treatment for unilateral Hürthle cell adenomas. When Hürthle cell neoplasms are found to be invasive on definitive paraffin-section histology, then total thyroidectomy should be performed. These patients should also undergo routine central neck node removal, similar to patients with MTC, and modified radical neck dissection when lateral neck nodes are palpable or identified by ultrasonography. Although RAI scanning and ablation usually are ineffective, they probably should be considered to ablate any residual normal thyroid tissue and occasionally ablate tumors because there is no other good therapy.

Postoperative Management of Differentiated Thyroid Cancer

Radioiodine Therapy The issue of whether RAI therapy offers any benefit to patients with differentiated thyroid cancer remains controversial in the absence of prospective, randomized controlled trials. Long-term cohort studies by Mazzaferri and associates and DeGroot and colleagues demonstrate that postoperative RAI therapy reduces recurrence (Fig. 38-19) and provides a small improvement in survival, even in low-risk patients.[28,32] Screening with RAI is more sensitive than chest x-ray or CT scanning for detecting metastases; however, it is less sensitive than Tg measurements for detecting metastatic disease in most differentiated thyroid cancers except Hürthle cell tumors. Screening and treatment are facilitated by the removal of all normal thyroid tissue, which effectively competes for iodine uptake. Metastatic differentiated thyroid carcinoma can be detected and treated by ^{131}I in about 75% of patients. Multiple studies show that RAI effectively treats >70% of lung micrometastases that are detected by RAI scan in the presence of a normal chest x-ray, whereas the success rates drop to <10% with pulmonary macrometastases. Early detection therefore appears to be very important to improve prognosis.

Several features place patients at increased risk for local recurrences or metastases. These high-risk features include certain histologic subtypes (such as tall cell, columnar, insular, solid variant and poorly differentiated thyroid cancer), presence of intrathyroidal vascular invasion, or gross or microscopic multifocal disease. However, there are currently inadequate data to determine whether RAI ablation has any benefits based on these features alone, independent of patient age, tumor size, and lymph node status. Thus, the current ATA guidelines strongly recommend RAI after total thyroidectomy only for patients with known distant metastases. In addition, RAI is also indicated for patients with gross extrathyroidal extension of tumor (regardless of size) or tumors >4 cm, even in the absence of other high-risk features. Ablation is also recommended, albeit based on expert opinion, for selected patients with 1- to 4-cm tumors with lymph node metastases or other high-risk features outlined above, when the combination of T and N status, age, and histology predicts an intermediate to high rate of tumor recurrence.[36] In contrast, RAI is not indicated for patients with unifocal cancers <1 cm in diameter or patients with multifocal tumors (all <1 cm) without additional high-risk features. *This latter indication is a major change from the 2006 guidelines wherein RAI was recommended for all multifocal tumors.*

Remnant ablation can be performed with either thyroid hormone withdrawal or recombinant TSH (rTSH) stimulation. This is based on randomized studies showing that both techniques are equally effective in preparing patients for ablation, with the latter being associated with an improved quality of life. If hormone withdrawal is used, T_4 therapy should be discontinued for approximately 6 weeks before scanning with ^{131}I. Patients should receive T_3 during this time period to decrease the period of hypothyroidism. T_3 has a shorter half-life than T_4 (1 day vs. 1 week) and needs to be discontinued for 2 weeks to allow TSH levels to rise before treatment. Levels >30 mU/L are considered optimal, based on noncontrolled studies. A low-iodine diet also is recommended during this 2-week period. The usual protocol involved administering a screening dose of 1 to 3 mCi and measuring uptake 24 hours later. After a total thyroidectomy, this value should be <1%. A "hot" spot in the neck after initial screening usually represents residual normal tissue in the thyroid bed. Some investigators recommend omitting the scanning dose altogether to minimize thyrocyte "stunning" and subsequent requirement for higher treatment doses. Others recommend scanning only if the size of the remnant cannot be determined by the operative report or ultrasound, or if the results would alter the decision to treat or the dose to be administered. Current guidelines recommend using either ^{123}I or low-activity ^{131}I (1- to 3-mCi dose) and delivering a therapeutic dose within 72 hours. Treatment doses of 30 to 100 mCi are recommended for ablation in low-risk patients as these doses show similar rates of ablation and recurrence rates. A 30-mCi dose is also effective at ablating the remnant with recombinant TSH. In higher risk patients (residual microscopic disease suspected or documented; tall cell, insular, or columnar cell histology), higher doses (100 to

B

Figure 38-19. Tumor recurrence at a median of 16.7 years after thyroid surgery. The numerator is the number of patients with recurrence, and the denominator is the number of patients in each time interval. The *P* values are derived from log-rank statistical analysis of 40-year life-table data. Figure shows that all recurrences (**A**) and distant metastases (**B**) were reduced in patients who received radioactive iodine (RAI) in addition to thyroxine (T4) therapy. *(Reproduced with permission from Mazzaferri E, Kloos R. Current approaches to primary therapy for papillary and follicular thyroid cancer.* J Clin Endocrinol Metab. *2001;86:1453. Copyright by The Endocrine Society.)*

200 mCi) are recommended. If patients have an elevated Tg level, but negative RAI scan, some physicians recommend treating once with 100 mCi of ^{131}I and repeating the imaging 1 to 2 weeks later. Approximately one third of these patients demonstrate uptake on posttreatment imaging, and Tg levels usually decrease in these patients, documenting therapeutic benefit. The maximum dose of radioiodine that can be administered at one time without performing dosimetry is approximately 200 mCi with a cumulative dose of 1000 to 1500 mCi. Up to 500 mCi can be given with proper pretreatment dosimetry. Recent studies also show an increase in the number of second cancers in patients treated with RAI.[42] The early and delayed complications of RAI therapy are listed in Table 38-7.

External-Beam Radiotherapy and Chemotherapy External-beam radiotherapy is occasionally required to control unresectable, locally invasive or recurrent disease and to treat metastases in support bones to decrease the risk of fractures. It also is of value for the treatment and control of pain from bony metastases when there is minimal or no RAIU. Single-drug and multidrug chemotherapy has been used with little success in disseminated thyroid cancer, and there is no role for routine chemotherapy.[36] Doxorubicin (Adriamycin) and paclitaxel (Taxol) are the most frequently used agents. The former acts as a radiation sensitizer and should be considered in patients undergoing external-beam radiation.

Novel Therapies These therapies are directed at the pathways known to be involved in various thyroid cancers.[43] Oncogenic kinase inhibitors that inhibit the mutant V600E BRAF kinase (PLX4032) selectively or both the wild-type and mutant kinase (XL281) have shown promise in the treatment of patients with metastatic papillary cancers. These drugs are associated with GI toxicity (nausea, vomiting, and diarrhea) and an increased risk of cutaneous squamous cell carcinomas. Other kinases targeting the VEGF and RET receptors have also shown promising results. However, the low rate of partial responses, lack of complete response, and ultimate resistance to therapy highlight the need for ongoing research in this area.

Table 38-7

Complications of radioactive iodine therapy (^{131}I) and doses at which they are observed

ACUTE	LONG-TERM
Neck pain, swelling, and tenderness	Hematologic
Thyroiditis (if remnant present)	Bone marrow suppression (>500 mCi)
Sialadenitis (50–450 mCi), taste dysfunction	Leukemia (>1000 mCi)
Hemorrhage (brain metastases)	Fertility
Cerebral edema (brain metastases, 200 mCi)	Ovarian/testicular damage, infertility
Vocal cord paralysis	Increased spontaneous abortion rate
Nausea and vomiting (50–450 mCi)	
Bone marrow suppression (200 mCi)	Pulmonary fibrosis
	Chronic sialadenitis, nodules, taste dysfunction
	Increased risk of cancer
	Anaplastic thyroid cancer
	Gastric cancer
	Hepatocellular cancer
	Lung cancer
	Breast cancer (>1000 mCi)
	Bladder cancer
	Hypoparathyroidism

Thyroid Hormone T_4 is necessary as replacement therapy in patients after total or near-total thyroidectomy, and also has the additional effect of suppressing TSH and reducing the growth stimulus for any possible residual thyroid cancer cells. TSH suppression reduces tumor recurrence rates. Current guidelines advise maintaining TSH levels <0.1 mU/mL in patients with persistent disease and maintaining TSH in the low normal range (0.3 to 2 mU/mL) in patients who are clinically and biochemically free of disease and at low risk for recurrence. For high-risk patients in the latter group, maintenance of TSH levels of 0.1 to 0.5 mU/mL is advised.[36] The risk of tumor recurrence must be balanced with the side effects associated with prolonged TSH suppression, including osteopenia and cardiac problems, particularly in older patients.

Follow-Up of Patients with Differentiated Thyroid Cancer

Thyroglobulin Measurement Tg and anti-Tg antibody levels should be measured initially at 6-month intervals. In low-risk patients, who have low suppressed Tg levels in the first year, serum Tg should be measured after T_4 withdrawal or recombinant TSH stimulation approximately 12 months after ablation. Patients with undetectable stimulated Tg levels can be followed annually with clinical exam and Tg levels on T_4 replacement. A single rTSH-stimulated Tg level of <0.5 ng/mL (with absent antibodies) has a 98% to 99.5% probability of identifying patients completely free of disease on follow-up. A Tg level of >2 ng/mL following rTSH stimulation is highly sensitive in identifying patients with recurrent tumor.[36] Tg measurements in FNAB aspirates have also been shown to be useful in the detection of nodal metastatic disease.[44]

Imaging After the first posttreatment scan, low-risk patients with negative TSH-stimulated Tg and cervical ultrasound do not require routine diagnostic whole-body radioiodine scans. However, diagnostic whole-body scans 6 to 12 months after remnant ablation may be of value in the follow-up of patients with high or intermediate risk of persistent disease. It also is recommended that cervical ultrasound be performed to evaluate the thyroid bed and central and lateral cervical nodal compartments at 6 and 12 months after thyroidectomy and then annually for at least 3 to 5 years, depending on the patient's risk for recurrent disease and Tg status. Sonographically suspicious nodes >5 to 8 mm on the smallest diameter measurement should be biopsied for cytology as well as Tg measurement in the aspirate washout. Smaller nodes can be followed and biopsied if there is continued growth.[36] FDG-PET and PET-CT scans have been shown to be useful to localize recurrent or persistent thyroid cancer in patients who have Tg-positive, RAI scan–negative disease. FDG-PET can also be useful for the initial staging of patients with poorly differentiated thyroid carcinomas or Hürthle cell tumors, particularly in patients with other evidence of disease on imaging or Tg levels. In addition, they may be used

Table 38-8

Clinical and genetic features of medullary thyroid cancer syndromes

SYNDROME	MANIFESTATIONS	*RET* MUTATIONS
MEN2A	MTC, pheochromocytoma, primary hyperparathyroidism, lichen planus amyloidosis	Exon 10—codons 609, 611, 618, 620
		Exon 11—codon 634 (more commonly associated with pheochromocytoma and primary hyperparathyroidism)

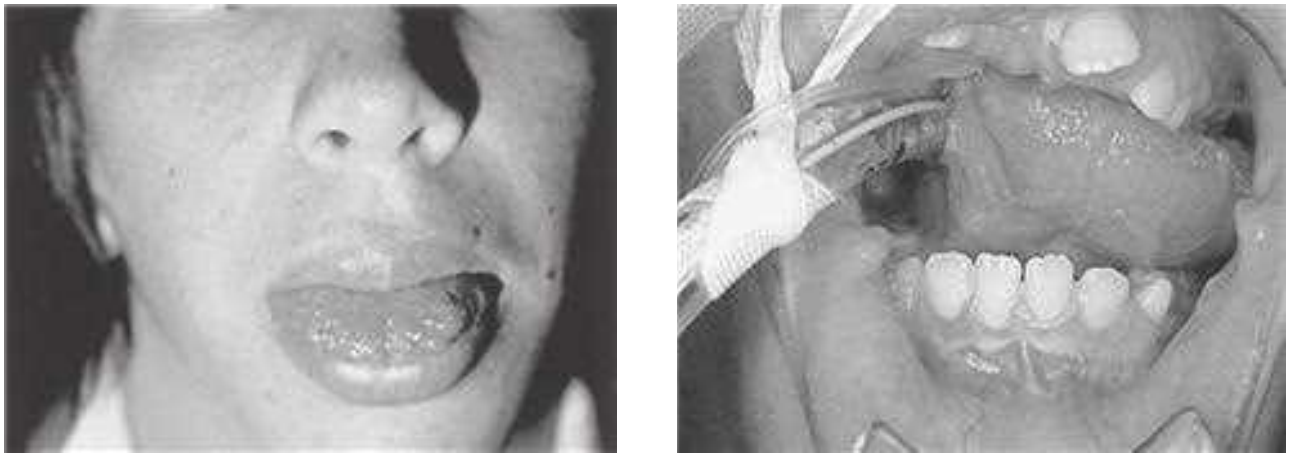
MEN2 = multiple endocrine neoplasia type 2; MTC = medullary thyroid cancer.

as a prognostic tool in patients with metastatic disease and to evaluate the response to treatment in patients with metastatic or locally advanced disease.

Medullary Carcinoma MTC accounts for about 5% of thyroid malignancies and arises from the parafollicular or C cells of the thyroid, which, in turn, are derived from the ultimobranchial bodies. These cells are concentrated superolaterally in the thyroid lobes, and this is where MTC usually develops. C cells secrete calcitonin, a 32-amino-acid polypeptide that functions to lower serum calcium levels, although its effects in humans are minimal. Most MTCs occur sporadically. However, approximately 25% occur within the spectrum of several inherited syndromes such as familial MTC, MEN2A, and MEN2B. All these variants are known to result secondary to germline mutations in the *RET* proto-oncogene. The syndromes also are characterized by genotype-phenotype correlations, with specific mutations leading to particular clinical manifestations. The salient clinical and genetic features of these syndromes are outlined in Table 38-8. Some clinical features of MEN2B patients are shown in Fig. 38-20.

Patients with MTC often present with a neck mass that may be associated with palpable cervical lymphadenopathy (15% to 20%). Pain or aching is more common in patients with these tumors, and local invasion may produce symptoms of dysphagia, dyspnea, or dysphonia. Distant blood-borne metastases to the liver, bone (frequently osteoblastic), and lung occur later in the disease. The female-to-male ratio is 1.5:1. Most patients present between 50 and 60 years old, although patients with familial disease present at a younger age. Medullary thyroid tumors secrete not only calcitonin and carcinoembryonic antigen (CEA), but also other peptides such as calcitonin gene–related peptide, histaminadases, prostaglandins E_2 and $F_2\alpha$, and serotonin. Patients with extensive metastatic disease frequently develop diarrhea, which may result from increased intestinal motility and impaired intestinal water and electrolyte flux. About 2% to 4% of patients develop Cushing's syndrome as a result of ectopic production of adrenocorticotropic hormone (ACTH).



A **B**

Figure 38-20. Features of MEN2B: thickened lips (**A**) and mucosal neuromas (**A** and **B**).

Pathology. MTCs typically are unilateral (80%) in patients with sporadic disease and multicentric in familial cases, with bilateral tumors occurring in up to 90% of familial patients. Familial cases also are associated with C-cell hyperplasia, which is considered a premalignant lesion. Microscopically, tumors are composed of sheets of infiltrating neoplastic cells separated by collagen and amyloid. Marked heterogeneity is present; cells may be polygonal or spindle shaped. The presence of amyloid is a diagnostic finding, but immunohistochemistry for calcitonin is more commonly used as a diagnostic tumor marker. These tumors also stain positively for CEA and calcitonin gene–related peptide.

Diagnosis. The diagnosis of MTC is established by history, physical examination, raised serum calcitonin, or CEA levels, and FNAB cytology of the thyroid mass. Attention to family history is important because about 25% of patients with MTC have familial disease. Because it is not possible to distinguish sporadic from familial disease at initial presentation, all new patients with MTC should be screened for *RET* point mutations, pheochromocytoma, and HPT. Screening of patients with familial MTC for *RET* point mutations has largely replaced using provocative testing with pentagastrin or calcium-stimulated calcitonin levels to make the diagnosis. Calcitonin and CEA are used to identify patients with persistent or recurrent MTC. Calcitonin is a more sensitive tumor marker, but CEA is a better predictor of prognosis.

Treatment. The ATA published guidelines for the management of medullary cancers in 2009.[45] A neck ultrasound is recommended to evaluate the central and lateral neck compartments and the superior mediastinum. Serum calcitonin, CEA, and calcium levels should also be measured, and *RET* proto-oncogene mutation testing should be performed. Pheochromocytomas need to be excluded. If patients are found to have a pheochromocytoma, this must be operated on first. These tumors are generally (>50%) bilateral. Total thyroidectomy is the treatment of choice for patients with MTC because of the high incidence of multicentricity, the more aggressive course, and the fact that ^{131}I therapy usually is not effective.

Central compartment nodes frequently are involved early in the disease process, so that a bilateral prophylactic central neck node dissection should be routinely performed. In patients with palpable or imaging-detected cervical nodes or calcitonin levels >400 pg/mL, additional imaging to include a neck and chest CT and a triple-phase liver CT or contrast-enhanced MRI is recommended to assess for metastatic disease. In patients with no distant disease, an ipsilateral or bilateral lateral neck dissection (levels IIA, III, IV, and V) is advised. Less aggressive neck surgery should be considered to preserve speech and swallowing while maintaining locoregional control in patients with limited metastatic disease. The role of prophylactic lateral neck dissection is controversial. Some groups favor this procedure if central neck lymph nodes are involved or if the primary tumor is ≥1.5 cm.

In the case of locally recurrent or widely metastatic disease, tumor debulking is advised not only to ameliorate symptoms of pain, flushing, and diarrhea, but also to decrease risk of death from recurrent central neck or mediastinal disease. External-beam radiotherapy is controversial but can be considered for patients with resected T4 disease and for patients with unresectable residual or recurrent tumor and symptomatic bony metastases. Liver metastases tend to be multiple and are typically not amenable to resection, percutaneous ethanol ablation, or radiofrequency ablation. However, chemoembolization may be helpful in this setting. There is no effective chemotherapy regimen.

Various targeted therapies directed against the RET kinase have been investigated for the treatment of MTC.[43] Many of these also inhibit vascular endothelial growth factor receptor (VEGFR), due to their close structural similarities. Sorafenib, sunitinib, lenvatinib (E7080), and cabozantinib (XL-184) are some such multikinase inhibitors, whereas axitinib and pazopanib act only on VEGFR. Vandetanib inhibits both targets and is also an epidermal growth factor receptor (EGFR) inhibitor, and is the only drug approved by the U.S. Food and Drug Administration for the treatment of advanced and progressive MTC based on data that it prolongs progression-free survival, in addition to reducing secretion of calcitonin and CEA. An anti-CEA monoclonal antibody (labetuzumab) also has shown antitumor response in a small group of patients. Patients with recurrent/metastatic disease should be enrolled in well-designed clinical trials.

In patients who have hypercalcemia and an increased PTH at the time of thyroidectomy, only obviously enlarged parathyroid glands should be removed. The other parathyroid glands should be preserved and marked in patients with normocalcemia, as only about 20% of patients with MEN2A develop HPT. When a normal parathyroid cannot be maintained on a vascular pedicle, it should be removed, biopsied to confirm that it is a parathyroid, and then autotransplanted to the forearm of the nondominant arm, particularly in patients with MEN2A. Re-implantation into the sternocleidomastoid muscle is also acceptable for patients with known MEN2B and familial MTC.

Prophylactic total thyroidectomy is indicated in *RET* mutation carriers once the mutation is confirmed. The ATA stratifies mutation into various risk levels to offer recommendations regarding age at which a prophylactic thyroidectomy should be performed and to predict phenotypes, including pheochromocytomas. In general, in patients with less aggressive mutations, thyroidectomy may be delayed >5 years, especially if there is a normal annual serum calcitonin, neck ultrasound, less aggressive family history, or family preference. Children with mutations at codon 634 are advised to undergo thyroidectomy at <5 years of age, and those with MEN2B-related mutations should undergo the procedure before age 1. Central neck dissection can be avoided in children who are *RET*-positive and calcitonin-negative with a normal ultrasound examination. When the calcitonin is increased or the ultrasound suggests a thyroid cancer, a prophylactic central neck dissection is indicated.

Postoperative Follow-Up and Prognosis. Patients are followed by annual measurements of calcitonin and CEA levels, in addition to history and physical examination. Other modalities used to localize recurrent disease include ultrasound, CT, MRI, and more recently, FDG-PET/CT scans. Prognosis is related to disease stage. The 10-year survival rate is approximately 80% but decreases to 45% in patients with lymph node involvement. Survival also is significantly influenced by disease type. It is best in patients with non-MEN familial MTC, followed by those with MEN2A, and then those with sporadic disease. Prognosis is the worst (survival of 35% at 10 years) in patients with MEN2B. Performing prophylactic surgery in *RET* oncogene mutation carriers not only improves survival rates but also renders most patients calcitonin free.

Anaplastic Carcinoma Anaplastic carcinoma accounts for approximately 1% of all thyroid malignancies in the United

Figure 38-21. Magnetic resonance imaging scan of a patient with anaplastic thyroid cancer. Note heterogeneity consistent with necrosis.

States. Women are more commonly affected, and the majority of tumors present in the seventh and eighth decade of life. The typical patient has a long-standing neck mass, which rapidly enlarges and may be painful. Associated symptoms such as dysphonia, dysphagia, and dyspnea are common. The tumor is large and may be fixed to surrounding structures or may be ulcerated with areas of necrosis (Fig. 38-21). Lymph nodes usually are palpable at presentation. Evidence of metastatic spread also may be present. Diagnosis is confirmed by FNAB revealing characteristic giant and multinucleated cells. Differential diagnoses on FNA can include lymphomas, medullary carcinomas, direct extension from a laryngeal carcinoma, or other metastatic carcinomas or melanoma. When spindle cell elements are present, primary and metastatic sarcomas need to be considered as well. Immunohistochemical markers can aid with excluding other diagnoses. Core or incisional biopsy occasionally is needed to confirm the diagnosis, especially when there is necrotic material on the FNA.

Pathology. On gross inspection, anaplastic tumors are firm and whitish in appearance. Microscopically, sheets of cells with marked heterogeneity are seen. The three main histologic growth patterns are spindle cell, squamoid, and pleomorphic giant cell. Tumors may show a predominance of one pattern or a mixture of various patterns. Foci of more differentiated thyroid tumors, either follicular or papillary, may be seen, suggesting that anaplastic tumors arise from more well-differentiated tumors.

Treatment and Prognosis. This tumor is one of the most aggressive thyroid malignancies, with few patients surviving 6 months beyond diagnosis. All forms of treatment have been disappointing. The ATA recently published guidelines for the management of patients with anaplastic cancer.[46] Imaging (ultrasound, CT, MRI, or PET-CT) should be obtained to assess resectability. All patients should have preoperative laryngoscopy to assess the status of the vocal cords. A total or near-total thyroidectomy with therapeutic lymph node dissection is recommended for patients with an intrathyroidal mass (although lobectomy may also be appropriate, particularly if there is concern for vocal cord paralysis). If extrathyroidal extension is present, an en bloc resection should be considered if all gross disease can be removed (R1). Tracheostomy should be avoided as long as possible unless there is impending airway loss. Adjuvant radiation with should be offered to patients with a good performance status and no metastatic disease who desire aggressive management. Cytotoxic chemotherapy (with some combination of a taxane, anthracycline, and platinum) is typically given concurrently and has been associated with prolonged survival, although these agents are also being used in a neoadjuvant fashion particularly in patients with unresectable disease.

Lymphoma Lymphomas account for <1% of thyroid malignancies, and most are of the non-Hodgkin's B-cell type. Although the disease can arise as part of a generalized lymphomatous condition, most thyroid lymphomas develop in patients with chronic lymphocytic thyroiditis. Chronic antigenic lymphocyte stimulation has been suggested to result in lymphocyte transformation. Patients usually present with symptoms similar to those of patients with anaplastic carcinoma, although the rapidly enlarging neck mass often is painless. Patients may present with acute respiratory distress. Ultrasound can be useful for early diagnosis, and lymphoma appears as a well-defined hypoechoic mass. The diagnosis usually is suggested by FNAB, but FNAB can be nondiagnostic, particularly in the setting of low-grade lymphomas. Therefore, needle core or open biopsy may be necessary for definitive diagnosis. Staging studies should be obtained expeditiously to assess the extent of extrathyroidal spread.[39]

Treatment and Prognosis Patients with thyroid lymphoma respond rapidly to chemotherapy (CHOP—cyclophosphamide, doxorubicin, vincristine, and prednisone), which also has been associated with improved survival. Combined treatment with radiotherapy and chemotherapy often is recommended. Thyroidectomy and nodal resection are used to alleviate symptoms of airway obstruction in patients who do not respond quickly to the above regimens or who have completed the regimen before diagnosis. Prognosis depends on the histologic grade of the tumor and whether the lymphoma is confined to the thyroid gland or is disseminated. The overall 5-year survival rate is about 50%; patients with extrathyroidal disease have markedly lower survival rates.

Metastatic Carcinoma The thyroid gland is a rare site of metastases from other cancers, including kidney, breast, lung, and melanoma. Clinical examination and a review of the patient's history often suggest the source of the metastatic disease, and FNAB usually provides definitive diagnosis. Resection of the thyroid, usually lobectomy, may be helpful in many patients, depending on the status of their primary tumor.

Thyroid Surgery

Conduct of Thyroidectomy Patients with any recent or remote history of altered phonation or prior neck surgery should undergo vocal cord assessment by direct or indirect laryngoscopy before thyroidectomy. The patient is positioned supine, with a sandbag between the scapulae. The head is placed on a donut cushion, and the neck is extended to provide maximal exposure. A Kocher transverse collar incision, typically 4 to 5 cm in length, is placed in or parallel to a natural skin crease 1 cm below the cricoid cartilage (Fig. 38-22A), although longer incisions may be needed. The subcutaneous tissues and platysma are incised sharply, and subplatysmal flaps are raised superiorly to the level of the thyroid

cartilage and inferiorly to the suprasternal notch (Fig. 38-22B). The strap muscles are divided in the midline along the entire length of the mobilized flaps, and the thyroid gland is exposed. On the side to be approached first, the sternohyoid muscles are separated from the underlying sternothyroid muscle by blunt dissection until the internal jugular vein and ansa cervicalis nerve are identified. The strap muscles rarely need to be divided to gain exposure to the thyroid gland. If this maneuver is necessary, the muscles should be divided high to preserve their innervation by branches of the ansa cervicalis. If there is evidence of direct

Figure 38-22. (*Continued*)

tumor invasion into the strap muscles, the portion of involved muscle should be resected en bloc with the thyroid gland. The sternothyroid muscle is then dissected off the underlying thyroid by a combination of sharp and blunt dissection, thus exposing the middle thyroid veins. The thyroid lobe is retracted medially and anteriorly, and the lateral tissues are swept posterolaterally using a peanut sponge. The middle thyroid veins are ligated and divided (Fig. 38-22C). Attention is then turned to the midline where Delphian nodes and the pyramidal lobe are identified. The fascia just cephalad and caudad to the isthmus is divided. The superior thyroid pole is identified by retracting the thyroid first inferiorly and medially, and then the upper pole of the thyroid is mobilized caudally and laterally. The dissection plane is kept as close to the thyroid as possible, and the superior pole vessels are individually identified, skeletonized, ligated, and divided low on the thyroid gland to avoid injury to the external branch of the superior laryngeal nerve (Fig. 38-22D). Once these vessels are divided, the tissues posterior and lateral to the superior pole can be swept from the gland in a posteromedial direction, to reduce the risk of damaging vessels supplying the upper parathyroid.

The RLNs should then be identified. The course of the right RLN is more oblique than the left RLN. The nerves can be most consistently identified at the level of the cricoid cartilage. The parathyroids usually can be identified within 1 cm of the crossing of the inferior thyroid artery and the RLN, although they also may be ectopic in location. The lower pole of the thyroid gland

should be mobilized by gently sweeping all tissues dorsally. The inferior thyroid vessels are dissected, skeletonized, ligated, and divided as close to the surface of the thyroid gland as possible to minimize devascularization of the parathyroids (extracapsular dissection) or injury to the RLN. The RLN is most vulnerable to injury in the vicinity of the ligament of Berry. The nerve often passes through this structure along with small crossing arterial and venous branches (Fig. 38-22E). Any bleeding in this area should be controlled with gentle pressure before carefully identifying the vessel and ligating it. Use of the electrocautery should be avoided in proximity to the RLN. Once the ligament is divided, the thyroid can be separated from the underlying trachea by sharp dissection. The pyramidal lobe, if present, must be dissected in a cephalad direction to above the level of the notch in the thyroid cartilage or higher in continuity with the thyroid gland. If a lobectomy is to be performed, the isthmus is divided flush with the trachea on the contralateral side and suture ligated. The procedure is repeated on the opposite side for a total thyroidectomy.

Parathyroid glands that are located anteriorly on the surface of the thyroid cannot be dissected from the thyroid with a good blood supply or that have been inadvertently removed during the thyroidectomy should be resected, confirmed as parathyroid tissue by frozen section, divided into 1-mm fragments, and reimplanted into individual pockets in the sternocleidomastoid muscle. The sites should be marked with silk sutures and a clip. If a subtotal thyroidectomy is to be performed, once the superior pole vessels are divided and the thyroid lobe mobilized anteriorly, the thyroid lobe is cross-clamped with a Mayo clamp, leaving approximately 4 g of the posterior portion of the thyroid. The thyroid remnant is suture ligated, taking care to avoid injury to the RLN. Routine drain placement rarely is necessary. After adequate hemostasis is obtained, the strap muscles are reapproximated in the midline. The platysma is approximated in a similar fashion. The skin can be closed with subcuticular sutures or clips.

Minimally Invasive Approaches Several approaches to minimally invasive thyroidectomy have been described. Mini-incision procedures use a small, 3-cm incision with no flap creation and minimal dissection to deliver the thyroid into the wound and then perform the pretracheal and paratracheal dissection. Video assistance can be used to improve the visualization via the small incision. Totally endoscopic approaches also have been described, via the supraclavicular, anterior chest, axillary, and breast approach. The axillary, anterior chest, and breast approaches eliminate the skin incision in the neck but are more invasive. The endoscopic approaches can also be performed with the assistance of robotic techniques. More recently, there have been reports of transoral robotic-assisted thyroidectomy in which the thyroid is approached through the oral cavity. These methods are feasible, but clear benefits over the "traditional" open approach via small neck incisions have not been established.[48]

Typically, endoscopic thyroidectomies are performed under general anesthesia. For the axillary approach, a 30-mm skin incision is made in the axilla, and 12-mm and 5-mm trocars are inserted through this incision (Fig. 38-22F). An additional 5-mm trocar is inserted adjacent to the incision. For the anterior chest approach, a 12-mm skin incision is made in the skin of the anterior chest approximately 3 to 5 cm below the border of the ipsilateral clavicle. Two additional 5-mm trocars are inserted by endoscopic guidance below the ipsilateral clavicle, and carbon dioxide (CO_2) is then insufflated up to a pressure of 4 mmHg to facilitate creation of a working space. The anterior border of the sternocleidomastoid muscle is then separated from the sternohyoid muscle to expose the sternothyroid muscle. The thyroid gland is exposed by splitting the sternothyroid muscle. The lower pole is retracted upward and dissected from the adipose tissue to identify the RLN. As the RLN is exposed, Berry's ligament is exposed and incised with a 5-mm clip or laparoscopic coagulating shears. The upper pole of the thyroid gland is separated from the cricothyroid muscle, and the external branch of the superior laryngeal nerve can be identified during this maneuver. The upper pole of the thyroid gland then is dissected free.

Surgical Removal of Intrathoracic Goiter A goiter is considered mediastinal if at least 50% of the thyroid tissue is located intrathoracically. Mediastinal goiters can be primary or secondary. Primary mediastinal goiters constitute approximately 1% of all mediastinal goiters and arise from accessory (ectopic) thyroid tissue located in the chest. These goiters are supplied by intrathoracic blood vessels and do not have any connection to thyroid tissue in the neck. The vast majority of mediastinal goiters are, however, secondary mediastinal goiters that arise from downward extension of cervical thyroid tissue along the fascial planes of the neck and derive their blood supply from the superior and inferior thyroid arteries. Virtually all intrathoracic goiters can be removed via a cervical incision. Patients who have (a) invasive thyroid cancers, (b) had previous thyroid operations and may have developed parasitic mediastinal vessels, or (c) primary mediastinal goiters with no thyroid tissue in the neck may require a median sternotomy for removal.[49] The chest, however, should be prepared in most cases in the event it is necessary to perform a median sternotomy to control mediastinal bleeding or completely remove an unsuspected invasive cancer. The goiter is approached via a neck incision. The superior pole vessels and the middle thyroid veins are identified and ligated first. Early division of the isthmus helps with subsequent mobilization of the substernal goiter from beneath the sternum. Placement of large 1-0 or 2-0 sutures deep into the goiter, when necessary, helps deliver it. For patients in whom thyroid cancer is suspected or demonstrated in an intrathoracic gland, attempts should be made to avoid rupture of the thyroid capsule. When sternotomy is indicated, the sternum usually should be divided to the level of the third intercostal space and then laterally on one side at the space between the third and fourth ribs (Fig. 38-23).

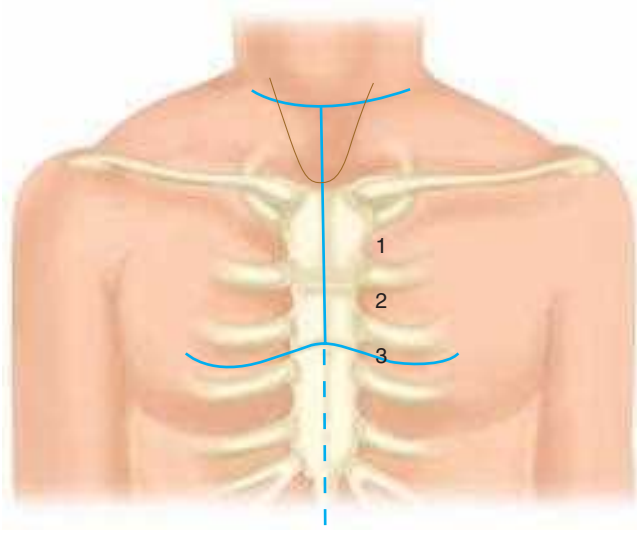

Figure 38-23. Conduct of thyroidectomy. Incisions for a partial sternotomy.

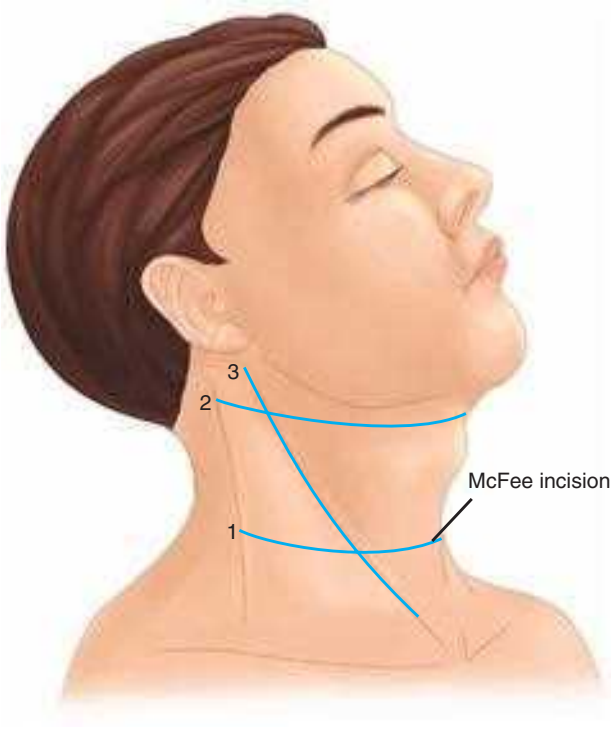
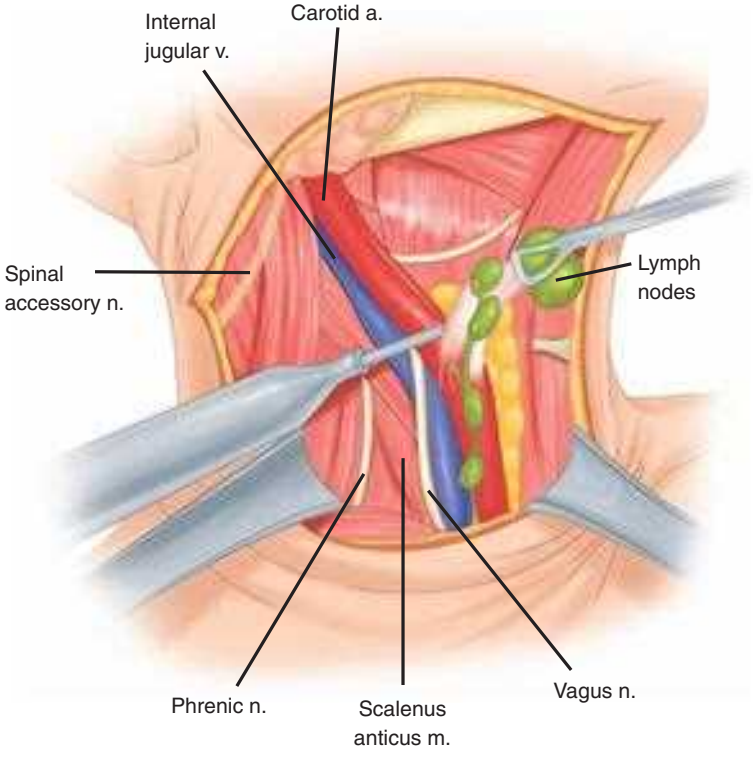
Central and Lateral Neck Dissection for Nodal Metastases

Central compartment (medial to the carotid sheath) lymph nodes frequently are involved in patients with papillary, medullary, and Hürthle cell carcinomas and should be removed at the time of thyroidectomy, preserving the RLNs and parathyroid glands. Central neck dissection is particularly important in patients with medullary and Hürthle cell carcinoma because of the high frequency of microscopic tumor spread and because these tumors cannot be ablated with ^{131}I. An ipsilateral modified radical neck dissection is indicated in the presence of palpable cervical lymph nodes or prophylactically in some patients with medullary carcinoma.

A modified radical (functional) neck dissection can be performed via the cervical incision used for thyroidectomy, which can be extended laterally (Fig. 38-24A) to the anterior margin of the trapezius muscle. The procedure involves removal of all fibro-fatty tissue along the internal jugular vein (levels II, III, and IV) and the posterior triangle (level V). In contrast to



A



B

Figure 38-24. Conduct of neck dissection. **A.** Incisions for modified radical neck dissection. **B.** Anatomic relations of structures identified during a modified radical neck dissection. a. = artery; m. = muscle; n. = nerve.

a radical neck dissection, the internal jugular vein, the spinal accessory nerve, the cervical sensory nerves, and the sternocleidomastoid muscle are preserved unless they are adherent to or invaded by tumor. The procedure begins by opening the plane between the strap muscles medially and the sternocleidomastoid muscle laterally. The anterior belly of the omohyoid muscle is retracted laterally, and the dissection is carried posteriorly until the carotid sheath is reached. The internal jugular vein is retracted medially with a vein retractor and the fibro-fatty tissue and lymph nodes are dissected away from it by a combination of sharp and blunt dissection. The lateral dissection is carried along the posterior border of the sternocleidomastoid muscle, removing the tissue from the posterior triangle. The deep dissection plane is the anterior scalenus muscle, the phrenic nerve, the brachial plexus, and the medial scalenus muscle. The phrenic nerve is preserved on the scalenus anterior muscle, as are the cervical sensory nerves in most patients (Fig. 38-24B). Dissection along the spinal accessory nerve superiorly is most important because this is a frequent site of metastatic disease.

Complications of Thyroid Surgery Nerves, parathyroids, and surrounding structures are all at risk of injury during thyroidectomy. Injury to the RLN may occur by severance, ligation, or traction, but should occur in <1% of patients undergoing thyroidectomy by experienced surgeons. The RLN is most vulnerable to injury during the last 2 to 3 cm of its course, but also can be damaged if the surgeon is not alert to the possibility of nerve branches and the presence of a nonrecurrent nerve, particularly on the right side. If the injury is recognized intraoperatively, most surgeons advocate primary reapproximation of the perineurium using nonabsorbable sutures. Approximately 20% of patients are at risk of injury to the external branches of the superior laryngeal nerve, especially if superior pole vessels are ligated en masse. The cervical sympathetic trunk is at risk of injury in invasive thyroid cancers and retroesophageal goiters and may result in Horner's syndrome. Transient hypocalcemia (from surgical injury or inadvertent removal of parathyroid tissue) has been reported in up to 50% of cases, but permanent hypoparathyroidism occurs <2% of the time. Postoperative hypocalcemia is more likely in patients who undergo concomitant thyroidectomy and central and lateral neck dissection and in patients with Graves' disease. Postoperative hematomas or bleeding may also complicate thyroidectomies and rarely necessitate emergency reoperation to evacuate the hematoma. Bilateral vocal cord dysfunction with airway compromises requires immediate reintubation and tracheostomy. Seromas may need aspiration to relieve patient discomfort. Wound cellulitis and infection and injury to surrounding structures, such as the carotid artery, jugular vein, and esophagus, are infrequent.

Nerve Monitoring Intraoperative RLN and external laryngeal nerve monitoring techniques are being increasingly used during thyroid and parathyroid surgery. Both continuous monitoring using endotracheal tube electrodes and intermittent monitoring by periodic stimulation and laryngeal palpation are used. Many published studies have established the feasibility of nerve monitoring; however, none were able to shown that the technique equivocally reduces nerve injury (particularly by experienced surgeons and especially when the RLN is routinely visually identified) until recently. In 2009, Barczynski and colleagues[50] were the first to demonstrate, in their prospective randomized trial with 2000 nerves at risk that neuromonitoring was associated with a statistically significant improvement in transient RLN injury rates when compared to the practice of visualization of the nerve alone and particularly in patients at higher risk of nerve injury. Of note, there was no difference in permanent RLN injury rates, and a later meta-analysis of all the published studies also failed to show a protective effect of neuromonitoring. Despite this, the technology has become widely adopted. As additional studies have documented that direct RLN stimulation has a low sensitivity of predicting vocal cord paralysis, when compared to vagal stimulation, attempts have been made to identify critical steps in the process. Currently, adequate RLN monitoring includes (a) stimulation of the vagus nerve prior to any dissection in the tracheoesophageal groove; (b) stimulation of the RLN prior to resecting the thyroid; (c) stimulation of the most proximally exposed portion of the RLN after the ligament of Berry has been completely divided; and (d) stimulation of the vagus nerve after complete hemostasis has been achieved on that side of the neck prior to closing or going on to the opposite lobe. Recently, an international group has proposed guidelines for RLN monitoring in thyroid and parathyroid surgery, and pre- and postoperative laryngoscopy is recommended, in addition to vagal stimulation. Not all experts agree with this recommendation.

PARATHYROID

Historical Background

In 1849, the curator of the London Zoological Gardens, Sir Richard Owen, provided the first accurate description of the normal parathyroid gland after autopsy examination of an Indian rhinoceros. However, human parathyroids were not grossly and microscopically described until 1879 by Ivar Sandström, a medical student in Uppsala, Sweden. He suggested that these glands be named the *glandulae parathyroideae*, although their function was not known.

The association of HPT and the bone disease osteitis fibrosa cystica (described by von Recklinghausen) was recognized in 1903. Calcium measurement became possible in 1909, and the association between serum calcium levels and the parathyroid glands was established. The first successful parathyroidectomy was performed in 1925 by Felix Mandl on a 38-year-old man who had severe bone pain secondary to advanced osteitis fibrosa cystica. The patient's condition dramatically improved after the operation, and he lived for another 7 years before dying of recurrent HPT or renal failure. In 1926, the first parathyroid operation was performed at Massachusetts General Hospital. Edward Churchill, assisted by an intern named Oliver Cope, operated on the famous sea captain Charles Martell for severe primary HPT (PHPT). It was not until his seventh operation, which included total thyroidectomy, that an ectopic adenoma was found substernally. Unfortunately, Captain Martell died 6 weeks later, likely due to laryngeal spasm and complications of renal stones and ureteral obstruction. The first successful parathyroidectomy for HPT in the United States was performed on a 56-year-old woman in 1928 by Isaac Y. Olch at the Barnes Hospital in St. Louis, Missouri. At operation, a parathyroid adenoma was found attached to the left lower lobe of the thyroid gland. Postoperatively, the patient developed tetany, requiring lifelong supplemental calcium.

Embryology

In humans, the superior parathyroid glands are derived from the fourth branchial pouch, which also gives rise to the thyroid gland. The third branchial pouches give rise to the inferior parathyroid glands and the thymus (Fig. 38-25). The parathyroids

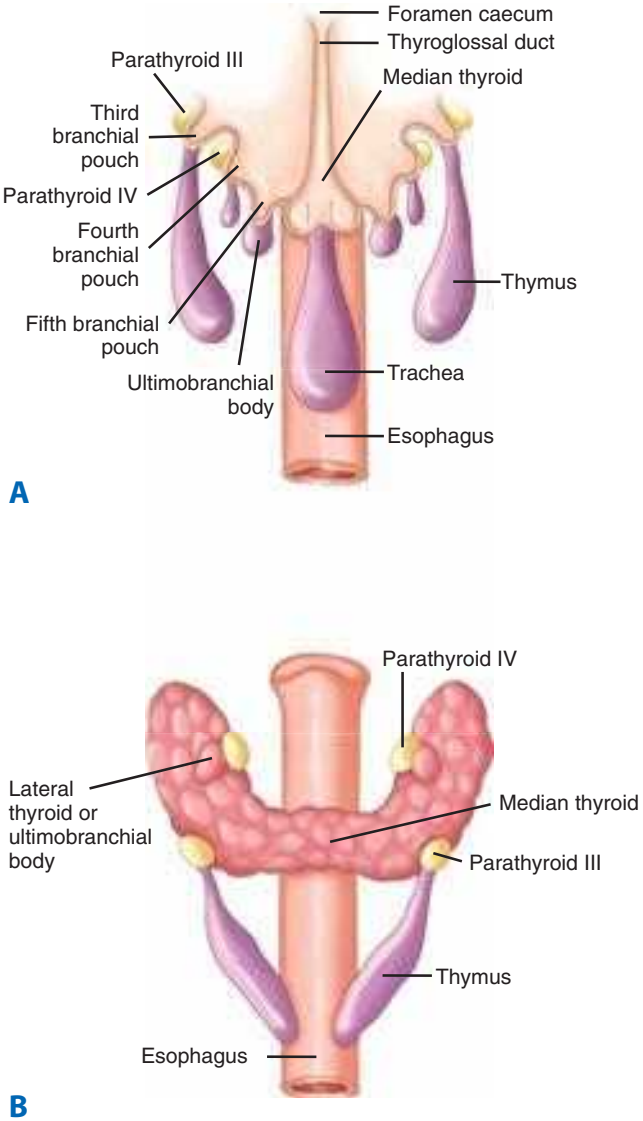


Figure 38-25. Parathyroid embryology. Figure demonstrates a schematic view of the pharynx of an 8- to 10-mm embryo (**A**) and locations of the thyroid, parathyroid, and thymic tissues in a 13- to 14-mm embryo (**B**). The lower parathyroids are derived from the third branchial pouch and migrate with the thymus, whereas the upper parathyroids are derived from the fourth branchial pouch and lie in close proximity to the ultimobranchial bodies. *(Reproduced with permission from Henry J. Applied embryology of the thyroid and parathyroid glands. In: Randolph G, ed.* Surgery of the Thyroid and Parathyroid Glands. *Philadelphia: WB Saunders Company; 2003. Copyright Elsevier.)*

remain closely associated with their respective branchial pouch derivatives. The position of normal superior parathyroid glands is more consistent, with 80% of these glands being found near the posterior aspect of the upper and middle thyroid lobes, at the level of the cricoid cartilage.[51] Approximately 1% of normal upper glands may be found in the paraesophageal or retroesophageal space. Enlarged superior glands may descend in the tracheoesophageal groove and come to lie caudal to the inferior glands. Truly ectopic superior parathyroid glands are rare, but may be found in the middle or posterior mediastinum or in the aortopulmonary window.[51] As the embryo matures, the thymus and inferior parathyroids migrate together caudally in the neck. The most common location for inferior glands is within a distance of 1 cm from a point centered where the inferior thyroid artery and RLN cross. Approximately 15% of inferior glands are found in the thymus. The position of the inferior glands, however, tends to be more variable due to their longer migratory path. Undescended inferior glands may be found near the skull base, angle of the mandible, or superior to the upper parathyroid glands along with an undescended thymus. The frequency of intrathyroidal glands is about 2%.

Anatomy and Histology

Most patients have four parathyroid glands. The superior glands usually are dorsal to the RLN at the level of the cricoid cartilage, whereas the inferior parathyroid glands are located ventral to the nerve. Normal parathyroid glands are gray and semitransparent in newborns but appear golden yellow to light brown in adults. Parathyroid color depends on cellularity, fat content, and vascularity. Moreover, they often are embedded in and sometimes difficult to discern from surrounding fat. Normal parathyroid glands are located in loose tissue or fat and are ovoid. They measure up to 7 mm in size and weigh approximately 40 to 50 mg each. Parathyroid glands usually derive their blood supply from branches of the inferior thyroid artery, although branches from the superior thyroid artery supply at least 20% of upper glands. Branches from the thyroidea ima, and vessels to the trachea, esophagus, larynx, and mediastinum may also be found. The parathyroid glands drain ipsilaterally by the superior, middle, and inferior thyroid veins.

Akerström and colleagues,[52] in an autopsy series of 503 cadavers, found four parathyroid glands in 84% of cases. Supernumerary glands were present in 13% of patients, most commonly in the thymus. Only 3% of patients had less than four glands. Similar results were obtained in other dissection studies of 428 human subjects by Gilmour who reported a 6.7% incidence of supernumerary glands.[53]

Histologically, parathyroid glands are composed of chief cells and oxyphil cells arranged in trabeculae, within a stroma composed primarily of adipose cells (Fig. 38-26). The parathyroid glands of infants and children are composed mainly of chief cells, which produce parathyroid hormone (PTH). Acidophilic, mitochondria-rich oxyphil cells are derived from chief cells, can be seen around puberty, and increase in numbers in adulthood. A third group of cells, known as *water-clear cells*, also

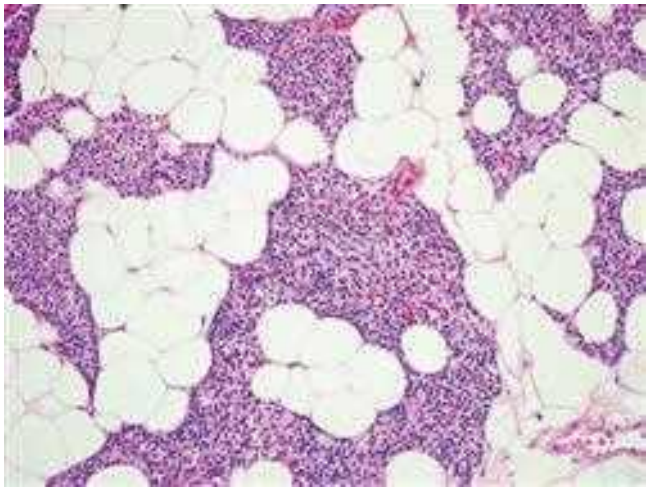

Figure 38-26. Normal parathyroid histology showing chief cells interspersed with adipose cells.

are derived from chief cells, are present in small numbers, and are rich in glycogen. Although most oxyphil and water-clear cells retain the ability to secrete PTH, their functional significance is not known.

Parathyroid Physiology and Calcium Homeostasis

Calcium is the most abundant cation in human beings and has several crucial functions. Extracellular calcium levels are 10,000-fold higher than intracellular levels, and both are tightly controlled. Extracellular calcium is important for excitation-contraction coupling in muscle tissues, synaptic transmission in the nervous system, coagulation, and secretion of other hormones. Intracellular calcium is an important second messenger regulating cell division, motility, membrane trafficking, and secretion. Calcium is absorbed from the small intestine in its inorganic form. Calcium fluxes in the steady state are depicted in Fig. 38-27.

Extracellular calcium (900 mg) accounts for only 1% of the body's calcium stores, the majority of which is sequestered in the skeletal system. Approximately 50% of the serum calcium is in the ionized form, which is the active component. The remainder is bound to albumin (40%) and organic anions such as phosphate and citrate (10%). The total serum calcium levels range from 8.5 to 10.5 mg/dL (2.1 to 2.6 mmol/L), and ionized calcium levels range from 4.4 to 5.2 mg/dL (1.1 to 1.3 mmol/L). Both concentrations are tightly regulated. The total serum calcium level must always be considered in its relationship to plasma protein levels, especially serum albumin. For each gram per deciliter of alteration of serum albumin above or below 4.0 mg/dL, there is a 0.8 mg/dL increase or decrease in protein-bound calcium and, thus, in total serum calcium levels. Total and, particularly, ionized calcium levels are influenced by various hormone systems.

Parathyroid Hormone. The parathyroid cells rely on a G-protein–coupled membrane receptor, designated the calcium-sensing receptor (CASR), to regulate PTH secretion by sensing extracellular calcium levels[54] (Fig. 38-28). PTH secretion also is stimulated by low levels of 1,25-dihydroxy vitamin D, catecholamines, and hypomagnesemia. The PTH gene is located on chromosome 11. PTH is synthesized in the parathyroid gland as a precursor hormone preproPTH, which is cleaved first to pro-PTH and then to the final 84-amino-acid PTH. Secreted PTH has a half-life of 2 to 4 minutes. In the liver, PTH is metabolized into the active N-terminal component and the relatively inactive C-terminal fraction. The C-terminal component is excreted by the kidneys and accumulates in chronic renal failure.

PTH functions to regulate calcium levels via its actions on three target organs, the bone, kidney, and gut. PTH increases the resorption of bone by stimulating osteoclasts and promotes the release of calcium and phosphate into the circulation. At the kidney, calcium is primarily absorbed in concert with sodium in the proximal convoluted tubule, but fine adjustments occur more distally. PTH acts to limit calcium excretion at the distal convoluted tubule via an active transport mechanism. PTH also inhibits phosphate reabsorption (at the proximal convoluted tubule) and bicarbonate reabsorption. It also inhibits the Na^+/H^+ antiporter, which results in a mild metabolic acidosis in hyperparathyroid states. PTH and hypophosphatemia also enhance 1-hydroxylation of 25-hydroxyvitamin D, which is responsible for its indirect effect of increasing intestinal calcium absorption.

Calcitonin. Calcitonin is produced by thyroid C cells and functions as an antihypercalcemic hormone by inhibiting osteoclast-mediated bone resorption. Calcitonin production is stimulated by calcium and pentagastrin and also by catecholamines, cholecystokinin, and glucagon. When administered intravenously to experimental animals, it produces hypocalcemia. At the kidney, calcitonin increases phosphate excretion by inhibiting its reabsorption. Calcitonin plays a minimal, if any, role in the regulation of calcium levels in humans. However, it is very useful as a marker of MTC and in treating acute hypercalcemic crisis.

Vitamin D. Vitamin D refers to vitamin D_2 and vitamin D_3, both of which are produced by photolysis of naturally occurring sterol precursors. Vitamin D_2 is available commercially in pharma-

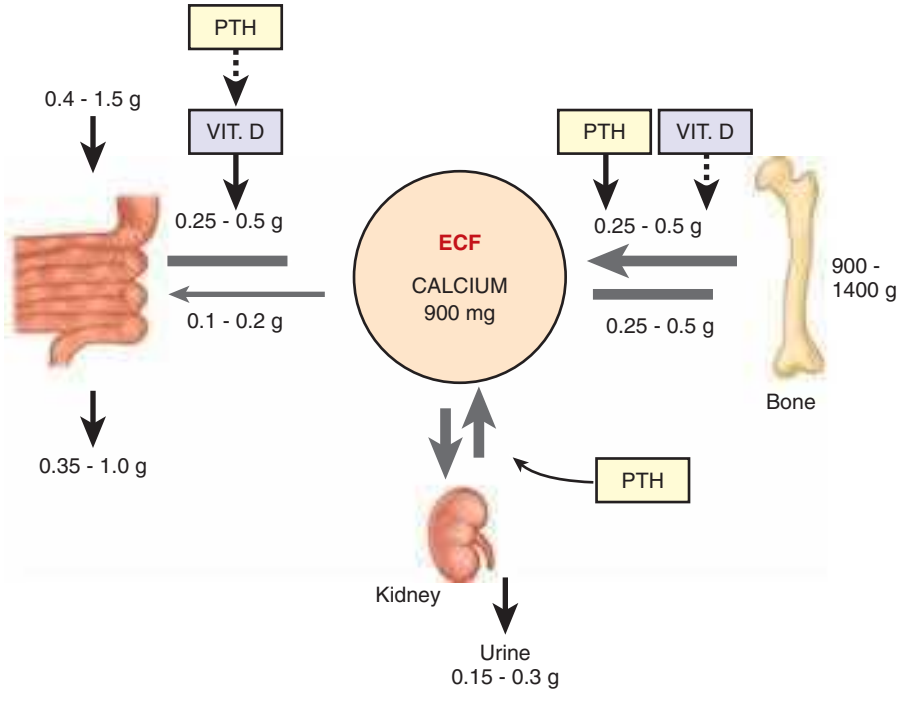

Figure 38-27. Calcium balance and fluxes in a normal human. *Solid arrows* depict a direct effect, whereas *dashed arrows* depict an indirect effect. The thickness of the arrows is representative of the magnitude of the flux. ECF = extracellular fluid; PTH = parathyroid hormone; VIT. = vitamin. *(Reproduced with permission from Bruder J, et al. Mineral metabolism. In: Felig P, Frohman L, eds.* Endocrinology and Metabolism. *New York: McGraw-Hill Publishers, Inc; 2001:1081. Copyright © The McGraw-Hill Companies, Inc.)*

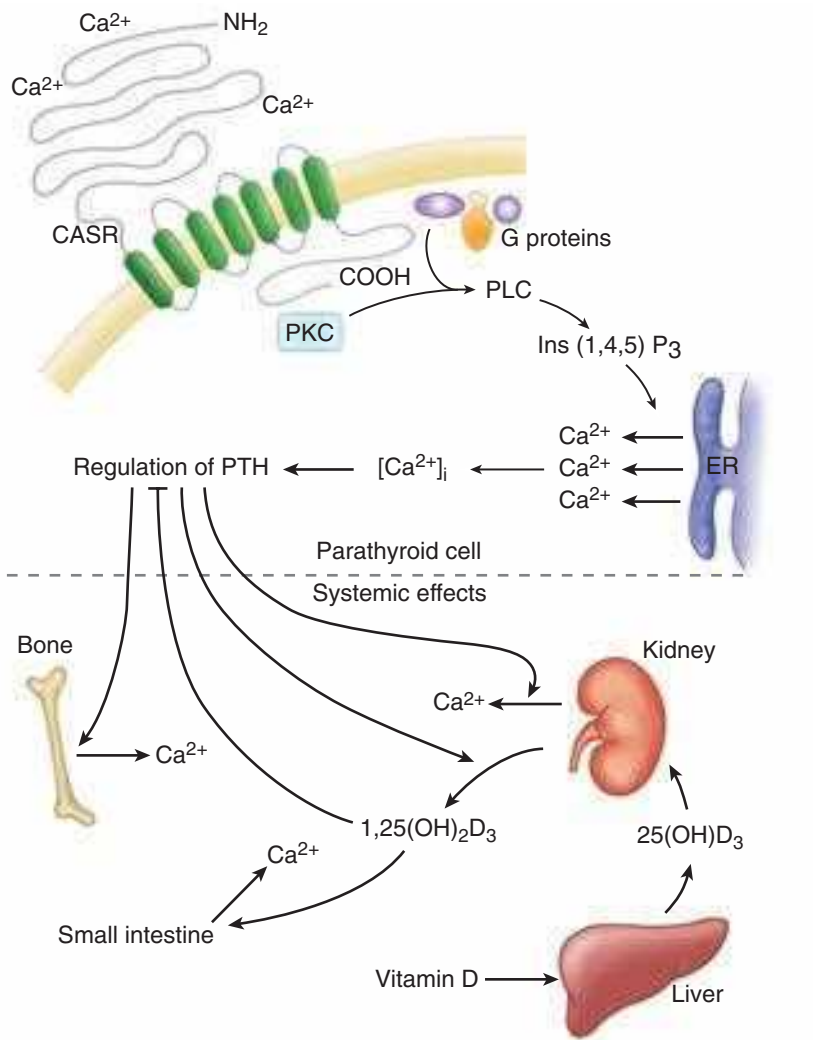

Figure 38-28. Regulation of calcium homeostasis. The calcium-sensing receptor (CASR) is expressed on the surface of the parathyroid cell and senses fluctuations in the concentration of extracellular calcium. Activation of the receptor is thought to increase intracellular calcium levels, which, in turn, inhibit parathyroid hormone (PTH) secretion via posttranslational mechanisms. Increased PTH secretion leads to an increase in serum calcium levels by increasing bone resorption and enhancing renal calcium reabsorption. PTH also stimulates renal 1-α-hydroxylase activity, leading to an increase in 1,25-dihydroxy vitamin D, which also exerts a negative feedback on PTH secretion. PKC = protein kinase C; PLC = phospholipase C. *(Reproduced with permission from Carling T. Molecular pathology of parathyroid tumors.* Trends Endocrinol Metab. *2001;12:54. Copyright Elsevier.)*

ceutical preparations, whereas vitamin D_3 is the most important physiologic compound and is produced from 7-dehydrocholesterol, which is found in the skin. Vitamin D is metabolized in the liver to its primary circulating form, 25-hydroxyvitamin D. Further hydroxylation in the kidney results in 1,25-dihydroxy vitamin D, which is the most metabolically active form of vitamin D. Vitamin D stimulates the absorption of calcium and phosphate from the gut and the resorption of calcium from the bone.

Hyperparathyroidism

Hyperfunction of the parathyroid glands may be classified as primary, secondary, or tertiary. PHPT arises from increased PTH production from abnormal parathyroid glands and results from a disturbance of normal feedback control exerted by serum calcium. Elevated PTH levels may also occur as a compensatory response to hypocalcemic states resulting from chronic renal failure or GI malabsorption of calcium. This secondary HPT can be reversed by correction of the underlying problem (e.g., kidney transplantation for chronic renal failure). However, chronically stimulated glands may occasionally become autonomous, resulting in persistence or recurrence of hypercalcemia after successful renal transplantation, resulting in tertiary HPT.

Primary Hyperparathyroidism. PHPT is a common disorder, affecting 100,000 individuals annually in the United States. PHPT occurs in 0.1% to 0.3% of the general population and is more common in women (1:500) than in men (1:2000). Increased PTH production leads to hypercalcemia via increased GI absorption of calcium, increased production of vitamin D_3, and reduced renal calcium clearance. PHPT is characterized by increased parathyroid cell proliferation and PTH secretion that is independent of calcium levels.

Etiology. The exact cause of PHPT is unknown, although exposure to low-dose therapeutic ionizing radiation and familial predisposition account for some cases. Various diets and intermittent exposure to sunshine may also be related. Other causes include renal leak of calcium and declining renal function with

age as well as alteration in the sensitivity of parathyroid glands to suppression by calcium. The latency period for development of PHPT after radiation exposure is longer than that for the development of thyroid tumors, with most cases occurring 30 to 40 years after exposure. Patients who have been exposed to radiation have similar clinical presentations and calcium levels when compared to patients without a history of radiation exposure. However, the former tend to have higher PTH levels and a higher incidence of concomitant thyroid neoplasms. Lithium therapy has been known to shift the set point for PTH secretion in parathyroid cells, thereby resulting in elevated PTH levels and mild hypercalcemia. Lithium stimulates the growth of abnormal parathyroid glands in vitro and also in susceptible patients in vivo.[55] PHPT results from the enlargement of a single gland or parathyroid adenoma in approximately 80% of cases, multiple adenomas or hyperplasia in 15% to 20% of patients, and parathyroid carcinoma in 1% of patients. Existence of two enlarged glands or double adenomas is supported by biochemical (calcium and PTH), intraoperative PTH (IOPTH), molecular, and histologic data. This entity is less common in younger patients but accounts for up to 10% of older patients with PHPT. It should be emphasized that when more than one abnormal parathyroid gland is identified preoperatively or intraoperatively, the patient has hyperplasia (all glands abnormal) until proven otherwise.

Genetics Most cases of PHPT are sporadic. However, PHPT also occurs within the spectrum of a number of inherited disorders such as MEN1, MEN2A, isolated familial HPT, and familial HPT with jaw-tumor syndrome. All of these syndromes are inherited in an autosomal dominant fashion. PHPT is the earliest and most common manifestation of MEN1[56] and develops in 80% to 100% of patients by age 40 years old. These patients also are prone to pancreatic neuroendocrine tumors and pituitary adenomas and, less commonly, to adrenocortical tumors, lipomas, skin angiomas, and carcinoid tumors of the bronchus, thymus, or stomach. About 50% of patients develop gastrinomas, which often are multiple and metastatic at diagnosis. Insulinomas develop in 10% to 15% of cases, whereas many patients have nonfunctional pancreatic endocrine tumors. Prolactinomas occur in 10% to 50% of MEN1 patients and constitute the most common pituitary lesion. MEN1 has been shown to result from germline mutations in the *MEN1* gene, a tumor suppressor gene located on chromosome 11q12-13 that encodes menin, a protein that is postulated to interact with the transcription factors JunD and nuclear factor-κB in the nucleus, in addition to replication protein A and other proteins.[57] Most *MEN1* mutations result in a nonfunctional protein and are scattered throughout the translated nine exons of the gene. This makes presymptomatic screening for mutation carriers difficult. *MEN1* mutations also have been found in kindreds initially suspected to represent isolated familial HPT. HPT develops in about 20% of patients with MEN2A and generally is less severe. MEN2A is caused by germline mutations of the *RET* proto-oncogene located on chromosome 10. In contrast to MEN1, genotype-phenotype correlations have been noted in this syndrome in that individuals with mutations at codon 634 are more likely to develop HPT. Patients with the familial HPT with jaw-tumor syndrome have an increased predisposition to parathyroid carcinoma. This syndrome maps to a tumor suppressor locus *HRPT2* (CDC73 or parafibromin) on chromosome 1. Patients belonging to isolated HPT kindreds also appear to demonstrate linkage to *HRPT2*.

Approximately 25% to 40% of sporadic parathyroid adenomas and some hyperplastic parathyroid glands have loss of heterozygosity (LOH) at 11q13, the site of the *MEN1* gene. The parathyroid adenoma 1 oncogene (*PRAD1*), which encodes cyclin D1, a cell cycle control protein, is overexpressed in about 18% of parathyroid adenomas. This was demonstrated to result from a rearrangement on chromosome 11 that places the *PRAD1* gene under the control of the PTH promoter. Other chromosomal regions deleted in parathyroid adenomas and possibly reflecting loss of tumor suppressor genes include 1p, 6q, and 15q, whereas amplified regions suggesting oncogenes have been identified at 16p and 19p. *RET* mutations are rare in sporadic parathyroid tumors. Sporadic parathyroid cancers are characterized by uniform loss of the tumor suppressor gene *RB*, which is involved in cell cycle regulation, and 60% have *HRPT2* (CDC73) mutations. These alterations are rare in benign parathyroid tumors and may have implications for diagnosis. The *p53* tumor suppressor gene is also inactivated in a subset (30%) of parathyroid carcinomas.

Clinical Manifestations Patients with PHPT formerly presented with the "classic" pentad of symptoms (i.e., kidney stones, painful bones, abdominal groans, psychic moans, and fatigue overtones). With the advent and widespread use of automated blood analyzers in the early 1970s, there has been an alteration in the "typical" patient with PHPT. They are more likely to be minimally symptomatic or asymptomatic. Currently, most patients present with weakness, fatigue, polydipsia, polyuria, nocturia, bone and joint pain, constipation, decreased appetite, nausea, heartburn, pruritus, depression, and memory loss. Patients with PHPT also tend to score lower than healthy controls when assessed by general multidimensional health assessment tools such as the Medical Outcomes Study Short-Form Health Survey (SF-36) and other specific questionnaires. Furthermore, these symptoms and signs improve in most, but certainly not all, patients after parathyroidectomy. Truly "asymptomatic" PHPT appears to be rare, occurring in <5% of patients, as determined by prospectively administered questionnaires. Complications of PHPT are described below.

Renal Disease. Approximately 80% of patients with PHPT have some degree of renal dysfunction or symptoms. Kidney stones were previously reported in up to 80% of patients but now occur in about 20% to 25%. The calculi are typically composed of calcium phosphate or oxalate. In contrast, PHPT is found to be the underlying disorder in only 3% of patients presenting with nephrolithiasis. *Nephrocalcinosis*, which refers to renal parenchymal calcification, is found in <5% of patients and is more likely to lead to renal dysfunction. Chronic hypercalcemia also can impair concentrating ability, thereby resulting in polyuria, polydipsia, and nocturia. The incidence of hypertension is variable but has been reported to occur in up to 50% of patients with PHPT. Hypertension appears to be more common in older patients and correlates with the magnitude of renal dysfunction and, in contrast to other symptoms, is least likely to improve after parathyroidectomy.

Bone Disease. Bone disease, including osteopenia, osteoporosis, and osteitis fibrosa cystica, is found in about 15% of patients with PHPT. Increased bone turnover, as found in patients with osteitis fibrosa cystica, can be determined by documenting an elevated blood alkaline phosphatase level. Advanced PHPT with osteitis fibrosa cystica now occurs in <5% of patients. It has pathognomonic radiologic findings, which are best seen

on x-rays of the hands and are characterized by subperiosteal resorption (most apparent on the radial aspect of the middle phalanx of the second and third fingers), bone cysts, and tufting of the distal phalanges (Fig. 38-29). The skull also may be affected and appears mottled with a loss of definition of the inner and outer cortices. Brown or osteoclastic tumors and bone cysts also may be present. Severe bone disease, resulting in bone pain and tenderness and/or pathologic fractures, is rarely observed nowadays. However, reductions of bone mineral density (BMD) with osteopenia and osteoporosis are more common. Patients with normal serum alkaline phosphatase levels almost never have clinically apparent osteitis fibrosa cystica. HPT typically results in a loss of bone mass at sites of cortical bone such as the radius and relative preservation of cancellous bone such as that located at the vertebral bodies. Patients with PHPT, however, also may have osteoporosis of the lumbar spine that improves dramatically following parathyroidectomy. Fractures also occur more frequently in patients with PHPT, and the incidence of fractures also decreases after parathyroidectomy. Bone disease correlates with serum PTH and vitamin D levels.

Figure 38-29. X-ray of the hand showing subperiosteal bone resorption most apparent along the radial aspect of the middle phalanx, characteristic of osteitis fibrosa cystica.

Gastrointestinal Complications. PHPT has been associated with peptic ulcer disease. In experimental animals, hypergastrinemia has been shown to result from PTH infusion into blood vessels supplying the stomach, independent of its effects on serum calcium. An increased incidence of pancreatitis also has been reported in patients with PHPT, although this appears to occur only in patients with profound hypercalcemia (Ca^{2+} ≥12.5 mg/dL). Patients with PHPT also have an increased incidence of cholelithiasis, presumably due to an increase in biliary calcium, which leads to the formation of calcium bilirubinate stones.

Neuropsychiatric Complications. Severe hypercalcemia may lead to various neuropsychiatric manifestations such as florid psychosis, obtundation, or coma. Other findings such as depression, anxiety, and fatigue are more commonly observed in patients with only mild hypercalcemia. The etiology of these symptoms is not known. Studies demonstrate that levels of certain neurotransmitters (monoamine metabolites 5-hydroxyindoleacetic acid and homovanillic acid) are reduced in the cerebrospinal fluid of patients with PHPT when compared to controls. Electroencephalogram abnormalities also occur in patients with primary and secondary HPT and normalize following parathyroidectomy.

Other Features. PHPT also can lead to fatigue and muscle weakness, which is prominent in the proximal muscle groups. Although the exact etiology of this finding is not known, muscle biopsy studies show that weakness results from a neuropathy, rather than a primary myopathic abnormality. Patients with HPT also have an increased incidence of chondrocalcinosis, gout, and pseudogout, with deposition of uric acid and calcium pyrophosphate crystals in the joints. Calcification at ectopic sites such as blood vessels, cardiac valves, and skin also has been reported, as has hypertrophy of the left ventricle independent of the presence of hypertension. There is also evidence for subtle cardiovascular manifestations in mild disease, such as changes in endothelial function, increased vascular stiffness, and perhaps subtle diastolic dysfunction. Several large studies from Europe also suggest that PHPT is associated with increased death rates from cardiovascular disease and cancer even in patients with mild HPT, although this finding was not substantiated in North American studies.

Physical Findings Parathyroid tumors are seldom palpable, except in patients with profound hypercalcemia or parathyroid cancer. A palpable neck mass in a patient with PHPT is more likely to be thyroid in origin or a parathyroid cancer. Patients also may demonstrate evidence of band keratopathy, a deposition of calcium in Bowman's membrane just inside the iris of the eye. This nonspecific condition generally is caused by chronic eye diseases such as uveitis, glaucoma, and trauma but also may occur in the presence of conditions associated with high calcium or phosphate levels. Fibro-osseous jaw tumors, and/or the presence of familial disease in patients with PHPT and jaw tumors, if present, should alert the physician to the possibility of parathyroid carcinoma.

Differential Diagnosis Hypercalcemia may be caused by a multitude of conditions, as listed in Table 38-9. PHPT and malignancy account for >90% of all cases of hypercalcemia. PHPT is more common in the outpatient setting, whereas malignancy is the leading cause of hypercalcemia in hospitalized patients. PHPT can virtually always be distinguished from other diseases causing hypercalcemia by a combination of history, physical examination, and appropriate laboratory investigations.

Table 38-9

Differential diagnosis of hypercalcemia

Hyperparathyroidism
Malignancy—hematologic (multiple myeloma), solid tumors (due to PTHrP)
Endocrine diseases—hyperthyroidism, Addisonian crisis, VIPoma
Granulomatous diseases—sarcoidosis, tuberculosis, berylliosis, histoplasmosis
Milk-alkali syndrome
Drugs—thiazide diuretics, lithium, vitamin A or D intoxication
Familial hypocalciuric hypercalcemia
Paget's disease
Immobilization

PTHrP = parathyroid hormone-related protein; VIP = vasoactive intestinal peptide.

Hypercalcemia associated with malignancy includes three distinct syndromes. Although bone metastases may cause hypercalcemia, patients with solid tumors of the lung, breast, kidney, head and neck, and ovary often have humoral hypercalcemia of malignancy, without any associated bony metastases. In addition, hypercalcemia also may be associated with hematologic malignancies such as multiple myeloma. Humoral hypercalcemia of malignancy is known to be mediated primarily by PTH-related peptide (PTHrP), which also plays a role in the hypercalcemia associated with bone metastases and multiple myeloma.

Thiazide diuretics cause hypercalcemia by decreasing renal clearance of calcium. This corrects in normal patients within days to weeks after discontinuing the diuretic, but patients with PHPT continue to be hypercalcemic. Thiazide diuretics can, therefore, exacerbate underlying PHPT and can be used to unmask PHPT in patients with borderline hypercalcemia. Familial hypocalciuric hypercalcemia (FHH) is a rare autosomal dominant condition with nearly 100% penetrance and results from inherited heterozygous mutations in the CASR gene located on chromosome 3.[54] Homozygous germline mutations at this locus result in neonatal hypercalcemia, a condition that can rapidly prove fatal. Patients with FHH have lifelong hypercalcemia, which is not corrected by parathyroidectomy. Hypercalcemia also is found in approximately 10% of patients with sarcoidosis secondary to increased 25-hydroxy vitamin D 1-hydroxylase activity in lymphoid tissue and pulmonary macrophages, which is not subject to inhibitory feedback control by serum calcium. Thyroid hormone also has bone-resorption properties, thus causing hypercalcemia in thyrotoxic states, especially in immobilized patients. Hemoconcentration appears to be an important factor in the hypercalcemia associated with adrenal insufficiency and pheochromocytoma, although the latter patients may have associated parathyroid tumors (MEN2A), and some pheochromocytomas are known to secrete PTHrP. Other endocrine lesions such as vasoactive intestinal peptide–secreting tumors may be associated with hypercalcemia due to increased secretion of PTHrP. Milk-alkali syndrome requires the ingestion of large quantities of calcium with an absorbable alkali such as that used in the treatment of peptic ulcer disease with antacids. Ingestions of large quantities of vitamins D and A are infrequent causes of hypercalcemia, as is immobilization.

Diagnostic Investigations

Biochemical Studies. The presence of an elevated serum calcium and intact PTH or two-site PTH levels, without hypocalciuria, establishes the diagnosis of PHPT with virtual certainty. These sensitive PTH assays use immunoradiometric or immunochemiluminescent techniques and can reliably distinguish PHPT from other causes of hypercalcemia. Furthermore, they do not cross-react with PTHrP (Fig. 38-30). In patients with metastatic cancer and hypercalcemia, intact PTH levels help to determine whether the patient also has concurrent PHPT. Although extremely rare, a patient with hypercalcemia may have a tumor that secretes PTH. FNAB of such a tumor for PTH levels or selective venous catheterization of the veins draining such tumors can help clarify the diagnosis.

Patients with PHPT also typically have decreased serum phosphate (~50%) and elevated 24-hour urinary calcium concentrations (~60%). A mild hyperchloremic metabolic acidosis also is present (80%), thereby leading to an elevated chloride-to-phosphate ratio (>33). Urinary calcium levels need not be measured routinely, except in patients who have not had previously documented normocalcemia or have a family history of hypercalcemia to rule out FHH. In patients with FHH, 24-hour urinary calcium excretion is characteristically low (<100 mg/d). Furthermore, the serum calcium-to-creatinine clearance ratio usually is <0.01 in patients with FHH, whereas it is typically >0.02 in patients with PHPT. Other biochemical features of PHPT are listed in Table 38-10. Elevated levels of alkaline

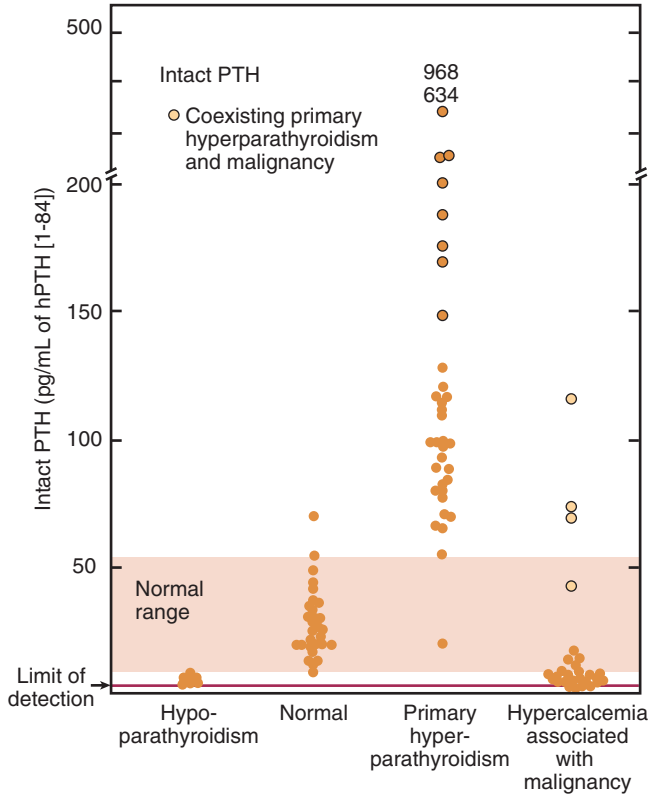

Figure 38-30. Intact parathyroid hormone (PTH) measurement allows differentiation between the various causes of hypercalcemia. *(Reproduced with permission from Endres D, et al. Measurement of parathyroid hormone.* Endocrinol Metab Clin North Am. *1989;18:622. Copyright Elsevier.)*

Table 38-10

Biochemical features of primary hyperparathyroidism

SERUM TESTS	ALTERATION
Calcium	Increased, except in normocalcemic primary hyperparathyroidism
Intact PTH	Increased or inappropriately high
Chloride	Increased or high normal
Phosphate	Decreased or low normal
Chloride:phosphate ratio	Increased (usually >33)
Magnesium	Unchanged or decreased (in patients with osteitis fibrosa cystica)
Uric acid	Normal or increased
Alkaline phosphatase	Normal or increased (in the presence of high turnover bone disease)
Acid-base status	Mild hyperchloremic metabolic acidosis
Calcium:creatinine clearance ratio	>0.02 (vs. <0.01 in FHH)
1,25-dihydroxy vitamin D	Normal or increased
Urine tests	
24-h urinary calcium	Normal or increased

BFHH = benign familial hypocalciuric hypercalcemia; PTH = parathyroid hormone.

phosphatase may be found in approximately 10% of patients with PHPT and are indicative of high-turnover bone disease. These patients are prone to developing postoperative hypocalcemia due to bone hunger. Serum and urine protein electrophoresis may be necessary to exclude multiple myeloma.

Occasionally, patients present with normocalcemic PHPT due to vitamin D deficiency, a low serum albumin, excessive hydration, a high-phosphate diet, or a low normal blood calcium set point. These patients have increased total PTH levels with or without increased blood ionized calcium levels and must be distinguished from patients with renal leak hypercalciuria who also have increased PTH levels due to excessive calcium loss in the urine. This can be accomplished by administering thiazide diuretics. In patients with idiopathic hypercalciuria, the urinary calcium level falls, and the secondary increase in the blood PTH level also decreases to normal, whereas patients with normocalcemic HPT continue to have elevated urine calcium and blood PTH levels and may, in fact, become hypercalcemic.

Radiologic Tests. In patients with profound hypercalcemia or PHPT associated with vitamin D deficiency, hand and skull x-rays may demonstrate osteitis fibrosa cystica, but this is rare in current clinical practice. BMD studies using dual-energy absorptiometry are being increasingly used to assess the effects of PHPT on bone. Abdominal ultrasound examination is used selectively to document renal stones. Parathyroid localization studies are not used to confirm the diagnosis of PHPT, but rather to aid in identifying the location of the offending gland(s), as discussed later in Preoperative Localization Tests.

Treatment

Indications for Parathyroidectomy and Role of Medical Management. Most authorities agree that patients who have developed complications and have "classic" symptoms of PHPT should undergo parathyroidectomy. However, the treatment of patients with asymptomatic PHPT has been the subject of controversy, due, in part, to the fact that there is little agreement on what constitutes an asymptomatic patient.

At the National Institutes of Health consensus conference in 1990, "asymptomatic" PHPT was defined as "the absence of common symptoms and signs of PHPT, including no bone, renal, gastrointestinal, or neuromuscular disorders." To determine the best course of action for these patients, it is important to consider the natural history of untreated PHPT and the outcomes of treatment options, both medical and surgical.

With respect to the natural history, the panel advocated nonoperative management of these patients with mild PHPT based on observational studies, which suggested relative stability of biochemical parameters over time. However, the consensus panel considered certain patients to be candidates for surgery based on testing or other information indicating end-organ effects or a higher likelihood of disease progression, and this led to the establishment of initial guidelines for parathyroidectomy.[58] Subsequently, another observational study on the natural history of treated versus untreated HPT was published by Silverberg and colleagues.[59] In their cohort of 52 patients with asymptomatic HPT followed without surgery, levels of serum and urinary calcium, PTH, alkaline phosphatase, and vitamin D metabolites remained relatively stable over a 10-year period in most patients. Average bone mass also remained relatively stable. However, the study also reported development of a new indication for surgery in 14 (27%) of 52 of their asymptomatic patients and, because approximately 50% of their patients were initially treated surgically, overall, about 75% of patients were underwent parathyroidectomy. Age <50 years was predictive of progression, and patients undergoing parathyroidectomy showed not only normalization of calcium and PTH levels, but also improved BMD at the spine and hip. Based on these and other studies, the guidelines were reassessed at a second workshop on asymptomatic PHPT held at the National Institutes of Health in 2002.[60]

Since that time, additional studies have provided further insights into the natural history of treated and untreated HPT. Three of these were randomized, controlled, prospective studies ranging in duration from 1 to 3.5 years. One was an observational study (a continuation of the Columbia University PHPT Project) but was notable for its long duration of follow-up of 15 years.[61] These studies confirmed the relative stability of various biochemical indices, thus validating the need for guidelines. However, the long-term study suggested that the stability was not indefinite as calcium levels tended to rise in years 13 to 15. In addition, the study also demonstrated that bone density measurements remained stable for 8 to 10 years, but cortical bone density worsened after year 10. More concerning was the fact that 60% of patients lost >10% of their BMD over the 15-year observation period. Furthermore, whether patients met the 2002 guidelines for surgery did not appear to predict the risk of progressive disease, with 40% of patients undergoing follow-up eventually needing surgery. Although there are no randomized trials, registry data also suggest that fracture risk is increased for PHPT up to 10 years prior to diagnosis and treatment.

Medical options for treating PHPT and its complications include antiresorptive treatments such as bisphosphonates,

hormone replacement therapy (HRT), and selective estrogen receptor modulators such as raloxifene.[62] Bisphosphonates and HRT are reasonable options in patients for whom skeletal protection is needed, as evidence from randomized, placebo-controlled trials indicates that these medications are very effective at decreasing bone turnover and increasing BMD in PHPT, with the effects being comparable to patients undergoing parathyroidectomy. Caution needs to be exercised due to the nonskeletal effects of HRT, and hence, bisphosphonates are preferred. There are no clinical studies regarding the effects of raloxifene on BMD in HPT, and none of these agents affects calcium or PTH levels. More recently, calcimimetics (modifiers of the sensitivity of the CASR) have been used in randomized, multicenter controlled trials and have been shown to decrease both serum calcium and PTH levels in both symptomatic and asymptomatic PHPT patients. Unfortunately, bone density failed to improve in medically treated patients. Although this therapy shows promise, long-term outcome data are lacking, and their routine use is not advocated at this time, except in patients who are very poor operative risks or refuse surgery.

Successful parathyroidectomy results in resolution of osteitis fibrosa cystica and decreased formation of renal stones in symptomatic (classic) patients. In addition, it results in improved BMD (6% to 8% in the first year and up to 12% to 15% at 15 years) and fracture risk (by 50% at hip and upper arm and 30% overall) after adjustment for age, sex, and previous fractures over a 20-year observation period.[59] There are also data to show that it improves a number of the nonspecific manifestations of PHPT such as fatigue, polydipsia, polyuria and nocturia, bone and joint pain, constipation, nausea, and depression in many patients. This also has been demonstrated using symptom questionnaires and various standardized general quality-of-life assessments such as the SF-36 and a specific parathyroidectomy assessment of symptoms scale.[63] The increased death rate in patients with PHPT appears to be reversible by successful parathyroidectomy, at least in some studies. Lastly, parathyroidectomy can be accomplished with >95% success rates with minimal morbidity, even in elderly patients and is the only curative treatment option for PHPT. Previous investigations also have documented that parathyroidectomy is more cost-effective than medical management or follow-up.[64]

6▶

Given the above, it is recommended that parathyroidectomy should be offered to virtually all patients except those in whom the operative risks are prohibitive. This is also acknowledged by the panel of the latest workshop, which stated that "even though patients may not meet the guidelines for surgical intervention, it is always a reasonable option in those who do not have medical contraindications."

Currently, parathyroidectomy is recommended for patients with smaller elevations in serum calcium levels (>1 mg/dL above the upper limit of normal) and if BMD measured at any of three sites (radius, spine, or hip) is greater than 2.5 standard deviations below those of gender- and race-matched, not age-matched, controls (i.e., peak bone density or T score [rather than Z score] <2.5). In addition, patients <50 years of age are advised to undergo parathyroidectomy. The significant changes from the previous guidelines pertain to the fact that (a) hypercalciuria (>400 mg/24 h), in the absence of nephrolithiasis, is no longer considered an indication for parathyroidectomy; and (b) an absolute glomerular filtration rate <60 mL/min, rather than a reduction of creatinine clearance by 30%, is used as a threshold for recommending surgery. These changes are based on (a) data that demonstrate that hypercalciuria per se is not a risk factor for kidney stones, and (b) the most recent epidemiologic data from the U.S. National Health and Nutrition Examination Survey using a numerical cutoff for kidney function that relies on an age invariant standard, similar to densitometric guidelines. Although the guidelines for BMD did not change, it was noted that a patient with a history of fragility fracture(s) should also undergo parathyroidectomy.[55] The current guidelines are summarized in Table 38-11.

Table 38-11

Indications for parathyroidectomy in patients with asymptomatic primary HPT (2009 NIH consensus conference guidelines)

• Serum calcium >1 mg/dL above the upper limits of normal
• GFR <60 mL/min
• Substantially decreased bone mineral density at the lumbar spine, hip, or distal radius (>2.5 SD below peak bone mass, T score <–2.5
• Age <50 y
• Long-term medical surveillance not desired or possible

GFR = glomerular filtration rate; HPT = hyperparathyroidism; NIH = National Institutes of Health; SD = standard deviation.

It is important to point out that the neurocognitive and neuropsychological aspects of PHPT remain a topic of controversy with respect to the guidelines for parathyroidectomy. Although there were more studies since the previous iteration of the guidelines, there were concerns that while some lacked adequate controls and were plagued by problems related to the instruments used to quantify these nonspecific symptoms, others showed variability in improvement of neurocognitive symptoms following parathyroidectomy. Similarly, uncertainty is also present concerning the cardiovascular consequences of mild HPT. Therefore, the workshop panel emphasizes that these criteria alone should not be used as guidelines for surgical intervention.

Since there are no definitive criteria to indicate which patients with mild PHPT will develop progressive disease, more clinical studies are required. Patients who do not undergo surgery should undergo routine follow-up as outlined in the recent workshop summary statement, consisting of annual calcium and serum creatinine measurements, and measurements of BMD at three sites every 1 to 2 years.[65]

Preoperative Localization Tests. Localization studies may be classified into noninvasive or invasive modalities. These studies have variable performance characteristics, which, in turn, vary with operator and institutional experience, as outlined in Table 38-12. Localization studies have permitted surgeons to perform more limited operations, some of them under local anesthesia. These "minimally invasive" procedures include unilateral and focused neck exploration, radio-guided parathyroidectomy, and several endoscopic or video-assisted approaches. The use of localization studies has been shown in some studies to be associated with lower morbidity rates (hypoparathyroidism and RLN injury) and decreased operative times, reduced duration of hospital stay, and improved cosmetic outcomes, while maintaining success rates similar to those obtained with traditional bilateral neck explorations. Some studies also show that use of localization studies may be more cost-effective. Overall, it

Table 38-12

Commonly used parathyroid localization studies

STUDY	ADVANTAGES	DISADVANTAGES
Preoperative, noninvasive		
Sestamibi-technetium-99m scan	Allows planar and SPECT imaging	False-positive tests due to thyroid neoplasms, lymphadenopathy
Ultrasound	Identification of juxta- and intrathyroidal tumors Relatively inexpensive	False-positive results due to thyroid nodules, cysts, lymph nodes, esophageal lesions False-negatives result from substernal, ectopic, and undescended tumors
CT scan	Localization of ectopic (mediastinal) glands	Not useful for juxta- or intrathyroidal glands False-positive results from lymph nodes Relatively high cost Radiation exposure Requires IV contrast Interference from shoulders and metallic clips
MRI scan	Localization of ectopic tumors	Expensive
	No radiation exposure	False-positive results from lymph nodes and thyroid nodules
	No IV contrast	Cannot be used in claustrophobic patients
Four-dimensional CT scan	Structural and functional information	Similar to CT scan
Preoperative, invasive		
FNAB	Can distinguish parathyroid tumor from lymphadenopathy using PTH assay	Experienced cytologist needed
Angiogram	Provides a road map for selective venous sampling	Expensive
	Treatment of mediastinal tumors by embolization	Experienced radiologist needed
		Neurologic complications
Venous sampling	Useful to lateralize tumor in equivocal cases or negative localization studies	Expensive, experienced radiologist needed
Intraoperative		
PTH assay	Immediate confirmation of tumor removal	Expensive
		Increased operative time, decreased accuracy in multiple-gland disease

CT = computed tomography; FNAB = fine-needle aspiration biopsy; IV = intravenous; MRI = magnetic resonance imaging; PTH = parathyroid hormone; SPECT = single-photon emission computed tomography.

has become routine to localize hyperfunctioning parathyroid glands before parathyroidectomy. It is important to point out that imaging is not a diagnostic approach, and the decision for exploration should be made before any imaging is performed.

^{99m}Tc-labeled sestamibi (Fig. 38-31A) is the most widely used and accurate modality with a sensitivity >80% for detection of parathyroid adenomas. Sestamibi (Cardiolite) initially was introduced for cardiac imaging and is concentrated in mitochondria-rich tissue. It was subsequently noted to be useful for parathyroid localization due to the delayed washout of the radionuclide from hypercellular parathyroid tissue compared to thyroid tissue. Sestamibi scans generally are complemented by neck ultrasound (Fig. 38-31B), which can identify adenomas with >75% sensitivity in experienced centers and is most useful in identifying intrathyroidal parathyroids. Single-photon emission CT, particularly when used with CT, has been shown to be superior to other nuclear medicine–based imaging. Specifically, single-photon emission CT can indicate whether an adenoma is located in the anterior or posterior mediastinum (aortopulmonary window), thus enabling the surgeon to modify the operative approach accordingly. CT and MRI scans are less sensitive than sestamibi scans, but are helpful in localizing large paraesophageal and mediastinal glands. More recently, four-dimensional CT (4D-CT) has shown utility in parathyroid localization. This technique incorporates the perfusion of contrast in hyperfunctioning parathyroid tissue over time, thus providing functional information in addition to the

anatomic information provided by conventional three-dimensional CT imaging. In one study, 4D-CT showed improved sensitivity of 88% compared to that of sestamibi (65%) and ultrasound (57%) for lateralization of the enlarged gland and also showed superiority when localization to the correct quadrant was examined.[66] A combination of 4D-CT and ultrasound has been reported to have a positive predictive value of 92% for single-gland disease and 75% for multiple-gland disease.

IOPTH was initially introduced in 1993 and is used to determine the adequacy of parathyroid resection (Fig. 38-32).[67] According to one commonly used criterion, when the PTH falls by 50% or greater 10 minutes after removal of a parathyroid tumor, as compared to the highest preremoval value, the test is considered positive, and the operation is terminated. IOPTH measurements, like localization studies, are less reliable in multiglandular disease. Bilateral internal jugular vein sampling has also been used to lateralize tumors intraoperatively but is less accurate.

Operative Approaches Unilateral parathyroid exploration was first carried out using intraoperative staining of a biopsy from

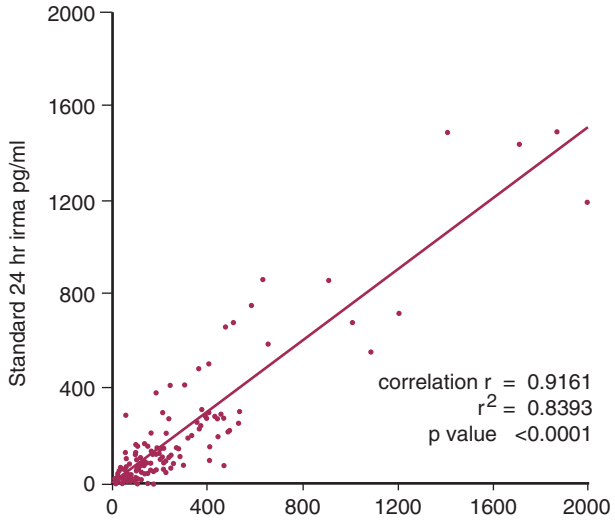

Figure 38-32. Correlation of the 10-minute incubation time quick parathyroid hormone assay with the 24-hour immunoradiometric (irma) parathyroid hormone assay from 138 paired intraoperative samples from 38 patients undergoing parathyroidectomy. *(Reproduced with permission from Irvin G, et al. Clinical usefulness of an intraoperative "quick parathyroid hormone" assay.* Surgery. *1993;114:1020. Copyright Elsevier.)*

the normal parathyroid gland with Sudan black dye to rule out a double adenoma. Initially, the choice of side to be explored was random, but the introduction of preoperative localization studies has enabled a more directed approach. In contrast, the focused approach identifies only the enlarged parathyroid gland, and no attempts are made to locate other parathyroid glands. Unilateral neck explorations have several advantages over bilateral neck exploration, including reduced operative times and complications, such as injury to the RLN and hypoparathyroidism. However, most existing studies comparing the two approaches are retrospective and do not analyze the results on an intent-to-treat basis. Another argument against a unilateral exploration is the risk of missing another adenoma on the opposite side of the neck. The incidence of double adenomas has been reported to range from 0% to 10%, with an increased incidence in elderly patients. The risk of missing a second adenoma is higher in populations with a higher incidence of multiple adenomas, such as those with familial HPT, MEN syndromes, and the elderly. Another difficulty inherent with unilateral exploration is the inability to discern whether the combination of an abnormal gland and a normal gland on the initial side constitutes a single adenoma or asymmetric hyperplasia. A recently published update on the 5-year results of a randomized trial comparing unilateral versus bilateral neck exploration did not note any difference in the rates of recurrent or persistent disease in the two groups of patients.[68] These issues will only be resolved by a large, prospective, multicenter study or improved molecular analytic techniques.

Radio-guided parathyroidectomy takes advantage of the ability of parathyroid tumors to retain ^{99m}Tc-sestamibi. One to 2 mCi of the isotope is injected before surgery, and a hand-held gamma probe is used to guide the identification of the enlarged gland, taking care to ensure the equilibration of radioactivity counts in all quadrants. Reported advantages include easier localization, particularly in reoperative cases, and the ability to perform the procedure under local anesthetic or sedation using smaller incisions. Many studies demonstrated the feasibility of this technique; however, it is rarely used now, largely because it offers little advantage over preoperative sestamibi scans and is associated with increased operative times. Like preoperative scanning, it also has reduced accuracy in the presence of multiglandular disease.

Endoscopic approaches include both video-assisted and total endoscopic techniques. Total endoscopic parathyroidectomy was first described by Gagner in 1996,[69] and several other investigators have since reported on this technique. Although port placements are variable, as is the case with endoscopic thyroidectomy, they all involve creation of a working space in the neck using CO_2 insufflation, with the reported advantages being superior cosmesis and excellent visualization. Although feasible, these techniques also have been associated with increased operating times, more personnel, and greater expense, and have, in general, not been useful for patients with multiglandular disease, a large thyroid mass, or previous neck surgery and irradiation. Their greatest use has been in patients with tumors at ectopic sites such as the mediastinum where thoracoscopic parathyroidectomy is an excellent alternative to sternotomy. Robotic approaches using a gasless, transaxillary technique are also being used for parathyroidectomy. Reported advantages include improved three-dimensional magnified visualization, refined ergonomic control, more freedom of motion with multiarticulated instruments, and improved cosmetic result as a result of incision placement in the axilla.[70]

Studies have shown that if both sestamibi scan and neck ultrasound studies independently identify the same, enlarged parathyroid gland, and no other gland, it is indeed the abnormal gland in approximately 95% of cases. These patients with sporadic PHPT are candidates for a focused neck exploration, an approach that is most commonly referred to as *minimally invasive parathyroidectomy*. A standard bilateral neck exploration is planned if parathyroid localization studies or IOPTH are not available; if the localizing studies fail to identify any abnormal parathyroid gland or identify multiple abnormal glands in patients with a family history of PHPT, MEN1, or MEN2A; or if a concomitant thyroid disorder requires bilateral exploration. In addition, finding a minimally abnormal parathyroid gland on the side indicated by localization studies during focal exploration should prompt a bilateral exploration or at least the identification of a normal parathyroid gland on the same side. In patients with MEN1, HPT should be corrected before treatment of gastrinomas because gastrin levels decline after parathyroidectomy.

7▶

Conduct of Parathyroidectomy (Standard Bilateral Exploration) An experienced parathyroid surgeon with a thorough knowledge of parathyroid anatomy and embryology and meticulous technique is crucial for the best surgical results. The procedure usually is performed under general anesthesia. The patient is positioned supine on the operating table with the neck extended. For a bilateral exploration, the neck is explored via a 3- to 4-cm incision just caudal to the cricoid cartilage. The initial dissection and exposure is similar to that used for thyroidectomy. After the strap muscles are separated in the midline, one side of the neck is chosen for exploration. In contrast to a thyroidectomy, the dissection during a parathyroidectomy is maintained lateral to the thyroid, making it easier to identify the parathyroid glands and not disturb their blood supply.

Identification of Parathyroids. A bloodless field is important to allow identification of parathyroid glands. The middle thyroid

veins are ligated and divided, thus enabling medial and anterior retraction of the thyroid lobe, with the aid of a peanut sponge or placement of 2-0 silk sutures into the thyroid. The space between the carotid sheath and thyroid is then opened by gentle sharp and blunt dissection, from the cricoid cartilage superiorly to the thymus inferiorly and the RLN is identified. Approximately 85% of the parathyroid glands are found within 1 cm of the junction of the inferior thyroid artery and RLNs. The upper parathyroid glands usually are superior to this junction and dorsal (posterior) to the nerve, whereas the lower glands are located inferior to the junction and ventral (anterior) to the recurrent nerve. Because parathyroid glands are partly surrounded by fat, any fat lobule at typical parathyroid locations should be explored because the normal or abnormal parathyroid gland may be concealed in the fatty tissue. The thin fascia overlying a "suspicious" fat lobule should be incised using a sharp curved hemostat and scalpel. This maneuver often causes the parathyroid gland to "pop" out. Alternatively, gentle, blunt peanut sponge dissection between the carotid sheath and the thyroid gland often reveals a "float" sign, suggesting the site of the abnormal parathyroid gland. Normal parathyroids are light beige and only slightly darker or brown compared to adjacent fat.

Parathyroid tissue needs to be distinguished from normal or brown fat tissue, thyroid nodules, lymph nodes, and ectopic thymus. Lymph nodes generally are light beige to whitish gray in color, glassy, and multiple in number, whereas thyroid nodules generally are more vascular, firm, dark or reddish brown in color, and have a more variegated appearance. Intraoperatively, a suspicious nodule may be aspirated using a fine needle attached to a syringe containing 1 cc of saline. Very high PTH levels in the aspirate have been shown to be diagnostic in the intraoperative identification of parathyroid glands. Several characteristics such as size (>7 mm), weight, and color are used to distinguish normal from hypercellular parathyroid glands. Hypercellular glands generally are darker, more firm, and more vascular than normocellular glands. No single method is 100% reliable, and therefore, the parathyroid surgeon must rely on experience and, at times, advice from a pathologist to help distinguish normal from hypercellular glands. Although several molecular studies have shown use in distinguishing parathyroid adenomas from hyperplasia, this determination also must be made by the surgeon intraoperatively by documenting the presence of a normal parathyroid gland.

Location of Parathyroid Glands. The majority of lower parathyroid glands are found in proximity to the lower thyroid pole (Fig. 38-33A). If not found at this location, the thyrothymic ligament and thymus should be mobilized. The upper end of the cervical thymus is gently grasped with a right angle clamp, and the distal portion is bluntly dissected from perithymic fat with a peanut sponge. One can then "walk down" the thymus with successive right-angle clamps (Fig. 38-33B). Applying light tension along with a "twisting" motion helps to free the upper thymus. The carotid sheath also should be opened from the bifurcation to the base of the neck if the parathyroid tumor cannot be found. If these maneuvers are unsuccessful, an intrathyroidal gland should be sought by using intraoperative ultrasound, incising the thyroid capsule on its posterolateral surface, or by performing an ipsilateral thyroid lobectomy and "bread-loafing" the thyroid lobe. Preoperative or intraoperative ultrasonography can be useful for identifying intrathyroidal parathyroid glands. Rarely, the third branchial pouch may maldescend and be found high in the neck (undescended parathymus), anterior to the carotid

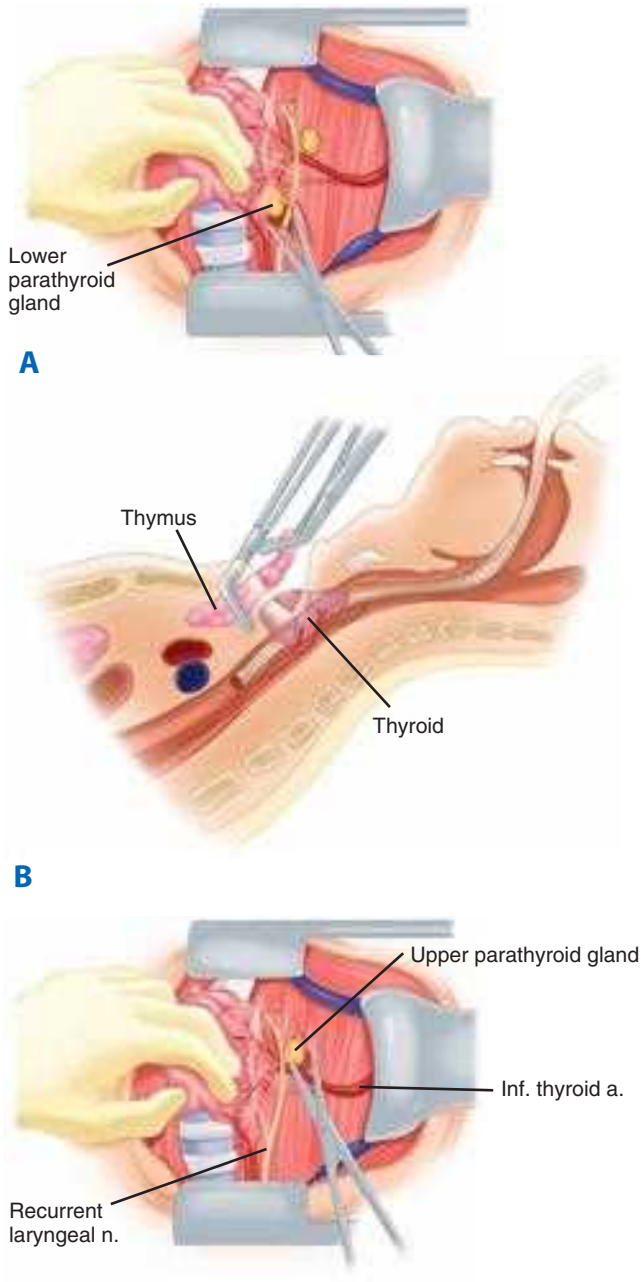

Figure 38-33. Conduct of parathyroidectomy. **A.** Exposure of the lower parathyroid gland near the inferior pole of the thyroid gland and anterior to the recurrent laryngeal nerve. **B.** A thymectomy may be necessary if the lower parathyroid cannot be found in its usual location, or if the patient has familial primary hyperparathyroidism or secondary hyperparathyroidism. **C.** Exposure of the upper parathyroid gland near the insertion of the recurrent laryngeal nerve at the level of the cricothyroid muscle. a. = artery; Inf. = inferior; n. = nerve.

bulb, along with the missing parathyroid gland. Upper parathyroid glands are more consistent in position and usually are found near the junction of the upper and middle thirds of the gland, at the level of the cricoid cartilage (Fig. 38-33C). Ectopic upper glands may be found in carotid sheath, tracheoesophageal groove, retroesophageal, or in the posterior mediastinum. The locations of ectopic upper and lower parathyroid glands are shown in Fig. 38-34. Every attempt must be made to identify

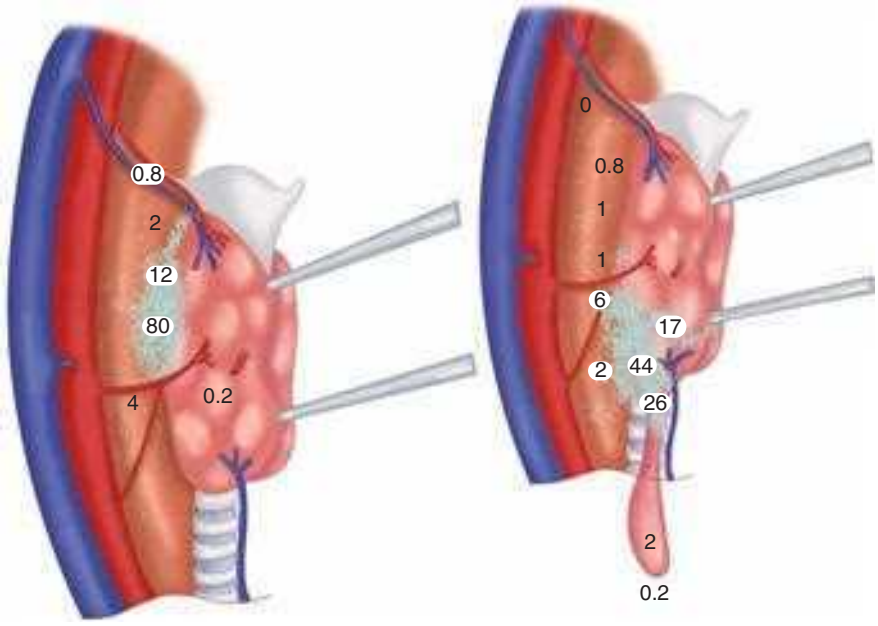

Figure 38-34. Location of ectopic upper and lower parathyroid glands. *(Reproduced with permission from Akerström G, et al. Surgical anatomy of human parathyroid glands.* Surgery. *1984;95:15. Copyright Elsevier.)*

all four glands. Treatment depends on the number of abnormal glands.

1. A single adenoma is presumed to be the cause of a patient's PHPT if only one parathyroid tumor is identified and the other parathyroid glands are normal, a situation present in about 80% of patients with PHPT. Adenomas typically have an atrophic rim of normal parathyroid tissue, but this characteristic may be absent. The adenoma is dissected free of surrounding tissue, taking care to stay immediately adjacent to the tumor, without fracturing it. The vascular pedicle is clamped, divided, and ligated. Care should be taken to not rupture the parathyroid gland to decrease the risk of parathyromatosis. If there is any question about the presumed normal glands, one of them should be biopsied and examined by frozen section.
2. If two abnormal and two normal glands are identified, the patient has double adenomas. Triple adenomas are present if three glands are abnormal and one is normal. Multiple adenomas are more common in older patients with an incidence of up to 10% in patients >60 years old. The abnormal glands should be excised, provided the remaining glands are confirmed as such, thus excluding asymmetric hyperplasia after biopsy and frozen section.
3. If all parathyroid glands are enlarged or hypercellular, patients have parathyroid hyperplasia that has been shown to occur in about 15% of patients in various series. These glands are often lobulated, usually lack the rim of normal parathyroid gland seen in adenomas, and may be variable in size. It often is difficult to distinguish multiple adenomas from hyperplasia with variable gland size. Hyperplasia may be of the chief cell (more common), mixed, or clear cell type. Patients with hyperplasia may be treated by subtotal parathyroidectomy or by total parathyroidectomy and autotransplantation, with the choice of procedure being determined by rates of recurrence, postoperative hypocalcemia, and failure rates of autotransplanted tissue. Initial studies demonstrated equivalent cure rates and postoperative hypocalcemia for the two techniques, with the latter having the added advantage of avoiding recurrence in the neck. However, autotransplanted tissue may fail to function in about 5% of cases.

All four parathyroid glands are identified and carefully mobilized. For patients with hyperplasia, a titanium clip is placed across the most normal gland, leaving a 50-mg remnant and taking care to avoid disturbing the vascular pedicle and that the gland is resected with a sharp scalpel. If possible, it is preferable to subtotally resect an inferior gland, which is more easily accessible in case of recurrence due to its anterior location with respect to the RLN. The resected parathyroid tissue is confirmed by frozen section or PTH assay. If the remnant appears to be viable, the remaining glands are resected. If there is any question as to the viability of the initially subtotally resected gland, another gland is chosen for subtotal resection and the initial remnant is removed. Whenever multiple parathyroids are resected, it is preferable to cryopreserve tissue, so that it may be autotransplanted should the patient become hypoparathyroid. Parathyroid tissue usually is transplanted into the nondominant forearm. A horizontal skin incision is made overlying the brachioradialis muscle a few centimeters below the antecubital fossa. Pockets are made in the belly of the muscle, and one to two pieces of parathyroid tissue measuring 1 mm each are placed into each pocket. A total of 12 to 14 pieces are transplanted. Autotransplanted tissue also has been reported to function when transplanted into fat.

Indications for Sternotomy A sternotomy is usually not recommended at the initial operation, unless the calcium level is >13 mg/dL. Rather, it is preferred to biopsy the normal glands and subsequently close the patient's neck and obtain localizing studies, if they were not obtained previously. Intraoperative PTH assay during the operation from large veins may be helpful. Using highly selective venous catheterization postoperatively also may be needed when noninvasive localization studies are negative, equivocal, or conflicting. Lower parathyroid glands tend to migrate into the anterior mediastinum in the thymus or perithymic fat and usually can be approached via a cervical incision. A sternotomy is needed to deliver these tumors in approximately 5% of cases. Generally, the gland can be approached by

a partial sternotomy to the third intercostal space. The midline sternotomy can be extended to the left or right side as required. Upper glands tend to migrate to the posterior mediastinum in the tracheoesophageal groove. Mediastinal glands also may be found in the aortopulmonary window or pericardium, or attached to the ascending aorta, aortic arch, or its branches.

Special Situations

Normocalcemic Hyperparathyroidism. This disorder is becoming increasingly recognized in clinical practice and is defined by the presence of an elevated PTH level with normal calcium (including ionized calcium) levels. In addition, other secondary causes of elevated PTH should be ruled out, namely, vitamin D deficiency, osteomalacia, hypercalciuria (renal leak), and renal insufficiency. Data regarding the natural history of this disorder are limited. In a series of 37 patients, Lowe and colleagues[71] showed that 19% of patients became frankly hypercalcemic within 3 years. In addition, 57% developed osteoporosis, 11% developed fragility fractures, and 14% developed nephrolithiasis. Although the study had some limitations, it led the authors to suggest that normocalcemic HPT may represent a variant of "symptomatic" PHPT and may not be an early form of "asymptomatic" disease. There is still uncertainty about whether normocalcemic HPT carries the same cardiovascular morbidity that is associated with the more severe form of the disease. Limited studies show that parathyroidectomy is more likely to be unsuccessful in these patients. In the absence of strong data, no guidelines are available for this entity.[65] As such, most clinicians follow a conservative course unless patients have symptoms that can be attributable to HPT.

8▶

Parathyroid Carcinoma. Parathyroid cancer accounts for approximately 1% of PHPT cases. It may be suspected preoperatively by the presence of severe symptoms, serum calcium levels >14 mg/dL, significantly elevated PTH levels (five times normal), and a palpable parathyroid gland. Local invasion is quite common; approximately 15% of patients have lymph node metastases and 33% have distant metastases at presentation. Intraoperatively, parathyroid cancer is suggested by the presence of a large, gray-white to gray-brown parathyroid tumor that is adherent to or invasive into surrounding tissues like muscle, thyroid, RLN, trachea, or esophagus. Enlarged lymph nodes also may be present. Frozen sections are generally unreliable. Accurate diagnosis necessitates histologic examination. The major diagnostic criteria include vascular or capsular invasion, trabecular or fibrous stroma, and frequent mitoses. It is, however, important to emphasize that these classic findings are not as frequently noted as previously reported, and some may be found in benign adenomas as well.

9▶

Treatment of parathyroid cancer consists of neck exploration, with en bloc excision of the tumor and the ipsilateral thyroid lobe, in addition to the removal of contiguous lymph nodes (tracheoesophageal, paratracheal, and upper mediastinal). The recurrent nerve is not sacrificed unless it is directly involved with tumor. Adherent soft tissue structures (strap muscles or other soft tissues) should also be resected. Modified radical neck dissection is recommended in the presence of lateral lymph node metastases. Prophylactic neck dissection is not advised. If the diagnosis is made postoperatively, a decision must be made regarding the adequacy of initial surgery based on a review of operative notes, pathology reports, localization studies, and calcium and PTH levels. If any question exists, histologic review by another experienced pathologist can be helpful. Additional procedures can include ipsilateral thyroid lobectomy with resection of contiguous structures and lymph nodes if the features are typical or the patient remains hypercalcemic. Patients with equivocal pathologic findings and normocalcemia may be monitored closely. Reoperation is indicated for locally recurrent or metastatic disease to control hypercalcemia. Adjuvant radiation therapy should be considered in patients at high risk of local recurrence such as those with close or positive margins, invasion of surrounding structures, or tumor rupture. Radiation may also be used as primary therapy in unresectable disease or for palliation of bone metastases. Chemotherapy is not very effective. Bisphosphonates have shown some effectiveness in treating hypercalcemia associated with parathyroid carcinoma. Cinacalcet hydrochloride, a calcimimetic, can reduce PTH levels by directly binding to the CASR cells on the parathyroid gland and has been shown to be useful in controlling hypercalcemia in patients with refractory parathyroid carcinoma.[72] Other promising approaches include anti-parathyroid hormone immunotherapy, octreotide, and the telomerase inhibitor azidothymidine, but additional investigations are needed in this area.

Familial Hyperparathyroidism. PHPT may occur as a component of various inherited syndromes such as MEN1 and MEN2A. Inherited PHPT also can occur as isolated familial HPT (non-MEN) or familial HPT with jaw tumors. The diagnosis of familial HPT is known or suspected in approximately 85% of patients preoperatively. Furthermore, patients with hereditary HPT generally have a higher incidence of multiglandular disease, supernumerary glands, and recurrent or persistent disease. Therefore, these patients warrant a more aggressive approach and are not candidates for various focused surgical approaches.[66] Although not absolutely necessary, preoperative sestamibi scan and ultrasound can be obtained in patients with inherited HPT to identify potential ectopic glands. A standard bilateral neck exploration is performed, along with a bilateral cervical thymectomy, regardless of the results of localization studies. Both subtotal parathyroidectomy and total parathyroidectomy with autotransplantation are appropriate, and parathyroid tissue also should be cryopreserved. If an adenoma is found in patients with familial HPT, the adenoma and the ipsilateral normal parathyroid glands are resected. The normal-appearing glands on the contralateral side are biopsied and marked, so that only one side of the neck will need to be explored in the event of recurrence. Patients with MEN2A require total thyroidectomy and central neck dissection for prevention/treatment of MTC, a procedure that places the parathyroids at risk. Moreover, HPT is less aggressive in these patients. Hence, only abnormal parathyroid glands need to be resected at neck exploration. The other normal parathyroid glands should be marked with a clip.

Neonatal Hyperparathyroidism. Infants with neonatal HPT present with severe hypercalcemia, lethargy, hypotonia, and mental retardation. This disorder is associated with homozygous mutations in the CASR gene. Urgent total parathyroidectomy (with autotransplantation and cryopreservation) and thymectomy are indicated. Subtotal resection is associated with high recurrence rates.

Parathyromatosis. Parathyromatosis is a rare condition characterized by the finding of multiple nodules of hyperfunctioning parathyroid tissue throughout the neck and mediastinum, usually following a previous parathyroidectomy. The true etiology of parathyromatosis is not known. It is postulated to arise either from overgrowth of congenital parathyroid rests (ontogenous

parathyromatosis) or seeding at surgery from rupture of parathyroid tumors or subtotal resection of hyperplastic glands. Parathyromatosis represents a rare cause of persistent or recurrent HPT[73] and can be identified intraoperatively. Aggressive local resection of these deposits can result in normocalcemia but is rarely curative. Some studies suggest that these patients have low-grade carcinoma because of invasion into muscle and other structures distant from the resected parathyroid tumor.

Postoperative Care and Follow-Up Patients who have undergone parathyroidectomy are advised to undergo calcium level checks 2 weeks postoperatively, at 6 months, and then annually. Recurrences are rare (<1%), except in patients with familial HPT. Recurrence rates of 15% at 2 years and 67% at 8 years have been reported for MEN1 patients.

Persistent and Recurrent Hyperparathyroidism. Persistence is defined as hypercalcemia that fails to resolve after parathyroidectomy and is more common than recurrence, which refers to HPT occurring after an intervening period of at least 6 months of biochemically documented normocalcemia.[74] Recurrent disease is far less common than persistent HPT; however, both occur more frequently in the setting of familial HPT and MEN1, in particular. The most common causes for both these states include ectopic parathyroids, unrecognized hyperplasia, or supernumerary glands. More rare causes include parathyroid carcinoma, missed adenoma in a normal position, incomplete resection of an abnormal gland, parathyromatosis, or an inexperienced surgeon. The most common sites of ectopic parathyroid glands in patients with persistent or recurrent HPT are paraesophageal (28%), mediastinal (26%), intrathymic (24%), intrathyroidal (11%), carotid sheath (9%), and high cervical or undescended (2%) (Fig. 38-35).

Once the diagnosis of persistent or recurrent HPT is suspected, it should be confirmed by the necessary biochemical tests. Other causes of an elevated serum PTH such as renal insufficiency, renal calcium leak, and GI tract abnormalities should be considered. A detailed family history should be performed to screen for familial disease, as this will influence the operative approach. In particular, a 24-hour urine collection should be performed to rule out FHH. In redo-parathyroid surgery, the glands are more likely to be in ectopic locations, and postoperative scarring tends to make the procedure more technically demanding. Cure rates are generally lower (80%–90% compared with 95%–99% for initial operation), and risk of injury to RLNs and permanent hypocalcemia are higher. Therefore, an evaluation of severity of HPT and the patient's anesthetic risk (using the American Society of Anesthesiology classification of physical status or the Goldman cardiac index) is important. There are no published guidelines directly applicable to this group of patients. In general, patients with significant and ongoing problems such as recurrent kidney stones, a markedly elevated calcium level, or ongoing bone loss will need re-exploration. Patients in whom the diagnosis remains in question or those with equivocal or minimal symptoms may be considered for conservative management. Preoperative localization studies are routinely performed. Noninvasive studies such as a sestamibi scan and ultrasound are obtained, supplemented by 4D-CT scans. If these studies are negative, discordant, or equivocal, obtaining an ultrasound-guided aspirate of a suspicious cervical lesion or a highly selective venous catheterization for PTH

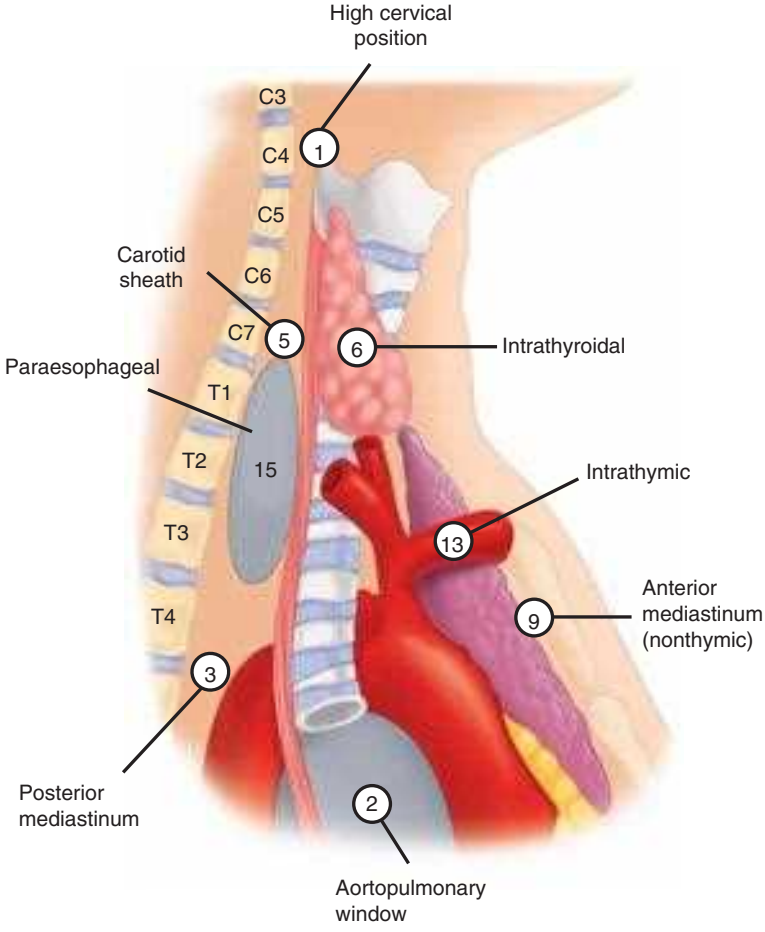

Figure 38-35. Anatomic location of ectopic parathyroid glands. Numbers represent number of glands found in each location, with a total of 54. *(Reproduced with permission from Shen W, et al. Re-operation for persistent or recurrent primary hyperparathyroidism.* Arch Surg. *1996;131:864. Copyright © 1996 American Medical Association. All rights reserved.)*

levels (by an experienced angiographer) is recommended. Previous operative notes and pathology reports should be carefully reviewed and reconciled with the information obtained from localization studies before any neck re-exploration. An algorithm for the treatment of patients with recurrent and persistent HPT is shown in Fig. 38-36.

Generally, these patients are approached with a focused exploration. The lateral approach is frequently used and can be achieved via the previous incision. The plane between the sternocleidomastoid and strap muscle is opened and allows for early identification of the RLN. Parathyroid tissue is cryopreserved routinely. Use of adjuncts, such as measuring intraoperative PTH levels, is critical to ensure adequate resection and avoid potentially harmful additional explorations. In case of difficult re-explorations, additional techniques such as bilateral internal jugular vein sampling for PTH, thyroid lobectomy on the side of the missing gland, cervical thymectomy, and ligation of the ipsilateral inferior thyroid artery (after lobectomy, to cause infarction of the missing gland) may be needed. Blind mediastinal exploration is not recommended. In patients who are denied, refuse, or fail exploration, medical options such as cinacalcet may be considered.

Hypercalcemic Crisis. Patients with PHPT may occasionally present acutely with nausea, vomiting, fatigue, muscle weakness, confusion, and a decreased level of consciousness—a complex referred to as *hypercalcemic crisis*. These symptoms result from severe hypercalcemia from uncontrolled PTH secretion, worsened by polyuria, dehydration, and reduced kidney function and may occur with other conditions causing hypercalcemia.

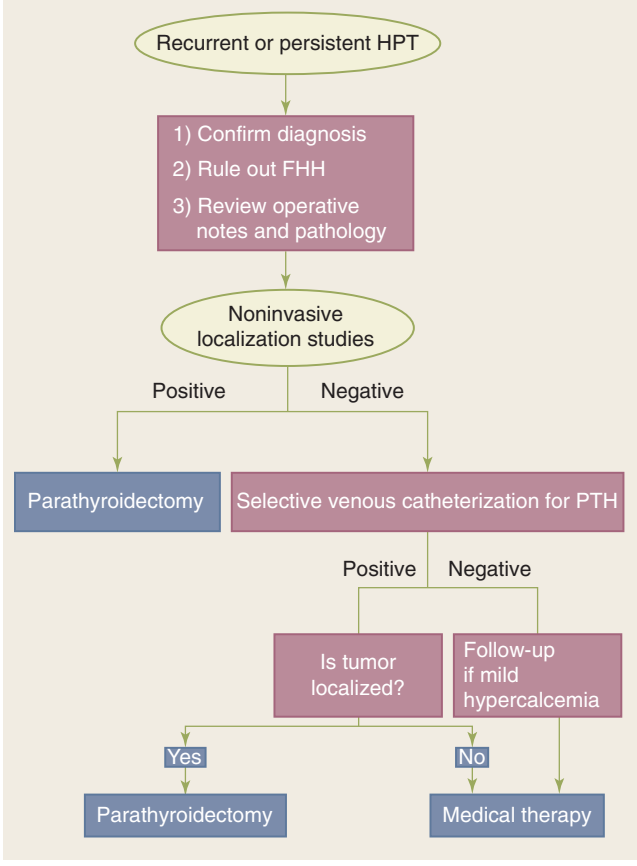

Figure 38-36. Management of recurrent and persistent hyperparathyroidism (HPT). FHH = familial hypocalciuric hypercalcemia; PTH = parathyroid hormone.

Calcium levels are markedly elevated and may be as high as 16 to 20 mg/dL. Parathyroid tumors tend to be large or multiple and may be palpable. Patients with parathyroid cancer or familial HPT are more likely to present with hypercalcemic crisis.

Treatment consists of therapies to lower serum calcium levels followed by surgery to correct HPT. The mainstay of therapy involves rehydration with a 0.9% saline solution to keep urine output >100 cc/h. Once urine output is established, diuresis with furosemide (which increases renal calcium clearance) is begun. If these methods are unsuccessful, other drugs may be used to lower serum calcium levels as outlined in Table 38-13. Occasionally, in life-threatening cases, hemodialysis may be of benefit.

Secondary Hyperparathyroidism. Secondary HPT commonly occurs in patients with chronic renal failure but also may occur in those with hypocalcemia secondary to inadequate calcium or vitamin D intake or malabsorption. The pathophysiology of HPT in chronic renal failure is complex and appears to be related to hyperphosphatemia (and resultant hypocalcemia), deficiency of 1,25-dihydroxy vitamin D due to loss of renal tissue, low calcium intake, decreased calcium absorption, and abnormal parathyroid cell response to extracellular calcium or vitamin D in vitro and in vivo. Patients generally are hypocalcemic or normocalcemic. Aluminum hydroxide, which often was used as a phosphate binder, has been shown to contribute to the osteomalacia observed in this disease. These patients generally are treated medically with a low-phosphate diet, phosphate binders, adequate intake of calcium and 1, 25-dihydroxy vitamin D, and a high-calcium, low-aluminum dialysis bath. Calcimimetics have been shown to control parathyroid hyperplasia and osteitis fibrosa cystica associated with secondary HPT in animal studies and to decrease plasma PTH and total and ionized calcium levels in humans.

Surgical treatment was traditionally recommended for patients with bone pain, pruritus, and (a) a calcium-phosphate product ≥70, (b) calcium >11 mg/dL with markedly elevated PTH, (c) calciphylaxis, (d) progressive renal osteodystrophy, and (e) soft tissue calcification and tumoral calcinosis, despite maximal medical therapy. Assessment of parathyroid mass is thought to be an important factor for predicting the response to medical management. Therefore, some groups recommend parathyroidectomy if the glands are >1 cm (or >500 mm^3) on ultrasound. These glands are apparently more likely to have developed nodular hyperplasia and hence might be refractory to medical management. Following the introduction of calcimimetics, there appears to have been a reduction in parathyroidectomy rates. While parathyroidectomy has been reported to maintain biochemical targets for up to 5 years and improve bone density, fracture risk, calcinosis, hemoglobin levels, and even long-term survival, the effects of calcimimetics on these parameters awaits results of various trials. Studies also show that calcimimetics may be less cost-effective in the long-term. The role of parathyroidectomy in the era of calcimimetics will require long-term studies, specifically prospective studies comparing outcomes of calcimimetics with standard therapy versus parathyroidectomy. In general, parathyroidectomy should be considered if PTH levels remain high despite therapy that includes calcimimetics. Calciphylaxis is a rare, limb- and life-threatening complication of secondary HPT characterized by painful (sometimes throbbing), violaceous, and mottled lesions usually on the extremities, which often become necrotic and progress to nonhealing ulcers, gangrene, sepsis, and death. Skin

Table 38-13

Medications commonly used to treat hypercalcemia

MEDICATION	DOSAGE AND ADMINISTRATION	MECHANISM, ONSET OF ACTION, AND DURATION	SIDE EFFECTS
Bisphosphonates (pamidronate)	60–90 mg IV over 4–24 h	Inhibits osteoclastic bone resorption; rapid onset, 2–3 d	May cause local pain and swelling, low-grade fever, lymphopenia, electrolyte abnormalities
Calcitonin	4 IU/kg SC/IM	Inhibits osteoclast function, augments renal calcium excretion; onset of action in hours; but short lived, therefore not useful as sole therapy	Transient nausea and vomiting, abdominal cramps, flushing, and local skin reaction
Mithramycin (plicamycin)	25 µg/kg/d IV for 3–4 d	Inhibits osteoclasts RNA secretion; rapid onset of action (12 h); peaks at 48–72 h and lasts days to several weeks	May cause renal, hepatic, and hematologic complications, nausea and vomiting
Gallium nitrate	200 mg/m^2 BSA/d IV for 5 d	Reduces urinary calcium excretion; onset of action delayed (5–7 d)	Nephrotoxicity, nausea, vomiting, hypotension, anemia, hypophosphatemia
Glucocorticoids	Hydrocortisone 100 mg IV q8h	Delayed onset of action (7–10 d); useful for hematologic malignancies, sarcoidosis, vitamin D intoxication, hyperthyroidism	Hypertension, hyperglycemia

BSA = body surface area; IM = intramuscular; IV = intravenous; SC = subcutaneous.

biopsy can be helpful to make the diagnosis. These are critically ill, high-risk patients, but successful parathyroidectomy sometimes relieves symptoms. Not all patients with calciphylaxis will have high PTH levels, and parathyroidectomy should not be undertaken in the absence of documented hyperparathyroidism.

Patients should undergo routine dialysis the day before surgery to correct electrolyte abnormalities. Localization studies are not necessary but can identify ectopic parathyroid glands. A bilateral neck exploration is indicated. The parathyroid glands in secondary HPT are characterized by asymmetric enlargement and nodular hyperplasia. These patients may be treated by subtotal resection, leaving about 50 mg of the most normal parathyroid gland or total parathyroidectomy and autotransplantation of parathyroid tissue into the brachioradialis muscle of the nondominant forearm, with parathyroid cryopreservation. Upper thymectomy usually is performed because 15% to 20% of patients have one or more parathyroid glands situated in the thymus or perithymic fat. Some groups recommend total parathyroidectomy without autotransplantation because it is associated with a lower rate of recurrence. While it may be preferable in patients with calciphylaxis, this procedure is contraindicated in patients eligible for renal transplant. Since the evidence needed to determine the superiority of one approach over another is lacking, the choice of procedure is influenced by surgeon preference and experience and various patient factors, as indicated earlier.[75]

Tertiary Hyperparathyroidism. Generally, renal transplantation is an excellent method of treating secondary HPT, but some patients develop autonomous parathyroid gland function and tertiary HPT. Tertiary HPT can cause problems similar to PHPT, such as pathologic fractures, bone pain and worsened bone disease, renal stones, peptic ulcer disease, pancreatitis, and mental status changes. The transplanted kidney is also at risk from tubulointerstitial calcification and volume depletion.[76] Similar to patients with secondary HPT, many patients with tertiary HPT are being treated with cinacalcet. Although the drug is effective and well-tolerated in these patients, the long-term effects on kidney allograft function are not known, and many of these patients have persistence of their hypercalcemic symptoms. On the other hand, parathyroidectomy has been shown to lead to a more immediate and dramatic reduction in hypercalcemic symptoms. As such, operative intervention is indicated for symptomatic disease or if autonomous PTH secretion persists for >1 year after a successful transplant in patients who are deemed operative candidates. All parathyroid glands should be identified. The traditional surgical management of these patients consisted of subtotal or total parathyroidectomy with autotransplantation and an upper thymectomy. Some authors suggest that these patients derive similar benefit from excision of only obviously enlarged glands, while avoiding the higher risks of hypocalcemia associated with the former approach. Others recommend that all parathyroid glands be identified and subtotal parathyroidectomy be performed as long-term follow-up studies show that limited excisions in these patients are associated with an up to fivefold increased risk of recurrent or persistent disease. Further studies are needed to define the best operative approach for these patients.

Complications of Parathyroid Surgery. Parathyroidectomy can be accomplished successfully in >95% of patients with minimal mortality and morbidity, provided the procedure is

performed by a surgeon experienced in parathyroid surgery. Specific complications include transient and permanent vocal cord palsy and hypoparathyroidism. The latter is more likely to occur in patients who undergo four-gland exploration with biopsies, subtotal resection with an inadequate remnant, or total parathyroidectomy with a failure of autotransplanted tissue. Furthermore, hypocalcemia is more likely to occur in patients with high-turnover bone disease as evidenced by elevated preoperative alkaline phosphatase levels. Vocal cord paralysis and hypoparathyroidism are considered permanent if they persist for >6 months. Fortunately, these complications are rare, occurring in approximately 1% of patients undergoing surgery by experienced parathyroid surgeons.

Patients with symptomatic hypocalcemia or those with calcium levels <8 mg/dL are treated with oral calcium supplementation (up to 1–2 g every 4 hours). 1,25-Dihydroxy vitamin D (calcitriol [Rocaltrol] 0.25–0.5 µg bid) may also be required, particularly in patients with severe hypercalcemia and elevated serum alkaline phosphatase levels preoperatively and with osteitis fibrosa cystica. Intravenous calcium supplementation rarely is needed, except in cases of severe, symptomatic hypocalcemia.

Hypoparathyroidism

Hypocalcemia can be the result of a multitude of conditions, which are listed in Table 38-14. The parathyroid glands may be congenitally absent in DiGeorge syndrome, which also is characterized by lack of thymic development and, therefore, a thymus-dependent lymphoid system. By far, the most common cause of hypoparathyroidism is thyroid surgery, particularly total thyroidectomy with a concomitant central neck dissection. Patients often develop transient hypocalcemia due to ischemia of the parathyroid glands; permanent hypoparathyroidism is rare. Hypoparathyroidism also may occur after parathyroid surgery, which is more likely if patients undergo a subtotal resection or total parathyroidectomy with parathyroid autotransplantation.

Acute hypocalcemia results in decreased ionized calcium and increased neuromuscular excitability. Patients initially develop circumoral and fingertip numbness and tingling. Mental symptoms include anxiety, confusion, and depression. Physical examination reveals positive Chvostek's sign (contraction of facial muscles elicited by tapping on the facial nerve anterior to the ear) and Trousseau's sign (carpopedal spasm that is elicited by occluding blood flow to the forearm with a blood pressure cuff for 2–3 minutes). Tetany, which is characterized by tonic-clonic seizures, carpopedal spasm, and laryngeal stridor, may prove fatal and should be avoided. Most patients with postoperative hypocalcemia can be treated with oral calcium and vitamin D supplements; IV calcium infusion is rarely required except in patients with preoperative osteitis fibrosa cystica.

Table 38-14

Conditions causing hypocalcemia

Hypoparathyroidism
• Surgical
• Neonatal
• Familial
• Heavy metal deposition
• Magnesium depletion
Resistance to the action of parathyroid hormone
• Pseudohypoparathyroidism
• Renal failure
• Medications—calcitonin, bisphosphonates, mithramycin
Failure of normal 1,25-dihydroxy vitamin D production
Resistance to the action of 1,25-dihydroxy vitamin D
Acute complex formation or deposition of calcium
• Acute hyperphosphatemia
• Acute pancreatitis
• Massive blood transfusion (citrate overload)
• "Hungry bones"

ADRENAL

Historical Background

Eustachius provided the first accurate anatomic account of the adrenals in 1563. The anatomic division of the adrenals into the cortex and medulla was described much later, by Cuvier in 1805. Subsequently, Thomas Addison in 1855 described the features of adrenal insufficiency, which still bear his name. DeCreccio provided the first description of congenital adrenal hyperplasia (CAH) occurring in a female pseudohermaphrodite in 1865. Pheochromocytomas were first identified by Frankel in 1885, but were not named as such until 1912 by Pick, who noted the characteristic chromaffin reaction of the tumor cells. Adrenaline was identified as an agent from the adrenal medulla that elevated blood pressure in dogs and was subsequently named epinephrine in 1897. The first successful adrenalectomies for pheochromocytoma were performed by Roux in Switzerland, and Charles Mayo in the United States.

In 1932, Harvey Cushing described 11 patients who had moon facies, truncal obesity, hypertension, and other features of the syndrome that now bears his name. Although several individuals prepared adrenocortical extracts to treat adrenalectomized animals, cortisone was first synthesized by Kendall. Aldosterone was identified in 1952, and the syndrome resulting from excessive secretion of this mineralocorticoid was first described in 1955 by Conn.

Embryology

The adrenal or suprarenal glands are two endocrine organs in one; an outer cortex and an inner medulla, each with distinct embryologic, anatomic, histologic, and secretory features. The cortex originates around the fifth week of gestation from mesodermal tissue near the gonads on the adrenogenital ridge (Fig. 38-37). Therefore, ectopic adrenocortical tissue may be found in the ovaries, spermatic cord, and testes. The cortex differentiates further into a thin, definitive cortex and a thicker, inner fetal cortex. The latter is functional and produces fetal adrenal steroids by the eighth week of gestation, but undergoes involution after birth, resulting in a decrease in adrenal weight during the first three postpartum months. The definitive cortex persists after birth to form the adult cortex over the first 3 years of life. In contrast, the adrenal medulla is ectodermal in origin and arises from the neural crest. At around the same time as cortical development, neural crest cells migrate to the paraaortic and paravertebral areas and toward the medial aspect of the developing cortex to form the medulla. Most extra-adrenal neural tissue regresses but may persist at several sites. The largest of these is located to the left of the aortic bifurcation near the

Figure 38-37. Cells migrate from the neural crest to form the ganglia of the sympathetic trunk (*A*), sympathetic plexi (*B*), and the adrenal medulla and paraganglia (*C*). *(Reproduced with permission from Avisse C, et al. Surgical anatomy and embryology of the adrenal glands.* Surg Clin North Am. *2000;80:414. Copyright Elsevier.)*

inferior mesenteric artery origin and is designated as the organ of Zuckerkandl. Adrenal medullary tissue also may be found in neck, urinary bladder, and para-aortic regions. Several factors are involved in adrenal development and include insulin-like growth factor 2; gastric inhibitory peptide; and the dosage-sensitive, sex-reversal adrenal hypoplasia (*DAX1*) gene.

Anatomy

The adrenal glands are paired, retroperitoneal organs located superior and medial to the kidneys at the level of the eleventh ribs. The normal adrenal gland measures 5 × 3 × 1 cm and weighs 4 to 5 g. The right gland is pyramidal shaped and lies in close proximity to the right hemidiaphragm, liver, and inferior vena cava (IVC). The left adrenal is closely associated with the aorta, spleen, and tail of the pancreas. Each gland is supplied by three groups of vessels—the superior adrenal arteries derived from the inferior phrenic artery, the middle adrenal arteries derived from the aorta, and the inferior adrenal arteries derived from the renal artery. Other vessels originating from the intercostal and gonadal vessels may also supply the adrenals. These arteries branch into about 50 arterioles to form a rich plexus beneath the glandular capsule and require careful dissection, ligation, and division during adrenalectomy. In contrast to the arterial supply, each adrenal usually is drained by a single, major adrenal vein. The right adrenal vein is usually short and drains into the IVC, whereas the left adrenal vein is longer and empties into the left renal vein after joining the inferior phrenic vein. Accessory veins occur in 5% to 10% of patients—on the right, these vessels may drain into the right hepatic vein or the right renal vein; on the left, accessory veins may drain directly into the left renal vein. The anatomic relationships of the adrenals and surrounding structures are depicted in Fig. 38-38.

The adrenal cortex appears yellow due to its high lipid content and accounts for about 80% to 90% of the gland's volume. Histologically, the cortex is divided into three zones—the zona glomerulosa, zona fasciculata, and zona reticularis. The outer area of the zona glomerulosa consists of small cells and is the site of production of the mineralocorticoid hormone, aldosterone. The zona fasciculata is made up of larger cells, which often appear foamy due to multiple lipid inclusions, whereas the zona reticularis cells are smaller. These latter zones are the site of production of glucocorticoids and adrenal androgens. The adrenal medulla constitutes up to 10% to 20% of the gland's volume and is reddish-brown in color. It produces the catecholamine hormones epinephrine and norepinephrine. The cells of the adrenal medulla are arranged in cords and are polyhedral in shape. They often are referred to as chromaffin cells because they stain specifically with chromium salts.

Adrenal Physiology

Cholesterol, derived from the plasma or synthesized in the adrenal, is the common precursor of all steroid hormones derived from the adrenal cortex. Cholesterol initially is cleaved within mitochondria to 5-δ-pregnolone, which in turn is transported to the smooth endoplasmic reticulum where it forms the substrate for various biosynthetic pathways leading to steroidogenesis (Fig. 38-39).

Mineralocorticoids. The major adrenal mineralocorticoid hormones are aldosterone, 11-deoxycorticosterone (DOC), and cortisol. Cortisol has minimal effects on the kidney due to hormone degradation. Aldosterone secretion is regulated primarily by the renin-angiotensin system. Decreased renal blood flow, decreased plasma sodium, and increased sympathetic tone all stimulate the release of renin from juxtaglomerular cells. Renin, in turn, leads to the production of angiotensin I from its precursor angiotensinogen. Angiotensin I is cleaved by pulmonary angiotensin-converting enzyme (ACE) to angiotensin II; the latter is not only a potent vasoconstrictor, but also leads to increased aldosterone synthesis and release. Hyperkalemia is another potent stimulator of aldosterone synthesis, whereas ACTH, pituitary pro-opiomelanocortin, and antidiuretic hormone are weak stimulators.

Aldosterone is secreted at a rate of 50 to 250 µg/d (depending on sodium intake) and circulates in plasma chiefly as a complex with albumin. Small amounts of the hormone bind to corticosteroid-binding globulin, and approximately 30% to 50% of secreted aldosterone circulates in a free form. The hormone has a half-life of only 15 to 20 minutes and is rapidly cleared via the liver and kidney. A small quantity of free aldosterone also is excreted in the urine. Mineralocorticoids cross the cell membrane and bind to cytosolic receptors. The receptor-ligand complex subsequently is transported into the nucleus where it induces the transcription and translation of specific genes.

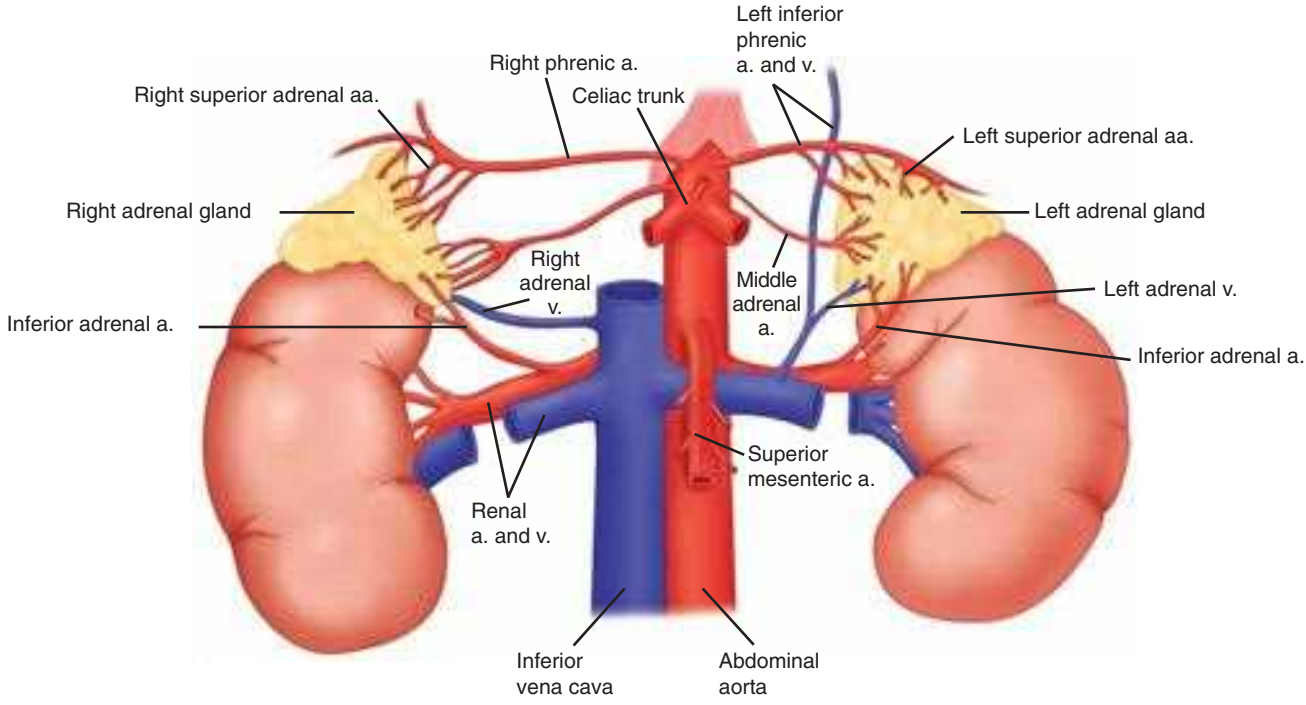

Figure 38-38. Anatomy of the adrenals and surrounding structures. a. = artery; v. = vein.

Aldosterone functions mainly to increase sodium reabsorption and potassium and hydrogen ion excretion at the level of the renal distal convoluted tubule. Less commonly, aldosterone increases sodium absorption in salivary glands and GI mucosal surfaces.

Glucocorticoids. The secretion of cortisol, the major adrenal glucocorticoid, is regulated by ACTH secreted by the anterior pituitary, which, in turn, is under the control of corticotrophin-releasing hormone (CRH) secreted by the hypothalamus. ACTH is a 39-amino-acid protein, which is derived by cleavage from a

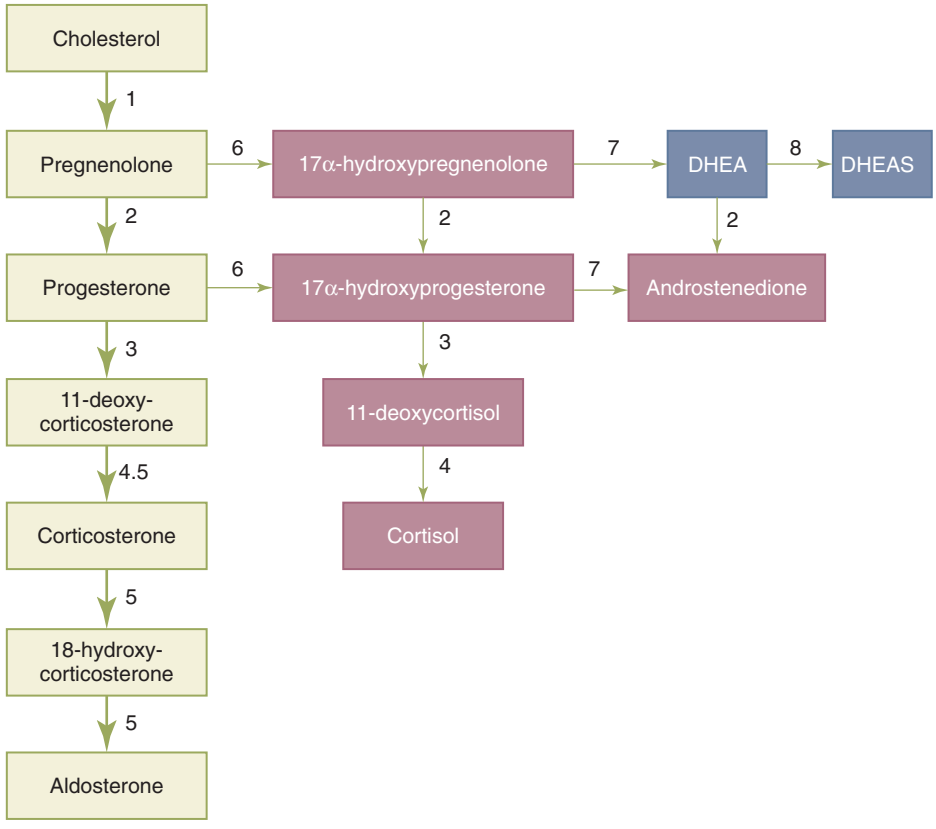

Figure 38-39. Synthesis of adrenal steroids. The enzymes involved are (*1*) p450scc (cholesterol side chain cleavage), (*2*) 3β-hydroxysteroid dehydrogenase, (*3*) p450c21 (21β-hydroxylase), (*4*) p450c11 (11β-hydroxylase), (*5*) p450c11AS (aldosterone synthase), (*6*) p450c17 (17α-hydroxylase activity), (*7*) p450c17 (17,20-lyase/desmolase activity), and (*8*) sulfokinase. DHEAS = dehydroepiandrosterone sulfate.

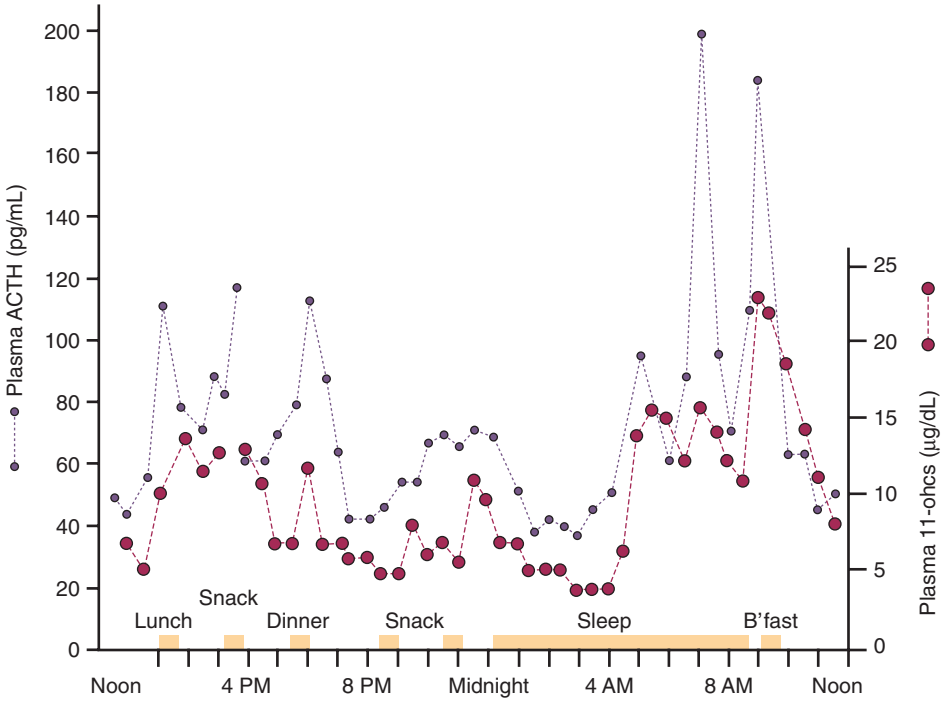

Figure 38-40. Diurnal variation in cortisol levels as determined by half-hourly sampling in a 16-year-old girl. *(Reproduced with permission from Krieger DT, et al. Characterization of the normal temporal pattern of corticosteroid levels.* J Clin Endocrinol Metab. *1971;32:269. Copyright by The Endocrine Society.)*

larger precursor, pro-opiomelanocortin. ACTH is further cleaved into α-melanocyte-stimulating hormone and corticotrophin-like intermediate peptide. ACTH not only stimulates the secretion of glucocorticoids, mineralocorticoids, and adrenal androgens, but is also trophic for the adrenal glands. ACTH secretion may be stimulated by pain, stress, hypoxia, hypothermia, trauma, and hypoglycemia. ACTH secretion fluctuates, peaking in the morning and reaching nadir levels in the late afternoon. Thus, there is a diurnal variation in the secretion of cortisol, with peak cortisol excretion also occurring in the early morning and declining during the day to its lowest levels in the evening (Fig. 38-40). Cortisol controls the secretion of both CRH and ACTH via a negative feedback loop. A similar mechanism leads to the inhibition of CRH secretion by ACTH.

Cortisol is transported in plasma bound primarily to corticosteroid-binding globulin (75%) and albumin (15%). Approximately 10% of circulating cortisol is free and is the biologically active component. The plasma half-life of cortisol is 60 to 90 minutes and is determined by the extent of binding and rate of inactivation. Cortisol is converted to di- and tetrahydrocortisol and cortisone metabolites in the liver and the kidney. The majority (95%) of cortisol and cortisone metabolites are conjugated with glucuronic acid in the liver, thus facilitating their renal excretion. A small amount of unmetabolized cortisol is excreted unchanged in the urine.

Glucocorticoid hormones enter the cell and bind cytosolic steroid receptors. The activated receptor-ligand complex is then transported to the nucleus where it stimulates the transcription of specific target genes via a "zinc finger" DNA binding element. Cortisol also binds the mineralocorticoid receptor with an affinity similar to aldosterone. However, the specificity of mineralocorticoid action is maintained by the production of 11β-hydroxysteroid dehydrogenase, an enzyme that inactivates cortisol to cortisone in the kidney. Glucocorticoids have important functions in intermediary metabolism but also affect connective tissue, bone, immune, cardiovascular, renal, and central nervous systems, as outlined in Table 38-15.

Sex Steroids. Adrenal androgens are produced in the zona fasciculata and reticularis from 17-hydroxypregnenolone in response to ACTH stimulation. They include dehydroepiandrosterone (DHEA) and its sulfated counterpart (DHEAS), androstenedione, and small amounts of testosterone and estrogen. Adrenal androgens are weakly bound to plasma albumin. They exert their major effects by peripheral conversion to the more potent testosterone and dihydrotestosterone but also have weak intrinsic androgen activity. Androgen metabolites are conjugated as glucuronides or sulfates and excreted in the urine. During fetal development, adrenal androgens promote the formation of male genitalia. In normal adult males, the contribution of adrenal androgens is minimal; however, they are responsible for the development of secondary sexual characteristics at puberty. Adrenal androgen excess leads to precocious puberty in boys and virilization, acne, and hirsutism in girls and women.

Catecholamines. Catecholamine hormones (epinephrine, norepinephrine, and dopamine) are produced not only in the central and sympathetic nervous system but also the adrenal medulla. The substrate, tyrosine, is converted to catecholamines via a series of steps shown in Fig. 38-41A. Phenylethanolamine *N*-methyltransferase, which converts norepinephrine to epinephrine, is only present in the adrenal medulla and the organ of Zuckerkandl. Therefore, the primary catecholamine produced may be used to distinguish adrenal medullary tumors from those situated at extra-adrenal sites. Catecholamines are stored in granules in combination with other neuropeptides, ATP, calcium, magnesium, and water-soluble proteins called *chromogranins*. Hormonal secretion is stimulated by various stress stimuli and mediated by the release of acetylcholine at

Table 38-15

Functions of glucocorticoid hormones

FUNCTION/SYSTEM	EFFECTS
Glucose metabolism	Increased hepatic glycogen deposition, gluconeogenesis, decreased muscle glucose uptake and metabolism
Protein metabolism	Decreased muscle protein synthesis, increased catabolism
Fat metabolism	Increased lipolysis in adipose tissue
Connective tissue	Inhibition of fibroblasts, loss of collagen, thinning of skin, striae formation
Skeletal system	Inhibition of bone formation, increased osteoclast activity, potentiate the action of PTH
Immune system	Increases circulation of polymorphonuclear cells; decreases numbers of lymphocytes, monocytes, and eosinophils; reduces migration of inflammatory cells to sites of injury
Cardiovascular system	Increases cardiac output and peripheral vascular tone
Renal system	Sodium retention, hypokalemia, hypertension via mineralocorticoid effect, increased glomerular filtration via glucocorticoid effects
Endocrine system	Inhibits TSH synthesis and release, decreased TBG levels, decreased conversion of T_4 to T_3

PTH = parathyroid hormone; T_3 = 3,5',3-triiodothyronine; T_4 = thyroxine; TBG = thyroxine-binding globulin; TSH = thyroid-stimulating hormone.

the preganglionic nerve terminals. In the circulation, these proteins are bound to albumin and other proteins. Catecholamines are cleared by several mechanisms including reuptake by sympathetic nerve endings, peripheral inactivation by catechol *O*-methyltransferase and monoamine oxidase, and direct excretion by the kidneys. Metabolism of catecholamines takes place primarily in the liver and kidneys and leads to the formation of metabolites such as metanephrines, normetanephrines, and VMA, which may undergo further glucuronidation or sulfation before being excreted in the urine (Fig. 38-41B).

Adrenergic receptors are transmembrane-spanning molecules that are coupled to G proteins. They may be subdivided into α and β subtypes, which are localized in different tissues, have varying affinity to various catecholamines, and mediate distinct biologic effects (Table 38-16). The receptor affinities for α receptors are—epinephrine > norepinephrine >> isoproterenol; β_1 receptors—isoproterenol > epinephrine = norepinephrine; and β_2 receptors—isoproterenol > epinephrine >> norepinephrine.

Disorders of the Adrenal Cortex

Hyperaldosteronism. Hyperaldosteronism may be secondary to stimulation of the renin-angiotensin system from renal artery stenosis and to low-flow states such as congestive heart failure and cirrhosis. Hyperaldosteronism resulting from these conditions is reversible by treatment of the underlying cause. Primary hyperaldosteronism results from autonomous aldosterone secretion, which, in turn, leads to suppression of renin secretion. Primary aldosteronism usually occurs in individuals between the ages of 30 to 50 years old and accounts for 1% of hypertension cases. It is associated with hypokalemia; however, more patients with Conn's syndrome are being diagnosed with normal potassium levels. Most cases result from a solitary functioning adrenal adenoma (~70%) and idiopathic bilateral hyperplasia (30%). Adrenocortical carcinoma and glucocorticoid-suppressible hyperaldosteronism are rare, each accounting for <1% of cases. Glucocorticoid-suppressible hyperaldosteronism is an autosomal dominant form of hypertension in which aldosterone secretion is abnormally regulated by ACTH. This condition is caused by recombinations between linked genes encoding closely related isozymes, 11β-hydroxylase (CYP11B1), and aldosterone synthase (CYP11B2) generating a dysregulated chimeric gene with aldosterone synthase activity.

Symptoms and Signs Patients typically present with hypertension, which is long-standing, moderate to severe, and may be difficult to control despite multiple-drug therapy. Other symptoms include muscle weakness, polydipsia, polyuria, nocturia, headaches, and fatigue. Weakness and fatigue are related to the presence of hypokalemia.

Diagnostic Studies

Laboratory Studies. Hypokalemia is a common finding, and hyperaldosteronism must be suspected in any hypertensive patient who presents with coexisting spontaneous hypokalemia (K <3.2 mmol/L) or hypokalemia (<3 mmol/L) while on diuretic therapy, despite potassium replacements. However, it is important to note that up to 40% of patients with a confirmed aldosteronoma were normokalemic preoperatively. Once the diagnosis is suspected, further tests are necessary to confirm the diagnosis. Before testing, patients must receive adequate sodium and potassium. Antihypertensive medications should be held, if possible, and spironolactone, β-blockers, ACE inhibitors, and angiotensin II receptor blockers should be avoided. Patients with primary hyperaldosteronism have an elevated plasma aldosterone concentration level with a suppressed plasma renin activity; a plasma aldosterone concentration–to–plasma renin activity ratio of 1:25 to 30 is strongly suggestive of the diagnosis.[77] False-positive results can occur, particularly in patients with chronic renal failure. Patients with primary hyperaldosteronism also fail to suppress aldosterone levels with sodium loading. This test can be performed by performing a 24-hour urine collection for cortisol, sodium, and aldosterone after 5 days of a high-sodium diet or alternatively giving the patient 2 L of saline while in the supine position, 2 to 3 days after being on a low-sodium diet. Plasma aldosterone level <5 ng/dL or a 24-hour urine aldosterone <14 μg after saline loading essentially rules out primary hyperaldosteronism. Once the biochemical diagnosis is confirmed, further evaluation should be directed at

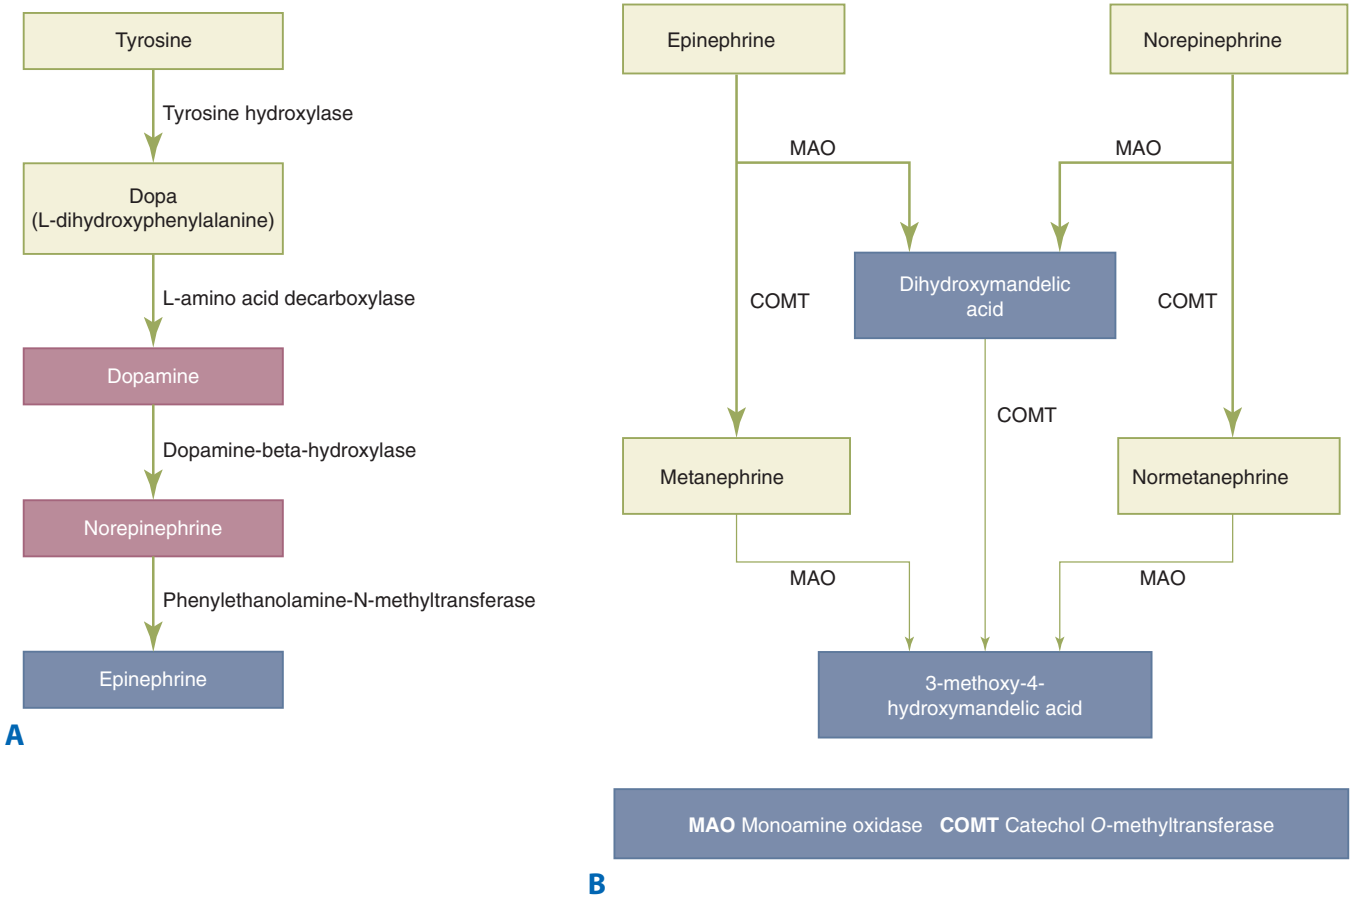

Figure 38-41. **A.** Synthesis of catecholamines. **B.** Metabolism of catecholamine hormones.

Table 38-16

Catecholamine hormone receptors and effects they mediate

RECEPTOR	TISSUE	FUNCTION
α_1	Blood vessels	Contraction
	Gut	Decreased motility, increased sphincter tone
	Pancreas	Decreased insulin and glucagon release
	Liver	Glycogenolysis, gluconeogenesis
	Eyes	Pupil dilation
	Uterus	Contraction
	Skin	Sweating
α_2	Synapse (sympathetic)	Inhibits norepinephrine release
	Platelet	Aggregation
β_1	Heart	Chronotropic, inotropic
	Adipose tissue	Lipolysis
	Gut	Decreased motility, increased sphincter tone
	Pancreas	Increased insulin and glucagon release
β_2	Blood vessels	Vasodilation
	Bronchioles	Dilation
	Uterus	Relaxation

determining which patients have a unilateral aldosteronoma vs. bilateral hyperplasia, because surgery is almost always curative for the former, but usually not the latter. No biochemical studies can make this distinction with 100% sensitivity; thus imaging studies are necessary.

Radiologic Studies. CT scans with 0.5-cm cuts in the adrenal area can localize aldosteronomas with a sensitivity of 90%. A unilateral 0.5- to 2-cm adrenal tumor with a normal-appearing contralateral gland confirms an aldosteronoma in the presence of appropriate biochemical parameters. MRI scans are less sensitive but more specific, particularly if opposed phase chemical shift images are obtained. MRI scans also have increased use in pregnant patients or those unable to tolerate intravenous contrast. If adrenal hyperplasia is suspected, the algorithm depicted in Fig. 38-42 is useful. Selective venous catheterization and adrenal vein sampling for aldosterone have been demonstrated to be 95% sensitive and 90% specific in localizing the aldosteronoma. In this procedure, the adrenal veins are cannulated, and blood samples for aldosterone and cortisol are obtained from both adrenal veins and the vena cava after ACTH administration.[78] Measurement of cortisol levels is necessary to confirm proper placement of the catheters in the adrenal veins. A greater than fourfold difference in the aldosterone:cortisol ratios between the adrenal veins indicates the presence of a unilateral tumor. Some investigators use this study routinely, but it is invasive, requires an experienced interventional radiologist, and can lead to adrenal vein rupture in approximately 1% of cases. Therefore, most groups advocate use of this modality selectively in ambiguous cases, when the tumor cannot be localized and in patients with bilateral adrenal enlargement to determine whether there is unilateral or bilateral increased secretion of aldosterone. Scintigraphy with ^{131}I-6β-iodomethyl noriodocholesterol (NP-59) also may be used for the same purpose. Like cholesterol, this compound is taken up by the adrenal cortex, but unlike cholesterol, it remains in the gland without undergoing further metabolism. Adrenal adenomas appear as "hot" nodules with suppressed contralateral uptake, whereas hyperplastic glands show bilaterally increased uptake. This test, however, is not widely available.

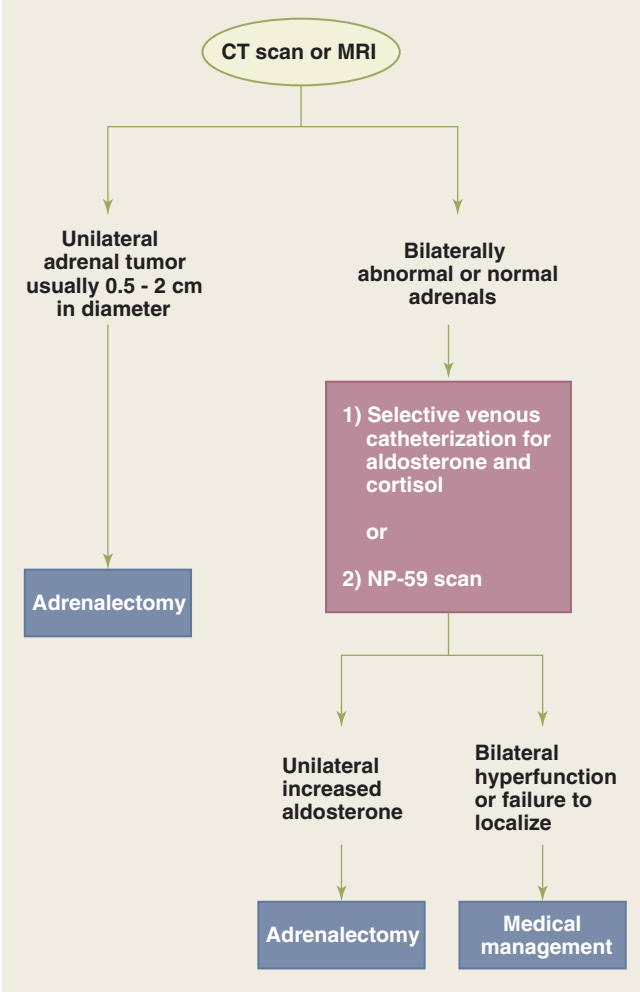

Figure 38-42. Management of an adrenal aldosteronoma. CT = computed tomography; MRI = magnetic resonance imaging.

Treatment Preoperatively, control of hypertension and adequate potassium supplementation (to keep K >3.5 mmol/L) are important. Patients generally are treated with spironolactone (an aldosterone antagonist), amiloride (a potassium-sparing diuretic that blocks sodium channels in the distal nephron), nifedipine (a calcium channel blocker), or captopril (an ACE inhibitor). Unilateral tumors producing aldosterone are best managed by adrenalectomy, either by a laparoscopic approach (preferred) or via a posterior open approach. If a carcinoma is suspected because of the large size of the adrenal lesion or mixed hormone secretion, an anterior transabdominal approach is preferred to permit adequate determination of local invasion and distal metastases. Only 20% to 30% of patients with hyperaldosteronism secondary to bilateral adrenal hyperplasia benefit from surgery, and as described, selective venous catheterization is useful to predict which patients will respond. For the other patients, medical therapy with spironolactone, amiloride, or triamterene is the mainstay of management. Glucocorticoid-suppressible hyperaldosteronism is treated by administering exogenous dexamethasone at doses of 0.5 to 1 mg daily. Treatment with spironolactone may help decrease glucocorticoid requirements in this condition and avoid symptoms of Cushing's syndrome. Postoperatively, some patients experience transient hypoaldosteronism requiring mineralocorticoids for up to 3 months. Rarely, acute Addison's disease may occur 2 to 3 days after adrenalectomy. Adrenalectomy is >90% successful in improving hypokalemia and about 70% successful in correcting hypertension. Patients who respond to spironolactone therapy and those with a shorter duration of hypertension with minimal renal damage are more likely to achieve improvement in hypertension, whereas male patients, those >50 years old, and those with multiple adrenal nodules, are least likely to benefit from adrenalectomy.

Cushing's Syndrome. Cushing described patients with a peculiar fat deposition, amenorrhea, impotence (in men), hirsutism, purple striae, hypertension, diabetes, and other features that constitute the syndrome (Fig. 38-43). He also recognized that several of these patients had basophilic tumors of the pituitary gland and concluded that these tumors produced hormones that caused adrenocortical hyperplasia, thus resulting in the manifestations of the syndrome. Today, the term *Cushing's syndrome* refers to a complex of symptoms and signs resulting from hypersecretion of cortisol regardless of etiology. In contrast, *Cushing's disease* refers to a pituitary tumor, usually an adenoma, which leads to bilateral adrenal hyperplasia and hypercortisolism. Cushing's syndrome (endogenous) is a rare disease, affecting 10 in 1 million individuals. It is more common in adults but may occur in children. Women are more commonly affected (male:female ratio 1:8).

Figure 38-43. Some characteristic features of Cushing's syndrome—moon facies, hirsutism, and acne.

Although most individuals have sporadic disease, Cushing's syndrome may be found in MEN1 families and can result from ACTH-secreting pituitary tumors, primary adrenal neoplasms, or an ectopic ACTH-secreting carcinoid tumor (more common in men) or bronchial adenoma (more common in women).

Cushing's syndrome may be classified as ACTH-dependent or ACTH-independent (Table 38-17). The most common cause of hypercortisolism is exogenous administration of steroids. However, approximately 70% of cases of endogenous Cushing's syndrome are caused by an ACTH-producing pituitary tumor. Primary adrenal sources (adenoma, hyperplasia, and carcinoma) account for about 20% of cases, and ectopic ACTH-secreting tumors account for <10% of cases. CRH also may be secreted ectopically in bronchial carcinoid tumors, pheochromocytomas, and other tumors. These patients are difficult to distinguish from those with ectopic ACTH production, but can be diagnosed by determining CRH levels. Patients with major depression, alcoholism, pregnancy, chronic renal failure, or stress also may have elevated cortisol levels and symptoms of hypercortisolism. However, these manifestations resolve with treatment of the underlying disorder, and these patients are deemed to have pseudo-Cushing's syndrome.

Primary adrenal hyperplasia may be micronodular, macronodular, or massively macronodular. Adrenal hyperplasia resulting from ACTH stimulation usually is macronodular (3-cm nodules). Primary pigmented nodular adrenocortical disease is a rare cause of ACTH-independent Cushing's syndrome, which is characterized by the presence of small (<5 mm), black adrenal nodules. Primary pigmented nodular adrenocortical disease may be associated with Carney complex (atrial myxomas, schwannomas, and pigmented nevi) and is thought to be immune related.

Table 38-17

Etiology of Cushing's syndrome

ACTH-dependent (70%) • Pituitary adenoma or Cushing's disease (~70%) • Ectopic ACTH production*a* (~10%) • Ectopic CRH production (<1%)
ACTH-independent (20%–30%) • Adrenal adenoma (10%–15%) • Adrenal carcinoma (5%–10%) • Adrenal hyperplasia—pigmented micronodular cortical hyperplasia or gastric inhibitory peptide-sensitive macronodular hyperplasia (5%)
Other • Pseudo-Cushing's syndrome • Iatrogenic—exogenous administration of steroids

*a*From small cell lung tumors, pancreatic islet cell tumors, medullary thyroid cancers, pheochromocytomas, and carcinoid tumors of the lung, thymus, gut, pancreas, and ovary.
ACTH = adrenocorticotropic hormone; CRH = corticotrophin-releasing hormone.

Symptoms and Signs The classical features of Cushing's syndrome are listed in Table 38-18. Early diagnosis of this disease requires a thorough knowledge of these manifestations, coupled with a high clinical suspicion. In some patients, symptoms are less pronounced and may be more difficult to recognize, particularly given their diversity and the absence of a single defining symptom or sign. Progressive truncal obesity is the most common symptom, occurring in up to 95% of patients.

Table 38-18

Features of Cushing's syndrome

SYSTEM	MANIFESTATION
General	Weight gain—central obesity, buffalo hump, supraclavicular fat pads
Integumentary	Hirsutism, plethora, purple striae, acne, ecchymosis
Cardiovascular	Hypertension
Musculoskeletal	Generalized weakness, osteopenia
Neuropsychiatric	Emotional lability, psychosis, depression
Metabolic	Diabetes or glucose intolerance, hyperlipidemia
Renal	Polyuria, renal stones
Gonadal	Impotence, decreased libido, menstrual irregularities

This pattern results from the lipogenic action of excessive corticosteroids centrally and catabolic effects peripherally, along with peripheral muscle wasting. Fat deposition also occurs in unusual sites, such as the supraclavicular space and posterior neck region, leading to the so-called buffalo hump. Purple striae are often visible on the protuberant abdomen. Rounding of the face leads to moon facies, and thinning of subcutaneous tissues leads to plethora. There is an increase in fine hair growth on the face, upper back, and arms, although true virilization is more commonly seen with adrenocortical cancers. Endocrine abnormalities include glucose intolerance, amenorrhea, and decreased libido or impotence. In children, Cushing's syndrome is characterized by obesity and stunted growth. Patients with Cushing's disease also may present with headaches, visual field defects, and panhypopituitarism. Hyperpigmentation of the skin, if present, suggests an ectopic ACTH-producing tumor with high levels of circulating ACTH.

Diagnostic Tests The aims of diagnostic tests in the evaluation of patients suspected of having Cushing's syndrome are twofold: to confirm the presence of Cushing's syndrome and to determine its etiology (Fig. 38-44).

Laboratory Studies. Cushing's syndrome is characterized by elevated glucocorticoid levels that are not suppressible by exogenous hormone administration and loss of diurnal variation. This phenomenon is used to screen patients using the overnight low-dose dexamethasone suppression test. In this test, 1 mg of a synthetic glucocorticoid (dexamethasone) is given at 11 p.m. and plasma cortisol levels are measured at 8 a.m. the following morning. Physiologically normal adults suppress cortisol levels to <3 μg/dL, whereas most patients with Cushing's syndrome do not. False-negative results may be obtained in patients with mild disease; therefore, some authors consider the test positive only if cortisol levels are suppressed to <1.8 μg/dL. False-positive results can occur in up to 3% of patients with chronic renal

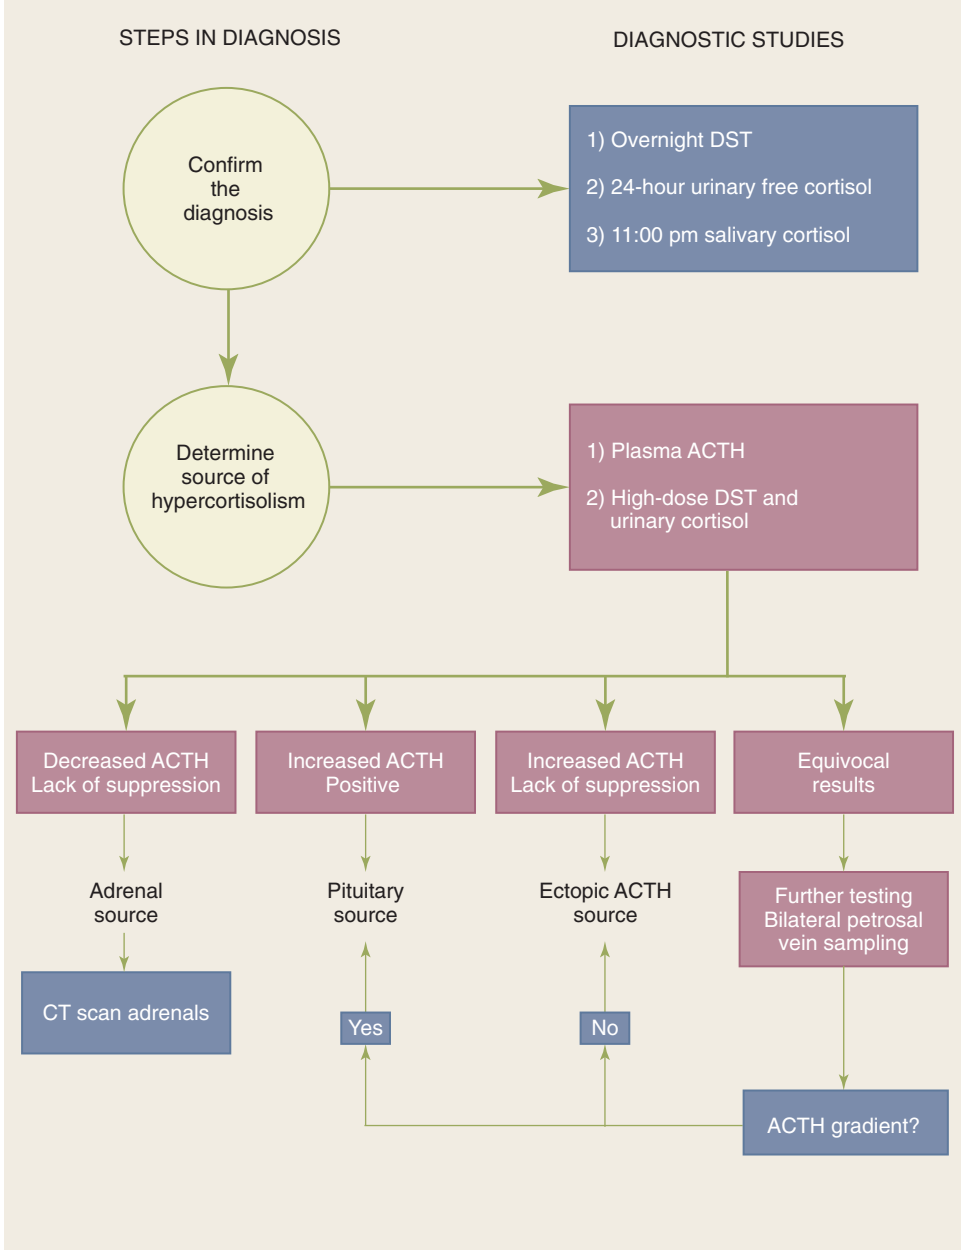

Figure 38-44. Diagnosis of Cushing's syndrome. ACTH = adrenocorticotropic hormone; CT = computed tomography; DST = dexamethasone suppression test.

failure, depression, or those taking medications such as phenytoin, which enhance dexamethasone metabolism. In patients with a negative test but a high clinical suspicion, the classic low-dose dexamethasone (0.5 mg every 6 hours for eight doses, or 2 mg over 48 hours) suppression test or urinary cortisol measurement should be performed. Measurement of elevated 24-hour urinary cortisol levels is a very sensitive (95%–100%) and specific (98%) modality of diagnosing Cushing's syndrome and is particularly useful for identifying patients with pseudo-Cushing's syndrome. A urinary cortisol-free excretion of less than 100 μg/dL (in most laboratories) rules out hypercortisolism. Recently, salivary cortisol measurements using commercially available kits also have demonstrated superior sensitivity in diagnosing Cushing's syndrome and are being increasingly used. Overall, 24-hour urinary tests for free cortisol and the overnight dexamethasone suppression test at the 5 μg/dL cutoff have the highest specificity for the diagnosis of Cushing's syndrome.[79]

Once a diagnosis of hypercortisolism is established, further testing is aimed at determining whether it is ACTH-dependent or ACTH-independent Cushing's syndrome. This is best accomplished by measurement of plasma ACTH levels (normal 10–100 pg/mL). Elevated ACTH levels are found in patients with adrenal hyperplasia due to Cushing's disease (15–500 pg/mL) and those with CRH-secreting tumors, but the highest levels are found in patients with ectopic sources of ACTH (>1000 pg/mL). In contrast, ACTH levels are characteristically suppressed (<5 pg/mL) in patients with primary cortisol-secreting adrenal tumors. The high-dose dexamethasone suppression test is used to distinguish between the causes of ACTH-dependent Cushing's syndrome (pituitary vs. ectopic). The standard test (2 mg dexamethasone every 6 hours for 2 days) or the overnight test (8 mg) may be used, with 24-hour urine collections for cortisol and 17-hydroxy steroids performed over the second day. Failure to suppress urinary cortisol by 50% confirms the diagnosis of an ectopic ACTH-producing tumor. Patients suspected of having ectopic tumors should also undergo testing for MTC and pheochromocytoma. Bilateral petrosal vein sampling also is helpful for determining whether the patient has Cushing's disease or ectopic Cushing's syndrome.

The CRH test also is helpful in determining the etiology of Cushing's syndrome. Ovine CRH (1 μg/kg) is administered intravenously, followed by serial measurements of ACTH and cortisol at 15-minute intervals for 1 hour. Patients with a primary adrenal hypercortisolism exhibit a blunted response (ACTH peak <10 pg/mL), whereas those with ACTH-dependent Cushing's syndrome demonstrate a higher elevation of ACTH (>30 pg/mL). CRH stimulation also can enhance the usefulness of petrosal vein sampling. Patients with pituitary tumors also have a higher peak ACTH than those with ectopic ACTH-producing tumors.

Radiologic Studies. CT and MRI scans of the abdomen can identify adrenal tumors with 95% sensitivity. They also are helpful in distinguishing adrenal adenomas from carcinomas, as discussed in the subsequent section Adrenocortical Cancer. MRI scans have the added advantage of allowing assessment of vascular anatomy. Adrenal adenomas appear darker than the liver on T2-weighted imaging. Radioscintigraphic imaging of the adrenals using NP-59 also can be used to distinguish adenoma from hyperplasia. Reports suggest that "cold" adrenal nodules are more likely to be cancerous, although this distinction is not absolute. NP-59 scanning is most useful in identifying patients with an adrenal source of hypercortisolism and primary pigmented micronodular hyperplasia.

Thin-section head CT scans are 22% sensitive, and contrast-enhanced brain MRI scans are 33% to 67% sensitive at identifying pituitary tumors. Inferior petrosal sinus sampling for ACTH before and after CRH injection has been helpful in this regard and has a sensitivity approaching 100%. In this study, catheters are placed in both internal jugular veins and a peripheral vein. A ratio of petrosal to peripheral vein ACTH level of >2 in the basal state and >3 after CRH stimulation is diagnostic of a pituitary tumor. In patients suspected of having ectopic ACTH production, CT or MRI scans of the chest and anterior mediastinum are performed first, followed by imaging of the neck, abdomen, and pelvis if the initial studies are negative.

Treatment Laparoscopic adrenalectomy is the treatment of choice for patients with adrenal adenomas. Open adrenalectomy is reserved for large tumors (≥6 cm) or those suspected to be adrenocortical cancers. Bilateral adrenalectomy is curative for primary adrenal hyperplasia.

The treatment of choice in Cushing's disease is transsphenoidal excision of the pituitary adenoma, which is successful in 80% of patients. Pituitary irradiation has been used for patients with persistent or recurrent disease after surgery. However, it is associated with a high rate of panhypopituitarism, and some patients develop visual deficits. This has led to increased use of stereotactic radiosurgery, which uses CT guidance to deliver high doses of radiotherapy to the tumor (photon or gamma knife) and also bilateral laparoscopic adrenalectomy. Patients who fail to respond to either treatment are candidates for pharmacologic therapy with adrenal inhibitors (medical adrenalectomy) such as ketoconazole, metyrapone, or aminoglutethimide.

Patients with ectopic ACTH production are best managed by treating the primary tumor, including recurrences, if possible. Medical or bilateral laparoscopic adrenalectomy has been used to palliate patients with unresectable disease and those whose ectopic ACTH-secreting tumor cannot be localized.

Patients undergoing surgery for a primary adrenal adenoma secreting glucocorticoids require preoperative and postoperative steroids due to suppression of the contralateral adrenal gland. These patients are also at increased predisposition for infectious and thromboembolic complications, the latter due to a hypercoagulable state resulting from an increase in clotting factors including factor VIII and von Willebrand's factor complex, and by impaired fibrinolysis. Duration of steroid therapy is determined by the ACTH stimulation test. Exogenous steroids may be needed for up to 2 years but are needed indefinitely in patients who have undergone bilateral adrenalectomy. This latter group of patients also may require mineralocorticoid replacement therapy. Typical replacement doses include hydrocortisone (10–20 mg every morning and 5–10 mg every evening) and fludrocortisone (0.05–0.1 mg/d every morning).

Adrenocortical Cancer. Adrenal carcinomas are rare neoplasms with a worldwide incidence of two per 1 million. These tumors have a bimodal age distribution, with an increased incidence in children and adults in the fourth and fifth decades of life. The majority are sporadic, but adrenocortical carcinomas also occur in association with germline mutations of *p53* (Li-Fraumeni syndrome) and *MENIN* (multiple endocrine neoplasia type 1) genes. Loci on 11p (Beckwith-Wiedemann syndrome), 2p (Carney complex), and 9q also have been implicated. Somatic *p53* mutations are present in up to 33% of tumors, and LOH at the *p53* locus has been reported in >85% of adrenocortical carcinomas. In addition, Insulin-like growth factor II is overexpressed

in 90% of tumors, and approximately 30% harbor somatic activating mutations in the β-catenin gene.[80]

Symptoms and Signs Approximately 50% of adrenocortical cancers are nonfunctioning.[81] The remaining secrete cortisol (30%), androgens (20%), estrogens (10%), aldosterone (2%), or multiple hormones (35%). Patients with functioning tumors often present with the rapid onset of Cushing's syndrome accompanied by virilizing features. Nonfunctioning tumors more commonly present with an enlarging abdominal mass and abdominal or back pain. Rarely, weight loss, anorexia, and nausea may be present.

Diagnostic Tests Diagnostic evaluation of these patients begins with measurement of serum electrolyte levels to rule out hypokalemia, urinary catecholamines to rule out pheochromocytomas, an overnight 1-mg dexamethasone suppression test, and a 24-hour urine collection for cortisol and 17-ketosteroids to rule out Cushing's syndrome.

CT and MRI scans are useful to image these tumors (Fig. 38-45). The size of the adrenal mass on imaging studies is the single most important criterion to help diagnose malignancy. In the series reported by Copeland, 92% of adrenal cancers were >6 cm in diameter.[82] The sensitivity, specificity, and likelihood ratio of tumor size in predicting malignancy (based on Surveillance, Epidemiology, and End Results program data) were recently reported as 96%, 51%, and 2 for tumors ≥4 cm, and 90%, 78%, and 4.1 for tumors ≥6 cm.[83] Other CT imaging characteristics suggesting malignancy include tumor heterogeneity, irregular margins, and the presence of hemorrhage and adjacent lymphadenopathy or liver metastases. Moderately bright signal intensity on T2-weighted images (adrenal mass–to–liver ratio 1.2:2.8), significant lesion enhancement, and slow washout after injection of gadolinium contrast also indicate malignancy, as does evidence of local invasion into adjacent structures such as the liver, blood vessels (IVC), and distant metastases. FDG-PET or PET-CT scans may have some utility in distinguishing benign from malignant lesions, as discussed in the section on incidentalomas. Once adrenal cancer is diagnosed, CT scans of the chest and pelvis or FDG-PET or PET-CT scans are performed for staging. The tumor-node-metastasis (TNM) staging system for adrenocortical carcinoma is depicted in Table 38-19. Up to 70% of patients present with stage III or IV disease.

Figure 38-45. Computed tomography scan of the abdomen showing a left adrenocortical cancer with synchronous liver metastasis.

Table 38-19

TNM staging for adrenocortical cancer

STAGE	TNM CLASS
I	T1, N0, M0
II	T2, N0, M0
III	T3, N0, M0
	T1–2, N1, M0
IV	T3–4, N1, M0
	Any T, any N, M1

Primary tumor (T): T1, size ≤5 cm without local invasion; T2, size >5 cm without local invasion; T3, any size with local invasion but no involvement of adjacent organs; T4, any size with involvement of adjacent organs.

Nodes (N): N0, no involvement of regional nodes; N1, positive regional lymph nodes.

Metastasis (M): M0, no known distal metastases, M1, distant metastases present.

Pathology Most adrenocortical cancers are large, weighing between 100 and 1000 g. On gross examination, areas of hemorrhage and necrosis often are evident. Microscopically, cells are hyperchromatic and typically have large nuclei and prominent nucleoli. It is very difficult to distinguish benign adrenal adenomas from carcinomas by histologic examination alone. Capsular or vascular invasion is the most reliable sign of cancer. Weiss and associates studied a combination of nine criteria for their usefulness in distinguishing malignant from benign adrenal tumors: nuclear grade III or IV; mitotic rate greater than 5 per 50 high-power fields; atypical mitoses; clear cells comprising 25% or less of the tumor; a diffuse architecture; microscopic necrosis; and invasion of venous, sinusoidal, and capsular structure. Tumors with four or more of these criteria were likely to metastasize and/or recur.[84] Rarely, the diagnosis of malignancy of a completely resected adrenal tumor is often only made in retrospect by the finding of metastatic disease many years later. Molecular markers such as Ki67 (indicating proliferative activity) can also be useful in this regard.

Treatment The most important predictor of survival in patients with adrenal cancer is the adequacy of resection. Patients who undergo complete resection have 5-year actuarial survival rates ranging from 32% to 48%, whereas median survival is <1 year in those undergoing incomplete excision. Therefore, adrenocortical carcinomas are treated by excision of the tumor en bloc with any contiguously involved lymph nodes or organs such as the diaphragm, kidney, pancreas, liver, or IVC. This is best accomplished by open adrenalectomy via a generous subcostal incision or a thoracoabdominal incision (on the right side). The incisions should permit wide exposure, minimize chances of capsule rupture and tumor spillage, and allow vascular control of the aorta, IVC, and renal vessels, as needed.

Mitotane or o,p-DDD or 1,1-dichloro-2-(o-chlorophenyl)-2-(p-chlorophenyl) ethane, which is a derivative of the insecticide DDT, has adrenolytic activity and has been used in the

adjuvant setting and for the treatment of unresectable or metastatic disease. However, the therapeutic effectiveness is conflicting, and consistent improvement in survival rates is lacking. Moreover, the drug is associated with significant GI and neurologic side effects, particularly at the effective doses of 2 to 6 g/d. Terzolo and associates retrospectively evaluated the use of mitotane in the adjuvant setting and reported significantly increased recurrence-free survival in the treatment group.[85] However, the routine use of this medication awaits evaluation in randomized, controlled trials. Determination of blood mitotane levels is helpful to ascertain whether therapeutic and nontoxic levels are present. Adrenocortical tumors commonly metastasize to the liver, lung, and bone.

Surgical debulking is recommended for isolated, recurrent disease and has been demonstrated to prolong survival. Systemic chemotherapeutic agents used in this tumor include etoposide, cisplatin, doxorubicin, and, more recently, paclitaxel, but consistent responses are rare, possibly due to the expression of the multidrug resistance gene (*MDR-1*) in tumor cells. In vitro data indicate that mitotane may be able to reverse this resistance when combined with various chemotherapeutic agents. Results from the First International Randomized Trial in Advanced or Metastatic Adrenocortical Carcinoma Treatment (FIRM-ACT) showed that patients receiving etoposide, doxorubicin, cisplatin, and mitotane had better response rates and progression-free survival rates than patients receiving streptozotocin and mitotane.[72] There has been recent interest in the use of suramin, a growth factor inhibitor, as therapy for adrenocortical carcinoma; however, this requires further study, particularly because this drug may be associated with significant neurotoxicity. Gossypol, a naturally occurring insecticide (from the cotton plant *Gossypium* species), also appears to inhibit the growth of adrenocortical cancer cell lines and tumors in vivo. However, poor response rates combined with high death rates in limited clinical studies have reduced enthusiasm for this agent. Adrenocortical cancers also are relatively insensitive to conventional external-beam radiation therapy. However, this modality is used in the palliation of bony metastases. Ketoconazole, metyrapone, or aminoglutethimide may also be useful in controlling steroid hypersecretion.

Sex Steroid Excess. Adrenal adenomas or carcinomas that secrete adrenal androgens lead to virilizing syndromes. Although women with virilizing tumors develop hirsutism, amenorrhea, infertility, and other signs of masculinization, such as increased muscle mass, deepened voice, and temporal balding, men with these tumors are more difficult to diagnose and, hence, usually present with disease in advanced stages. Children with virilizing tumors have accelerated growth, premature development of facial and pubic hair, acne, genital enlargement, and deepening of their voice. Feminizing adrenal tumors are less common and occur in men in the third to fifth decades of life. These tumors lead to gynecomastia, impotence, and testicular atrophy. Women with these tumors develop irregular menses or dysfunctional uterine bleeding. Vaginal bleeding may occur in postmenopausal women. Girls with these tumors experience precocious puberty with breast enlargement and early menarche.

Diagnostic Tests Virilizing tumors produce excessive amounts of the androgen precursor, DHEA, which can be measured in plasma or urine as 17-ketosteroids. Patients with feminizing tumors also have elevated urinary 17-ketosteroids in addition to increased estrogen levels. Androgen-producing tumors often are associated with production of other hormones such as glucocorticoids.

Treatment Virilizing and feminizing tumors are treated by adrenalectomy. Malignancy is difficult to diagnose histologically but is suggested by the presence of local invasion, recurrence, or distal metastases. Adrenolytic drugs such as mitotane, aminoglutethimide, and ketoconazole may be useful in controlling symptoms in patients with metastatic disease.

Congenital Adrenal Hyperplasia. CAH refers to a group of disorders that result from deficiencies or complete absence of enzymes involved in adrenal steroidogenesis. 21-Hydroxylase (CYP21A2) deficiency is the most common enzymatic defect, accounting for >90% of cases of CAH. This deficiency prevents the production of 11-deoxycortisol and 11-DOC from progesterone precursors. Deficiency of glucocorticoids and aldosterone leads to elevated ACTH levels and overproduction of adrenal androgens and corticosteroid precursors such as 17-hydroxyprogesterone and Δ^4-androstenedione. These compounds are converted to testosterone in the peripheral tissues, thereby leading to virilization. Complete deficiency of 21-hydroxylase presents at birth with virilization, diarrhea, hypovolemia, hyponatremia, hyperkalemia, and hyperpigmentation. Partial enzyme deficiency may present at birth or later with virilizing features. These patients are less prone to the salt wasting that characterizes complete enzyme deficiency. 11β-Hydroxylase deficiency is the second most common form of CAH and leads to hypertension (from 11-DOC accumulation), virilization, and hyperpigmentation. Other enzyme deficiencies include 3β-hydroxydehydrogenase and 17-hydroxylase deficiency. Congenital adrenal lipoid hyperplasia is the most severe form of CAH, which is caused by cholesterol desmolase deficiency. It leads to the disruption of all steroid biosynthetic pathways, thus resulting in a fatal salt-wasting syndrome in phenotypic female patients.

Diagnostic Tests The particular enzyme deficiency can be diagnosed by karyotype analysis and measurement of plasma and urinary steroids. The most common enzyme deficiency, absence of 21-hydroxylase, leads to increased plasma 17-hydroxyprogesterone and progesterone levels, because these compounds cannot be converted to 11-deoxycortisol and 11-DOC, respectively. 11β-Hydroxylase deficiency is the next most common disorder and results in elevated plasma 11-DOC and 11-deoxycortisol. Urinary 17-hydroxyprogesterone, androgens, and 17-ketosteroids also are elevated. The dexamethasone suppression test (2–4 mg divided qid for 7 days) can be used to distinguish adrenal hyperplasia from neoplasia. CT, MRI, and iodocholesterol scans generally are used to localize the tumors.

Treatment Patients with CAH traditionally have been managed medically, with cortisol and mineralocorticoid replacement to suppress the hypothalamic-pituitary-adrenal axis. However, the doses of steroids required often are supraphysiologic and lead to iatrogenic hypercortisolism. More recently, bilateral laparoscopic adrenalectomy has been proposed as an alternative treatment for this disease and has been successfully performed in a limited number of patients for various forms of CAH.

Disorders of the Adrenal Medulla

Pheochromocytomas. Pheochromocytomas are rare tumors with prevalence rates ranging from 0.3% to 0.95% in autopsy series and approximately 1.9% in series using biochemical screening. They can occur at any age, with a peak incidence in the fourth and fifth decades of life, and have no gender predilection.

Extra-adrenal tumors, also called functional paragangliomas, may be found at sites of sympathetic ganglia in the organ of Zuckerkandl, neck, mediastinum, abdomen, and pelvis. Pheochromocytomas often are called the *10 percent tumor* because 10% are bilateral, 10% are malignant, 10% occur in pediatric patients, 10% are extra-adrenal, and 10% are familial.

Pheochromocytomas occur in families with MEN2A and MEN2B in approximately 50% of patients. Both syndromes are inherited in an autosomal dominant fashion and are caused by germline mutations in the *RET* proto-oncogene. Another syndrome with an increased risk of pheochromocytomas is von Hippel-Lindau (VHL) disease, which also is inherited in an autosomal dominant manner. This syndrome also includes retinal angioma, hemangioblastomas of the central nervous system, renal cysts and carcinomas, pancreatic cysts, and epididymal cystadenomas. The incidence of pheochromocytomas in the syndrome is approximately 14%. The gene causing VHL has been mapped to chromosome 3p and is a tumor suppressor gene. Pheochromocytomas also are included within the tumor spectrum of neurofibromatosis type 1 (*NF1* gene) and other neuroectodermal disorders (Sturge-Weber syndrome and tuberous sclerosis), Carney's syndrome (gastric epithelioid leiomyosarcoma, pulmonary chondroma, and extra-adrenal paraganglioma), MEN1 syndrome, and the familial paraganglioma and pheochromocytoma syndrome caused by mutations in the succinyl dehydrogenase family of genes (*SDHB, SDHC*, and *SDHD*), which comprise portions of the mitochondrial complex II.[87] More recently, mutations in *SDHA* and *SDH5* have also been identified. Additional susceptibility loci include *TMEM127* (involved in the mTORC1 signaling pathway) and *MAX* (*myc-associated factor X*).

Symptoms and Signs Headache, palpitations, and diaphoresis constitute the "classic triad" of pheochromocytomas. Symptoms such as anxiety, tremulousness, paresthesias, flushing, chest pain, shortness of breath, abdominal pain, nausea, vomiting, and others are nonspecific and may be episodic in nature. Cardiovascular complications such as myocardial infarction and cerebrovascular accidents may ensue. These symptoms can be incited by a range of stimuli including exercise, micturition, and defecation. The most common clinical sign is hypertension. Pheochromocytomas are one of the few curable causes of hypertension and are found in 0.1% to 0.2% of hypertensive patients. Hypertension related to this tumor may be paroxysmal with intervening normotension, sustained with paroxysms or sustained hypertension alone. Sudden death may occur in patients with undiagnosed tumors who undergo other surgeries or biopsy.

Diagnostic Tests

Biochemical Studies. Pheochromocytomas are diagnosed by testing 24-hour urine samples for catecholamines and their metabolites as well as by determining plasma metanephrine levels. Urinary metanephrines are 98% sensitive and also about 98% specific for pheochromocytomas, whereas VMA measurements are slightly less sensitive and specific. False-positive VMA tests may result from ingestion of caffeine, raw fruits, or medications (α-methyldopa). Fractionated urinary catecholamines (norepinephrine, epinephrine, and dopamine) also are very sensitive but less specific for pheochromocytomas. Because extra-adrenal sites lack phenylethanolamine *N*-methyltransferase, these tumors secrete norepinephrine, whereas epinephrine is the main hormone secreted from adrenal pheochromocytomas. Many physiologic and pathologic states can alter the levels of plasma catecholamines. Hence, they often are thought to be less accurate than urinary tests. Both epinephrine and norepinephrine should be measured, as tumors often secrete one or the other hormone. Sensitivities of 85% and specificities of 95% have been reported using cutoff values of 2000 pg/mL for norepinephrine and 200 pg/mL for epinephrine. Clonidine is an agent that suppresses neurogenically mediated catecholamine excess but not secretion from pheochromocytomas. A normal clonidine suppression test is defined by a decrease of basal catecholamine levels to <500 pg/mL within 2 to 3 hours after an oral dose of 0.3 mg of clonidine. Chromogranin A is a monomeric, acidic protein, which is stored in the adrenal medulla and other neuroendocrine tumors and released along with catecholamine hormones. It has been reported to have a sensitivity of 83% and a specificity of 96% and is useful in conjunction with catecholamine measurement for diagnosing pheochromocytomas. Some studies have shown that plasma metanephrines should be the first-line test to identify pheochromocytomas, as the predictive value of a negative test is very high and normal levels exclude pheochromocytoma in patients with preclinical disease or dopamine secreting tumors. Although sensitivities of 96% to 100% have been reported, specificity is lower at 85% to 89% and may be much lower at 77% in elderly patients. Although attractive because of the simplicity of a blood test, measurement of plasma metanephrines is generally reserved for cases for which there is a high index of suspicion.

Radiologic Studies. Radiologic studies are useful to localize tumors and to assess the extent of spread once the diagnosis has been made with biochemical tests. CT scans are 85% to 95% sensitive and 70% to 100% specific for pheochromocytomas (Fig. 38-46A). The scans should be performed without contrast to minimize the risk of precipitating a hypertensive crisis, although some recent studies suggest that intravenous contrast may be used. Images should include the region from the diaphragm to the aortic bifurcation so as to include the organ of Zuckerkandl. CT scans do not provide functional information and cannot definitively diagnose pheochromocytomas. MRI scans are 95% sensitive and almost 100% specific for pheochromocytomas because these tumors have a characteristic appearance on T2-weighted images or after gadolinium. MRI is also the study of choice in pregnant women as there is no risk of radiation exposure. Metaiodobenzylguanidine (MIBG) is taken up and concentrated by vesicles in the adrenal medullar cells because its structure is similar to norepinephrine. Normal adrenal medullary tissue does not take up appreciable MIBG. ^{131}I-radiolabeled MIBG is, therefore, useful for localizing pheochromocytomas (Fig. 38-46B), especially those in ectopic positions. This test has a reported sensitivity of 77% to 89% and specificity ranging from 88% to 100%.

Treatment The medical management of pheochromocytomas is aimed chiefly at blood pressure control and volume repletion. Irreversible, long-acting α-blockers such as phenoxybenzamine are started 1 to 3 weeks before surgery at doses of 10 mg twice daily, which may be increased to 300 to 400 mg/d with rehydration. Patients should be warned about orthostatic hypotension. β-Blockers such as propranolol at doses of 10 to 40 mg every 6 to 8 hours often need to be added preoperatively in patients who have persistent tachycardia and arrhythmias. β-Blockers should only be instituted after adequate α-blockade and hydration to avoid the effects of unopposed α stimulation (i.e., hypertensive

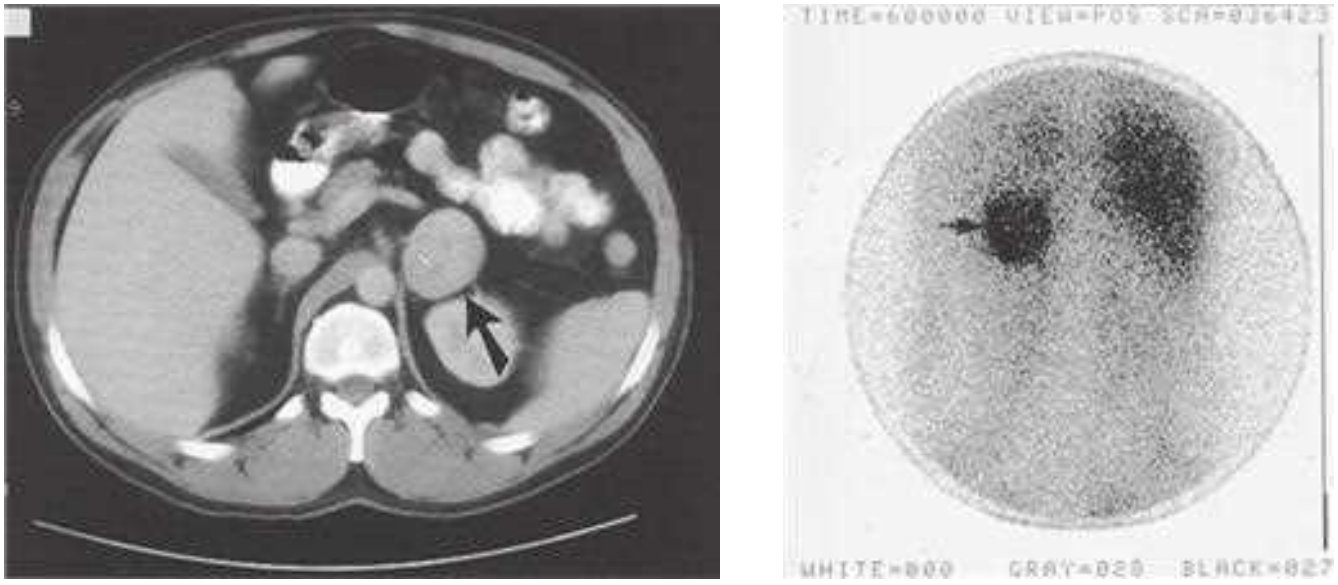

Figure 38-46. A left-sided pheochromocytoma (*arrows*) imaged by a computed tomography scan of the abdomen (**A**) and a metaiodobenzylguanidine scan viewed posteriorly (**B**).

crisis and congestive heart failure) and are typically initiated 3 to 4 days preoperatively. Patients also should be volume repleted preoperatively to avoid postoperative hypotension, which ensues with the loss of vasoconstriction after tumor removal. Other α-blockers such as prazosin, terazosin, and doxazosin, which are selective α_1-adrenergic blockers, have a better side effect profile and are preferable to phenoxybenzamine when long-term pharmacologic therapy is needed, as in patients with metastatic pheochromocytoma. Nicardipine is the most commonly used calcium channel blocker and inhibits norepinephrine-mediated calcium transport into vascular smooth muscle. When used as the primary mode of treatment, it appears to be just as effective as α- and β-blockade preoperatively. In some patients, catecholamine-synthesis inhibitors such as α-methyl-p-l-tyrosine (metyrosine) may need to be added if standard α- and β-blockade is poorly tolerated or is ineffective in reaching target blood pressure and when moderate intraoperative tumor manipulation is anticipated.

Adrenalectomy is the treatment of choice for patients with pheochromocytoma. The chief goal of surgery is to resect the tumor completely with minimal tumor manipulation or rupture of the tumor capsule. Surgery should be performed with both noninvasive and invasive monitors, including an arterial line and central venous lines. In patients with congestive heart failure or underlying coronary artery disease, Swan-Ganz catheters may be necessary. Stress must be avoided during anesthesia induction, and use of inhaled agents like isoflurane and enflurane are preferred because they have minimal cardiac depressant effects. Fentanyl, ketamine, and morphine should be avoided as they can potentially stimulate catecholamine release from the tumor. The common medications used for intraoperative blood pressure control include nitroprusside, nitroglycerin, phentolamine, and nicardipine. Intraoperative arrhythmias are best managed by short-acting β-blockers such as esmolol. Adrenalectomy usually was performed via an open anterior approach to facilitate detection of bilateral tumors, extra-adrenal lesions, or metastatic lesions. However, most pheochromocytomas <5 cm in diameter can be safely resected laparoscopically. Postoperatively, these patients are prone to hypotension due to loss of adrenergic stimulation and consequent vasodilatation and therefore need large volume resuscitation.

Hereditary Pheochromocytomas. Inherited pheochromocytomas tend to be multiple and bilateral. Generally, unilateral adrenalectomy is recommended in the absence of obvious lesions in the contralateral adrenal gland because of Addison's disease, requiring lifelong steroid replacement in patients undergoing bilateral adrenalectomy. For patients with tumors in both adrenal glands, cortical-sparing subtotal adrenalectomy may preserve adrenocortical function and avoid the morbidity of bilateral total adrenalectomy. Laparoscopic subtotal adrenalectomy has been shown to provide short-term clinical results comparable to total adrenalectomy, with reduced surgical morbidity.[88] However, these patients remain at risk for recurrent pheochromocytoma, which has been reported in 20% of patients with VHL disease a median of 40 months after partial adrenalectomy, and in 33% of MEN2 patients followed for 54 to 88 months after surgery. Autotransplantation of adrenocortical tissue after total adrenalectomy may be another option for these patients. However, the transplanted cortical tissue rarely provides full function, and steroid replacement usually is required.

Malignant Pheochromocytomas. Approximately 12% to 29% of pheochromocytomas are malignant, and these tumors are associated with decreased survival. There are no definitive histologic criteria defining malignant pheochromocytomas. In fact, pleomorphism, nuclear atypia, and abundant mitotic figures are seen in benign tumors. Capsular and vascular invasion may be seen in benign lesions as well. Malignancy usually is diagnosed when there is evidence of invasion into surrounding structures or distant metastases. The most common sites for metastatic disease are bone, liver, regional lymph nodes, lung, and peritoneum, although the brain, pleura, skin, and muscles may also occasionally be involved. Some studies also suggest that older patient age and larger tumors are associated with a higher risk of malignancy. Although risk of malignancy increases with size for all pheochromocytomas, size does not seem to reliably predict malignancy in pheochromocytomas with local disease

only.[89] Given this difficulty defining malignancy clinically (in the absence of metastatic disease), a number of other features such as DNA ploidy, tumor size, and necrosis, neuropeptide Y mRNA expression, and serum neuron-specific enolase expression have been studied. Malignant pheochromocytomas are more likely to express p53 and bcl-2 and have activated telomerase. Recent data suggest that flow cytometry and molecular markers such as expression of Ki-67, tissue inhibitor of metalloproteinase, and COX-2 also have shown some use in determining malignancy. When pheochromocytomas develop in the MEN syndromes, they rarely are malignant. In contrast, patients with germline *SDHB* mutations appear to have a higher propensity for extra-adrenal and malignant tumors. In general, soft tissue lesions are treated with resection if feasible. External-beam radiation can be used for unresectable lesions or symptomatic skeletal metastases. Therapeutic ^{131}I-MIBG irradiation may be useful in patients with diffuse disease showing ^{123}-I-MIBG uptake on a diagnostic scan. If the tumor is positive on somatostatin receptor imaging, long-acting octreotide may be used.

The Adrenal Incidentaloma

Adrenal lesions discovered during imaging performed for unrelated reasons are referred to as *incidentalomas*. This definition excludes tumors discovered on imaging studies performed for evaluating symptoms of hormone hypersecretion or staging patients with known cancer. The incidence of these lesions identified by CT scans ranges from 0.4% to 4.4%.

Differential Diagnosis. The differential diagnosis of adrenal incidentalomas is shown in Table 38-20. Nonfunctional cortical adenomas account for the majority (36%–94%) of adrenal incidentalomas in patients without a history of cancer. In a series of patients from the Mayo Clinic, no nonfunctional lesion progressed to cause clinical or biochemical abnormalities. However, other studies indicate that 5% to 20% of patients with apparently nonfunctioning cortical adenomas have underlying, subtle abnormalities of glucocorticoid secretion, and a rare benign-appearing incidentaloma is a cancer.

By definition, patients with incidentalomas do not have clinically overt Cushing's syndrome, but subclinical Cushing's syndrome is estimated to occur in approximately 8% of patients. This disorder is characterized by subtle features of cortisol excess, such as weight gain, skin atrophy, facial fullness, diabetes, and hypertension, accompanied by loss of normal diurnal variation in cortisol secretion, autonomous cortisol secretion, and resistance to suppression by dexamethasone. Total cortisol produced and 24-hour urinary cortisol levels may be normal. Examination of the natural history of subclinical Cushing's syndrome indicates that, although most patients remain asymptomatic, some do progress to clinically evident Cushing's syndrome. Furthermore, cases of postoperative adrenal crisis from unrecognized suppression of the contralateral adrenal have been reported, making preoperative identification of this condition imperative, particularly in the era of early discharge following laparoscopic adrenalectomy.

The adrenal is a common site of metastases of lung and breast tumors, melanoma, renal cell cancer, and lymphoma. In patients with a history of nonadrenal cancer and a unilateral adrenal mass, the incidence of metastatic disease has been reported to range from 32% to 73%. Myelolipomas are benign, biochemically nonfunctioning lesions composed of elements of hematopoietic and mature adipose tissue, which are rare causes of adrenal incidentaloma. Other less commonly encountered lesions include adrenal cysts, ganglioneuromas, and hemorrhage.

Diagnostic Investigations. The diagnostic workup of an adrenal incidentaloma is aimed at identifying patients who would benefit from adrenalectomy (i.e., patients with functioning tumors and tumors at increased risk of being malignant). It is not necessary for asymptomatic patients whose imaging studies are consistent with obvious cysts, hemorrhage, myelolipomas, or diffuse metastatic disease to undergo additional investigations. All other patients should be tested for underlying hormonally active tumors using (a) a low-dose (1 mg) overnight dexamethasone suppression test to rule out subclinical Cushing's syndrome and 17-ketosteroids (if sex steroid excess is suspected); (b) a 24-hour urine collection for catecholamines, metanephrines, VMA, or plasma metanephrine to rule out pheochromocytoma; and (c) in hypertensive patients, serum electrolytes, plasma aldosterone, and plasma renin to rule out an aldosteronoma. In patients with a high index of suspicion for subclinical Cushing's (those with hypertension, obesity, or diabetes), three tests (i.e., dexamethasone suppression test, salivary cortisol, and 24-hour urine free cortisol) may be used. Confirmatory tests can be performed based on the results of the initial screening studies.

Determination of the malignant potential of an incidentaloma is more difficult. The risk of malignancy in an adrenal lesion is related to its size. Lesions >6 cm in diameter have an approximate risk of malignancy of about 25%.[82] However, this size cutoff is not absolute because adrenal carcinomas also have been reported in lesions <6 cm. Carcinomas account for 2% of lesions <4 cm and 6% of lesions 4.1 to 6 cm in size. This has led to increased use of the imaging characteristics of incidentalomas to predict malignancy. Benign adrenal adenomas tend to be homogeneous, well encapsulated, and have smooth and regular margins. They also tend to be hypoattenuating lesions (<10 Hounsfield units) on CT scanning. In contrast, adrenal cancers tend to be hyperattenuating (>18 Hounsfield units) and inhomogeneous, have irregular borders, and may show evidence of local invasion or adjacent lymphadenopathy. On MRI T2-weighted imaging, adenomas demonstrate low signal intensity when compared to the liver (adrenal mass–to–liver ratio <1.4), whereas carcinomas and metastases have moderate intensity (mass-to-liver ratio 1.2:2.8). Pheochromocytomas are extremely bright, with mass-to-liver ratios >3. Unfortunately, the ranges overlap, and signal intensity is not 100% reliable for

Table 38-20

Differential diagnosis of adrenal incidentaloma

FUNCTIONING LESIONS	NONFUNCTIONING LESIONS
Benign Aldosteronoma Cortisol-producing adenoma Sex steroid–producing adenoma Pheochromocytoma	Benign Cortical adenoma Myelolipoma Cyst Ganglioneuroma Hemorrhage

determining the nature of the lesion. Radionuclide imaging with NP-59 also has been used to distinguish between various adrenal lesions, with some investigators suggesting that uptake of NP-59 was 100% predictive of a benign lesion (adenoma), whereas absence of imaging was 100% predictive of a nonadenomatous lesion. However, the technique has not gained widespread acceptance because patients need to be given cold iodine 1 week before the study to prevent thyroid uptake, imaging needs to be delayed by 5 to 7 days after administration of the contrast, and false-positive and false-negative results occur. FDG-PET or PET-CT scans may have some utility in distinguishing potentially malignant from benign lesions in cases of inconclusive CT densitometry. However, caution must be exercised for false-positive (some adenomas and pheochromocytomas) and false-negative results (small lesions or those with hemorrhage or necrosis).[90] FNAB cannot be used to distinguish adrenal adenomas from carcinomas. This being said, FNAB is useful in the setting of a patient with a history of cancer and a solitary adrenal mass. The positive predictive value of FNAB in this situation has been shown to be almost 100%, although false-negative rates of up to 33% have been reported. Biopsies usually are performed under CT guidance, and appropriate testing to rule out pheochromocytomas should be undertaken before the procedure to avoid precipitating a hypertensive crisis.

11▶

Management. An algorithm for the management of patients with incidentalomas is shown in Fig. 38-47. The AACE and American Association of Endocrine Surgeons (AAES) have recently published management guidelines for patients with adrenal incidentalomas.[91] Patients with functional tumors or obviously malignant lesions should undergo adrenalectomy. The optimal management of patients with subclinical Cushing's syndrome is controversial, especially due to the paucity of data from high-quality prospective trials. In general, operative intervention is advised in patients with subclinical Cushing's syndrome with suppressed plasma ACTH levels and elevated urinary cortisol levels because these patients are at high risk for progression to overt Cushing's syndrome. The adrenal incidentaloma guidelines also recommend adrenalectomy in patients with worsening hypertension, abnormal glucose tolerance, or osteoporosis.

For nonfunctional lesions, the risk of malignancy needs to be balanced with operative morbidity and mortality. The AACE/AAES guidelines recommend that lesions with suspicious features on imaging studies such as heterogeneity, irregular capsule, or adjacent nodes should be treated by adrenalectomy. Nonoperative therapy, with close periodic follow-up, is advised for lesions <4 cm in diameter with benign imaging characteristics, whereas adrenalectomy is recommended for lesions ≥4 cm in size due to the increased risk of cancer.

However, several important points must be considered in the management of these patients. First, size criteria for malignancy are not definitive and are derived from a selected series of patients. Second, the actual size of adrenal tumors can be underestimated by at least 1 cm by modalities such as CT and MRI scans, because tumors are larger in a cephalocaudal axis. Third, the natural history of incidentalomas is variable and depends on the underlying diagnosis, age of the study population, and the size of the mass. Older patients are more likely to have nonfunctioning adenomas. Existing data in terms of the long-term behavior of these nonfunctional lesions, although limited, indicate that malignant transformation is uncommon. Furthermore, tumors that increase in size by at least 1 cm over a 2-year follow-up period and those with subtle hormonal abnormalities appear to be more likely to enlarge. Overt hormone overproduction is more likely in tumors >3 cm and those with increased NP-59 uptake. Surgeons are more likely to operate on a 40-year-old patient with a 4-cm lesion, while electing to follow an 80-year-old patient with a similar lesion but multiple concurrent comorbidities. Based on the above considerations,

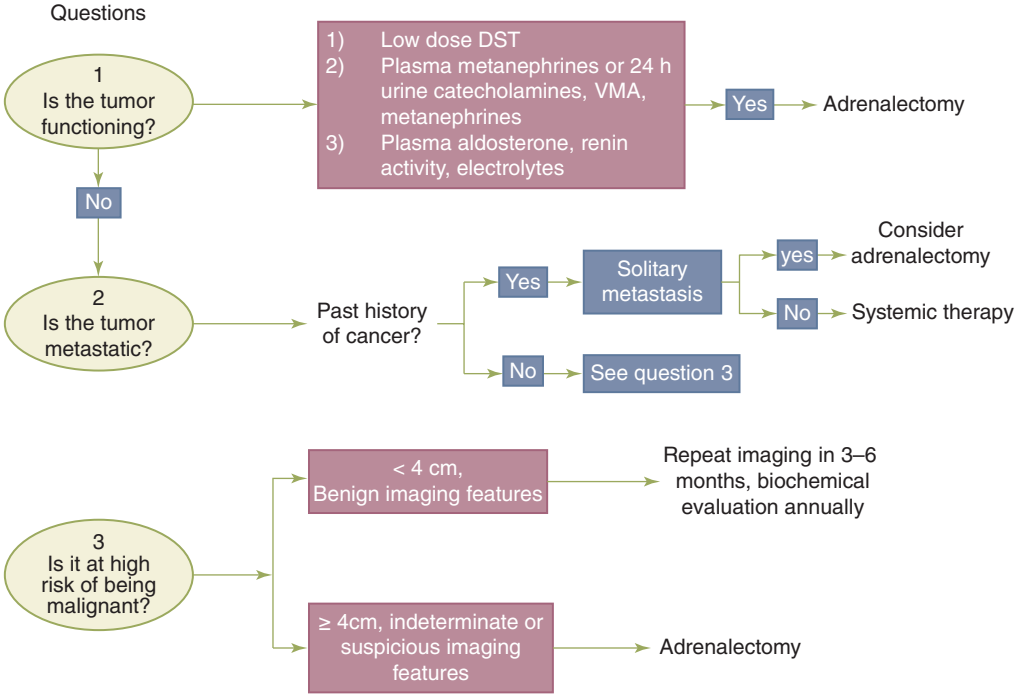

Figure 38-47. Management algorithm for an adrenal incidentaloma. CT = computed tomography; DST = dexamethasone suppression test; VMA = vanillylmandelic acid.

some surgeons use a size threshold for adrenalectomy with a nonfunctioning homogeneous tumor of 3 to 4 cm in young patients with no comorbidities and 5 cm in older patients with significant comorbidity.

Lesions that grow during follow-up also are treated by adrenalectomy. Myelolipomas generally do not warrant adrenalectomy unless there is concern regarding malignancy, which is rare, or bleeding into the lesion, which is more likely in myelolipomas >4 cm in size. These tumors, even when large, can be removed laparoscopically. Resection of solitary adrenal metastases in patients with a history of nonadrenal cancer has been demonstrated to lead to prolonged patient survival. Suspected adrenal metastases also may be resected for diagnosis.

There is no consensus regarding the follow up of patients with adrenal incidentaloma. The AACE/AAES guidelines recommend repeating hormonal screening with a 1-mg dexamethasone suppression test and urinary catecholamines and metabolites yearly for 5 years as the risk of hypersecretion appears to plateau after this time period.[91] It also recommends repeat imaging at 3 to 6 months and then annually for 1 to 2 years. Less frequent imaging is reasonable or small (<2 cm), uniform, hypodense cortical nodules in patients without a history of malignant disease. Adrenalectomy is recommended for lesions that grow ≥1 cm or if autonomous hormone secretion develops during follow-up.

Adrenal Insufficiency

Adrenal insufficiency may be primary, resulting from adrenal disease, or secondary, due to a deficiency of ACTH (Table 38-21). The most commonly encountered causes of primary adrenal insufficiency are autoimmune disease, infections, and metastatic deposits. Spontaneous adrenal hemorrhage can occur in patients with fulminant meningococcal septicemia (Waterhouse-Friderichsen syndrome). Bilateral adrenal hemorrhage also can occur secondary to trauma, severe stress, infection, and coagulopathies and, if unrecognized, is lethal. Exogenous glucocorticoid therapy with suppression of the adrenal glands is the most common cause of secondary adrenal insufficiency.

Symptoms and Signs. Acute adrenal insufficiency should be suspected in stressed patients with any of the relevant risk factors. It may mimic sepsis, myocardial infarction, or pulmonary embolus and presents with fever, weakness, confusion, nausea, vomiting, lethargy, abdominal pain, or severe hypotension. Chronic adrenal insufficiency, such as that occurring in patients with metastatic tumors, may be more subtle. Symptoms include fatigue, salt craving, weight loss, nausea, vomiting, and abdominal pain. These patients may appear hyperpigmented from increased secretion of CRH and ACTH, with increased α-melanocyte-stimulating hormone side-products.

Diagnostic Studies. Characteristic laboratory findings include hyponatremia, hyperkalemia, eosinophilia, mild azotemia, and fasting or reactive hypoglycemia. The peripheral blood smear may demonstrate eosinophilia in approximately 20% of patients. Adrenal insufficiency is diagnosed by the ACTH stimulation test. ACTH (250 µg) is infused intravenously, and cortisol levels are measured at 0, 30, and 60 minutes. Peak cortisol levels <20 µg/dL suggest adrenal insufficiency. ACTH levels also allow primary insufficiency to be distinguished from secondary causes. High ACTH levels with low plasma cortisol levels are diagnostic of primary adrenal insufficiency.

Table 38-21

Etiology of adrenal insufficiency

PRIMARY	SECONDARY
Autoimmune (autoimmune polyglandular disease type I and II)	Exogenous glucocorticoid therapy
Infectious—TB, fungi, CMV, HIV	Bilateral adrenalectomy
Hemorrhage—spontaneous (Waterhouse-Friderichsen syndrome) and secondary to stress, trauma, infections, coagulopathy, or anticoagulants	Pituitary or hypothalamic tumors
Metastases	Pituitary hemorrhage (postpartum Sheehan's syndrome)
Infiltrative disorders—amyloidosis, hemochromatosis	Transsphenoidal resection of pituitary tumor
Adrenoleukodystrophy	
Congenital adrenal hyperplasia	
Drugs—ketoconazole, metyrapone, aminoglutethimide, mitotane	

CMV = cytomegalovirus; HIV = human immunodeficiency virus; TB = tuberculosis.

Treatment. Treatment must be initiated based on clinical suspicion alone, even before test results are obtained, or the patient is unlikely to survive. Management includes volume resuscitation with at least 2 to 3 L of a 0.9% saline solution or 5% dextrose in saline solution. Blood should be obtained for electrolyte (decreased Na^+ and increased K^+), glucose (low), and cortisol (low) levels; ACTH (increased in primary and decreased in secondary); and quantitative eosinophilic count. Dexamethasone (4 mg) should be administered intravenously. Hydrocortisone (100 mg intravenously every 8 hours) also may be used, but it interferes with testing of cortisol levels. Once the patient has been stabilized, underlying conditions such as infection should be sought, identified, and treated. The ACTH stimulation test should be performed to confirm the diagnosis. Glucocorticoids can then be tapered to maintenance doses (oral hydrocortisone 15–20 mg in the morning and 10 mg in the evening). Mineralocorticoids (fludrocortisone 0.05–0.1 mg daily) may be required once the saline infusions are discontinued.

Adrenal Surgery

Choice of Procedure. Adrenalectomy may be performed via a laparoscopic or open approach. In either approach, the gland may be approached anteriorly, laterally, or posteriorly via the retroperitoneum. The choice of approach depends on the size and nature of the lesion and expertise of the surgeon. Laparoscopic adrenalectomy has rapidly become the standard procedure of choice for the excision of most benign-appearing adrenal lesions <6 cm in diameter. The role of laparoscopic adrenalectomy in the

management of adrenocortical cancers is controversial. The data with respect to local tumor recurrence and intra-abdominal carcinomatosis from laparoscopic adrenalectomy for malignant adrenal tumors that were not appreciated as such, preoperatively or intraoperatively, are conflicting. Although laparoscopic adrenalectomy appears to be feasible and safe for solitary adrenal metastasis[92] (provided there is no local invasion and the tumor can be resected intact), open adrenalectomy or laparoscopic-assisted open adrenalectomy is the safest option for suspected or known adrenocortical cancers and malignant pheochromocytomas. Technical considerations and surgeon experience, rather than absolute tumor size, usually determine the size threshold for laparoscopic resection. Hand-assisted laparoscopic adrenalectomy may provide a bridge between laparoscopic adrenalectomy and conversion to an open procedure. There have been no randomized trials directly comparing open vs. laparoscopic adrenalectomy. However, studies have shown that laparoscopic adrenalectomy is associated with decreased blood loss, postoperative pain, and narcotic use; reduced length of hospital stay; and faster return to work.

12▶

Laparoscopic Adrenalectomy. The procedure is performed under general anesthesia. Arterial lines are used routinely, and central lines are necessary for patients in whom massive fluid shifts are anticipated (e.g., those with large, active pheochromocytomas). A nasogastric tube and Foley catheter are recommended. Routine preoperative antibiotics are not needed, except in patients with Cushing's syndrome. The adrenals can be removed laparoscopically via a transabdominal (anterior or lateral) or retroperitoneal (lateral or posterior) approach. The lateral approach is preferred by most laparoscopic surgeons and uses gravity to aid retraction of surrounding organs. Patients, however, need to be repositioned for a bilateral procedure. The anterior transabdominal approach offers the advantage of a conventional view of the abdominal cavity and allows a bilateral adrenalectomy to be performed without the necessity of repositioning the patient. The posterior retroperitoneal approach has also been gaining popularity in recent years, particularly in patients with previous anterior abdominal surgery and peritoneal adhesions. In addition, several centers have successfully utilized robotic approaches for both lateral transabdominal and retroperitoneal laparoscopic adrenal surgery. Single incision laparoscopic adrenalectomy is another option; however, widespread use of these latter approaches awaits analysis of long-term outcomes data and cost analyses. The lateral transabdominal approach is widely used and described in detail below.

Lateral Transabdominal Approach The patient is placed in the lateral decubitus position, and the operating table is flexed at the waist to open the space between the lower rib cage and the iliac crest (Fig. 38-48). The surgeon and assistant both stand on the same side, facing the front of the patient. Pneumoperitoneum is created using a Veress needle or insufflation via a Hasson port. In general, four 10-mm trocars are placed between the midclavicular line medially and anterior axillary line laterally, one to two fingerbreadths below the costal margin (see Fig. 38-48), although additional ports may be placed, if needed. A 30° laparoscope is inserted through the second or midclavicular port. Most of the dissection is carried out via the two most lateral ports. However, the instruments and ports may be changed to provide optimum exposure, as needed.

For a right adrenalectomy, a fan retractor is inserted through the most medial port to retract the liver. An atraumatic grasper and an L-hook cautery are inserted via the two lateral ports for the dissection. The right triangular ligament is divided and the liver is rotated medially (Fig. 38-49A). Rarely, the hepatic flexure of the colon may need mobilization during a right adrenalectomy. The right kidney is identified visually and by palpation with an atraumatic grasper. The adrenal gland is identified on the superomedial aspect of the kidney. Gerota's fascia is incised with the hook cautery. Dissection of the adrenal is started superomedially and then proceeds inferiorly, dissecting around the adrenal in a clockwise manner. The periadrenal tissues are grasped or moved with a blunt grasper to facilitate circumferential dissection. The right adrenal vein is identified at its junction with the IVC, ligated with clips, and divided using endoscopic scissors. Alternatively, a vascular stapler may be used to divide the vein endoscopically. There may be a second adrenal vein on the right. Generally, two clips are left on the vena cava side. Although early identification of the adrenal vein is helpful to facilitate mobilization and prevent injury, it can be dissected whenever it is safe to do so. Early ligation of the adrenal vein makes it easier to mobilize the gland but may make subsequent dissection more difficult due to venous congestion. The arterial branches to the adrenal gland can be electrocoagulated if small or clipped and divided.

For a left adrenalectomy, the fan retractor is used to retract the spleen. The splenic flexure is mobilized early, and the lateral attachments to the spleen and the tail of the pancreas are

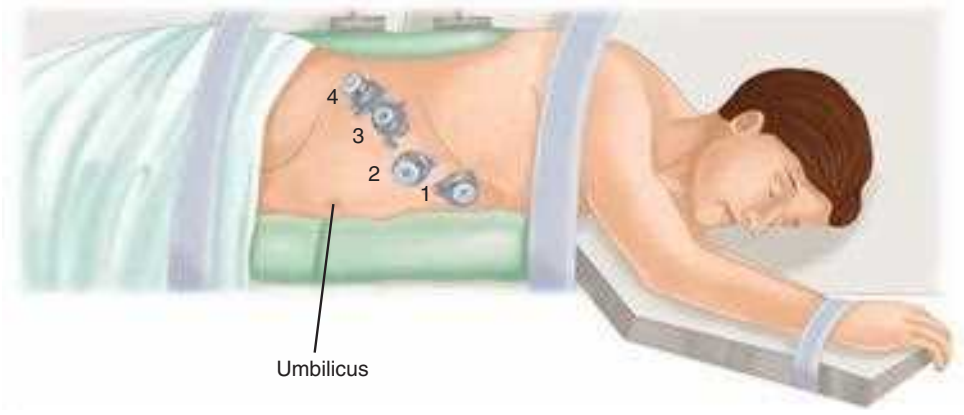

Figure 38-48. Positioning of the patient and placement of trocars for a laparoscopic adrenalectomy. Four trocars are placed from the midclavicular to the anterior axillary line.

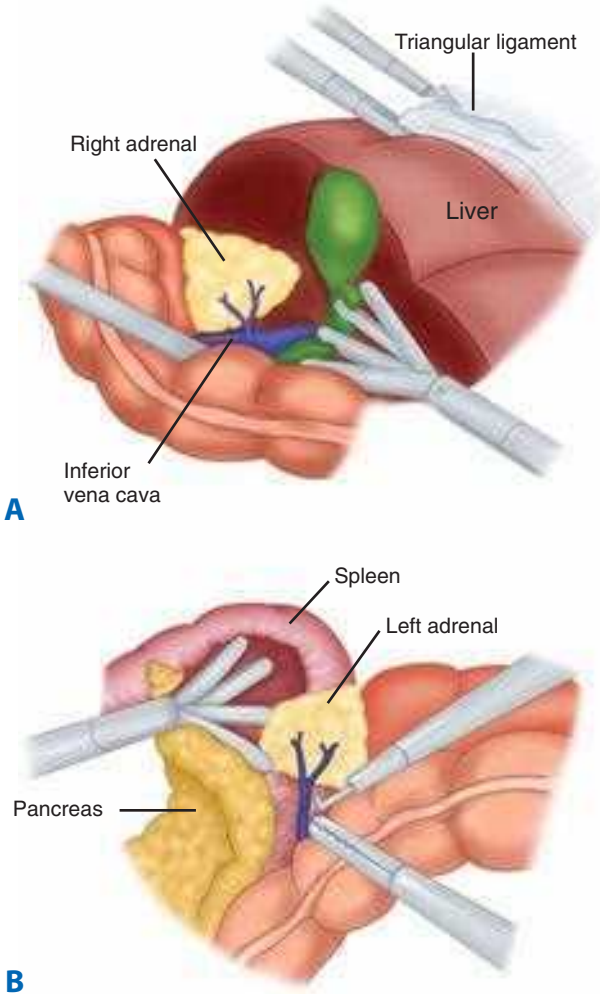

Figure 38-49. Technique of laparoscopic adrenalectomy. Exposure of the right adrenal is facilitated by division of the triangular ligament (**A**) and dissection and reflection of the spleen and tail of the pancreas aids in identifying the left adrenal (**B**).

divided using the electrocautery (Fig. 38-49B). Gravity allows the spleen and the pancreatic tail to fall medially. The remainder of the dissection proceeds similarly to that described for the right adrenal. In addition to the adrenal vein, the inferior phrenic vein, which joins the left adrenal vein medially, also needs to be dissected, doubly clipped, and divided. As with the right adrenal vein, the left-sided veins also can be divided with a vascular stapler. Once the dissection is complete, the area of the adrenal bed can be irrigated and suctioned. A drain is rarely necessary. The gland is placed in a nylon specimen bag, which is brought out via one of the ports after morcellation, if necessary.

Posterior Retroperitoneal Approach The retroperitoneal approach provides a more direct access to the adrenal gland and avoids abdominal adhesions in patients who have had previous abdominal surgery. Furthermore, bilateral adrenalectomy can be performed without repositioning the patient. Intraoperative ultrasound is helpful for identifying the adrenal, but the dissection and exposure are more difficult because the working space is limited. This makes vascular control difficult and also renders it unsuitable for large (>5 cm) lesions. This technique is being increasingly used for small adenomas causing hyperaldosteronism.

The patient is placed in the prone-jackknife position, and the operating table is flexed at the waist to open the space between the posterior costal margin and the pelvis. Palpation is used to identify the position of the twelfth rib. Percutaneous ultrasound is performed to determine the outline of the underlying kidney and adrenal. When done laparoscopically, the surgeon stands on the side of the adrenal to be removed, and the assistant stands on the opposite side. A 1.5-cm incision is placed 2 cm inferior and parallel to the twelfth rib, laterally at the level of the inferior pole of the kidney. Gerota's space is entered under direct vision using a 12-mm direct viewing trocar with a 0° laparoscope through the muscle layers of the posterior abdominal wall. Alternatively, blunt dissection with the surgeon's finger also can identify the space behind Gerota's fascia. The trocar is then replaced by a dissecting balloon, which is manually inflated using a hand pump under direct vision through the laparoscope. A 12-mm trocar is then reinserted into this space, and CO_2 is insufflated to 12 to 15 mmHg pressure. The 0° laparoscope is replaced by a 45° laparoscope. Two additional 5- or 10-mm trocars are placed, one each on either side of the first port. Laparoscopic ultrasound then is used to help locate the adrenal gland and vessels. The adrenal dissection is begun at the superior pole and then proceeds to the lateral and inferior aspect. The medial dissection usually is performed last, and the vessels are identified and divided as described in the earlier Lateral Transabdominal Approach section.

Open Adrenalectomy. Open adrenalectomy may be performed via four approaches, each with specific advantages and disadvantages. The anterior approach allows examination of the abdominal cavity and resection of bilateral tumors via a single incision. The posterior approach avoids the morbidity of a laparotomy incision, especially in patients with cardiopulmonary disease and those prone to wound complications (Cushing's syndrome) and avoids abdominal adhesions in patients who have undergone previous abdominal surgery. Recovery time is also quicker and hospitalization shorter. However, the retroperitoneal exposure is difficult, particularly in obese patients, and the small working space makes it unsuitable for tumors >6 cm in diameter. The lateral approach is best for obese patients and for large tumors because it provides a bigger working space. The thoracoabdominal approach is most useful for en bloc resection of large (>10 cm), malignant lesions. However, it is associated with significant morbidity and should be used selectively.

Anterior Approach The adrenals may be removed via a midline incision or bilateral subcostal incision (Fig. 38-50). The former allows adequate infraumbilical exposure for examination of extra-adrenal tumors, whereas the latter provides better superior and lateral exposure. For the right side, the hepatic flexure of the colon is mobilized inferiorly, and the triangular ligament is incised to retract the liver medially and superiorly. A generous Kocher maneuver is used to mobilize the duodenum anteriorly and expose the retroperitoneal fat and the IVC (Fig. 38-51A). Gerota's fascia is incised, and the gland is freed of surrounding fibro-fatty tissue and the kidney inferiorly. The lateral and superior surfaces usually are mobilized first. Then, the short, right adrenal vein is dissected, ligated, and divided, taking care not to injure the hepatic veins and IVC. On the left side, the adrenal is located cephalad to the pancreatic tail and just lateral to the aorta. For large tumors, the adrenal is best approached by medial visceral rotation to mobilize the spleen, colon, and pancreas toward the midline (Fig. 38-51B). An alternative approach is to enter the lesser sac by division of the gastrocolic ligament. The pancreas is mobilized superiorly by

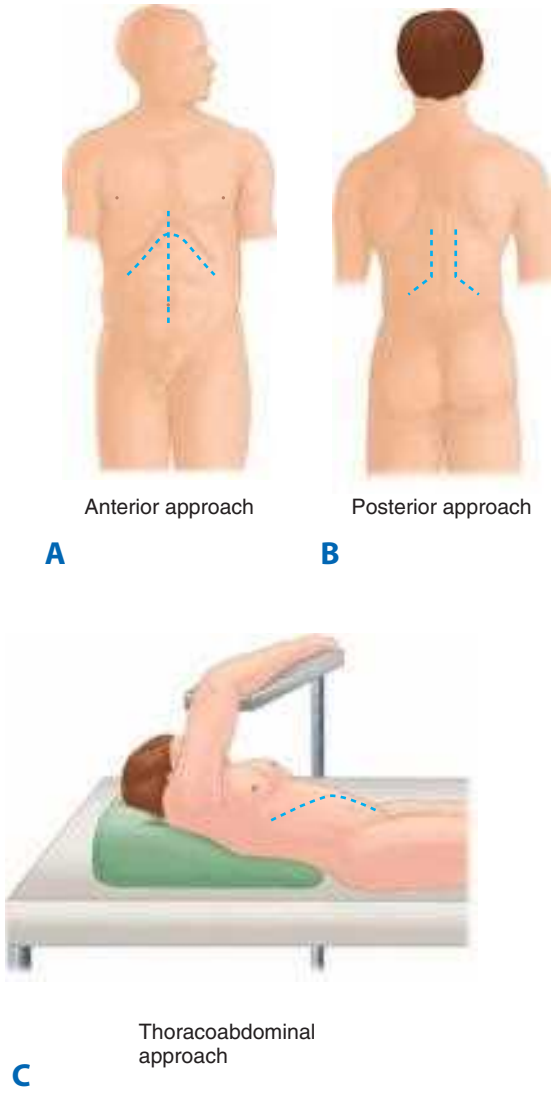

Figure 38-50. Incisions for open adrenalectomy. Anterior approach (**A**), posterior approach (**B**), and thoracoabdominal approach (**C**).

incision of its inferior peritoneal attachments, thus exposing the left kidney and adrenal. The gland is then mobilized as on the right side.

Posterior Approach The patient is placed prone on the operating table, similar to the laparoscopic approach. A hockey stick or curvilinear incision may be used, and extended through the latissimus dorsi and sacrospinous fascia. The twelfth rib generally is excised at its base, and the eleventh rib is retracted superiorly to reveal the pleura and the lateral arcuate ligament of the liver on the right side. The pleura also is mobilized cephalad, and the adrenal and kidney are identified. The superior aspect of the gland is dissected first, and the superior vessels are identified and ligated. This prevents superior retraction of the adrenal gland. The remainder of the gland is then dissected and the adrenal gland and tumor removed. The resulting space generally is filled with perinephric fat and closed in layers. A chest x-ray is obtained postoperatively to rule out a pneumothorax.

Lateral Approach The patient is placed in a lateral position with the table flexed, and an incision is made between the eleventh and twelfth ribs or subcostally. The dissection then is performed as indicated previously in Anterior Approach.

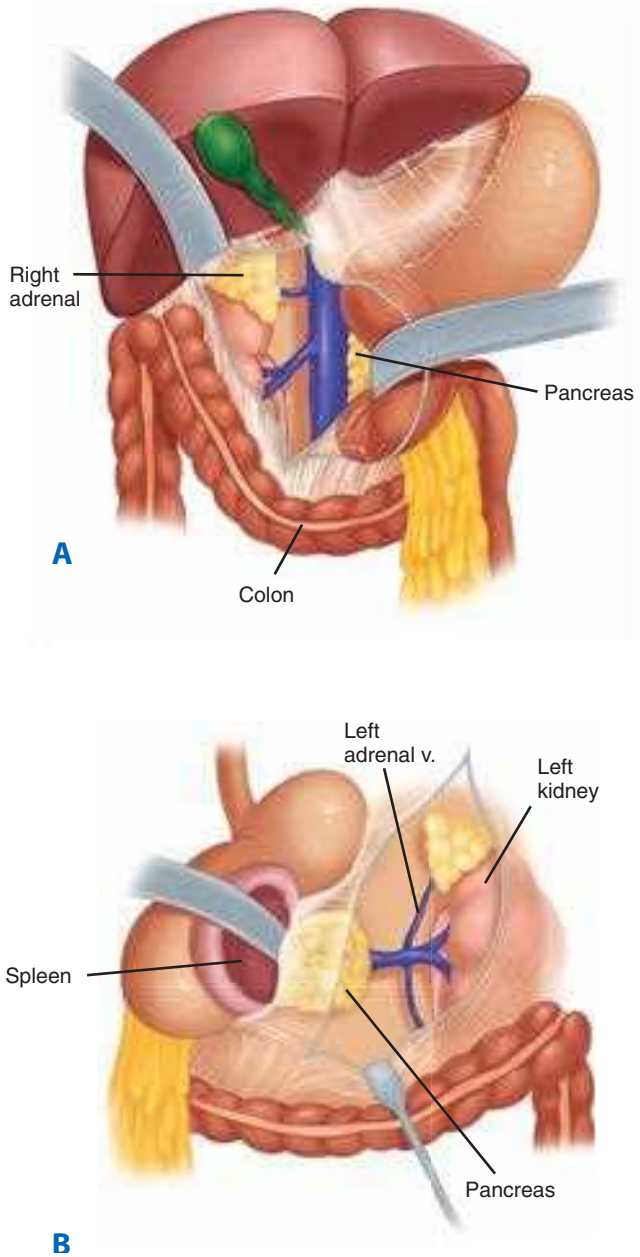

Figure 38-51. Technique of open adrenalectomy. Exposure of the right adrenal is facilitated by a Kocher maneuver to mobilize the duodenum and upward retraction of the liver (**A**). The left adrenal can be exposed by medial visceral rotation of the spleen and pancreas (**B**). v. = vein.

Complications of Adrenal Surgery. Patients with Cushing's syndrome are more prone to infectious (incisional and intra-abdominal abscess) and thrombotic complications. Creation of pneumoperitoneum may result in injury to various organs from Veress needle and trocar insertion, subcutaneous emphysema, pneumothorax, and hemodynamic compromise. Excessive retraction and dissection may lead to bleeding from injury to the IVC and renal vessels, or from injury to surrounding organs such as the liver, pancreas, spleen, and stomach. Postoperative hemodynamic instability may be evident in patients with pheochromocytomas, and patients are at risk of adrenal insufficiency after bilateral adrenalectomy and sometimes after unilateral adrenalectomy (unrecognized Cushing's syndrome or, very rarely, Conn's syndrome). Long-term morbidity results mainly

from injury to nerve roots during trocar insertion, which can lead to chronic pain syndromes or muscle weakness, although this is more of an issue in case of open procedures.

Approximately 30% of patients who undergo bilateral adrenalectomy for Cushing's disease are at risk of developing Nelson's syndrome from progressive growth of the pre-existing pituitary tumor. This leads to increased ACTH levels, hyperpigmentation, visual field defects, headaches, and extraocular muscle palsies. Transsphenoidal pituitary resection is the initial mode of therapy, and external-beam radiotherapy is used in patients with residual tumor or extrasellar invasion.

Pediatric Surgery

David J. Hackam, Tracy Grikscheit, Kasper Wang, Jeffrey S. Upperman, and Henri R. Ford

INTRODUCTION

In his 1953 classic textbook entitled *The Surgery of Infancy and Childhood*, Dr. Robert E. Gross summarized the essential challenge of pediatric surgery: "Those who daily operate upon adults, even with the greatest of skill, are sometimes appalled – or certainly are not at their best – when called upon to operate upon and care for a tiny patient. Something more than diminutive instruments or scaled-down operative manipulations are necessary to do the job in a suitable manner." To this day, surgical residents and other trainees often approach the pediatric surgical patient with the same mix of fear, trepidation, and anxiety. Importantly, these same trainees typically complete their pediatric surgical rotations with a profound respect for the resilience of young children to undergo complex operations, and with an appreciation for the precision required from their caregivers, both in the operating room and during the perioperative period. Over the decades, the specialty of pediatric surgery has evolved considerably to encompass not only the care of the smallest patients with surgical disorders, who may require in utero interventions in certain circumstances, but also the care of older infants, children, adolescents, and young adults. Similarly, our understanding of the pathophysiology of the diseases that pediatric surgeons face has evolved to the point that some pediatric surgical diseases are now understood at the level of molecular or cellular signaling pathways. Pediatric surgery provides the opportunity to intervene positively in a wide array of diseases

Key Points

1. In infants with Bochdalek-type congenital diaphragmatic hernia, the severity of pulmonary hypoplasia and the resultant pulmonary hypertension are key determinants of survival. Barotrauma and hypoxia should be avoided.
2. During initial management of an infant with esophageal atresia and distal tracheoesophageal fistula, every effort should be made to avoid distending the gastrointestinal tract, especially when using mechanical ventilation. The patient should be evaluated for components of the VACTERRL (vertebral, anorectal, cardiac, tracheoesophageal, renal, radial limb) anomalies. Timing and extent of surgery are dictated by the stability of the patient.
3. Although malrotation with midgut volvulus occurs most commonly within the first few weeks of life, it should always be considered in the differential diagnosis in a child with bilious emesis. Volvulus is a surgical emergency; therefore, in a critically ill child, prompt surgical intervention should not be delayed for any reason.
4. When evaluating a newborn infant for vomiting, it is critical to distinguish between proximal and distal causes of intestinal obstruction using both prenatal and postnatal history, physical examination, and abdominal radiographs.
5. Risk factors for necrotizing enterocolitis (NEC) include prematurity, formula feeding, bacterial infection, and intestinal ischemia. Critical to the management of infants with advanced (Bell stage III) or perforated NEC is timely and adequate source control of peritoneal contamination. Early sequelae of NEC include perforation, sepsis, and death. Later sequelae include short bowel syndrome and stricture.
6. In patients with intestinal obstruction secondary to Hirschsprung's disease, a leveling ostomy or endorectal pull-through should be performed using ganglionated bowel, proximal to the transition zone between ganglionic and aganglionic intestine.
7. Prognosis of infants with biliary atresia is directly related to age at diagnosis and timing of portoenterostomy. Infants with advanced age at the time of diagnosis or infants who fail to demonstrate evidence of bile drainage after portoenterostomy usually require liver transplantation.
8. Infants with omphaloceles have greater associated morbidity and mortality than infants with gastroschisis due to a higher incidence of congenital anomalies and pulmonary hypoplasia. Gastroschisis can be associated with intestinal atresia, but not with other congenital anomalies. An intact omphalocele can be repaired electively, whereas gastroschisis requires urgent intervention to protect the exposed intestine.
9. Prognosis for children with Wilms' tumor is defined by the stage of disease at the time of diagnosis and the histologic type (favorable vs. unfavorable). Preoperative chemotherapy is indicated for bilateral involvement, a solitary kidney, or tumor in the inferior vena cava above the hepatic veins. Gross tumor rupture during surgery automatically changes the stage to 3 (at a minimum).
10. Injury is the leading cause of death in children older than 1 year of age. Blunt mechanisms account for the majority of pediatric injuries. The central nervous system is the most commonly injured organ system and the leading cause of death in injured children.

and to exert a long-lasting impact on the lives of children and their grateful parents. The scope of diseases encountered in the standard practice of pediatric surgery is immense and includes anomalies of the head and neck, thoracic, gastrointestinal, and genitourinary areas. This chapter is not designed to cover the entire spectrum of diseases a pediatric surgeon is expected to master; rather, it presents a synopsis of a handful of pediatric surgical conditions that a practicing general surgeon is likely to encounter over the course of his or her career.

PEDIATRIC SURGICAL THEMES: PITFALLS AND PEARLS

This chapter focuses on the unique considerations regarding the diagnosis and management of surgical diseases in the pediatric population. Many surgical trainees approach the surgical care of children with some degree of fear and trepidation. As any pediatric caregiver will attest to, the surgical management of infants and children requires delicate, careful, and professional interactions with their parents. The stress that the parents of sick children experience in the hospital setting can, at times, be overwhelming. It is due, in part, to the uncertainty regarding a particular prognosis, the feeling of helplessness that evolves when one is unable to care for one's own child, and in certain cases, the guilt or remorse that one feels for not seeking medical care earlier or for consenting to a particular procedure. Management of the sick child and his or her family requires not only a certain set of skills, but also a unique knowledge base. This section is included to summarize some important general principles in accomplishing this task.

1. *Children are not little adults, but they are little people.* In practical terms, this often-heard refrain implies that children have unique fluid, electrolyte, and medication needs. Thus, the dosage of medications and the administration of intravenous fluids should be based on their weight. The corollary of this point is that infants and young children are extremely sensitive to perturbations in their normal physiology, and as such may easily experience fluid overload or dehydration.
2. *Sick children whisper before they shout.* Children with surgical diseases can deteriorate very quickly. But before they deteriorate, they often manifest subtle physical findings. These findings—referred to as "whispers"—may include signs such as tachycardia, bradycardia, hypothermia, fever, recurrent emesis, or feeding intolerance. Meticulous attention to these subtle findings may unmask the development of potentially serious, life-threatening physiologic disturbances.
3. *Always listen to the mother and the father.* Surgical diseases in children can be very difficult to diagnose because children are often minimally communicative and information that they communicate may be confusing, conflicting, or both. In all cases, it is wise to listen to the child's parents, who

have closely observed their child and know him or her best. Most importantly, the child's parents know with certainty whether or not the child is sick despite not always knowing the precise diagnosis.

4. *Children suffer pain after surgery.* Timely and adequate pain management must accompany surgical interventions.
5. *Pediatric tissue must be handled delicately and with profound respect.*

GENERAL CONSIDERATIONS

Fluid and Electrolyte Balance

In managing the pediatric surgical patient, an understanding of fluid and electrolyte balance is critical, as the margin between dehydration and fluid overload is rather small. This is particularly true in infants, who have little reserve when ill. Failure to pay meticulous attention to their hydration status can result in significant fluid overload or dehydration. Several surgical diagnoses such as gastroschisis or short-gut syndrome are characterized by a predisposition to fluid loss. Others require judicious restoration of intravascular volume in order to prevent cardiac failure, as is the case in patients with congenital diaphragmatic hernia and associated pulmonary hypertension. The infant's physiologic day is approximately 8 hours in duration. Accordingly, careful assessment of the individual patient's fluid balance, including fluid intake and output for the previous 8 hours, is essential to prevent dehydration or fluid overload. Clinical signs of dehydration include tachycardia, decreased urine output, reduced skin turgor, a depressed fontanelle, absent tears, lethargy, and poor feeding. Fluid overload is often manifested by the onset of new oxygen requirement, respiratory distress, tachypnea, and tachycardia. The physical assessment of the fluid status of each child must include a complete head-to-toe evaluation, with emphasis on determining whether perturbations in normal physiology are present.

At 12 weeks' gestation, the total body water of a fetus is approximately 94 cc/kg. By the time the fetus reaches full term, the total body water has decreased to approximately 80 cc/kg. Total body water drops an additional 5% within the first week of life, and by 1 year of life, total body water approaches adult levels, around 60 to 65 cc/kg. Parallel to the drop in total body water is the reduction in extracellular fluid. These changes are accelerated in the preterm infant who may face additional fluid losses due to coexisting congenital anomalies or surgery. Normal daily maintenance fluids for most children can be estimated using the following formula: 100 mL/kg for the first 10 kg, plus 50 mL/kg for 11 to 20 kg, plus 25 mL/kg for each additional kilogram of body weight thereafter. Because intravenous (IV) fluid orders are written as milliliters per hour, this can be conveniently converted as follows: 4 mL/kg/h up to 10 kg, add 2 mL/kg/h for 11 to 20 kg, and add 1 mL/kg/h for each additional kilogram of body weight thereafter. For example, a 26-kg child has an estimated maintenance fluid requirement of $(10 \times 4) + (10 \times 2) + (6 \times 1) = 66$ mL/h in the absence of massive fluid losses or shock. A newborn infant with gastroschisis will manifest significant evaporative losses from the exposed bowel such that fluid requirements may range from 150 to 180 cc/kg/d. Precise management of a neonate's fluid status requires an understanding of changes in the glomerular filtration rate (GFR) and tubular function of the kidney. The term newborn's GFR is approximately 21 mL/min/1.73 m^2 compared to 70 mL/min/1.73 m^2 in an adult. Within the first 2 weeks of life, GFR increases to approximately 60, and by 2 years of age, it is essentially at adult levels. The capacity to concentrate urine is very limited in preterm and term infants. Compared with an adult who can concentrate urine to 1200 mOsm/kg, infants can concentrate urine at best to 600 mOsm/kg. While infants are capable of secreting antidiuretic hormone (ADH), the aquaporin water channel–mediated osmotic water permeability of the infant's collecting tubules is severely limited compared with that of adults, leading to insensitivity to ADH.

Sodium requirements range from 2 mEq/kg/d in term infants up to 5 mEq/kg/d in critically ill preterm infants as a consequence of salt wasting. Potassium requirements are on the order of 1 to 2 mEq/kg/d. Calcium and magnesium supplementation of IV fluids is essential to prevent laryngospasm, dysrhythmias, and tetany.

Acid-Base Equilibrium

Acute metabolic acidosis usually implies inadequate tissue perfusion and is a serious disorder in children. Potentially life-threatening causes that are specific for the pediatric population must be sought; they include intestinal ischemia from necrotizing enterocolitis (in the neonate), midgut volvulus, or incarcerated hernia. Other causes include chronic bicarbonate loss from the gastrointestinal tract or acid accumulation as in chronic renal failure. Respiratory acidosis implies hypoventilation, the cause of which should be apparent. Treatment of acute metabolic acidosis should be aimed at restoring tissue perfusion by addressing the underlying abnormality first. For severe metabolic acidemia where the serum pH is less than 7.25, sodium bicarbonate should be administered using the following guideline: base deficit $\times$ weight in kilograms $\times$ 0.5 (in newborns). The last factor in the equation should be 0.4 for smaller children and 0.3 for older children. The dose should be diluted to a concentration of 0.5 mEq/mL because full-strength sodium bicarbonate is hyperosmolar. One half of the corrective dose is given, and the serum pH is measured again. During cardiopulmonary resuscitation (CPR), one half of the corrective dose can be given as an IV bolus and the other half given slowly via IV.

Respiratory alkalosis is usually caused by hyperventilation, which is readily correctable. Metabolic alkalosis most commonly implies gastric acid loss, as in the child with pyloric stenosis, or aggressive diuretic therapy. In the child with gastric fluid loss, IV fluids of 5% dextrose, 0.5% normal saline, and 20 mEq KCl/L usually correct the alkalosis.

Blood Volume and Blood Replacement

Criteria for blood transfusion in infants and children remain poorly defined. The decision to transfuse a critically ill pediatric patient may depend on a number of clinical features that include the patient's age, primary diagnosis, the presence of ongoing bleeding, coagulopathy, hypoxia, hemodynamic compromise, lactic acidosis, cyanotic heart disease, and overall severity of illness. A recent survey of transfusion practices among pediatric intensivists showed that the baseline hemoglobin levels that would prompt them to recommend packed red blood cell (PRBC) transfusion ranged from 7 to 13 g/dL. Patients with cyanotic heart disease are often transfused to higher hemoglobin values, although the threshold for transfusion in this population remains to be defined. To decrease the need for transfusion, other strategies have been considered. Studies in both critically ill adults and neonates have shown that administration

of erythropoietin decreases PRBC transfusion requirements. In general terms, there is a trend toward an avoidance of the use of PRBC products whenever possible, as current studies suggest that lower hemoglobin concentrations are well tolerated by many groups of patients, whereas administration of PRBCs may have unintended negative consequences. In addition, there is increasing evidence that PRBC transfusion may have adverse effects on the host immune system, in both children and adults. These effects are poorly understood but may be due to red blood cell (RBC) storage or factors that are particular to the individual RBC donor.

A useful guideline for estimating blood volume for the newborn infant is approximately 80 mL/kg of body weight. When PRBCs are required, the transfusion requirement is usually administered in 10-mL/kg increments, which is roughly equivalent to a 500-mL transfusion for a 70-kg adult. The following formula may be used to determine the volume (mL) of PRBCs to be transfused:

(Target hematocrit – Current hematocrit) × weight (kg) × 80/65
(65 represents the estimated hematocrit of a unit of PRBC)

In the child, coagulation deficiencies rapidly may assume clinical significance after extensive blood transfusion. It is advisable to have fresh frozen plasma and platelets available if more than 30 mL/kg have been transfused. Plasma is given in a dose of 10 to 20 mL/kg, and platelets are given in a dose of 1 unit/5 kg. Each unit of platelets consists of 40 to 60 mL of fluid (plasma plus platelets). Following transfusion of PRBCs to neonates with tenuous fluid balance, a single dose of a diuretic (such as furosemide 1 mg/kg) may help to facilitate excretion of the extra fluid load. Many clinicians prefer to administer fresh products to minimize the deleterious effects of red cell storage.

Enteral and Parenteral Nutrition

The nutritional requirements of the surgical neonate must be met in order for the child to grow and to heal surgical wounds. If inadequate protein and carbohydrate calories are given, the child may not only fail to recover from surgery, but may also exhibit growth failure and impaired development of the central nervous system. In general terms, the adequacy of growth must be assessed frequently, by determining both total body weight and head circumference. Neonates who are particularly predisposed to protein-calorie malnutrition include those with gastroschisis, intestinal atresia, or intestinal insufficiency from other causes, such as necrotizing enterocolitis. The protein and caloric requirements for the surgical neonate are shown in Table 39-1.

Table 39-1
Nutritional requirements for the pediatric surgical patient

AGE	CALORIES (kcal/kg/d)	PROTEIN (g/kg/d)
0–6 months	100–120	2
6 months–1 year	100	1.5
1–3 years	100	1.2
4–6 years	90	1
7–10 years	70	1
11–14 years	55	1
15–18 years	45	1

Nutrition can be provided via either the enteral or parenteral route. Whenever possible, the enteral route is preferred because it not only promotes the growth and function of the gastrointestinal system, but also ensures that the infant learns how to feed. There are various enteral feeding preparations available; these are outlined in Table 39-2. The choice of formula is based on the individual clinical state of the child. Pediatric surgeons are often faced with situations where oral feeding is not possible. This problem can be seen in the extremely premature infant who has not yet developed feeding skills or in the infant with concomitant craniofacial anomalies that impair sucking, for example. In these instances, enteral feeds can be administered either via a nasojejunal or a gastrostomy tube.

When the gastrointestinal tract cannot be used because of mechanical, ischemic, inflammatory, or functional disorders,

parenteral alimentation must be given. Prolonged parenteral nutrition is delivered via a central venous catheter. Peripheral IV alimentation can be given, using less concentrated but greater volumes of solutions. Long-term parenteral nutrition should include supplemental copper, zinc, and iron to prevent the development of trace metal deficiencies. A major complication of long-term total parenteral nutrition (TPN) is the development of parenteral nutrition-associated cholestasis, which can eventually progress to liver failure. To prevent this major complication, concomitant enteral feedings should be instituted and the gastrointestinal tract should be used as soon as possible. When proximal stomas are in place, gastrointestinal continuity should be restored as soon as possible. Where intestinal insufficiency is associated with dilation of the small intestine, tapering or intestinal lengthening procedures may be beneficial. Other strategies to minimize the development of TPN-related liver disease include meticulous catheter care to avoid infection, which increases cholestatic symptoms, aggressive treatment of any infection, and early cycling of parenteral nutrition in older children who can tolerate not receiving continuous dextrose solution for a limited period. Preliminary evidence suggests the possibility that substituting omega-3 fish oil lipid emulsion in parenteral nutrition for the standard soybean-based emulsions may prevent the development of TPN-related cholestasis and reverse the effects of established liver disease.

Venous Access

Obtaining reliable vascular access in an infant or child is an important task that often becomes the responsibility of the pediatric surgeon. The goal should always be to place the catheter in the least invasive, least risky, and least painful manner, and in a location that is most accessible and allows for use of the catheter without complications for as long as it is needed. In infants, central venous access may be established using a cutdown approach, either in the antecubital fossa, external jugular vein, facial vein, or proximal saphenous vein. If the internal jugular vein is used, care is taken to prevent venous occlusion. In infants over 3 kg and in older children, percutaneous access of the subclavian, internal jugular, or femoral veins is possible in most cases, and central access is achieved using the Seldinger technique. The catheters are tunneled to an exit site separate from the venotomy site. Where available, peripherally inserted central catheter (PICC) lines may be placed, typically via the antecubital fossa. Regardless of whether the catheter is placed by a cutdown approach or percutaneously, a chest x-ray to confirm central location of the catheter tip and to exclude the presence of a pneumothorax or hemothorax is mandatory. When discussing the placement of central venous catheters with parents, it is important to note that the complication rate for central venous lines in children can be high. The incidence of catheter-related sepsis or infection approaches 10% in many series, although recent reports show a lower incidence. Superior or inferior vena caval occlusion is a significant risk after the placement of multiple lines, particularly in the smallest premature patients.

Thermoregulation

Careful regulation of the ambient environment of infants and children is crucial, as these patients are extremely thermolabile. Premature infants are particularly susceptible to changes in environmental temperature. Because they are unable to shiver and lack stores of fat, their potential for thermogenesis is impaired. The innate inability to regulate temperature is compounded by the administration of anesthetic and paralyzing agents. Since these patients lack adaptive mechanisms to cope with the environment, the environmental temperature must be regulated. Attention to heat conservation during transport of the infant to and from the operating room is essential. Transport systems incorporating heating units are necessary for premature infants. In the operating room, the infant is kept warm by the use of overhead heating lamps, a heating blanket, warming the room as well as inspired gases, and coverage of the extremities and head with occlusive materials. During abdominal surgery, extreme care is taken to avoid wet and cold drapes. All fluids used to irrigate the chest or abdomen must be warmed to body temperature. Laparoscopic approaches for abdominal operations may result in more stable thermoregulation due to decreased heat loss from the smaller wound size. Constant monitoring of the child's temperature is critical in a lengthy procedure, and the surgeon should continuously communicate with the anesthesiologist regarding the temperature of the patient. The development of hypothermia in infants and children can result in cardiac arrhythmias or coagulopathy. These potentially life-threatening complications can be avoided by careful attention to thermoregulation.

Pain Control

All children, including neonates, experience pain. Therefore, careful recognition and management of pediatric pain represents an important component of the perioperative management of all pediatric surgical patients. There is a range of pain management options that can improve the child's well-being, as well as the parents' sense of comfort. The use of a pacifier, which may be dipped in sucrose, has been shown to decrease crying time and neonatal pain scores after minor procedures. For situations where more pain is expected, IV narcotic agents should be used. Morphine and fentanyl have an acceptable safety margin and can be administered judiciously to neonates and children. A randomized clinical trial involving neonates on ventilators showed that the use of a morphine infusion decreased the incidence of intraventricular hemorrhage by 50%. Additional analgesic modalities include the use of topical anesthetic ointment (EMLA cream), regional anesthesia such as caudal blocks for hernias, and epidural or incisional catheter infusions (On-Q™) for large abdominal or thoracic incisions. In surgical neonates who have received large concentrations of narcotics over a prolonged period, transient physical dependence should not only be expected, but anticipated. When narcotics are discontinued, symptoms of narcotic withdrawal may develop, including irritability, restlessness, and episodes of hypertension and tachycardia. Early recognition of these signs is essential, as is timely treatment using naloxone and other agents. In the postoperative period, patient-controlled analgesia is another excellent method of pain control. By ensuring that the pediatric surgical patient has adequate analgesia, the surgeon ensures that the patient receives the most humane and thorough treatment and provides important reassurance to all other members of the healthcare team and to the family that pain control is a very high priority.

NECK MASSES

The management of neck masses in children is determined by their location and the length of time that they have been present. Neck lesions are found either in the midline or lateral compartments. Midline masses include thyroglossal duct remnants, thyroid masses, thymic cysts, or dermoid cysts. Lateral lesions

include branchial cleft remnants, cystic hygromas, vascular malformations, salivary gland tumors, torticollis, and lipoblastoma (a rare benign mesenchymal tumor of embryonal fat occurring in infants and young children). Enlarged lymph nodes and rare malignancies such as rhabdomyosarcoma can occur either in the midline or laterally.

Lymphadenopathy

The most common cause of a neck mass in a child is an enlarged lymph node, which typically can be found laterally or in the midline. The patient is usually referred to the pediatric surgeon for evaluation after the mass has been present for several weeks. A detailed history and physical examination often helps determine the likely etiology of the lymph node and the need for excisional biopsy. Enlarged tender lymph nodes are usually the result of a bacterial infection (*Staphylococcus* or *Streptococcus*). Treatment of the primary cause (e.g., otitis media or pharyngitis) with antibiotics often is all that is necessary. However, when the involved nodes become fluctuant, incision and drainage are indicated. In many North American institutions, there has been an increasing prevalence of methicillin-resistant *Staphylococcus aureus* infection of the skin and soft tissues, leading to increased staphylococcal lymphadenitis in children. More chronic forms of lymphadenitis, including infections with atypical mycobacteria, as well as cat-scratch fever, are diagnosed based on serologic findings or excisional biopsy. The lymphadenopathy associated with infectious mononucleosis can be diagnosed based on serology. When the neck nodes are firm, fixed, and others are also present in the axillae or groin, or the history suggests lymphoma, excisional biopsy is indicated. In these cases, it is essential to obtain a chest radiograph to look for the presence of a mediastinal mass. Significant mediastinal load portends cardiorespiratory collapse due to loss of venous return and compression of the tracheobronchial tree with general anesthesia. Accordingly, such biopsies should be done under local anesthesia.

Thyroglossal Duct Remnants

Pathology and Clinical Manifestations. The thyroid gland buds off the foregut diverticulum at the base of the tongue in the region of the future foramen cecum at 3 weeks of embryonic life. As the fetal neck develops, the thyroid tissue becomes more anterior and caudad until it rests in its normal position. The "descent" of the thyroid is intimately connected with the development of the hyoid bone. Residual thyroid tissue left behind during the migration may persist and subsequently present in the midline of the neck as a thyroglossal duct cyst. The mass is most commonly appreciated in the 2- to 4-year-old child when the baby fat disappears and irregularities in the neck become more readily apparent. Usually the cyst is encountered in the midline at or below the level of the hyoid bone, and moves up and down with swallowing or with protrusion of the tongue. Occasionally it presents as an intrathyroidal mass. Most thyroglossal duct cysts are asymptomatic. If the duct retains its connection with the pharynx, infection may occur, and the resulting abscess will necessitate incision and drainage, occasionally resulting in a salivary fistula. Submental lymphadenopathy and midline dermoid cysts can be confused with a thyroglossal duct cyst. Rarely, midline ectopic thyroid tissue masquerades as a thyroglossal duct cyst and may represent the patient's only thyroid tissue. Therefore, if there is any question regarding the diagnosis or if the thyroid gland cannot be palpated in its normal anatomic position, it is advisable to obtain a nuclear scan to confirm the presence of a normal thyroid gland. Although rarely the case in children, in adults the thyroglossal duct may contain thyroid tissue that can undergo malignant degeneration. The presence of malignancy in a thyroglossal cyst should be suspected when the cyst grows rapidly or when the ultrasound demonstrates a complex anechoic pattern or the presence of calcification.

Treatment. If the cyst presents with an abscess, treatment should first consist of drainage and antibiotics. Following resolution of the inflammation, resection of the cyst in continuity with the central portion of the hyoid bone and the tract connecting to the pharynx in addition to ligation at the foramen cecum (the Sistrunk operation) is curative in over 90% of patients. Lesser operations result in unacceptably high recurrence rates, and recurrence is more frequent following infection. According to a recent review, factors predictive of recurrence included more than two infections prior to surgery, age under 2 years, and inadequate initial operation.

Branchial Cleft Anomalies

Paired branchial clefts and arches develop early in the fourth gestational week. The first cleft and the first, second, third, and fourth pouches give rise to adult organs. The embryologic communication between the pharynx and the external surface may persist as a fistula. A fistula is seen most commonly with the second branchial cleft, which normally disappears, and extends from the anterior border of the sternocleidomastoid muscle superiorly, inward through the bifurcation of the carotid artery, and enters the posterolateral pharynx just below the tonsillar fossa. In contrast, a third branchial cleft fistula passes posterior to the carotid bifurcation. The branchial cleft remnants may contain small pieces of cartilage and cysts, but internal fistulas are rare. A second branchial cleft sinus is suspected when clear fluid is noted draining from the external opening of the tract at the anterior border of the lower third of the sternomastoid muscle. Rarely, branchial cleft anomalies occur in association with biliary atresia and congenital cardiac anomalies, an association that is referred to as Goldenhar's complex.

Treatment. Complete excision of the cyst and sinus tract is necessary for cure. Dissection of the sinus tract is facilitated with passage of a fine lacrimal duct probe through the external opening into the tract and using it as a guide for dissection. Injection of a small amount of methylene blue dye into the tract also may be useful. A series of two or sometimes three small transverse incisions in a "stepladder" fashion is preferred to a long oblique incision in the neck, which is cosmetically undesirable. Branchial cleft cysts can present as abscesses. In these cases, initial treatment includes incision and drainage with a course of antibiotics to cover *Staphylococcus* and *Streptococcus* species, followed by excision of the cyst after the infection resolves.

Lymphatic Malformation

Etiology and Pathology. Lymphatic malformation (previously known as cystic hygroma or lymphangioma) occurs as a result of sequestration or obstruction of developing lymph vessels in approximately 1 in 12,000 births. Although the lesion can occur anywhere, the most common sites are in the posterior triangle of the neck, axilla, groin, and mediastinum. The cysts are lined by endothelium and filled with lymph. Occasionally unilocular cysts occur, but more often, there are multiple cysts "infiltrating" the surrounding structures and

A B

Figure 39-1. **A.** Left cervical lymphatic malformation in a 2-day-old baby. **B.** Intraoperative photograph showing a vessel loop around the spinal accessory nerve.

distorting the local anatomy. A particularly troublesome variant of lymphatic malformation is one that involves the tongue, floor of the mouth, and structures deep in the neck. Adjacent connective tissue may show extensive lymphocytic infiltration. The mass may be apparent at birth or may appear and enlarge rapidly in the early weeks or months of life as lymph accumulates; most present by age 2 years (Fig. 39-1A). Extension of the lesion into the axilla or mediastinum occurs about 10% of the time and can be demonstrated preoperatively by chest x-ray, ultrasound (US), or computed tomography (CT) scan. Occasionally lymphatic malformations contain nests of vascular tissue. These poorly supported vessels may bleed and produce rapid enlargement and discoloration of the mass. Infection within the cysts, usually caused by *Streptococcus* or *Staphylococcus,* may occur. In the neck, this can cause rapid enlargement, which may result in airway compromise. Rarely, it may be necessary to carry out percutaneous aspiration of a cyst to relieve respiratory distress.

The diagnosis of lymphatic malformation by prenatal US, before 30 weeks' gestation, has detected a "hidden mortality" as well as a high incidence of associated anomalies, including abnormal karyotypes and hydrops fetalis. Occasionally, very large lesions can cause obstruction of the fetal airway. Such obstruction can result in the development of polyhydramnios by impairing the ability of the fetus to swallow amniotic fluid. In these circumstances, the airway is usually markedly distorted, which can result in immediate airway obstruction unless the airway is secured at the time of delivery. Orotracheal intubation or emergency tracheostomy while the infant remains attached to the placenta, the so-called EXIT procedure (ex utero intrapartum treatment), may be necessary to secure the airway.

Treatment. The modern management of most lymphatic malformations includes the combination of surgical excision and image-guided sclerotherapy. The initial treatment typically involves surgery in an attempt to safely remove all gross disease without damaging vital structures. Total removal of all gross disease may not be possible because of the extent of the lymphatic malformation and its proximity to, and intimate relationship with, adjacent nerves, muscles, and blood vessels (Fig. 39-1B). Radical ablative surgery is not indicated for this lesion. A combined sclerotherapy/resectional approach is particularly useful for large lymphatic malformations and those that extend to the base of the tongue or the floor of the mouth. Conservative excision and unroofing of the cysts is advised along with sclerotherapy or repeated partial excision for any residual lymphatic malformation if necessary, preserving all adjacent crucial structures. Postoperative wound drainage is important and is best accomplished by closed-suction technique. Nevertheless, fluid may accumulate beneath the surgically created flaps, requiring multiple needle aspirations.

Torticollis

The presence of a lateral neck mass in infancy in association with rotation of the head toward the opposite side of the mass indicates the presence of congenital torticollis. This lesion results from fibrosis of the sternocleidomastoid muscle. The mass may be palpated in the affected muscle in approximately two thirds of cases. Histologically, the lesion is characterized by the deposition of collagen and fibroblasts around atrophied muscle cells. In the vast majority of cases, physical therapy based on passive stretching of the affected muscle is of benefit. Rarely, surgical transection of the sternocleidomastoid may be indicated.

RESPIRATORY SYSTEM

Congenital Diaphragmatic Hernia (Bochdalek)

Pathology. The septum transversum extends to divide the pleural and coelomic cavities during fetal development. This precursor of the diaphragm normally completes separation of these two cavities at the posterolateral aspects of this mesenchymally derived structure. The most common variant of a congenital diaphragmatic hernia is a posterolateral defect, also known as a Bochdalek hernia. Diaphragmatic defects allow abdominal viscera to fill the chest cavity. The abdominal cavity is small and underdeveloped and remains scaphoid after birth. Both lungs are hypoplastic, with decreased bronchial and pulmonary artery branching. Lung weight, lung volume, and DNA content are also decreased, and these findings are more striking

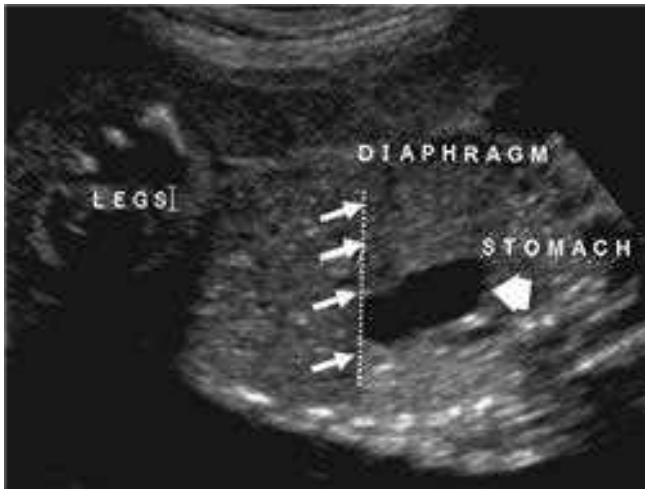

Figure 39-2. Prenatal ultrasound of a fetus with a congenital diaphragmatic hernia. *Arrows* point to the location of the diaphragm. *Arrow head* points to the stomach, which is in the thoracic cavity.

on the ipsilateral side. This anomaly is encountered more commonly on the left (80%–90%). Linkage analyses have recently implicated genetic mutations in syndromic variants of congenital diaphragmatic hernias. In many instances, there is a surfactant deficiency, which compounds the degree of respiratory insufficiency. Amniocentesis with karyotype may identify chromosomal defects, especially trisomy 18 and 21. Associated anomalies, once thought to be uncommon, were identified in 65 of 166 patients in one study, predominantly of the heart, followed by abdominal wall defects, chromosomal changes, and other defects. Prenatal ultrasonography is successful in making the diagnosis of congenital diaphragmatic hernia (CDH) as early as 15 weeks' gestation, and early antenatal diagnosis is associated with worse outcomes. US findings include herniated abdominal viscera in the chest, which may also look like a mass or lung anomaly, changes in liver position, and mediastinal shift away from the herniated viscera (Fig. 39-2). Accurate prenatal prediction of outcome for fetuses who have CDH is very difficult. One index of severity for patients with left CDH is the lung-to-head ratio (LHR), which is the product of the length and the width of the right lung at the level of the cardiac atria divided by the head circumference (all measurements in millimeters). An LHR value of less than 1.0 is associated with a very poor prognosis, whereas an LHR greater than 1.4 predicts a more favorable outcome. The utility of the LHR in predicting outcome in patients with CDH has recently been questioned, due to the tremendous interobserver variability in calculating this ratio for a particular patient, as well as the lack of reliable measures to determine postnatal disease severity.

1▶

Following delivery, the diagnosis of CDH is made by chest x-ray (Fig. 39-3). The differential diagnosis includes bronchopulmonary foregut malformations, in which the intrathoracic loops of bowel may be confused for lung or foregut pathology. The vast majority of infants with CDH develop immediate respiratory distress, which is due to the combined effects of three factors. First, the air-filled bowel in the chest compresses the mobile mediastinum, which shifts to the opposite side of the chest, compromising air exchange in the contralateral lung. Second, pulmonary hypertension develops. This phenomenon results in persistent fetal circulation, with resultant decreased pulmonary perfusion and impaired gas exchange. Finally, the

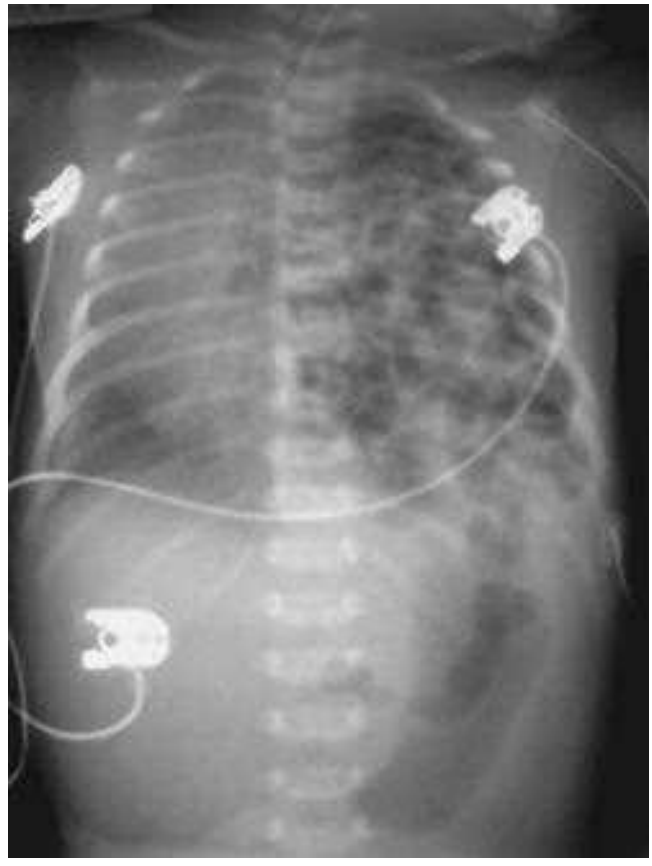

Figure 39-3. Chest x-ray showing a left congenital diaphragmatic hernia.

lung on the affected side is often hypoplastic, such that it is essentially nonfunctional. Varying degrees of pulmonary hypoplasia on the opposite side may compound these effects. The second and third factors are thought to be the most important. Neonates with CDH are usually in respiratory distress requiring ventilation and intensive care, and the overall mortality in most series is around 50%.

Treatment. CDH care has improved considerably through effective use of improved methods of ventilation and timely cannulation for extracorporeal membrane oxygenation (ECMO). Many infants are symptomatic at birth due to hypoxia, hypercarbia, and metabolic acidosis. Prompt cardiorespiratory stabilization is mandatory. It is noteworthy that in some infants, the first 24 to 48 hours after birth are often characterized by a period of relative stability with high levels of PaO_2 and relatively good perfusion. This has been termed the "honeymoon period" and is often followed by progressive cardiorespiratory deterioration. In the past, correction of the hernia was believed to be a surgical emergency, and patients underwent surgery shortly after birth. It is now accepted that the presence of persistent pulmonary hypertension that results in right-to-left shunting across the patent foramen ovale or the ductus arteriosus and the degree of pulmonary hypoplasia are the leading causes of cardiorespiratory insufficiency. Current management therefore is directed toward managing the pulmonary hypertension and minimizing barotrauma while optimizing oxygen delivery. To achieve this goal, infants are placed on mechanical ventilation using relatively low or "gentle" settings that prevent overinflation of the noninvolved lung. Levels of $PaCO_2$ in the range

of 50 to 60 mmHg or higher are accepted as long as the pH remains ≥ 7.25. If these objectives cannot be achieved using conventional ventilation, high-frequency oscillatory ventilation (HFOV) may be used to avoid the injurious effects of conventional tidal volume ventilation. Echocardiography will assess the degree of pulmonary hypertension and identify the presence of any coexisting cardiac anomaly. Intensive care unit goals include minimal sedation, meticulous attention to endotracheal tube secretions, and gradual changes to ventilator settings to avoid inducing pulmonary hypertension via hypoxia. To minimize the degree of pulmonary hypertension, inhaled nitric oxide may be administered and, in some patients, improves pulmonary perfusion. Nitric oxide is administered into the ventilation circuit and is used in concentrations up to 40 parts per million. Correction of acidosis using bicarbonate solution may minimize the degree of pulmonary hypertension. As the degree of pulmonary hypertension becomes hemodynamically significant, right-sided heart failure develops and systemic perfusion is impaired. Administration of excess IV fluid will compound the degree of cardiac failure and lead to marked peripheral edema. Inotropic support using epinephrine, dopamine, and milrinone alone or in combination may be useful in optimizing cardiac contractility and maintaining mean arterial pressure.

Infants with CDH who remain severely hypoxic despite maximal ventilatory care may be candidates for treatment of their respiratory failure by ECMO, with access via venovenous (VV) or venoarterial (VA) routes. VV bypass is established with a single cannula through the right internal jugular vein, with blood removed from and infused into the right atrium by separate ports. VA bypass provides additional cardiac support, whereas VV bypass requires a well-functioning heart and relies on the lungs for some oxygenation as well. In VA ECMO, the right atrium is cannulated by means of the internal jugular vein and the aortic arch through the right common carotid artery. As much of the cardiac output is directed through the membrane oxygenator as is necessary to provide oxygenated blood to the infant and remove carbon dioxide. The infant is maintained on bypass until the pulmonary hypertension is resolved and lung function, as measured by compliance and the ability to oxygenate and ventilate, is improved. This is usually seen within 7 to 10 days, but in some infants, it may take up to several weeks to occur. Complications associated with ECMO increase after 14 days and include cannula malposition, bleeding in multiple locations, and infection. The use of ECMO is associated with significant risk. Because patients require systemic anticoagulation, bleeding complications are the most significant. They may occur intracranially or at the site of cannula insertion and can be life threatening. Systemic sepsis is a significant problem and may necessitate decannulation. Criteria for placing infants on ECMO include the presence of normal cardiac anatomy by echocardiography, the absence of fatal chromosome anomalies, and the expectation that the infant would die without ECMO. Traditionally, a threshold of weight greater than 2 kg and gestational age greater than 34 weeks has been applied, although success has been achieved at weights as low as 1.8 kg. Upon decannulation, some centers repair the carotid artery. In instances in which the child is cannulated for a brief period (5 days or less) this may be feasible. A recent study failed to show any benefit from repairing the carotid artery, although this finding remains to be studied further.

A strategy that does not involve the use of ECMO, but instead emphasizes the use of permissive hypercapnia and the avoidance of barotrauma, may provide equal overall outcome in patients with CDH. This likely reflects the fact that mortality is related to the degree of pulmonary hypoplasia and the presence of congenital anomalies, neither of which are correctable by ECMO.

The timing of diaphragmatic hernia repair is still approached by various routes in major centers, particularly when the infant is on ECMO. In patients who are not on ECMO, repair should be performed once the hemodynamic status has been optimized. In neonates who are on ECMO, some surgeons perform early repair on bypass; others wait until the infant's lungs are improved and the pulmonary hypertension has subsided, repair the diaphragm, and discontinue bypass within hours of surgery. Still others repair the diaphragm only after the infant is off bypass. Operative repair of the diaphragmatic hernia may be accomplished by either an abdominal or transthoracic approach and can be performed either via open or minimally invasive techniques. Through a subcostal incision, the abdominal viscera are withdrawn from the chest, exposing the defect in the diaphragm. Care must be taken when reducing the spleen and liver, as bleeding from these structures can be fatal. The anterior margin is often apparent, while the posterior muscular rim is attenuated. If the infant is heparinized on bypass, minimal dissection of the muscular margins is performed. Electrocautery is used liberally to minimize postoperative bleeding. Most infants who require ECMO support prior to hernia repair have large defects, often lacking the medial and posterior margins. About three fourths of infants repaired on bypass require prosthetic material to patch the defect, suturing it to the diaphragmatic remnant or around ribs or costal cartilages for the large defects. If there is adequate muscle for closure, a single layer of nonabsorbable horizontal mattress sutures, pledgeted or not, closes the defect. Just before the repair is complete, a chest tube may be positioned in the thoracic cavity but is not mandatory. Patients repaired on ECMO are at risk for developing a hemothorax, which can significantly impair ventilation. Anatomic closure of the abdominal wall may be impossible after reduction of the viscera. Occasionally a prosthetic patch or acellular material may be sutured to the fascia to facilitate closure. The patch can be removed at a later time, and the ventral hernia can be closed at that time or subsequently. In patients who are deemed to be candidates for a minimally invasive approach (stable patients, >2 kg, no pulmonary hypertension), a thoracoscopic repair may be safely performed, although concerns have been raised about possible effects of the longer operative time for thoracoscopic repair and higher recurrence rates. If the diaphragm has been repaired on ECMO, weaning and decannulation are accomplished as soon as possible. All infants are ventilated postoperatively to maintain preductal arterial oxygenation of 80 to 100 Torr. Very slow weaning from the ventilator is necessary to avoid recurrent pulmonary hypertension.

Congenital Lobar Emphysema

Congenital lobar emphysema (CLE) is a condition manifested during the first few months of life as a progressive hyperexpansion of one or more lobes of the lung. It can be life-threatening in the newborn period if extensive lung tissue is involved, but in the older infant and in cases in which the lesion is less severely distended, it causes less respiratory distress. Air entering during inspiration is trapped in the lobe; on expiration, the lobe cannot deflate and progressively overexpands, causing atelectasis of the adjacent lobe or lobes. This hyperexpansion eventually

Figure 39-4. Congenital lobar emphysema of the left upper lobe in a 2-week-old boy. Mediastinal shift is present.

shifts the mediastinum to the opposite side and compromises the other lung. CLE usually occurs in the upper lobes of the lung (left greater than right), followed next in frequency by the right middle lobe, but it also can occur in the lower lobes. It is caused by intrinsic bronchial obstruction from poor bronchial cartilage development or extrinsic compression. Approximately 14% of children with this condition have cardiac defects, with an enlarged left atrium or a major vessel causing compression of the ipsilateral bronchus.

Symptoms range from mild respiratory distress to full-fledged respiratory failure with tachypnea, dyspnea, cough, and late cyanosis. These symptoms may be stationary, or they may progress rapidly or result in recurrent pneumonia. Occasionally, infants with CLE present with failure to thrive, which likely reflects the increased work associated with the overexpanded lung. A hyperexpanded hemithorax on the ipsilateral side is pathognomonic for CLE. Diagnosis is typically confirmed by chest x-ray, which shows a hyperlucent affected lobe with adjacent lobar compression and atelectasis. The mediastinum may be shifted as a consequence of mass effect to the contralateral side causing compression and atelectasis of the contralateral lung (Fig. 39-4). Although chest radiograph is usually sufficient, it is sometimes important to obtain a CT scan of the chest to clearly establish the diagnosis of CLE. This should be done only in the stable patient. Unless foreign body or mucus plugging is suspected as a cause of hyperinflation, bronchoscopy is not advisable because it can lead to more air trapping and cause life-threatening respiratory distress in a stable infant. Treatment is resection of the affected lobe, which can be safely performed using either an open or thoracoscopic approach. Unless symptoms necessitate earlier surgery, resection can usually be performed after the infant is several months of age. The prognosis is excellent.

Bronchopulmonary Foregut Malformations

Bronchopulmonary foregut malformations include foregut duplication cysts, congenital pulmonary airway malformations, and pulmonary sequestrations as discussed below.

Figure 39-5. Computed tomography scan of the chest showing a congenital pulmonary airway malformation involving the left lower lobe.

Congenital Pulmonary Airway Malformations. Previously denoted as congenital cystic adenomatoid malformation (CCAM), congenital pulmonary airway malformation (CPAM) exhibits cystic proliferation of the terminal airway, producing cysts lined by mucus-producing respiratory epithelium, and elastic tissue in the cyst walls without cartilage formation. There may be a single cyst with a wall of connective tissue containing smooth muscle. Cysts may be large and multiple (type I), smaller and more numerous (type II), or resemble fetal lung without macroscopic cysts (type III). CPAMs frequently occur in the left lower lobe. However, this lesion can occur in any location and may occur in more than one lobe on more than one side, although this is rare. Clinical symptoms range from none to severe respiratory failure at birth. Over time, these malformations can be subject to repeated infections and produce fever and cough in older infants and children. The diagnosis is usually confirmed by CT for surgical planning and characteristic features that might delineate other bronchopulmonary foregut malformations (Fig. 39-5). Prenatal US may suggest the diagnosis. Resection is curative and may need to be performed urgently in the infant with severe respiratory distress. Long term, there is a risk of malignant degeneration in unresected CPAMs, but this risk occurs over decades and has not been fully defined. As a result, resection of the affected lobe is usually performed (Fig. 39-6).

Figure 39-6. Intraoperative photograph showing left lower lobe congenital pulmonary airway malformation seen in Fig. 39-5.

Pulmonary Sequestration. Pulmonary sequestration is uncommon and consists of a mass of lung tissue, usually in the left lower chest, occurring without the usual connections to the pulmonary artery or tracheobronchial tree, yet with a systemic blood supply from the aorta. There are two kinds of sequestration. Extralobar sequestration is usually a small area of nonaerated lung separated from the main lung mass, with a systemic blood supply, located immediately above the left diaphragm. It is commonly found in cases of CDH. Intralobar sequestration more commonly occurs within the parenchyma of the left lower lobe but can occur on the right. There is no major connection to the tracheobronchial tree, but a secondary connection may be established, perhaps through infection or via adjacent intrapulmonary shunts. The blood supply frequently originates from the aorta below the diaphragm; multiple vessels may be present (Fig. 39-7). Venous drainage of both types can be systemic or pulmonary. The cause of sequestration is unknown but most probably involves an abnormal budding of the developing lung that picks up a systemic blood supply and never becomes connected with the bronchus or pulmonary vessels. Sequestrations may, in some cases, exhibit mixed pathology with components consistent with CPAMs. Extralobar sequestration is asymptomatic and is usually discovered incidentally on chest x-ray. If the diagnosis can be confirmed (e.g., by CT scan), resection is not necessary. Diagnosis of intralobar sequestration may be made prenatally and confirmed on postnatal CT scan. Alternatively, the diagnosis of intralobar sequestration may be established after repeated infections manifested by cough, fever, and consolidation in the posterior basal segment of the left lower lobe. Increasingly the diagnosis is being made in the early months of life by US, and color Doppler often can be helpful in delineating the systemic arterial supply. Removal of the entire left lower lobe is usually necessary since the diagnosis often is made late after multiple infections. Occasionally segmental resection of the sequestered part of the lung can be performed using an open or, ideally, a thoracoscopic approach. If an open approach is used, it is important to open the chest through a low intercostal space (sixth or seventh) to gain access to the vascular attachments to the aorta. These attachments may insert into the aorta below the diaphragm; in these cases division of the vessels as they traverse the thoracic cavity is essential. Prognosis is generally excellent. However, failure to obtain adequate control of these vessels may result in their retraction into the abdomen and result in uncontrollable hemorrhage. It is also possible to perform a combined thoracoscopic and open approach, wherein the vessels are clipped and divided thoracoscopically and then the lesion is safely removed through a limited thoracotomy.

Figure 39-7. Arteriogram showing large systemic artery supply to intralobar sequestration of the left lower lobe.

Bronchogenic Cyst. Bronchogenic cysts are duplication cysts originating from the airway, regardless of the identity of the epithelial lining. They can occur anywhere along the respiratory tract and can present at any age, although typically they present after accumulation of intraluminal contents, and not within the newborn period. Histologically, they are hamartomatous and usually consist of a single cyst lined with an epithelium; the mesenchyme contains cartilage and smooth muscle. They are probably embryonic rests of foregut origin that have been pinched off from the main portion of the developing tracheobronchial tree and are closely associated in causation with other foregut duplication cysts such as those arising from the esophagus. Bronchogenic cysts may be seen on prenatal US but are discovered most often incidentally on postnatal chest x-ray. Although they may be completely asymptomatic, bronchogenic cysts may produce symptoms, usually compressive in nature, depending on the anatomic location and size, which increase over time if there is no egress of accumulating luminal contents. In the paratracheal region of the neck, they can produce airway compression and respiratory distress. In the lung parenchyma, they may become infected and present with fever and cough. In addition they may cause obstruction of the bronchial lumen with distal atelectasis and infection, or they may cause mediastinal compression. Rarely, rupture of the cyst can occur. Chest x-ray usually shows a dense mass, and CT scan or magnetic resonance imaging (MRI) delineates the precise anatomic location of the lesion. Treatment consists of resection of the cyst, which may need to be undertaken in emergency circumstances for airway or cardiac compression. Resection can be performed either as an open procedure or, more commonly, using a thoracoscopic approach. If resection of a common wall will result in injury to the airway, resection of the inner epithelial cyst lining after marsupialization is acceptable.

Bronchiectasis

Bronchiectasis is an abnormal and irreversible dilatation of the bronchi and bronchioles associated with chronic suppurative disease of the airways. Usually patients have an underlying congenital pulmonary anomaly, cystic fibrosis, or immunologic deficiency. Bronchiectasis can also result from chronic infection secondary to a neglected bronchial foreign body. The symptoms include a chronic cough, often productive of purulent secretions, recurrent pulmonary infection, and hemoptysis. The diagnosis is suggested by a chest x-ray that shows increased bronchovascular markings in the affected lobe. Chest CT delineates bronchiectasis with excellent resolution. The preferred treatment for bronchiectasis is medical, consisting of antibiotics, postural drainage, and bronchodilator therapy, since many children with the disease show signs of airflow obstruction and bronchial hyperresponsiveness. Lobectomy or segmental resection is indicated for localized disease that has not responded appropriately to medical therapy. In severe cases, lung transplantation may be required to replace the terminally damaged, septic lung.

Foreign Bodies

The inherent curiosity of children and their innate propensity to place new objects into their mouths to fully explore them place them at great risk for aspiration. Aspirated objects can be found either in the airway or in the esophagus; in both cases, the results can be life-threatening.

Airway Ingestion. Aspiration of foreign bodies most commonly occurs in the toddler age group. Peanuts are the most common object that is aspirated, although other materials (popcorn, for instance) may also be involved. A solid foreign body often will cause air trapping, with hyperlucency of the affected lobe or lung seen especially on expiration. Oil from the peanut is very irritating and may cause pneumonia. Delay in diagnosis can lead to atelectasis and infection. The most common anatomic location for a foreign body is the right main stem bronchus or the right lower lobe. The child usually will cough or choke while eating but may then become asymptomatic. Total respiratory obstruction with tracheal foreign body may occur; however, respiratory distress is usually mild if present at all. A unilateral wheeze is often heard on auscultation. This wheeze often leads to an inappropriate diagnosis of "asthma" and may delay the correct diagnosis for some time. Chest x-ray will show a radiopaque foreign body, but in the case of nuts, seeds, or plastic toy parts, the only clue may be hyperexpansion of the affected lobe on an expiratory film or fluoroscopy. Bronchoscopy confirms the diagnosis and allows removal of the foreign body. It can be a very simple procedure, or it may be extremely difficult, especially with a smooth foreign body that cannot be grasped easily or one that has been retained for some time. The rigid bronchoscope should be used in all cases, and utilization of the optical forceps facilitates grasping the inhaled object. Epinephrine may be injected into the mucosa when the object has been present for a long period of time, which minimizes bleeding. Bronchiectasis may be seen as an extremely late phenomenon after repeated infections of the poorly aerated lung and may require partial or total resection of the affected lobe. The differential diagnosis of a bronchial foreign body includes an intraluminal tumor (i.e., carcinoid, hemangioma, or neurofibroma).

Foreign Bodies and Esophageal Injury. The most common foreign body in the esophagus is a coin, followed by small toy parts. Toddlers are most commonly affected. The coin is retained in the esophagus at one of three locations: the cricopharyngeus, the area of the aortic arch, or the gastroesophageal junction—all areas of normal anatomic narrowing. Symptoms are variable depending on the anatomic position of the foreign body and the degree of obstruction. There is often a relatively asymptomatic period after ingestion. The initial symptoms are gastrointestinal and include dysphagia, drooling, and dehydration. The longer the foreign body remains in the esophagus with oral secretions unable to transit the esophagus, the greater the incidence of respiratory symptoms including cough, stridor, and wheezing. These findings may be interpreted as signs of upper respiratory infections. Objects that are present for a long period, particularly in children who have underlying neurologic impairment, may manifest as chronic dysphagia. The chest x-ray is diagnostic in the case of a coin. A contrast swallow, or preferably an esophagoscopy, may be required for nonradiopaque foreign bodies. Coins lodged within the upper esophagus for less than 24 hours may be removed using Magill forceps during direct laryngoscopy. For all other situations, the treatment is by esophagoscopy, rigid or flexible, and removal of the foreign body. In the case of sharp foreign bodies such as open safety pins, extreme care is required on extraction to avoid injury to the esophagus. Rarely, esophagotomy is required for removal, particularly of sharp objects. Diligent follow-up is required after removal of foreign bodies, especially batteries, which can cause strictures, and sharp objects, which can injure the underlying esophagus. In the case of a retained battery, this case should be handled as a surgical emergency, as the negative pole of the battery directly damages the surrounding tissue, and tracheoesophageal fistula, aortic exsanguination, and mediastinitis have all been described after local tissue necrosis at the site where the battery has lodged.

ESOPHAGUS

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia (EA) with tracheoesophageal fistula (TEF) is one of the most gratifying pediatric surgical conditions to treat. In the not-so-distant past, nearly all infants born with EA and TEF died. In 1939, Ladd and Leven performed the first successful repair by ligating the fistula, placing a gastrostomy, and reconstructing the esophagus at a later time. Subsequently, Dr. Cameron Haight in Ann Arbor, Michigan, performed the first successful primary anastomosis for EA, which remains the current approach for treatment of this condition. Despite the fact that there are several common varieties of this anomaly and the underlying cause remains obscure, a careful approach consisting of meticulous perioperative care and attention to the technical detail of the operation can result in an excellent prognosis in most cases.

Anatomic Varieties. The five major varieties of EA and TEF are shown in Fig. 39-8. The most commonly seen variety is EA

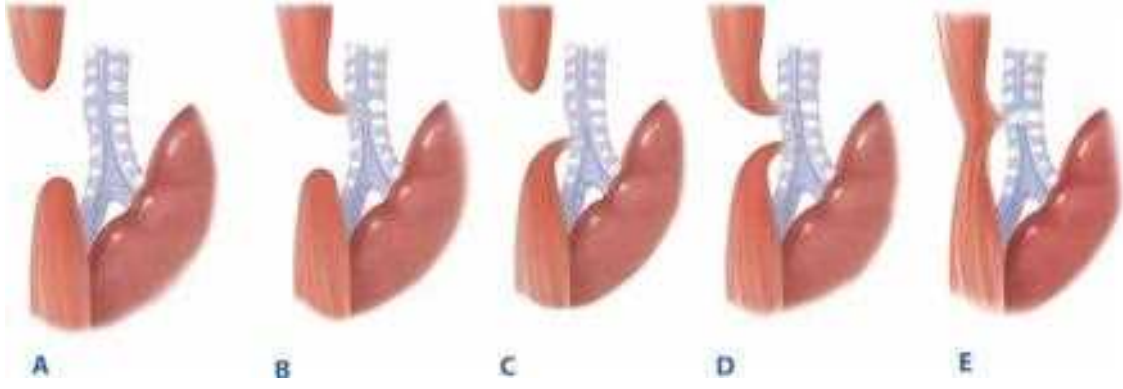

Figure 39-8. The five varieties of esophageal atresia and tracheoesophageal fistula. **A.** Isolated esophageal atresia. **B.** Esophageal atresia with tracheoesophageal fistula between proximal segment of esophagus and trachea. **C.** Esophageal atresia with tracheoesophageal fistula between distal esophagus and trachea. **D.** Esophageal atresia with fistula between both proximal and distal ends of esophagus and trachea. **E.** Tracheoesophageal fistula without esophageal atresia (H-type fistula).

Figure 39-9. Barium esophagram showing H-type tracheoesophageal fistula (*arrow*).

Figure 39-10. Type C esophageal atresia with tracheoesophageal fistula. Note the catheter that is coiled in the upper pouch and the presence of gas below the diaphragm, which confirms the presence of the tracheoesophageal fistula.

with distal TEF (type C), which occurs in approximately 85% of the cases in most series. The next most frequent type is pure EA (type A), occurring in 8% to 10% of patients, followed by TEF without EA (type E). This occurs in 8% of cases and is also referred to as an H-type fistula, based on the anatomic similarity to that letter (Fig. 39-9). EA with fistula between both proximal and distal ends of the esophagus and trachea (type D) is seen in approximately 2% of cases, and type B, EA with TEF between proximal esophagus and trachea, is seen in approximately 1% of all cases.

Etiology and Pathologic Presentation. The esophagus and trachea share a common embryologic origin. At approximately 4 weeks' gestation, a diverticulum forms off the anterior aspect of the proximal foregut in the region of the primitive pharynx. This diverticulum extends caudally with progressive formation of the laryngotracheal groove, thus creating a separate trachea and esophagus. Successful development of these structures is the consequence of extremely intricate interplay of growth and transcription factors necessary for rostral-caudal and anterior-posterior specification. The variations in clinically observed EA and TEF that must result in failure of successful formation of these structures are depicted in Fig. 39-8. Although definitive genetic mutations have been difficult to identify in isolated EA-TEF, mutations in *N-myc*, *Sox2*, and *CHD7* have been characterized in syndromic EA-TEF with associated anomalies.

Other congenital anomalies commonly occur in association with EA-TEF. For instance, VACTERRL syndrome is associated with *v*ertebral anomalies (absent vertebrae or hemivertebrae) and *a*norectal anomalies (imperforate anus), *c*ardiac defects, *t*racheo*e*sophageal fistula, *r*enal anomalies (renal agenesis, renal anomalies), and *r*adial *l*imb hyperplasia. In nearly 20% of the infants born with EA, some variant of congenital heart disease occurs.

Clinical Presentation of Infants with Esophageal Atresia and Tracheoesophageal Fistula.
The anatomic variant of infants with EA-TEF predicts the clinical presentation. When the esophagus ends either as a blind pouch or as a fistula into the trachea (as in types A, B, C, or D), infants present with excessive drooling, followed by chocking or coughing immediately after feeding is initiated as a result of aspiration through the fistula tract. As the neonate coughs and cries, air is transmitted through the fistula into the stomach, resulting in abdominal distention. As the abdomen distends, it becomes increasingly more difficult for the infant to breathe. This leads to further atelectasis and respiratory compromise. In patients with type C and D varieties, the regurgitated gastric juice passes through the fistula where it collects in the trachea and lungs and leads to a chemical pneumonitis, which further exacerbates the pulmonary difficulties. In many instances, the diagnosis is actually made by the nursing staff who attempt to feed the baby and notice the accumulation of oral secretions.

The diagnosis of EA is confirmed by the inability to pass an orogastric tube into the stomach (Fig. 39-10). The dilated upper pouch may be occasionally seen on a plain chest radiograph. If a soft feeding tube is used, the tube will coil in the upper pouch, which provides further diagnostic certainty. An important alternative diagnosis that must be considered when an orogastric tube does not enter the stomach is that of an esophageal perforation. This problem can occur in infants after traumatic insertion of a nasogastric or orogastric tube. In this instance, the perforation classically occurs at the level of the piriform sinus, and a false passage is created, which prevents the tube from entering the stomach. Whenever there is any diagnostic uncertainty, a contrast study will confirm the diagnosis of EA and occasionally document the TEF. The presence of a TEF can be demonstrated clinically by finding air in the gastrointestinal tract. This can be proven at the bedside by percussion of the abdomen and confirmed by obtaining a plain abdominal radiograph. Occasionally, a diagnosis of EA-TEF can be suspected prenatally on US evaluation. Typical features include failure to visualize the stomach and the presence of polyhydramnios. These findings reflect the absence of efficient swallowing by the fetus.

In a child with EA, it is important to identify whether coexisting anomalies are present. These include cardiac defects in 38%, skeletal defects in 19%, neurologic defects in 15%, renal defects in 15%, anorectal defects in 8%, and other abnormalities in 13%. Examination of the heart and great vessels with echocardiography is important to exclude cardiac defects, as these are often the most important predictors of survival in these infants. The echocardiogram also demonstrates whether the aortic arch is left sided or right sided, which may influence the approach to surgical repair. Vertebral anomalies are assessed by plain radiography, and a spinal US is obtained if any are detected. A patent anus should be confirmed clinically. The kidneys in

a newborn may be assessed clinically by palpation. An US of the abdomen will demonstrate the presence of renal anomalies, which should be suspected in the child who fails to make urine. The presence of extremity anomalies is suspected when there are missing digits and confirmed by plain radiographs of the hands, feet, forearms, and legs. Rib anomalies may also be present. These may include the presence of a thirteenth rib.

Initial Management. The initial treatment of infants with EA-TEF includes attention to the respiratory status, decompression of the upper pouch, and appropriate timing of surgery. Because the major determinant of poor survival is the presence of other severe anomalies, a search for other defects including congenital cardiac disease is undertaken in a timely fashion. The initial strategy after the diagnosis is confirmed is to place the neonate in an infant warmer with the head elevated at least 30°. A sump catheter is placed in the upper pouch on continuous suction. Both of these strategies are designed to minimize the degree of aspiration from the esophageal pouch. When saliva accumulates in the upper pouch and is aspirated into the lungs, coughing, bronchospasm, and desaturation episodes can occur, which may be minimized by ensuring the patency of the sump catheter. IV antibiotic therapy is initiated, and warmed electrolyte solution is administered. Where possible, the right upper extremity is avoided as a site to start an IV line, as this location may interfere with positioning of the patient during the surgical repair.

The timing of repair is influenced by the stability of the patient. Definitive repair of the EA-TEF is rarely a surgical emergency. If the child is hemodynamically stable and is oxygenating well, definitive repair may be performed within 1 to 2 days after birth. This allows for a careful determination of the presence of coexisting anomalies and for selection of an experienced anesthetic team.

Management of Esophageal Atresia and Tracheoesophageal Fistula in the Preterm Infant. The ventilated, premature neonate with EA-TEF and associated hyaline membrane disease represents a patient who may develop severe, progressive, cardiopulmonary dysfunction. The TEF can worsen the fragile pulmonary status as a result of recurrent aspiration through the fistula and increased abdominal distention, which impairs lung expansion. Moreover, the elevated airway pressure that is required to ventilate these patients can worsen the clinical course by forcing air through the fistula into the stomach, thereby exacerbating the degree of abdominal distention and compromising lung expansion. In this situation, the first priority is to minimize the degree of positive pressure needed to adequately ventilate the child. This can be accomplished using HFOV. If the gastric distention becomes severe, a gastrostomy tube should be placed. This procedure can be performed at the bedside under local anesthetic, if necessary. The dilated, air-filled stomach can easily be accessed through an incision in the left upper quadrant of the abdomen. Once the gastrostomy tube is placed and the abdominal pressure is relieved, the pulmonary status can paradoxically worsen. This is because the ventilated gas may pass preferentially through the fistula, which is the path of least resistance, and bypass the lungs, thereby worsening the hypoxemia. To correct this problem, the gastrostomy tube may be placed under water seal, elevated, or intermittently clamped. If these maneuvers are to no avail, ligation of the fistula may be required. This procedure can be performed in the neonatal intensive care unit if the infant is too unstable to be transported to the operating room. These interventions allow for the infant's underlying hyaline membrane disease to improve, for the pulmonary secretions to clear, and for the infant to reach a period of stability so that definitive repair can be performed.

2▶

Primary Surgical Correction. In a stable infant, definitive repair is achieved through performance of a primary esophagoesophagostomy. There are two approaches to this operation: open thoracotomy or thoracoscopy. In the open approach, the infant is brought to the operating room, intubated, and placed in the lateral decubitus position with the right side up in preparation for right posterolateral thoracotomy. If a right-sided arch was determined previously by echocardiography, consideration is given to performing the repair through the left chest, although most surgeons believe that the repair can be performed safely from the right side as well. Bronchoscopy may be performed to exclude the presence of additional, upper pouch fistulae in cases of EA (i.e., differentiation of type B, C, and D variants) and to identify a laryngotracheoesophageal cleft.

The operative technique for primary repair is as follows (Fig. 39-11). A retropleural approach is generally used, as this technique prevents widespread contamination of the thorax if a postoperative anastomotic leak occurs. The sequence of steps is as follows: (a) mobilization of the pleura to expose the structures in the posterior mediastinum; (b) division of the fistula and closure of the tracheal opening; (c) mobilization of the upper esophagus sufficiently to permit an anastomosis without tension and to determine whether a fistula is present between the upper esophagus and the trachea (forward pressure by the anesthesia staff on the sump drain in the pouch can greatly facilitate dissection at this stage of the operation; care must be taken when dissecting posteriorly to avoid violation of the lumen of the trachea and esophagus); (d) mobilization of the distal esophagus (this needs to be performed judiciously to avoid devascularization, since the blood supply to the distal esophagus is segmental from the aorta; most of the esophageal length is obtained from mobilizing the upper pouch, since the blood supply travels via the submucosa from above); (e) performing a primary esophagoesophageal anastomosis (most surgeons perform this procedure in a single layer using 5-0 sutures; if there is excess tension, the muscle of the upper pouch can be circumferentially incised without compromising blood supply to increase its length; many surgeons place a transanastomotic feeding tube in order to institute feeds in the early postoperative period); and (f) placement of a retropleural drain and closure of the incision in layers.

When a minimally invasive approach is selected, the patient is prepared for right-sided, transthoracic thoracoscopic repair. The same steps as described earlier for the open repair are undertaken, and the magnification and superb optics that are provided by the thoracoscopic approach provide for superb visualization. Identification of the fistula is performed as a first step; this can be readily ligated and divided between thoracoscopically placed sutures. The anastomosis is performed in a single layer. The thoracoscopically performed TEF repair requires clear and ongoing communication between the operating surgeons and the anesthesiologist; visualization can be significantly reduced with sudden changes in lung inflation, potentially leading to the need to convert to an open repair. Although clear guidelines for patient selection for a thoracoscopic repair as opposed to an open repair remain lacking, reasonable selection criteria include patients over 2.5 kg who are hemodynamically stable and without comorbidities.

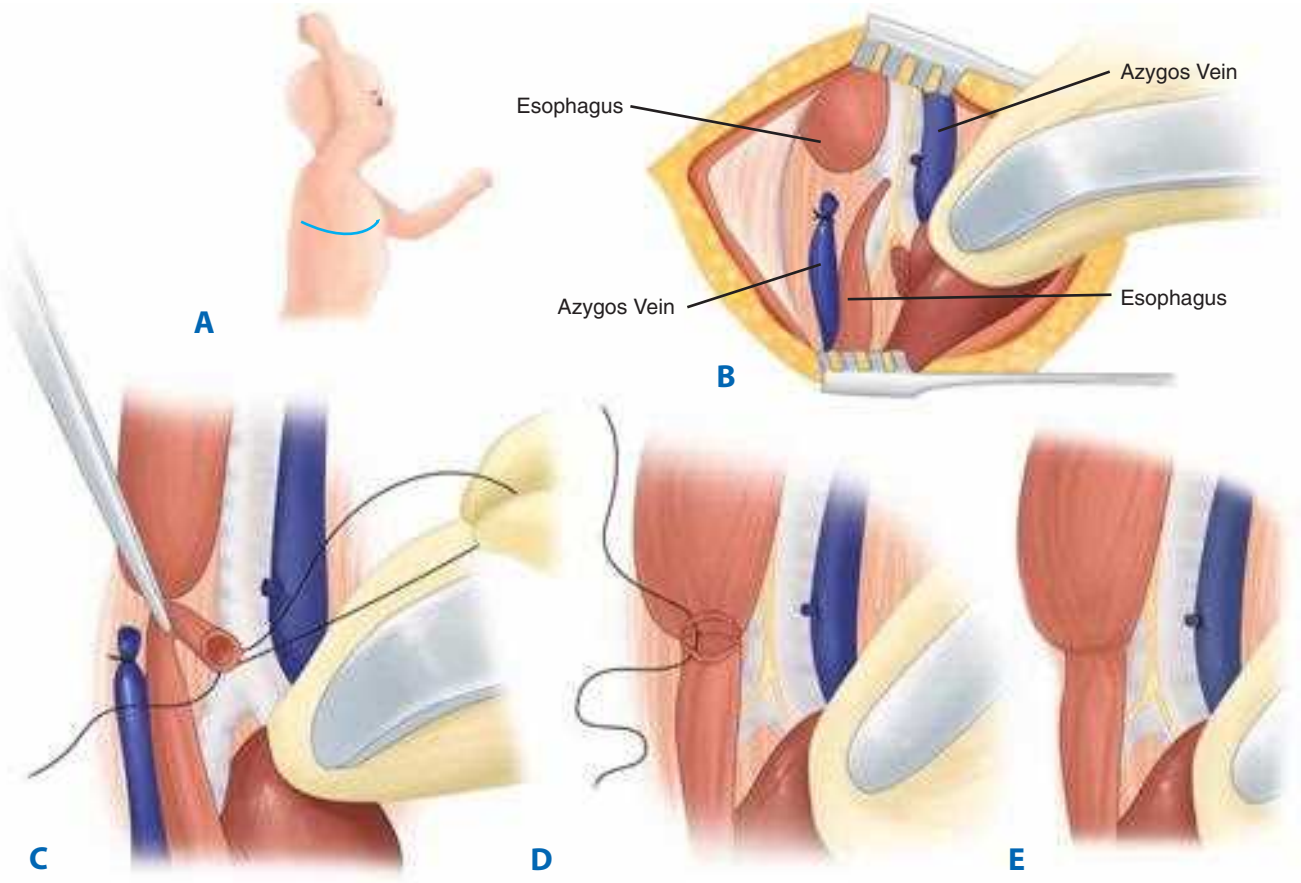

Figure 39-11. Primary repair of type C tracheosophageal fistula. **A.** Right thoracotomy incision. **B.** Azygos vein transected, proximal and distal esophagus demonstrated, and fistula identified. **C.** Tracheoesophageal fistula transected and defect in trachea closed. **D.** End-to-end anastomosis between proximal and distal esophagus (posterior row). **E.** Completed anastomosis.

Postoperative Course. The postoperative management strategy of patients with EA-TEF is influenced to a great degree by the preference of the individual surgeon and the institutional culture. Many surgeons prefer not to leave the infants intubated postoperatively, to avoid the effects of positive pressure on the site of tracheal closure. However, early extubation may not be possible in babies with preoperative lung disease either from prematurity or pneumonia or when there is any vocal cord edema. When a transanastomotic tube is placed, feeds are begun slowly in the postoperative period. Some surgeons institute parenteral nutrition for several days, using a central line. The retropleural drain is assessed daily for the presence of saliva, indicating an anastomotic leak. Many surgeons obtain a contrast swallow 1 week after repair to assess the caliber of the anastomosis and to determine whether a leak is present. If there is no leak, feedings are started. The principal benefit of the thoracoscopic approach is that postoperative pain is significantly reduced, as is the requirement for postoperative narcotic analgesia.

Complications of Surgery. Anastomotic leak occurs in 10% to 15% of patients and may be seen either in the immediate postoperative period or after several days. Early leakage (i.e., within the first 24 to 48 hours) is manifested by a new pleural effusion, pneumothorax, and sepsis, and requires immediate exploration. In these circumstances, the anastomosis may be completely disrupted, possibly due to excessive tension. Revision of the anastomosis may be possible. If not, cervical esophagostomy and gastrostomy placement are required, with a subsequent procedure to re-establish esophageal continuity. Anastomotic leakage that is detected after several days usually heals without intervention, particularly if a retropleural approach is used. Under these circumstances, broad-spectrum antibiotics, pulmonary toilet, and optimization of nutrition are important. After approximately a week or so, a repeat esophagram should be performed, at which time the leakage may have resolved.

Strictures are not infrequent (10%–20%), particularly if a leak has occurred. A stricture may become apparent at any time, from the early postoperative period to months or years later. It may present as choking, gagging, or failure to thrive, but often becomes clinically apparent with the transition to eating solid food. A contrast swallow or esophagoscopy is confirmatory, and simple dilatation is usually corrective. Occasionally, repeated dilatations are required. These may be performed in a retrograde fashion, during which a silk suture is placed into the oropharynx and delivered from the esophagus through a gastrostomy tube. Tucker dilators are then tied to the suture and passed in a retrograde fashion from the gastrostomy tube and delivered out of the oropharynx. Increasing sizes are used, and the silk is replaced at the end of the procedure where it is taped to the side of the face at one end and to the gastrostomy tube at the other. Alternatively, image-guided balloon dilation over a guide wire may be performed, using intraoperative contrast radiography to determine the precise location of the stricture and to assess the immediate response to the dilation.

"Recurrent" TEF may represent a missed upper pouch fistula or a true recurrence. This may occur after an anastomotic disruption, during which the recurrent fistula may heal spontaneously. Otherwise, reoperation may be required. Recently, the use of fibrin glue has been successful in treating recurrent fistulas, although long-term follow-up is lacking.

Gastroesophageal reflux commonly occurs after repair of EA-TEF, potentially due to alterations in esophageal motility and the anatomy of the gastroesophageal junction. The clinical manifestations of such reflux are similar to those seen in other infants with primary gastroesophageal reflux disease. A loose antireflux procedure, such as a Nissen fundoplication, is used to prevent further reflux, but the child may have feeding problems after antireflux surgery as a result of the intrinsic dysmotility of the distal esophagus. The fundoplication may be safely performed laparoscopically in experienced hands, although care should be taken to ensure that the wrap is not excessively tight.

Special Circumstances. Patients with type E TEFs (also called H-type) most commonly present beyond the newborn period. Presenting symptoms include recurrent chest infections, bronchospasm, and failure to thrive. The diagnosis is suspected using barium esophagography and confirmed by endoscopic visualization of the fistula. Surgical correction is generally possible through a cervical approach with concurrent placement of a balloon catheter across the fistula and requires mobilization and division of the fistula. Outcome is usually excellent.

Patients with duodenal atresia and EA-TEF may require urgent treatment due to the presence of a closed obstruction of the stomach and proximal duodenum. In stable patients, treatment consists of repair of the esophageal anomaly and correction of the duodenal atresia if the infant is stable during surgery. If not, a staged approach should be used consisting of ligation of the fistula and placement of a gastrostomy tube. Definitive repair can then be performed at a later point in time.

Primary EA (type A) represents a challenging problem, particularly if the upper and lower ends are too far apart for an anastomosis to be created. Under these circumstances, treatment strategies include placement of a gastrostomy tube and performing serial bougienage to increase the length of the upper pouch. This occasionally allows for primary anastomosis to be performed. Occasionally, when the two ends cannot be brought safely together, esophageal replacement is required using a gastric pull-up, reverse gastric tube, or colon interposition (see below).

Outcome. Various classification systems have been used to predict survival in patients with EA-TEF and to stratify treatment. A system devised by Waterston in 1962 was used to stratify neonates based on birth weight, the presence of pneumonia, and the identification of other congenital anomalies. In response to advances in neonatal care, the surgeons from the Montreal Children's Hospital proposed a new classification system. In the Montreal experience, only two characteristics independently affected survival: preoperative ventilator dependence and associated major anomalies. Pulmonary disease as defined by ventilator dependence appeared to be more accurate than pneumonia. When the two systems were compared, the Montreal system more accurately identified children at highest risk. Spitz and colleagues analyzed risk factors in infants who died with EA-TEF. Two criteria were found to be important predictors of outcome: birth weight less than 1500 g and the presence of major congenital cardiac disease. A new classification for predicting outcome in EA was therefore proposed: group I: birth weight ≥1500 g, without major cardiac disease, survival 97% (283 of 293); group II: birth weight <1500 g, or major cardiac disease, survival 59% (41 of 70); and group III: birth weight <1500 g, and major cardiac disease, survival 22% (2 of 9).

In general, surgical correction of EA-TEF leads to a satisfactory outcome with nearly normal esophageal function in most patients. Overall survival rates of greater than 90% have been achieved in patients classified as stable in all the various staging systems. Unstable infants have an increased mortality (40% to 60% survival) because of potentially fatal associated cardiac and chromosomal anomalies or prematurity. However, the use of a staged procedure also has increased survival in even these high-risk infants.

Corrosive Injury of the Esophagus

Injury to the esophagus after ingestion of corrosive substances most commonly occurs in the toddler age group. Both strong alkali and strong acids produce injury by liquefaction or coagulation necrosis, and since all corrosive agents are extremely hygroscopic, the caustic substance will cling to the esophageal epithelium. Subsequent strictures occur at the anatomic narrowed areas of the esophagus, cricopharyngeus, midesophagus, and gastroesophageal junction. A child who has swallowed an injurious substance may be symptom free but usually will be drooling and unable to swallow saliva. The injury may be restricted to the oropharynx and esophagus or may extend to include the stomach. There is no effective immediate antidote. Diagnosis is by careful physical examination of the mouth and endoscopy with a flexible or a rigid esophagoscope. It is important to endoscope only to the first level of the burn in order to avoid perforation. Early barium swallow may delineate the extent of the mucosal injury. It is important to realize that the esophagus may be burned without evidence of injury to the mouth. Although previously used routinely, steroids have not been shown to alter stricture development or modify the extent of injury. Therefore, they are no longer part of the management of caustic injuries. Antibiotics are administered during the acute period.

The extent of injury is graded endoscopically as either mild, moderate, or severe (grade I, II, or III). Circumferential esophageal injuries with necrosis have an extremely high likelihood of stricture formation. These patients should undergo placement of a gastrostomy tube once clinically stable. A string should be inserted through the esophagus either immediately or during repeat esophagoscopy several weeks later. When established strictures are present (usually 3–4 weeks), dilatation is performed. Retrograde dilatations are safest, using graduated dilators brought through the gastrostomy and advanced into the esophagus via the transesophageal string. For less severe injuries, dilatation may be attempted in antegrade fashion by either graded bougies or balloons. Management of esophageal perforation during dilation should include antibiotics, irrigation, and closed drainage of the thoracic cavity to prevent systemic sepsis. When recognition is delayed or if the patient is systemically ill, esophageal diversion may be required with staged reconstruction at a later time.

Although the native esophagus can be preserved in most cases, severe stricture formation that does not respond to dilation is best managed by esophageal replacement. The most commonly used options for esophageal substitution are the colon (right colon or transverse/left colon) and the stomach (gastric

tube or gastric pull-up). Pedicled or free grafts of the jejunum are less commonly used. The right colon is based on a pedicle of the middle colic artery, and the left colon on a pedicle of the middle colic or left colic artery. Gastric tubes are fashioned from the greater curvature of the stomach based on the pedicle of the left gastroepiploic artery. When the entire stomach is used, as in gastric pull-up, the blood supply is provided by the right gastric artery. The neoesophagus may traverse: (a) substernally; (b) through a transthoracic route; or (c) through the posterior mediastinum to reach the neck. A feeding jejunostomy is placed at the time of surgery, and tube feedings are instituted once the postoperative ileus has resolved. In a recent review of patients treated by gastric pull-up, long-term outcome was very good. Complications included esophagogastric anastomotic leak (n = 15, 36%), which uniformly resolved without intervention, and stricture formation (n = 20, 49%), which responded to a course of dilation. Long-term follow-up has shown that all methods of esophageal substitution can support normal growth and development, and the children enjoy reasonably normal eating habits. Because of the potential for late complications such as ulceration and stricture, follow-up into adulthood is mandatory, but complications appear to diminish with time.

Gastroesophageal Reflux

Gastroesophageal reflux (GER) occurs to some degree in all children and refers to the passage of gastric contents into the esophagus. By contrast, gastroesophageal reflux disease (GERD) describes the situation where reflux is symptomatic. Typical symptoms include failure to thrive, bleeding, stricture formation, reactive airway disease, aspiration pneumonia, and apnea. Failure to thrive and pulmonary problems are particularly common in infants with GERD, whereas strictures and esophagitis are more common in older children and adolescents. GERD is particularly problematic in neurologically impaired children.

Clinical Manifestations. Because all infants experience occasional episodes of GER to some degree, care must be taken before a child is labeled as having pathologic reflux. A history of repeated episodes of vomiting that interferes with growth and development or the presence of apparent life-threatening events is required for the diagnosis of GERD. In older children, esophageal bleeding, stricture formation, severe heartburn, or the development of Barrett's esophagus unequivocally connotes pathologic reflux or GERD. In neurologically impaired children, vomiting due to GER must be distinguished from chronic retching.

The workup of patients suspected of having GERD includes documentation of the episodes of reflux and evaluation of the anatomy. A barium swallow should be performed as an initial test. This will determine whether there is obstruction of the stomach or duodenum (due to duodenal webs or pyloric stenosis) and will determine whether malrotation is present. The frequency and severity of reflux should be assessed using a 24-hour pH probe study. Although this test is poorly tolerated, it provides the most accurate determination that GERD is present. Esophageal endoscopy with biopsies may identify the presence of esophagitis and is useful to determine the length of intra-abdominal esophagus and the presence of Barrett's esophagus. Some surgeons obtain a radioisotope "milk scan" to evaluate gastric emptying, although there is little evidence to show that this test changes management when a diagnosis of GERD has been confirmed using the above modalities.

Treatment. Most patients with GERD are treated initially by conservative means. In the infant, propping and thickening the formula with rice cereal are generally recommended. Some authors prefer a prone, head-up position. In the infant unresponsive to position and formula changes and the older child with severe GERD, medical therapy is based on gastric acid reduction with an H_2-blocking agent and/or a proton pump inhibitor. Medical therapy is successful in most neurologically normal infants and younger children, many of whom will outgrow their need for medications. In certain patients, however, medical treatment does not provide symptomatic relief, and surgery is therefore indicated. The least invasive surgical option includes the placement of a nasojejunal or gastrojejunal feeding tube. Because the stomach is bypassed, food contents do not enter the esophagus, and symptoms are often improved. However, as a long-term remedy, this therapy is associated with several problems. The tubes often become dislodged, acid reflux still occurs, and bolus feeding is generally not possible. Fundoplication provides definitive treatment for GER and is highly effective in most circumstances. The fundus may be wrapped around the distal esophagus either 360° (i.e., Nissen) or to lesser degrees (i.e., Thal or Toupet). At present, the standard approach in most children is to perform these procedures laparoscopically whenever possible. In children with feeding difficulties and in infants under 1 year of age, a gastrostomy tube should be placed at the time of surgery. Early postoperative complications include pneumonia and atelectasis, often due to inadequate pulmonary toilet and pain control with abdominal splinting. Late postoperative complications include wrap breakdown with recurrent reflux, which may require repeat fundoplication, and dysphagia due to a wrap performed too tightly, which generally responds to dilation. These complications are more common in children with neurologic impairment. The keys to successful surgical management of patients with GERD include careful patient selection and meticulous operative technique.

GASTROINTESTINAL TRACT

An Approach to the Vomiting Infant

The majority of infants vomit. Because infant vomiting is so common, it is important to differentiate between normal vomiting, which occurs in almost all babies, to some degree, and abnormal vomiting, which may be indicative of a potentially serious underlying disorder. To determine the seriousness of a particular infant's bouts of emesis, one needs to characterize what the vomit looks like and how sick the baby is. Vomit that looks like feeds and comes up immediately after a feeding is almost always *gastroesophageal reflux*. This may or may not be of concern, as described earlier. Vomiting that occurs a short while after feeding or vomiting that projects out of the baby's mouth may be indicative of *pyloric stenosis*. By contrast, **vomit that has any green color in it is always worrisome**. This may be reflective of intestinal *volvulus*, an underlying infection, or some other cause of intestinal obstruction. A more detailed description of the management of these conditions is provided in the following sections.

Hypertrophic Pyloric Stenosis

Clinical Presentation. Infants with hypertrophic pyloric stenosis (HPS) typically present with nonbilious vomiting that becomes increasingly projectile over the course of several days to weeks due to progressive thickening of the pylorus muscle.

HPS occurs in approximately 1 in 300 live births and commonly in infants between 3 and 6 weeks of age. Male-to-female ratio is nearly 5:1.

Eventually, as the pyloric muscle thickening progresses, the infant develops a complete gastric outlet obstruction and is no longer able to tolerate any feeds. Over time, the infant becomes increasingly hungry, unsuccessfully feeds repeatedly, and becomes increasingly dehydrated. Wet diapers become less frequent, and there may even be a perception of less passage of flatus. HPS may be associated with jaundice due to an indirect hyperbilirubinemia, although the nature of this relationship is unclear.

The cause of HPS has not been determined. Studies have shown that HPS is found in several generations of the same family, suggesting a familial link. Administration of erythromycin in early infancy has been linked to the subsequent development of HPS, although the cause is unclear. Infant positioning in the prone position was implicated as a cause of HPS particularly when, in Denmark and Sweden, a drop in both cases of sudden infant death syndrome (SIDS) and HPS were reported. More recently, a similar drop in both SIDS and HPS was noted in Germany, although the distribution of case rate declines were different across regions in Germany, suggesting that the etiology of HPS is not likely simply due to positioning.

Infants with HPS develop a hypochloremic, hypokalemic metabolic alkalosis. The urine pH level is high initially, but eventually drops because hydrogen ions are preferentially exchanged for sodium ions in the distal tubule of the kidney as the hypochloremia becomes severe (paradoxical aciduria). The diagnosis of pyloric stenosis usually can be made on physical examination by palpation of the typical "olive" in the right upper quadrant and the presence of visible gastric waves on the abdomen. When the olive cannot be palpated, US can diagnose the condition accurately in 95% of patients. Criteria for US diagnosis include a channel length of over 16 mm and pyloric thickness over 4 mm.

Treatment. Given frequent fluid and electrolyte abnormalities at time of presentation, pyloric stenosis is never a surgical emergency. Fluid resuscitation with correction of electrolyte abnormalities and metabolic alkalosis is essential prior to induction of general anesthesia for operation. For most infants, fluid containing 5% dextrose and 0.45% saline with added potassium of 2 to 4 mEq/kg over 24 hours at a rate of approximately 150 to 175 mL/kg per 24 hours will correct the underlying deficit. It is important to ensure that the child has an adequate urine output (>2 cc/kg/h) as further evidence that rehydration has occurred. After resuscitation, a Fredet-Ramstedt pyloromyotomy is performed (Fig. 39-12). It may be performed using an open or laparoscopic approach. The open pyloromyotomy is performed through either an umbilical or a right upper quadrant transverse abdominal incision. The former route is cosmetically more appealing, although the transverse incision provides easier access to the antrum and pylorus. In recent years, the laparoscopic approach has gained great popularity. Two randomized trials have demonstrated that both the open and laparoscopic approaches may be performed safely with equal incidence of postoperative complications, although the cosmetic result is clearly superior with the laparoscopic approach. Whether done through an open or laparoscopic approach, surgical treatment of pyloric stenosis involves splitting the pyloric muscle while leaving the underlying submucosa intact. The incision extends from just proximal to the pyloric vein of Mayo to the gastric antrum; it typically measures between 1 and 2 cm in length. Postoperatively, IV fluids are continued for several hours, after which Pedialyte is offered, followed by formula or breast milk, which is gradually increased to 60 cc every 3 hours. Most infants can be discharged home within 24–48 hours following surgery. Recently, several authors have shown that ad lib feeds are safely tolerated by the neonate and result in a shorter hospital stay.

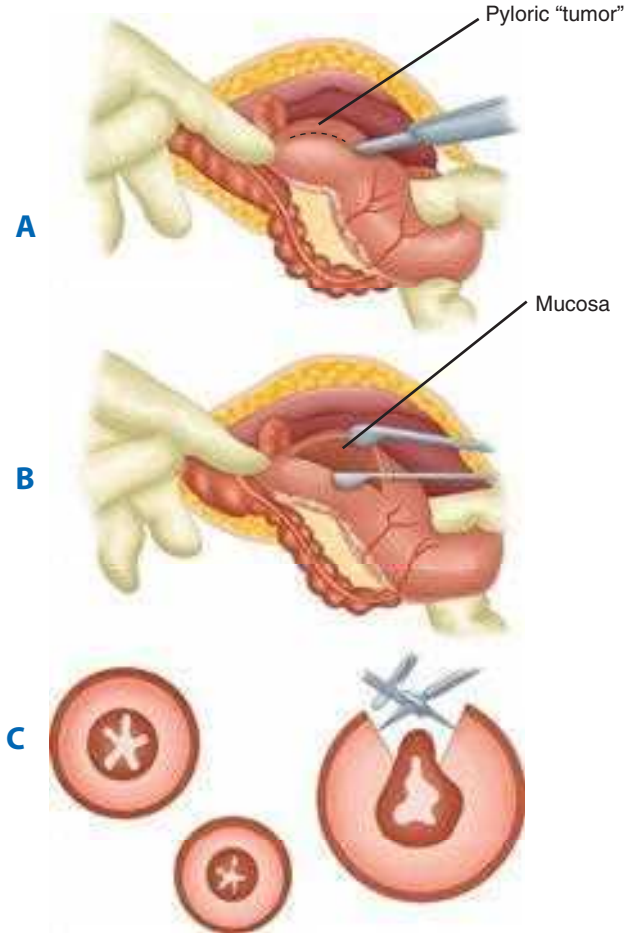

Figure 39-12. Fredet-Ramstedt pyloromyotomy. **A.** Pylorus delivered into wound and seromuscular layer incised. **B.** Seromuscular layer separated down to submucosal base to permit herniation of mucosa through pyloric incision. **C.** Cross-section demonstrating hypertrophied pylorus, depth of incision, and spreading of muscle to permit mucosa to herniate through incision.

The complications of pyloromyotomy include perforation of the mucosa (1%–3%), bleeding, wound infection, and recurrent symptoms due to inadequate myotomy. When perforation occurs, the mucosa is repaired with a stitch that is placed to tack the mucosa down and reapproximate the serosa in the region of the tear. A nasogastric tube is left in place for 24 hours. The outcome is generally very good.

Intestinal Obstruction in the Newborn

The cardinal symptom of intestinal obstruction in the newborn is bilious emesis. Prompt recognition and treatment of neonatal intestinal obstruction can truly be life saving.

3▶

The incidence of neonatal intestinal obstruction is 1 in 2000 live births. The approach to intestinal obstruction in the newborn infant is critical for timely and appropriate intervention. When a neonate develops bilious vomiting, one must

consider a surgical etiology. Indeed, the majority of newborns with bilious emesis have a surgical condition. In evaluating a potential intestinal obstruction, it is helpful to determine whether the intestinal obstruction is either proximal or distal to the ligament of Treitz. One must conduct a detailed prenatal and immediate postnatal history and a thorough physical examination. In all cases of intestinal obstruction, it is vital to obtain abdominal films in the supine and upright (or lateral decubitus) views to assess the presence of air-fluid levels or free air as well as how far downstream air has managed to travel. Importantly, one should recognize that it is difficult to determine whether a loop of bowel is part of either the small or large intestine, as neonatal bowel lacks clear features, such as haustra or plica circulares, normally present in older children or adults. As such, contrast imaging may be necessary for diagnosis in some instances.

4▶

Proximal intestinal obstructions typically present with bilious emesis and minimal abdominal distention. The normal neonate should have a rounded, soft abdomen; in contrast, a neonate with a proximal intestinal obstruction typically exhibits a flat or scaphoid abdomen. On a series of upright and supine abdominal radiographs, one may see a paucity or absence of bowel gas, which normally should be present throughout the gastrointestinal tract within 24 hours. Of utmost importance is the exclusion of a malrotation with midgut volvulus from all other intestinal obstructions as this is a surgical emergency.

Distal obstructions typically presents with bilious emesis and abdominal distention. Passage of black-green meconium should have occurred within the first 24 to 38 hours. Of great importance, one should determine whether or not there is tenderness or discoloration of the abdomen, visible or palpable loops of intestine, and presence or absence of a mass, and whether or not the anus is patent and in the appropriate location. Abdominal radiographs may demonstrate calcifications, which may indicate complicated meconium ileus; pneumatosis and/or pneumoperitoneum may indicate necrotizing enterocolitis. A contrast enema may show whether there is a microcolon indicative of jejunoileal atresia or meconium ileus. If a microcolon is not present, then the diagnoses of Hirschsprung's disease, small left colon syndrome, or meconium plug syndrome should be considered.

Duodenal Obstruction

Whenever the diagnosis of duodenal obstruction is entertained, malrotation and midgut volvulus must be excluded. This topic is covered in further detail later in this chapter. Other causes of duodenal obstruction include duodenal atresia, duodenal web, stenosis, annular pancreas, or duodenal duplication cyst. Duodenal obstruction is easily diagnosed on prenatal US, which demonstrates the fluid-filled stomach and proximal duodenum as two discrete cystic structures in the upper abdomen. Associated polyhydramnios is common and presents in the third trimester. In 85% of infants with duodenal obstruction, the entry of the bile duct is proximal to the level of obstruction, such that vomiting is bilious. Abdominal distention is typically not present because of the proximal level of obstruction. In infants with obstruction proximal to the bile duct entry, the vomiting is nonbilious. The classic finding on abdominal radiography is the "double bubble" sign, which represents the dilated stomach and duodenum (Fig. 39-13). In association with the appropriate clinical picture, this finding is sufficient to confirm the diagnosis of duodenal obstruction. However, if there is any uncertainty, particularly when a partial obstruction is suspected, a contrast upper gastrointestinal series is diagnostic.

Figure 39-13. Abdominal x-ray showing "double bubble" sign in a newborn infant with duodenal atresia. The two "bubbles" are numbered.

Treatment. An orogastric tube is inserted to decompress the stomach and duodenum, and the infant is given IV fluids to maintain adequate urine output. If the infant appears ill or if abdominal tenderness is present, a diagnosis of malrotation and midgut volvulus should be considered, and surgery should not be delayed. Typically, the abdomen is soft, and the infant is very stable. Under these circumstances, the infant should be evaluated thoroughly for other associated anomalies. Approximately one third of newborns with duodenal atresia have associated Down syndrome (trisomy 21). These patients should be evaluated for associated cardiac anomalies. Once the workup is complete and the infant is stable, he or she is taken to the operating room, and the abdomen is entered through a transverse right upper quadrant supraumbilical incision under general endotracheal anesthesia. Associated anomalies should be searched for at the time of the operation. These include malrotation, anterior portal vein, a second distal web, and biliary atresia. The surgical treatment of choice for duodenal obstruction due to duodenal stenosis or atresia or annular pancreas is a duodeno-duodenostomy. This procedure can be most easily performed using a proximal transverse-to-distal longitudinal (diamond-shaped) anastomosis. In cases where the duodenum is extremely dilated, the lumen may be tapered using a linear stapler with a large Foley catheter (24 F or greater) in the duodenal lumen. It is important to emphasize that an annular pancreas is never divided but rather is bypassed to avoid injury to the pancreatic ducts. Treatment of duodenal web includes vertical duodenotomy, excision of the web, oversewing of the mucosa, and closing the duodenotomy horizontally. Gastrostomy tube placement is not routinely performed. Recently reported survival rates exceed 90%. Late complications from repair of duodenal atresia occur in approximately 12% to 15% of patients and include megaduodenum, intestinal motility disorders, and GER.

Intestinal Atresia

Obstruction due to intestinal atresia can occur at any point along the intestinal tract. Intestinal atresias were previously thought to be the result of in utero mesenteric vascular accidents leading to segmental loss of the intestinal lumen, although, more likely they are due to developmental defects in normal intestinal organogenesis due to disruption of various signaling pathways such as fibroblast growth factor, bone morphogenic protein, and β-catenin pathways. The incidence of intestinal atresia has been

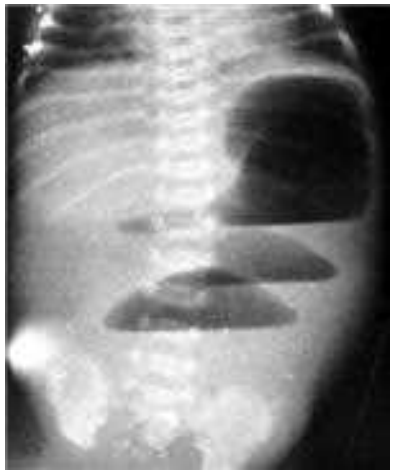

Figure 39-14. Intestinal obstruction in the newborn showing several loops of distended bowel with air-fluid levels. This child has jejunal atresia.

Figure 39-15. Operative photograph of newborn with "Christmas tree" type of ileal atresia.

estimated to be between 1 in 2000 and 1 in 5000 live births, with equal representation of the sexes. Infants with jejunal or ileal atresia present with bilious vomiting and progressive abdominal distention. The more distal the obstruction, the more distended the abdomen becomes, and the greater is the number of obstructed loops on upright abdominal films (Fig. 39-14).

In cases where the diagnosis of complete intestinal obstruction is ascertained by the clinical picture and the presence of staggered air-fluid levels on plain abdominal films, the child can be brought to the operating room after appropriate resuscitation. In these circumstances, there is little extra information to be gained by performing a barium enema. By contrast, when there is diagnostic uncertainty or when distal intestinal obstruction is apparent, a barium enema is useful to establish whether a microcolon is present and to diagnose the presence of meconium plugs, small left colon syndrome, Hirschsprung's disease, or meconium ileus. Judicious use of barium enema is therefore required in order to safely manage neonatal intestinal obstruction, based on an understanding of the expected level of obstruction.

Surgical correction of the small intestinal atresia should be performed urgently. At laparotomy, one of several types of atresia will be encountered. In type 1, there is a mucosal atresia with intact muscularis. In type 2, the atretic ends are connected by a fibrous band. In type 3A, the two ends of the atresia are separated by a V-shaped defect in the mesentery. Type 3B is an "apple peel" deformity or "Christmas tree" deformity in which the bowel distal to the atresia receives its blood supply in a retrograde fashion from the ileocolic or right colic artery (Fig. 39-15). In type 4 atresia, there are multiple atresias with a "string of sausage" or "string of beads" appearance. Disparity in lumen size between the proximal distended bowel and the small diameter of collapsed bowel distal to the atresia has led to a number of innovative techniques of anastomosis. However, under most circumstances, an anastomosis can be performed using the end-to-back technique in which the distal, compressed loop is "fish-mouthed" along its antimesenteric border. The proximal distended loop can be tapered as described earlier. Because the distended proximal bowel rarely has normal motility, the extremely dilated portion should be resected prior to performing the anastomosis.

Occasionally the infant with intestinal atresia will develop ischemia or necrosis of the proximal segment secondary to volvulus of the dilated, bulbous, blind-ending proximal bowel. Under these conditions, an end ileostomy and mucus fistula should be created, and the anastomosis should be deferred to another time after the infant stabilizes.

Malrotation and Midgut Volvulus

Embryology. During the sixth week of fetal development, the midgut grows too rapidly to be accommodated in the abdominal cavity and therefore herniates into the umbilical cord. Between the tenth and twelfth weeks, the midgut returns to the abdominal cavity, undergoing a 270° counterclockwise rotation around the superior mesenteric artery. Because the duodenum also rotates caudal to the artery, it acquires a C-loop that traces this path. The cecum rotates cephalad to the artery, which determines the location of the transverse and ascending colon. Subsequently, the duodenum becomes fixed retroperitoneally in its third portion and at the ligament of Treitz, while the cecum becomes fixed to the lateral abdominal wall by peritoneal bands. The takeoff of the branches of the superior mesenteric artery elongates and becomes fixed along a line extending from its emergence from the aorta to the cecum in the right lower quadrant. Genetic mutations likely disrupt the signaling critical for normal intestinal rotation. For instance, mutations in the gene *BCL6* resulting in absence of left-sided expression of its transcript lead to reversed cardiac orientation, defective ocular development, and malrotation. The essential role of the dorsal gut mesentery in mediating normal intestinal rotation and the role of the forkhead box transcription factor *Foxf1* in formation of the dorsal mesentery in mice are consistent with the noted association of intestinal malrotation with alveolar capillary dysplasia, caused by mutations in *FOXF1*. If rotation is incomplete, the cecum remains in the epigastrium, but the bands fixing the duodenum to the retroperitoneum and cecum continue to form. This results in (Ladd's) bands extending from the cecum to the lateral abdominal wall and crossing the duodenum, which creates the potential for obstruction. The mesenteric takeoff remains confined to the epigastrium, resulting in a narrow pedicle suspending all the branches of the superior mesenteric artery and the entire midgut. A volvulus may therefore occur around the mesentery. This twist not only obstructs the proximal jejunum, but also cuts off the blood

supply to the midgut. Intestinal obstruction and complete infarction of the midgut occur unless the problem is promptly corrected surgically.

Presentation and Management. Midgut volvulus can occur at any age, although it is seen most often in the first few weeks of life. Bilious vomiting is usually the first sign of volvulus, and all infants with bilious vomiting must be evaluated rapidly to ensure that they do not have intestinal malrotation with volvulus. The child with irritability and bilious emesis should raise particular suspicions for this diagnosis. If left untreated, vascular compromise of the midgut initially causes bloody stools, but eventually results in circulatory collapse. Additional clues to the presence of advanced ischemia of the intestine include erythema and edema of the abdominal wall, which progresses to shock and death. It must be re-emphasized that the index of suspicion for this condition must be high, since abdominal signs are minimal in the early stages. Abdominal films show a paucity of gas throughout the intestine with a few scattered air-fluid levels (Fig. 39-16). When these findings are present, the patient should undergo immediate fluid resuscitation to ensure adequate perfusion and urine output followed by prompt exploratory laparotomy. In cases where the child is stable, laparoscopy may be considered.

Often the patient will not appear ill, and the plain films may suggest partial duodenal obstruction. Under these conditions, the patient may have malrotation without volvulus. This is best diagnosed by an upper gastrointestinal series that shows incomplete rotation with the duodenojejunal junction displaced to the right. The duodenum may show a corkscrew effect diagnosing volvulus or complete duodenal obstruction, with the small bowel loops entirely in the right side of the abdomen. Barium enema may show a displaced cecum, but this sign is unreliable, especially in the small infant in whom the cecum is normally in a somewhat higher position than in the older child.

Figure 39-16. Abdominal x-ray of a 10-day-old infant with bilious emesis. Note the dilated proximal bowel and the paucity of distal bowel gas, characteristic of a volvulus.

When volvulus is suspected, early surgical intervention is mandatory if the ischemic process is to be avoided or reversed. Volvulus occurs clockwise and is therefore untwisted counterclockwise. This can be remembered using the memory aid "turn back the hands of time." Subsequently, a Ladd procedure is performed. This operation does not correct the malrotation, but does broaden the narrow mesenteric pedicle to prevent volvulus from recurring. This procedure is performed as follows (Fig. 39-17). The bands between the cecum and the abdominal wall and between the duodenum and terminal ileum are divided sharply to splay out the superior mesenteric artery and its branches. This maneuver brings the straightened duodenum into the right lower quadrant and the cecum into the left lower quadrant. The appendix is removed to avoid diagnostic errors in later life. No attempt is made to suture the cecum or duodenum in place. With advanced ischemia, reduction of the volvulus without the Ladd procedure is accomplished, and a "second look" 24 to 36 hours later often will show some vascular recovery. A plastic transparent silo may be placed to facilitate constant evaluation of the intestine and to plan for the timing of re-exploration. Frankly necrotic bowel can then be resected conservatively. With early diagnosis and correction the prognosis is excellent. However, diagnostic delay can lead to mortality or to short-gut syndrome requiring intestinal transplantation.

A subset of patients with malrotation will demonstrate chronic obstructive symptoms. These symptoms may result from Ladd's bands across the duodenum or, occasionally, from intermittent volvulus. Symptoms include intermittent abdominal pain and intermittent vomiting, which may occasionally be bilious. Infants with malrotation may demonstrate failure to thrive, and they may be diagnosed initially as having GERD. Surgical correction using the Ladd procedure, as described earlier, can prevent volvulus from occurring and improve symptoms in many instances.

Meconium Ileus

Pathogenesis and Clinical Presentation. Infants with cystic fibrosis have characteristic pancreatic enzyme deficiencies and abnormal chloride secretion in the intestine that result in the production of viscous, water-poor meconium. This phenotype is explained by the presence of mutations in the *CFTR* gene. Meconium ileus occurs when this thick, highly viscous meconium becomes impacted in the ileum and leads to high-grade intestinal obstruction. Recently, additional mutations were recently identified in genes encoding multiple apical plasma membrane proteins of infants with meconium ileus. Meconium ileus can be either uncomplicated, in which there is no intestinal perforation, or complicated, in which prenatal perforation of the intestine has occurred or vascular compromise of the distended ileum develops. Antenatal US may reveal the presence of intra-abdominal or scrotal calcifications or distended bowel loops. These infants present shortly after birth with progressive abdominal distention and failure to pass meconium with intermittent bilious emesis. Abdominal radiographs show dilated loops of intestine. Because the enteric contents are so viscous, air-fluid levels do not form, even when obstruction is complete. Small bubbles of gas become entrapped in the inspissated meconium in the distal ileum, where they produce a characteristic "ground glass" appearance.

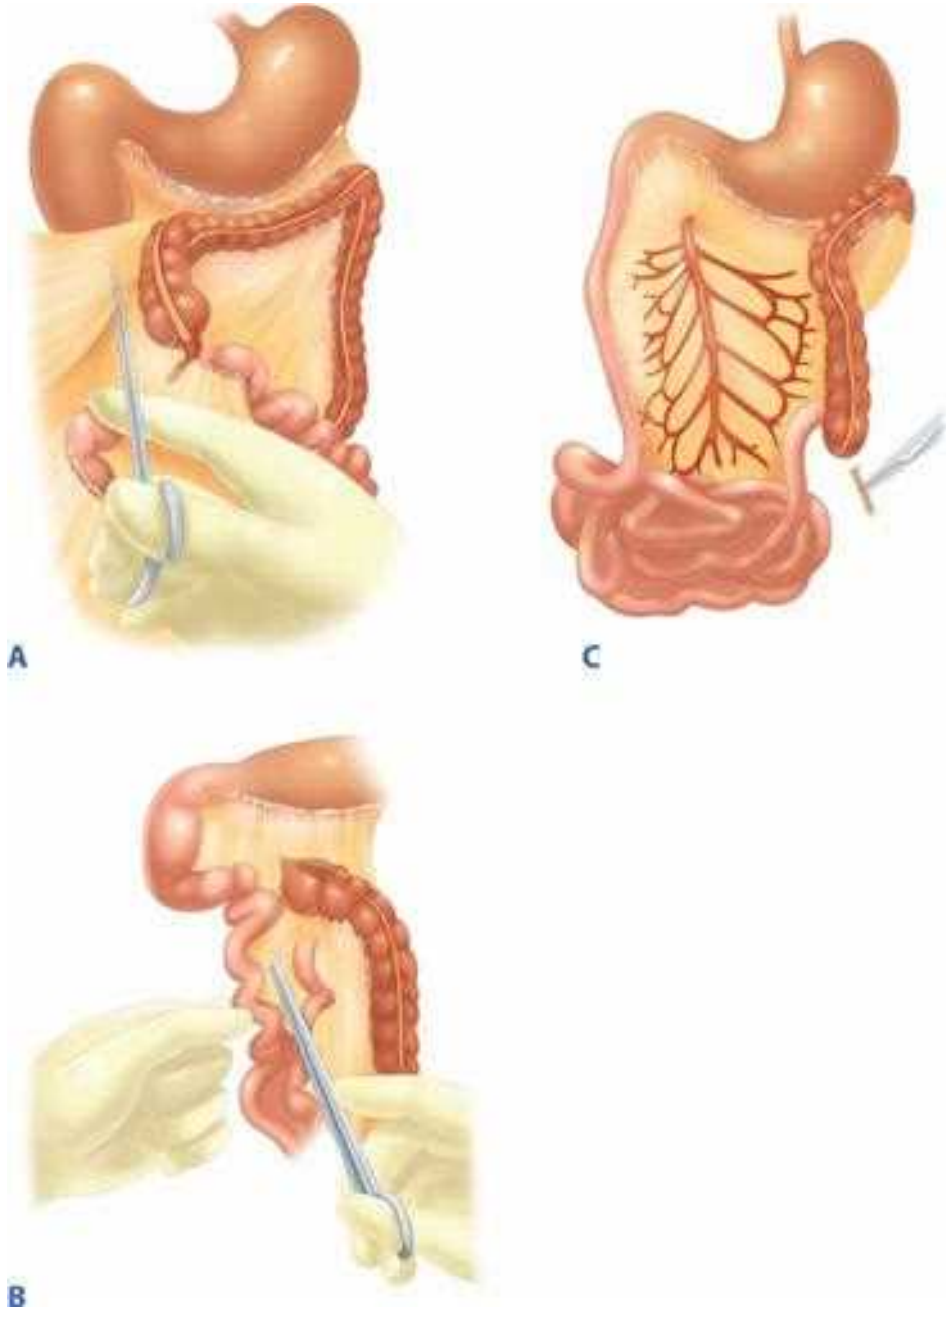

Figure 39-17. Ladd procedure for malrotation. **A.** Lysis of cecal and duodenal bands. **B.** Broadening the mesentery. **C.** Appendectomy.

The diagnosis of meconium ileus is confirmed by a contrast enema, which typically demonstrates a microcolon. In patients with uncomplicated meconium ileus, the terminal ileum is filled with pellets of meconium. In patients with complicated meconium ileus, intraperitoneal calcifications form, producing an eggshell pattern on plain abdominal x-ray.

Management. The treatment strategy depends on whether the patient has complicated or uncomplicated meconium ileus. Patients with uncomplicated meconium ileus can be treated nonoperatively. Either dilute water-soluble contrast or *N*-acetylcysteine (Mucomyst^{-}) is infused transanally via catheter under fluoroscopic control into the dilated portion of the ileum. Because these agents act by absorbing fluid from the bowel wall into the intestinal lumen, infants undergoing treatment are at risk of fluid and electrolyte abnormalities, so appropriate resuscitation of the infant during this maneuver is extremely important. The enema may be repeated at 12-hour intervals over several days until all the meconium is evacuated. Inability to reflux the contrast into the dilated portion of the ileum signifies the presence of an associated atresia or complicated meconium ileus, and thus warrants exploratory laparotomy. If surgical intervention is required because of failure of contrast enemas to relieve obstruction, operative irrigation with dilute contrast agent, *N*-acetylcysteine, or saline through a purse-string suture may be successful. Alternatively, resection of the distended terminal ileum is performed, and the meconium pellets are flushed from the distal small bowel. At this point, an end ileostomy may be created. The distal bowel may be brought up as a mucus fistula or sewn to the side of the ileum as a Bishop-Koop anastomosis.

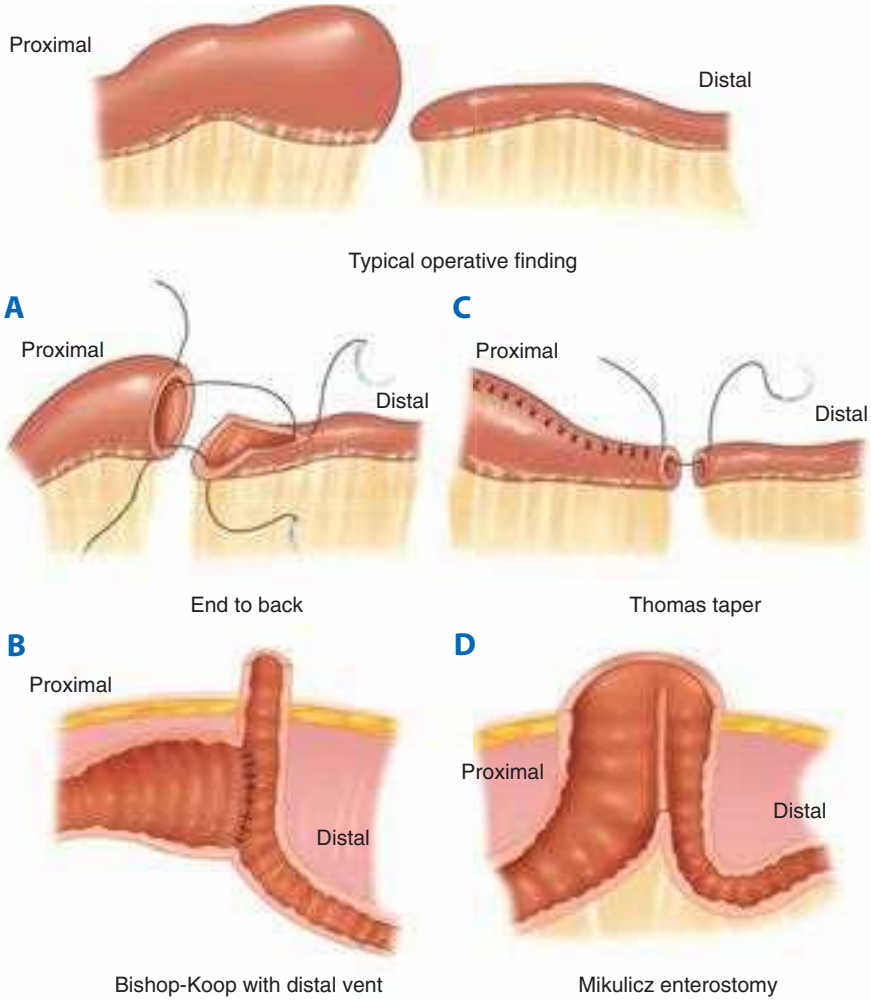

Figure 39-18. Techniques of intestinal anastomosis for infants with small bowel obstruction. **A.** End to back: distal limb has been incised, creating "fish mouth" to enlarge the lumen. **B.** Bishop-Koop: proximal distended limb joined to side of distal small bowel, which is vented by "chimney" to the abdominal wall. **C.** Tapering: portion of antimesenteric wall of proximal bowel excised, with longitudinal closure to minimize disparity in the limbs. **D.** Mikulicz double-barreled enterostomy is constructed by suturing the two limbs together and then exteriorizing the double stoma. The common wall can be crushed with a special clamp to create a large stoma. The stoma can be closed in an extraperitoneal manner.

An end-to-end anastomosis may also be considered in the appropriate setting (Fig. 39-18).

Necrotizing Enterocolitis

Clinical Features. Necrotizing enterocolitis (NEC) is the most frequent and lethal gastrointestinal disorder affecting the intestine of the stressed, preterm neonate. Over 25,000 cases of NEC are reported annually. The overall mortality ranges between 10% and 50%. Advances in neonatal care such as surfactant therapy and improved methods of mechanical ventilation have resulted in increasing numbers of low birth weight infants surviving neonatal hyaline membrane disease. An increasing proportion of survivors of neonatal respiratory distress syndrome will therefore be at risk for developing NEC. Consequently, it is estimated that NEC soon will surpass respiratory distress syndrome as the principal cause of death in the preterm infant.

Multiple risk factors have been associated with the development of NEC. These include prematurity, initiation of enteral feeding, bacterial infection, intestinal ischemia resulting from birth asphyxia, umbilical artery cannulation, persistence of a patent ductus arteriosus, cyanotic heart disease, and maternal cocaine abuse. Nonetheless, the mechanisms by which these complex interacting etiologies lead to the development of the disease remain undefined. The only consistent epidemiologic precursors for NEC are prematurity and enteral alimentation, representing the commonly encountered clinical situation of a stressed infant who is fed enterally. Of note, there is some debate regarding the type and strategy of enteral alimentation in the pathogenesis of NEC. A prospective randomized study showed no increase in the incidence of NEC despite an aggressive feeding strategy.

5▶

The indigenous intestinal microbial flora has been postulated to play a central role in the pathogenesis of NEC. Bacterial colonization may be a prerequisite for the development of this disease because oral prophylaxis with vancomycin or gentamicin reduced the incidence of NEC. The importance of bacteria in the pathogenesis of NEC is further supported by the finding that NEC occurs in episodic waves that can be abrogated by infection control measures and the fact that NEC usually develops at least 10 days postnatally, when the gastrointestinal tract is colonized by coliforms. More recently, outbreaks of NEC have

been reported in infants fed formula contaminated with *Cronobacter sakazakii*. Common bacterial isolates from the blood, peritoneal fluid, and stool of infants with advanced NEC include *Escherichia coli*, *Enterobacter*, *Klebsiella*, and occasionally, coagulase-negative *Staphylococcus* species.

NEC may involve single or multiple segments of the intestine, most commonly the terminal ileum, followed by the colon. The gross findings in NEC include bowel distention with patchy areas of thinning, pneumatosis, gangrene, or frank perforation. The microscopic features include the appearance of a "bland infarct" characterized by full-thickness necrosis.

Clinical Manifestations. Infants with NEC present with a spectrum of disease. In general, the infants are premature and may have sustained one or more episodes of stress, such as birth asphyxia, or they may have congenital cardiac disease. The clinical picture of NEC has been characterized by Bell and colleagues as progressing from a period of mild illness to that of severe, life-threatening sepsis. Although not all infants progress through the various "Bell stages," this classification scheme provides a useful format to describe the clinical picture associated with the development of NEC. In the earliest stage (Bell stage I), infants present with feeding intolerance. This is suggested by vomiting or by the presence of a large residual volume from a previous feeding in the stomach at the time of the next feeding. Following appropriate treatment, which consists of bowel rest and IV antibiotics, many of these infants will not progress to more advanced stages of NEC. These infants are colloquially described as suffering from a "NEC scare" and represent a population of neonates who are at risk of developing more severe NEC if a more prolonged period of stress supervenes.

Infants with Bell stage II have established NEC that is not immediately life threatening. Clinical findings include abdominal distention and tenderness, bilious nasogastric aspirate, and bloody stools. These findings indicate the development of intestinal ileus and mucosal ischemia, respectively. Abdominal examination may reveal a palpable mass indicating the presence of an inflamed loop of bowel, diffuse abdominal tenderness, cellulitis, and edema of the anterior abdominal wall. The infant may appear systemically ill, with decreased urine output, hypotension, tachycardia, and noncardiac pulmonary edema. Hematologic evaluation reveals either leukocytosis or leukopenia, an increase in the number of bands, and thrombocytopenia. An increase in the blood urea nitrogen and plasma creatinine levels may be found, which signifies the development of renal dysfunction. The diagnosis of NEC may be confirmed by abdominal radiography. The pathognomonic radiographic finding in NEC is pneumatosis intestinalis, which represents invasion of the ischemic mucosa by gas-producing microbes (Fig. 39-19). Other findings include the presence of ileus or portal venous gas. The latter is a transient finding that indicates the presence of severe NEC with intestinal necrosis. A fixed loop of bowel may be seen on serial abdominal radiographs, which suggests the possibility that a diseased loop of bowel, potentially with a localized perforation, is present. Although these infants are at risk of progressing to more severe disease, with timely and appropriate treatment, they often recover.

Infants with Bell stage III have the most advanced form of NEC. Abdominal radiographs often demonstrate the presence of pneumoperitoneum, indicating that intestinal perforation has occurred. These patients may develop a fulminant course with progressive peritonitis, acidosis, sepsis, disseminated intravascular coagulopathy, and death.

Figure 39-19. Abdominal radiograph of infant with necrotizing enterocolitis. *Arrows* point to area of pneumatosis intestinalis.

Pathogenesis of Necrotizing Enterocolitis. Several theories have been proposed to explain the development of NEC. To more precisely understand the mechanisms that contribute to the pathogenesis of NEC, several groups have focused on understanding the potential clues that may be revealed by studying patients who have progressed from Bell stage I to Bell stage III disease. In general terms, the development of diffuse pneumatosis intestinalis, which is associated with the development of stage II NEC, is thought to be due to the presence of gas within the wall of the intestine from enteric bacteria, suggesting the causative role of bacteria in the pathogenesis of NEC. Furthermore, the development of pneumoperitoneum indicates disease progression with severe disruption of the intestinal barrier (intestinal perforation). Finally, systemic sepsis with diffuse multisystem organ dysfunction suggests the role for circulating proinflammatory cytokines in the pathogenesis of NEC. It has also been demonstrated that the premature intestine responds in an exaggerated fashion to bacterial products, rendering the host susceptible to barrier dysfunction and the development of NEC. As was recently summarized by the 2006 National Institute of Child Health and Development (NICHD) workshop on NEC research, "NEC can be thought to arise from an uncontrolled exuberant inflammatory response to bacterial colonization that characterizes the intestine of premature infants."

Treatment. In all infants suspected of having NEC, feedings are discontinued, a nasogastric tube is placed, and broad-spectrum parenteral antibiotics are given. The infant is resuscitated, and inotropes are administered to maintain perfusion as needed. Intubation and mechanical ventilation may be required to maintain oxygenation. TPN is started. Subsequent treatment may be influenced by the particular stage of NEC that is present. Patients with Bell stage I are closely monitored and generally remain NPO (nothing by mouth) and on IV antibiotics for 5 to 7 days, prior to reinitiating enteral nutrition. If the infant fully recovers, feedings may be reinitiated.

Patients with Bell stage II disease merit close observation. Serial physical examinations are performed looking for the

development of diffuse peritonitis, a fixed mass, progressive abdominal wall cellulitis, or systemic sepsis. Serial abdominal radiographs are obtained at regular intervals to look for the presence of pneumoperitoneum or a fixed loop of bowel. If infants fail to improve after several days of treatment or if abdominal radiographs show a fixed intestinal loop, consideration should be given to exploratory laparotomy. Paracentesis may be performed, and if the Gram stain demonstrates multiple organisms and leukocytes, perforation of the bowel should be suspected, and patients should undergo laparotomy.

In the most severe form of NEC (Bell stage III), patients have definite intestinal perforation or have not responded to nonoperative therapy. Two schools of thought direct further management. One group favors exploratory laparotomy. At laparotomy, frankly gangrenous or perforated bowel is resected, and the intestinal ends are brought out as stomas. When there is massive intestinal involvement, marginally viable bowel is retained, and a "second look" procedure is carried out after the infant stabilizes (24–48 hours). Patients with extensive necrosis at the second look may be managed by placing a proximal diverting stoma, resecting bowel that is definitely not viable, and leaving questionably viable bowel behind, distal to the diverted segment. When the intestine is viable except for a localized perforation without diffuse peritonitis and if the infant's clinical condition permits, intestinal anastomosis may be performed. In cases where the diseased, perforated segment cannot be safely resected, drainage catheters may be left in the region of the diseased bowel, and the infant is allowed to stabilize.

An alternative approach to the management of infants with perforated NEC involves drainage of the peritoneal cavity. This may be performed under local anesthesia at the bedside and can be an effective means of stabilizing the desperately ill infant by relieving increased intra-abdominal pressure and allowing ventilation. When successful, this method also allows for drainage of perforated bowel by establishing a controlled fistula. Approximately one third of infants treated with drainage alone survive without requiring additional operations. Infants who do not respond to peritoneal drainage alone after 48 to 72 hours should undergo laparotomy. This procedure allows for the resection of frankly necrotic bowel diversion of the fecal stream and facilitates more effective drainage. It is noteworthy that a recent randomized controlled trial demonstrated that outcomes were similar in infants with NEC who were treated either with primary peritoneal drainage or laparotomy.

Necrotizing Enterocolitis in Older Infants. Although NEC is typically a disease that affects preterm infants, several independent groups have reported a tendency for early onset of NEC in term and near-term infants. In these patients, the pattern of disease was found to be different from that found in premature infants. Specifically, NEC in older infants typically is localized to the end of the small intestine and beginning of the colon, suggestive of an ischemic pathophysiology. There are four pertinent associations that are observed in term infants who develop NEC: congenital heart disease, in utero growth restriction, polycythemia, and perinatal hypoxic-ischemic events. As with NEC in preterm infants, NEC in older patients is also associated with formula consumption and is very rare in exclusively breast-fed infants. Patients with NEC at full term typically present with bloody stools and may be characterized by rapid onset of symptoms and a fulminant course. Thus, although it is true that NEC is typically a disease of premature babies, in the appropriate setting, NEC can develop at any age.

Spontaneous Intestinal Perforation Versus Necrotizing Enterocolitis. In addition to NEC, preterm infants with intestinal pathology may develop spontaneous intestinal perforation (SIP). SIP is a distinct clinical entity from NEC and is essentially a perforation in the terminal ileum. The histopathology of SIP is different from NEC. Specifically, the mucosa is intact and not necrotic, there is no sign of ischemia, and the submucosa is thinned at the site of perforation. In contrast to NEC, pneumatosis intestinalis is absent in SIP. Moreover, the demographics of NEC and SIP are slightly different, in that patients with SIP tend to be slightly more premature, smaller, and more likely to have been on inotropic support. However, both NEC and SIP occur with similar frequency in low birth weight infants. The outcome of patients in the two groups is slightly different. Because patients with SIP have isolated disease without necrosis or systemic inflammation, they tend to have a better outcome. In short, the diagnosis of SIP versus NEC has important prognostic significance. The treatment strategies, however, are essentially the same.

Outcome. Survival in patients with NEC is dependent on the stage of disease, the extent of prematurity, and the presence of associated comorbidities. Survival by stage has recently been shown to be approximately 85%, 65%, and 35% for stages I, II, and III, respectively. Strictures develop in 20% of medically or surgically treated patients, and a contrast enema is mandatory before re-establishing intestinal continuity. If all other factors are favorable, the ileostomy is closed when the child is between 2 and 2.5 kg. At the time of stoma closure, the entire intestine should be examined to search for strictures. Patients who develop massive intestinal necrosis are at risk of developing short bowel syndrome, particularly when the total length of the viable intestinal segment is less than 40 cm. These patients require TPN to provide adequate calories for growth and development and may develop parenteral nutrition–associated cholestasis and hepatic fibrosis. In a significant number of these patients, transplantation of the liver and small bowel may be required.

Short Bowel Syndrome

Short bowel syndrome (SBS) is an expensive, morbid condition with an increasing incidence. Various congenital and perinatal acquired conditions such as gastroschisis, malrotation, atresia, and NEC may lead to SBS. NEC is the most common gastrointestinal emergency in neonates and primarily occurs in premature infants. As rates of prematurity are increasing, so are the numbers of children with SBS. Medical and surgical treatment options carry high dollar and human costs and morbidities including multiple infections and hospitalizations for vascular access, liver failure in conjunction with parenteral nutrition-associated cholestasis, and death. Small bowel transplant has a reported 5-year graft survival of 48%, but is attended by rejection, the morbidity of major surgery, and a lifelong need for antirejection medication. A report on 989 grafts in 923 patients by the Intestine Transplant Registry reveals improving outcomes, but 1-year graft and patient survival rates are 65% and 77%, respectively. If successful in the human, engineered intestine from autologous cells could avoid the problems of transplantation: donor supply and immunosuppression. Because engineered small and large intestine, esophagus, stomach, and specific portions of the gastrointestinal tract such as the gastroesophageal junction form by the same process, other intestinal deficiencies may possibly be addressed.

Intussusception

Intussusception is the leading cause of intestinal obstruction in the young child. It refers to the condition whereby a segment of intestine becomes drawn into the lumen of the more proximal bowel. The process usually begins in the region of the terminal ileum and extends distally into the ascending, transverse, or descending colon. Rarely, an intussusception may prolapse through the rectum.

The cause of intussusception is not clear, although one hypothesis suggests that hypertrophy of the Peyer's patches in the terminal ileum from an antecedent viral infection acts as a lead point. Peristaltic action of the intestine then causes the bowel distal to the lead point to invaginate into itself. Idiopathic intussusception occurs in children between the ages of approximately 6 and 24 months of age. Beyond this age group, one should consider the possibility that a pathologic lead point may be present. These include polyps, malignant tumors such as lymphoma, enteric duplication cysts, or Meckel's diverticulum. Such intussusceptions are rarely reduced by air or contrast enema, and thus the lead point is identified when operative reduction of the intussusception is performed.

Clinical Manifestations. Since intussusception is frequently preceded by a gastrointestinal viral illness, the onset may not be easily determined. Typically, the infant develops paroxysms of crampy abdominal pain and intermittent vomiting. Between attacks, the infant may act normally, but as symptoms progress, increasing lethargy develops. Bloody mucus ("currant jelly" stool) may be passed per rectum. Ultimately, if reduction is not accomplished, gangrene of the intussusceptum occurs, and perforation may ensue. On physical examination, an elongated mass is detected in the right upper quadrant or epigastrium with an absence of bowel in the right lower quadrant (Dance's sign). The mass may be seen on plain abdominal x-ray but is more easily demonstrated on air or contrast enema.

Treatment. Patients with intussusception should be assessed for the presence of peritonitis and for the severity of systemic illness. Following resuscitation and administration of IV antibiotics, the child is assessed for suitability to proceed with radiographic versus surgical reduction. In the absence of peritonitis, the child should undergo radiographic reduction. If peritonitis is present or if the child appears systemically ill, urgent laparotomy is indicated.

In the stable patient, the air enema is diagnostic and may also be curative, and it is the preferred method of diagnosis and treatment of intussusception. Air is introduced with a manometer, and the pressure that is administered is carefully monitored. Under most instances, this should not exceed 120 mmHg. Successful reduction is marked by free reflux of air into multiple loops of small bowel and symptomatic improvement as the infant suddenly becomes pain free. Unless both of these signs are observed, it cannot be assumed that the intussusception is reduced. If reduction is unsuccessful and the infant remains stable, the infant should be brought back to the radiology suite for a repeat attempt at reduction after a few hours. This strategy has improved the success rate of nonoperative reduction in many centers. In addition, hydrostatic reduction with barium may be useful if pneumatic reduction is unsuccessful. The overall success rate of radiographic reduction varies based on the experience of the center and is typically between 60% and 90%.

If nonoperative reduction is successful, the infant may be given oral fluids after a period of observation. Failure to reduce the intussusception mandates surgery. Two approaches are used. In an open procedure, exploration is carried out through a right lower quadrant incision, delivering the intussuscepted mass into the wound. Reduction usually can be accomplished by gentle distal pressure, where the intussusceptum is gently milked out of the intussuscipiens (Fig. 39-20). Care should be taken not to pull the bowel out, as this can cause damage to the bowel wall. The blood supply to the appendix is often compromised, and appendectomy is performed. If the bowel is frankly gangrenous, resection and primary anastomosis are performed. In experienced hands, laparoscopic reduction may be performed, even in very young infants. This is performed using a 5-mm laparoscope placed in the umbilicus and two additional 5-mm ports in the left and right lower quadrants. The bowel is inspected, and if it appears to be viable, reduction is performed by milking the bowel or using gentle traction, although this approach is normally discouraged during manual reduction. Atraumatic bowel graspers allow the bowel to be handled without injuring it.

Figure 39-20. Open reduction of intussusception showing how the bowel is milked backward to relieve the obstruction.

IV fluids are continued until the postoperative ileus subsides. Patients are started on clear liquids, and their diet is advanced as tolerated. Of note, recurrent intussusception occurs in 5% to 10% of patients, independent of whether the bowel is reduced radiographically or surgically. Patients present with recurrent symptoms in the immediate postoperative period. Treatment involves repeat air enema, which is successful in most cases. In patients who experience three or more episodes of intussusception, the presence of a pathologic lead point should be suspected and carefully evaluated using contrast studies. After the third episode of intussusception, many pediatric surgeons will perform an exploratory laparotomy to reduce the bowel and to resect a pathologic lead point if identified.

Appendicitis

Presentation. Correct diagnosis of appendicitis in children can be one of the most humbling and challenging tasks facing the pediatric surgeon. The classical presentation is known to all students and practitioners of surgery: generalized abdominal pain that localizes to the right lower quadrant followed by nausea, vomiting, fever, and localized peritoneal irritation in the region of McBurney's point. When children present in this manner, there should be little diagnostic delay. The child should be made NPO, administered IV fluids and broad-spectrum antibiotics, and brought to the operating room for an appendectomy.

However, children often do not present in this manner. The coexistence of nonspecific viral syndromes and the inability of young children to describe the location and quality of their pain often result in diagnostic delay. As a result, children with appendicitis often present with perforation, particularly those who are under 5 years of age. Perforation increases the length of hospital stay and makes the overall course of the illness significantly more complex.

Diagnosis of Appendicitis in Children. Controversy exists regarding the role of radiographic studies in the diagnosis of acute appendicitis. Because children have less periappendiceal fat than adults, CT is less reliable in making the diagnosis. In addition, radiation exposure resulting from the CT scan may have potentially long-term adverse effects. Likewise, US is neither sufficiently sensitive nor specific to accurately make the diagnosis of appendicitis, although it is very useful for excluding ovarian causes of abdominal pain. Therefore, the diagnosis of appendicitis remains largely clinical, and each clinician should develop his or her own threshold to operate or to observe the patient. A reasonable practice guideline is as follows: When the diagnosis is clinically apparent, appendectomy should obviously be performed with minimal delay. Localized right lower quadrant tenderness associated with low-grade fever and leukocytosis in boys should prompt surgical exploration. In girls, ovarian or uterine pathology must also be considered. When there is diagnostic uncertainty, the child may be observed, rehydrated, and reassessed. In girls of menstruating age, US may be performed to exclude ovarian pathology (cysts, torsion, or tumor). If all studies are negative, yet the pain persists, and the abdominal findings remain equivocal, diagnostic laparoscopy may be employed to determine the etiology of the abdominal pain. The appendix should be removed even if it appears to be normal, unless another pathologic cause of the abdominal pain is definitively identified and the appendectomy would substantially increase morbidity.

Surgical Treatment of Appendicitis. The definitive treatment for acute appendicitis is appendectomy. Prior to surgery, it is important that patients receive adequate IV fluids in order to correct dehydration that commonly develops as a result of fever and vomiting in patients with appendicitis. Patients should also be started on antibiotics (such as a second-generation cephalosporin). Most surgeons will perform a laparoscopic appendectomy, which may have some advantage over removing the appendix through a single larger incision. During the laparoscopic appendectomy, a small incision is made at the umbilicus, and two additional incisions are made in the lower abdomen. The appendix is typically delivered through the umbilicus, and all incisions are then closed with dissolvable sutures. If the appendix is not ruptured, the patient may start drinking liquids shortly after waking up from the operation and may be advanced to a solid diet the next day. In general, the same steps are taken when appendectomy is performed through an open approach. The most common complication after appendectomy is a surgical site infection. Other risks, including bleeding or damage to other structures inside the abdomen, are extremely rare. Recovery from surgery is dependent on the individual patient. Most children are back to school approximately 1 week after surgery and usually are allowed to return to full physical activity after 2 to 3 weeks. During the recovery period, over-the-counter pain medication may be required. Older patients tend to require a longer time for full recovery.

Figure 39-21. Computed tomography scan of the abdomen showing the presence of a ruptured appendix with pelvic fluid and a fecalith (*arrow*).

Management of the Child with Perforated Appendicitis. The signs and symptoms of perforated appendicitis can closely mimic those of gastroenteritis and include abdominal pain, vomiting, and diarrhea. Alternatively, the child may present with symptoms of intestinal obstruction. An abdominal mass may be present in the lower abdomen. When the symptoms have been present for more than 4 or 5 days and an abscess is suspected, it is reasonable to obtain a CT of the abdomen and pelvis with IV, oral, and rectal contrast to visualize the appendix and the presence of an associated abscess, phlegmon, or fecalith (Fig. 39-21).

An individualized approach is necessary for the child who presents with perforated appendicitis. When there is evidence of generalized peritonitis, intestinal obstruction, or systemic toxicity, the child should undergo appendectomy. This should be delayed only for as long as is required to ensure adequate fluid resuscitation and administration of broad-spectrum antibiotics. The operation can be performed through an open or laparoscopic approach. One distinct advantage of the laparoscopic approach is that it provides excellent visualization of the pelvis and all four quadrants of the abdomen. At the time of surgery, adhesions are gently lysed, abscess cavities are drained, and the appendix is removed. Drains are seldom used, and the skin incisions can be closed primarily. If a fecalith is identified outside the appendix on CT, every effort should be made to retrieve it and to remove it along with the appendix, if at all possible. Often, the child in whom symptoms have been present for more than 4 or 5 days will present with an abscess without evidence of generalized peritonitis. Under these circumstances, it is appropriate to perform image-guided percutaneous drainage of the abscess followed by broad-spectrum antibiotic therapy. The inflammation will generally subside within several days, and the appendix can be safely removed as an outpatient 6 to 8 weeks later. If the child's symptoms do not improve or if the abscess is not amenable to percutaneous drainage, then laparoscopic or open appendectomy and abscess drainage is required. Patients who present with a phlegmon in the region of a perforated appendix may be managed in a similar manner. In general, children who are younger than 4 or 5 years of age do not respond as well to initial nonoperative approach because their bodies do not localize or isolate the inflammatory process. Thus, these patients are more likely to require early surgical intervention. Patients who have had symptoms of appendicitis for no more

than 4 days should probably undergo "early" appendectomy, since the inflammatory response is not as excessive during that initial period and the procedure can be performed safely.

Other Causes of Abdominal Pain That Mimic Appendicitis in Children. As mentioned earlier, appendicitis can be one of the most difficult diagnoses to establish in children with abdominal pain, in part because of the large number of diseases that present in a similar fashion. Patients with urinary tract infection can present very similar to those with appendicitis. However, patients with urinary tract infection are less likely to present with vomiting and are likely to also experience difficulty with urination, characterized by pressure, burning, and frequency. Constipation may be commonly confused with appendicitis in its earliest stages. However, patients with constipation rarely have fever and will not have abnormalities in their blood work. Ovarian torsion can mimic appendicitis, given the severe abdominal pain that accompanies this condition. However, patients with ovarian torsion are generally asymptomatic until the acute onset of severe pain. By contrast, patients with appendicitis generally experience gradual onset of pain associated with nausea and vomiting. Finally, children and young adults are always at risk for the development of gastroenteritis. However, unlike appendicitis, patients with gastroenteritis generally present with persistent vomiting and occasionally diarrhea, which precedes the onset of the abdominal pain.

Intestinal Duplications

Duplications represent mucosa-lined structures that are in continuity with the gastrointestinal tract. Although they can occur at any level in the gastrointestinal tract, duplications are found most commonly in the ileum within the leaves of the mesentery. Duplications may be long and tubular, but usually, they are cystic masses. In all cases, they share a common wall with the intestine. Symptoms associated with enteric duplication cysts include recurrent abdominal pain, emesis from intestinal obstruction, or hematochezia. Such bleeding typically results from ulceration in the duplication or in the adjacent intestine if the duplication contains ectopic gastric mucosa. On examination, a palpable mass is often identified. Children may also develop intestinal obstruction. Torsion may produce gangrene and perforation.

The ability to make a preoperative diagnosis of enteric duplication cyst usually depends on the presentation. CT, US, and technetium pertechnetate scanning can be very helpful. Occasionally, a duplication can be seen on small bowel follow-through or barium enema. In the case of short duplications, resection of the cyst and adjacent intestine with end-to-end anastomosis can be performed. If resection of long duplications would compromise intestinal length, multiple enterotomies and mucosal stripping in the duplicated segment will allow the walls to collapse and become adherent. An alternative method is to divide the common wall using the GIA stapler, forming a common lumen. Patients with duplications who undergo complete excision without compromise of the length of remaining intestine have an excellent prognosis.

Meckel's Diverticulum

A Meckel's diverticulum is a remnant of a portion of the embryonic omphalomesenteric (vitelline) duct. It is located on the antimesenteric border of the ileum, usually within 2 ft of the ileocecal valve (Fig. 39-22). It may be found incidentally at surgery or may present with inflammation masquerading as

Figure 39-22. Operative photograph showing the presence of a Meckel's diverticulum (*arrow*).

appendicitis. Perforation of a Meckel's diverticulum may occur if the outpouching becomes impacted with food, leading to distention and necrosis. Occasionally, bands of tissue extend from the Meckel's diverticulum to the anterior abdominal wall, and these may represent lead points around which internal hernias may develop. This is an important cause of intestinal obstruction in the older child who has a scarless abdomen. Similar to duplications, ectopic gastric mucosa may produce ileal ulcerations that bleed and lead to the passage of maroon-colored stools. Pancreatic mucosa may also be present. Diagnosis may be made by technetium pertechnetate scans when the patient presents with bleeding. Treatment is surgical. If the base is narrow and there is no mass present in the lumen of the diverticulum, a wedge resection of the diverticulum with transverse closure of the ileum can be performed. A linear stapler is especially useful in this circumstance. When a mass of ectopic tissue is palpable, if the base is wide, or when there is inflammation, it is preferable to perform a resection of the involved bowel and end-to-end ileoileostomy.

Mesenteric Cysts

Mesenteric cysts are similar to duplications in their location within the mesentery. However, they do not contain any mucosa or muscular wall. Chylous cysts may result from congenital lymphatic obstruction. Mesenteric cysts can cause intestinal obstruction or may present as an abdominal mass. The diagnosis may be made by abdominal US or CT. Treatment involves surgical excision. This may require resection of the adjacent intestine, particularly for extensive, multicystic lesions. In cases where complete excision is not possible due to the close proximity to vital structures, partial excision or marsupialization should be performed.

Hirschsprung's Disease

Pathogenesis. In his classic textbook entitled *Pediatric Surgery*, Dr. Orvar Swenson, who is eponymously associated with one of the classic surgical treatments for Hirschsprung's disease, described this condition as follows: "Congenital megacolon is caused by a malformation in the pelvic parasympathetic system which results in the absence of ganglion cells in Auerbach's plexus of a segment of distal colon. Not only is there an absence of ganglion cells, but the nerve fibers are large and excessive in number, indicating that the anomaly may be more extensive than the absence of ganglion cells." This narrative

of Hirschsprung's disease is as accurate today as it was more than 50 years ago and summarizes the essential pathologic features of this disease: absence of ganglion cells in Auerbach's plexus and hypertrophy of associated nerve trunks. The cause of Hirschsprung's disease remains incompletely understood, although current thinking suggests that the disease results from a defect in the migration of neural crest cells, which are the embryonic precursors of the intestinal ganglion cell. Under normal conditions, the neural crest cells migrate into the intestine from cephalad to caudad. The process is completed by the twelfth week of gestation, but the migration from midtransverse colon to anus takes 4 weeks. During this latter period, the fetus is most vulnerable to defects in migration of neural crest cells. This may explain why most cases of aganglionosis involve the rectum and rectosigmoid. The length of the aganglionic segment of bowel is therefore determined by the most distal region that the migrating neural crest cells reach. In rare instances, total colonic aganglionosis may occur.

Recent studies have shed light on the molecular basis for Hirschsprung's disease. Patients with Hirschsprung's disease have an increased frequency of mutations in several genes, including *GDNF*, its receptor *Ret*, or its coreceptor *Gfra-1*. Moreover, mutations in these genes also lead to aganglionic megacolon in mice, which provides the opportunity to study the function of the encoded proteins. Initial investigations indicate that GDNF promotes the survival, proliferation, and migration of mixed populations of neural crest cells in culture. Other studies have revealed that GDNF is expressed in the gut in advance of migrating neural crest cells and is chemoattractive for neural crest cells in culture. These findings raise the possibility that mutations in the *GDNF* or *Ret* genes could lead to impaired neural crest migration in utero and the development of Hirschsprung's disease.

Clinical Presentation. The incidence of sporadic Hirschsprung's disease is 1 in 5000 live births. There are reports of increased frequency of Hirschsprung's disease in multiple generations of the same family. Occasionally such families have mutations in the genes described earlier, including the *Ret* gene. Because the aganglionic colon does not permit normal peristalsis to occur, the presentation of children with Hirschsprung's disease is characterized by a functional distal intestinal obstruction. In the newborn period, the most common symptoms are abdominal distention, failure to pass meconium, and bilious emesis. Any infant who does not pass meconium beyond 48 hours of life must be investigated for the presence of Hirschsprung's disease. Occasionally, infants present with a dramatic complication of Hirschsprung's disease called enterocolitis. This pattern of presentation is characterized by abdominal distention and tenderness and is associated with manifestations of systemic toxicity that include fever, failure to thrive, and lethargy. Infants are often dehydrated and demonstrate a leukocytosis or increase in circulating band forms on hematologic evaluation. On rectal examination, forceful expulsion of foul-smelling liquid feces is typically observed and represents the accumulation of stool under pressure in an obstructed distal colon. Treatment includes rehydration, systemic antibiotics, nasogastric decompression, and rectal irrigations while the diagnosis of Hirschsprung's disease is being confirmed. In children who do not respond to nonoperative management, a decompressive stoma is required. It is important to ensure that this stoma is placed in ganglion-containing bowel, which must be confirmed by frozen section at the time of stoma creation.

In approximately 20% of cases, the diagnosis of Hirschsprung's disease is made beyond the newborn period. These children have severe constipation, which has usually been treated with laxatives and enemas. Abdominal distention and failure to thrive may also be present at diagnosis.

Diagnosis. The definitive diagnosis of Hirschsprung's disease is made by rectal biopsy. Samples of mucosa and submucosa are obtained at 1, 2, and 3 cm from the dentate line. This can be performed at the bedside in the neonatal period without anesthesia, as samples are taken in bowel that does not have somatic innervation and is thus not painful to the child. In older children, the procedure should be performed using IV sedation. The histopathology of Hirschsprung's disease is the absence of ganglion cells in the myenteric plexuses, increased acetylcholinesterase staining, and the presence of hypertrophied nerve bundles.

It is important to obtain a barium enema in children in whom the diagnosis of Hirschsprung's disease is suspected. This test may demonstrate the location of the transition zone between the dilated ganglionic colon and the distal constricted aganglionic rectal segment. Our practice is to obtain this test before instituting rectal irrigations if possible, so that the difference in size between the proximal and distal bowel is preserved. Although the barium enema can only suggest, but not reliably establish, the diagnosis of Hirschsprung's disease, it is very useful in excluding other causes of distal intestinal obstruction. These include small left colon syndrome (as occurs in infants of diabetic mothers), colonic atresia, meconium plug syndrome, or the unused colon observed in infants after the administration of magnesium or tocolytic agents. The barium enema in total colonic aganglionosis may show a markedly shortened colon. Some surgeons have found the use of rectal manometry helpful, particularly in older children, although it is relatively inaccurate.

Treatment. The diagnosis of Hirschsprung's disease requires surgery in all cases. The classic surgical approach consisted of a multiple-stage procedure. This included a colostomy in the newborn period, followed by a definitive pull-through operation after the child was over 10 kg. There are three viable options for the definitive pull-through procedure that are currently used. Although individual surgeons may advocate one procedure over another, studies have demonstrated that the outcome after each type of operation is similar. For each of the operations that is performed, the principles of treatment include confirming the location in the bowel where the transition zone between ganglionic and aganglionic bowel exists, resecting the aganglionic segment of bowel, and performing an anastomosis of ganglionated bowel to either the anus or a cuff of rectal mucosa (Fig. 39-23).

6▶

It is now well established that a primary pull-through procedure can be performed safely, even in the newborn period. This approach follows the same treatment principles as a staged procedure and saves the patient from an additional surgical procedure. Many surgeons perform the intra-abdominal dissection using the laparoscope. This approach is especially useful in the newborn period, as this provides excellent visualization of the pelvis. In children with significant colonic distention, it is important to allow for a period of decompression using a rectal tube if a single-staged pull-through is to be performed. In older children with very distended, hypertrophied colon, it may be prudent to perform a colostomy to allow the bowel to decompress, prior to performing a pull-through procedure. However,

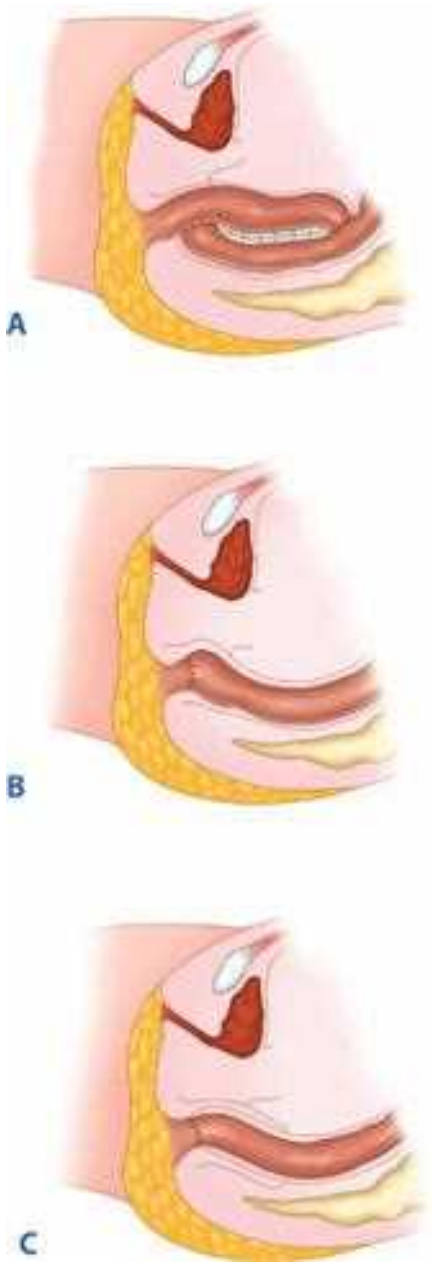

Figure 39-23. The three operations for surgical correction of Hirschsprung's disease. **A.** The Duhamel procedure leaves the rectum in place and brings ganglionic bowel into the retrorectal space. **B.** The Swenson procedure is a resection with end-to-end anastomosis performed by exteriorizing bowel ends through the anus. **C.** The Soave operation is performed by endorectal dissection and removal of mucosa from the aganglionic distal segment and bringing the ganglionic bowel down to the anus within the seromuscular tunnel.

it should be emphasized that there is no upper age limit for performing a primary pull-through.

Of the three pull-through procedures performed for Hirschsprung's disease, the first is the original Swenson procedure. In this operation, the aganglionic rectum is dissected in the pelvis and removed down to the anus. The ganglionic colon is then anastomosed to the anus via a perineal approach. In the Duhamel procedure, dissection outside the rectum is confined to the retrorectal space, and the ganglionic colon is anastomosed posteriorly just above the anus. The anterior wall of the ganglionic colon and the posterior wall of the aganglionic rectum are anastomosed using a stapler. Although both of these procedures are extremely effective, they are limited by the possibility of damage to the parasympathetic nerves that are adjacent to the rectum. To circumvent this potential problem, the Soave procedure involves dissection entirely within the rectum. The rectal mucosa is stripped from the muscular sleeve, and the ganglionic colon is brought through this sleeve and anastomosed to the anus. This operation may be performed completely from below. In all cases, it is critical that the level at which ganglionated bowel exists be determined. Most surgeons believe that the anastomosis should be performed at least 5 cm from the point at which ganglion cells are found. This avoids performing a pull-through in the transition zone, which is associated with a high incidence of complications due to inadequate emptying of the pull-through segment. Up to one third of patients who undergo a transition zone pull-through will require a reoperation.

The main complications of all of the procedures include postoperative enterocolitis, constipation, and anastomotic stricture. As mentioned, long-term results with the three procedures are comparable and generally excellent in experienced hands. These three procedures also can be adapted for total colonic aganglionosis in which the ileum is used for the pull-through segment.

Anorectal Malformations

Anatomic Description. Anorectal malformations describe a spectrum of congenital anomalies that include imperforate anus and persistent cloaca. Anorectal malformations occur in approximately 1 in 5000 live births and affect males and females almost equally. The embryologic basis includes failure of descent of the urorectal septum. The level to which this septum descends determines the type of anomaly that is present, which subsequently influences the surgical approach.

In patients with imperforate anus, the rectum fails to descend through the external sphincter complex. Instead, the rectal pouch ends "blindly" in the pelvis, above or below the levator ani muscle. In most cases, the blind rectal pouch communicates more distally with the genitourinary system or with the perineum through a fistulous tract. Traditionally, anatomic description of imperforate anus has been characterized as either "high" or "low" depending on whether the rectum ends above the levator ani muscle complex or partially descends through this muscle (Fig. 39-24). Based on this classification system, in male patients with high imperforate anus, the rectum usually

Figure 39-24. Low imperforate anus in a male. Note the well-developed buttocks. The perineal fistula was found at the midline raphe.

Figure 39-25. Imperforate anus in a female. A catheter has been placed into the fistula, which is in the vestibule of the vagina.

ends as a fistula into the membranous urethra. In females, high imperforate anus often occurs in the context of a persistent cloaca. In both males and females, low lesions are associated with a fistula to the perineum. In males, the fistula connects with the median raphe of the scrotum or penis. In females, the fistula may end within the vestibule of the vagina, which is located immediately outside the hymen or at the perineum.

Because this classification system is somewhat arbitrary, Peña proposed a classification system that specifically and unambiguously describes the location of the fistulous opening. In males, the fistula may communicate with: (a) the perineum (cutaneous perineal fistula); (b) the lowest portion of the posterior urethra (rectourethral bulbar fistula); (c) the upper portion of the posterior urethra (rectourethral prostatic fistula); or (d) the bladder neck (rectovesicular fistula). In females, the fistula may open to the perineum between the female genitalia and the center of the sphincter (cutaneous perineal fistula) or into the vestibule of the vagina (vestibular fistula) (Fig. 39-25). In both sexes, the rectum may end in a completely blind fashion (imperforate anus without fistula). In rare cases, patients may have a normal anal canal, yet there may be total atresia or severe stenosis of the rectum.

The most frequent defect in males is imperforate anus with rectourethral fistula, followed by rectoperineal fistula then rectovesical or rectobladder neck fistula. In females, the most frequent defect is the rectovestibular fistula, followed by the cutaneous perineal fistula. The third most common defect in females is the persistent cloaca. This lesion represents a wide spectrum of malformations in which the rectum, vagina, and urinary tract meet and fuse into a single common channel. On physical examination, a single perineal orifice is observed and is located at the place where the urethra normally opens. Typically, the external genitalia are hypoplastic.

Associated Malformations. Approximately 60% of patients have an associated malformation. The most common is a urinary tract defect, which occurs in approximately 50% of patients. Skeletal defects are also seen, and the sacrum is most commonly involved. Spinal cord anomalies, especially tethered cored, are common, particularly in children with high lesions. Gastrointestinal anomalies occur, most commonly EA. Cardiac anomalies may be noted, and occasionally patients present with a constellation of defects as part of the VACTERLL syndrome (described earlier).

Management of Patients with Imperforate Anus. Patients with imperforate anus are usually stable, and the diagnosis is readily apparent. Despite the obstruction, the abdomen is initially not distended, and there is rarely any urgency to intervene. The principles of management center around diagnosing the type of defect that is present (high vs. low) and evaluating the presence of associated anomalies. It may take up to 24 hours before the presence of a fistula on the skin is noted, and thus it is important to observe the neonate for some period before definitive surgery is undertaken. All patients should therefore have an orogastric tube placed and be monitored for the appearance of meconium in or around the perineum or in the urine. Investigation for associated defects should include an US of the abdomen to assess for the presence of urinary tract anomaly. Other tests should include an echocardiogram and spinal radiographs. A US of the spine should be performed to look for the presence of a tethered cord. To further classify the location of the fistula as either "high" vs. "low," a lateral abdominal radiograph can be obtained with a radiopaque marker on the perineum. By placing the infant in the inverted position, the distance between the most distal extent of air in the rectum and the perineal surface can be measured. This study is imprecise, however, and may add little to the overall management of these patients.

The surgical management of infants with imperforate anus is determined by the anatomic defect. In general, when a low lesion is present, only a perineal operation is required without a colostomy. Infants with a high lesion require a colostomy in the newborn period, followed by a pull-through procedure at approximately 2 months of age. When a persistent cloaca is present, the urinary tract needs to be carefully evaluated at the time of colostomy formation to ensure that normal emptying can occur and to determine whether the bladder needs to be drained by means of a vesicostomy. If there is any doubt about the type of lesion, it is safer to perform a colostomy rather than jeopardize the infant's long-term chances for continence by an injudicious perineal operation.

The type of pull-through procedure favored by most pediatric surgeons today is the posterior sagittal anorectoplasty (PSARP) procedure, as described by Peña and DeVries. This involves placing the patient in the prone jackknife position, dividing the levator ani and external sphincter complex in the midline posteriorly, dividing the communication between the gastrointestinal tract and the urinary tract, and bringing down the rectum after sufficient length is achieved. The muscles are then reconstructed and sutured to the rectum. The outcome of 1192 patients who had undergone this procedure has been reviewed by Peña and Hong. Seventy-five percent of patients were found to have voluntary bowel movements, and nearly 40% were considered totally continent. As a rule, patients with high lesions demonstrate an increased incidence of incontinence, whereas those with low lesions are more likely to be constipated. Management of patients with high imperforate anus can be greatly facilitated using a laparoscopic-assisted approach, in which the patient is operated on in the supine position, and the rectum is mobilized down to the fistulous connection to the bladder neck. This fistulous connection is then divided, and the rectum is completely mobilized down to below the peritoneal reflection. The operation then proceeds at the perineum, and the location of the muscle complex is determined using the nerve stimulator. A Veress needle is then advanced through the skin at the indicated site, with the laparoscope providing guidance to the exact intrapelvic orientation. Dilators are then placed over

the Veress needle, the rectum is pulled through this peritoneal opening, and an anoplasty is performed.

JAUNDICE

The Approach to the Jaundiced Infant

Jaundice is present during the first week of life in 60% of term infants and 80% of preterm infants. There is usually accumulation of unconjugated bilirubin, but there may also be deposition of direct bilirubin. During fetal life, the placenta is the principal route of elimination of unconjugated bilirubin. In the newborn infant, bilirubin is conjugated through the activity of *glucoronyl transferase*. In the conjugated form, bilirubin is water soluble, which results in its excretion into the biliary system and then into the gastrointestinal tract. Newborns have a relatively high level of circulating hemoglobin and relative immaturity of the conjugating machinery. This results in a transient accumulation of bilirubin in the tissues, which is manifested as jaundice. Physiologic jaundice is evident by the second or third day of life and usually resolves within approximately 5 to 7 days. By definition, jaundice that persists beyond 2 weeks is considered pathologic.

Pathologic jaundice may be due to biliary obstruction, increased hemoglobin load, or liver dysfunction. The workup of the jaundiced infant therefore should include a search for the following possibilities: (a) obstructive disorders, including biliary atresia, choledochal cyst, and inspissated bile syndrome; (b) hematologic disorders, including ABO incompatibility, Rh incompatibility, and spherocytosis; (c) metabolic disorders, including α_1-antitrypsin deficiency, galactosemia, and pyruvate kinase deficiency; and (d) congenital infection, including syphilis and rubella.

Biliary Atresia

Pathogenesis. Biliary atresia is a rare disease associated with significant morbidity and mortality. This disease is characterized by a fibroproliferative obliteration of the biliary tree, which progresses toward hepatic fibrosis, cirrhosis, and end-stage liver failure. The incidence of this disease is approximately 1 in 8000 to 1 in 18,000. The etiology of biliary atresia is likely multifactorial. In the classic textbook *Abdominal Surgery of Infancy and Childhood*, Ladd and Gross described the cause of biliary atresia as an "arrest of development during the solid stage of bile duct formation." Previously proposed theories on the etiology of biliary atresia have focused on defects in hepatogenesis, prenatal vasculogenesis, immune dysregulation, infectious agents, and exposure to toxins. More recently, genetic mutations in the *cfc1* gene, implicated in left-right axis determinations, were identified in patients with biliary atresia-splenic malformation syndrome. Additionally, the detection of a higher incidence of maternal microchimerism in the livers of males with biliary atresia has led to the suggestion that consequent expression of maternal antigens may lead to an autoimmune process leading to inflammation and obliteration of the biliary tree. Recent animal studies strongly implicate perinatal exposure to reovirus or rotavirus. Such viral exposure may lead to periportal inflammation mediated by interferon-γ and other cytokines.

Clinical Presentation. Infants with biliary atresia present with jaundice at birth or shortly thereafter. The diagnosis of biliary atresia is frequently not entertained by pediatricians in part because physiologic jaundice of the newborn is so common and biliary atresia is so uncommon. As such, it is not unusual for there to be a delay in diagnosis. However, infants with biliary atresia characteristically have acholic, pale gray–appearing stools, secondary to obstructed bile flow. With further passage of time, these infants manifest progressive failure to thrive, and if untreated, they develop stigmata of liver failure and portal hypertension, particularly splenomegaly and esophageal varices.

The obliterative process of biliary atresia involves the common duct, cystic duct, one or both hepatic ducts, and the gallbladder, in a variety of combinations. The histopathology of patients with biliary atresia includes inflammatory changes within the parenchyma of the liver, as well as fibrous deposition at the portal plates that is observed on trichrome staining of frozen tissue sections. In certain cases, bile duct proliferation may be seen, a relatively nonspecific marker of liver injury. Approximately 25% of patients with biliary atresia have coincidental malformations, often associated with polysplenia and which may include intestinal malrotation, preduodenal portal vein, and intrahepatic vena cava.

Diagnosis. In general, the diagnosis of biliary atresia is made using a combination of studies, as no single test is sufficiently sensitive or specific. Fractionation of the serum bilirubin is performed to determine if the associated hyperbilirubinemia is conjugated or unconjugated. Workup commonly includes the analysis of TORCH infection titers as well as viral hepatitis. Typically, US is performed to assess the presence of other causes of biliary tract obstruction including choledochal cyst. The absence of a gallbladder is highly suggestive of the diagnosis of biliary atresia. However, the presence of a gallbladder does not exclude the diagnosis of biliary atresia because in approximately 10% of biliary atresia patients, the distal biliary tract is patent and a gallbladder may be visualized, even though the proximal ducts are atretic. It is important to note that the intrahepatic bile ducts are never dilated in patients with biliary atresia. In many centers, a nuclear medicine scan using technetium-99m iminodiacetic acid, performed after pretreatment of the patient with phenobarbital, has proven to be an accurate and reliable study. If radionuclide appears in the intestine, there is patency of the biliary tree and the diagnosis of biliary atresia is excluded. If radionuclide is concentrated by the liver but not excreted despite treatment with phenobarbital and the metabolic screen, particularly α_1-antitrypsin determination, is normal, the presumptive diagnosis is biliary atresia. A percutaneous liver biopsy might potentially distinguish between biliary atresia and other sources of jaundice such as neonatal hepatitis. When these tests point to or cannot exclude the diagnosis of biliary atresia, surgical exploration is warranted. At surgery, a cholangiogram may be performed if possible, using the gallbladder as a point of access. This may be performed using a laparoscope. The cholangiogram demonstrates the anatomy of the biliary tree, determines whether extrahepatic bile duct atresia is present, and evaluates whether there is distal bile flow into the duodenum. The cholangiogram may demonstrate hypoplasia of the extrahepatic biliary system. This condition is associated with hepatic parenchymal disorders that cause severe intrahepatic cholestasis, including α_1-antitrypsin deficiency and biliary hypoplasia (Alagille's syndrome). Alternatively, a cursory assessment of the extrahepatic biliary tree may clearly delineate the atresia.

Inspissated Bile Syndrome. This term is applied to patients with normal biliary tracts who have persistent obstructive jaundice. Increased viscosity of bile and obstruction of the canaliculi

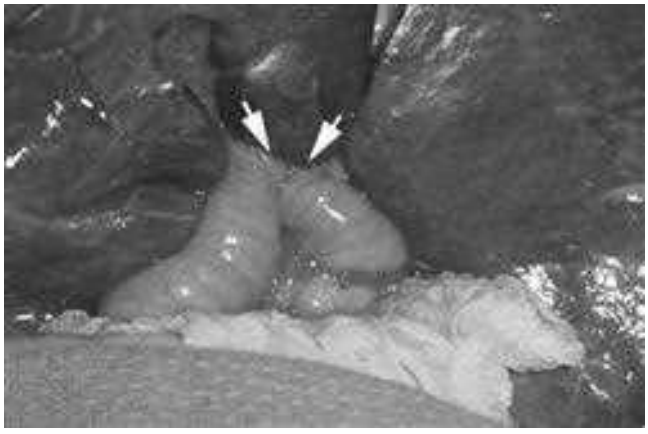

Figure 39-26. Operative photograph showing Kasai portoenterostomy. *Arrows* denote site of the anastomosis. Note the engorged liver.

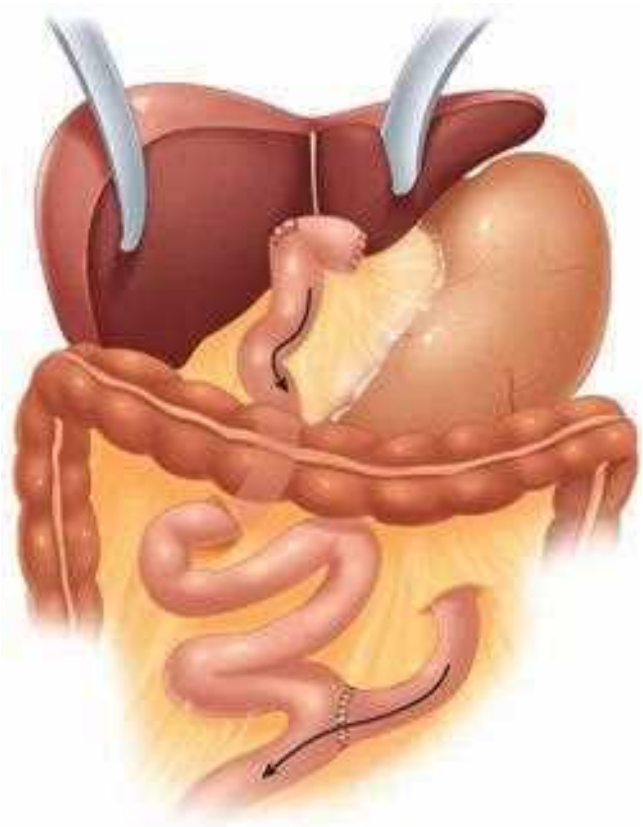

Figure 39-27. Schematic illustration of the Kasai portoenterostomy for biliary atresia. An isolated limb of jejunum is brought to the porta hepatis and anastomosed to the transected ducts at the liver plate.

are implicated as causes. The condition has been seen in infants receiving parenteral nutrition, but it is also encountered in conditions associated with hemolysis or in cystic fibrosis. In some instances, no etiologic factors can be defined. *Neonatal hepatitis* may present in a similar fashion to biliary atresia. This disease is characterized by persistent jaundice due to acquired biliary inflammation without obliteration of the bile ducts. There may be a viral etiology, and the disease is usually self-limited. In this case, cholangiography is both diagnostic and therapeutic.

Treatment. If the diagnosis of biliary atresia is confirmed intraoperatively, then surgical treatment is undertaken at the same setting. Currently, first-line therapy consists of creation of a hepatoportoenterostomy, as described by Kasai. The purpose of this procedure is to promote bile flow into the intestine. The procedure is based on Kasai's observation that the fibrous tissue at the porta hepatis invests microscopically patent biliary ductules that, in turn, communicate with the intrahepatic ductal system (Fig. 39-26). Transecting this fibrous tissue at the portal plate, invariably encountered cephalad to the bifurcating portal vein, opens these channels and establishes bile flow into a surgically constructed intestinal conduit, usually a Roux-en-Y limb of jejunum (Fig. 39-27). Some authors believe that an intussuscepted antireflux valve is useful in preventing retrograde bile reflux, although the data suggest that it does not impact outcome. A liver biopsy is performed at the time of surgery to determine the degree of hepatic fibrosis that is present. The diameter of bile ducts at the portal plate is predictive of likelihood of long-term success of biliary drainage through the portoenterostomy. Numerous studies also suggest that the likelihood of surgical success is inversely related to the age at the time of portoenterostomy. Infants treated prior to 60 days of life are more likely to achieve successful and long-term biliary drainage than older infants. Although the outlook is less favorable for patients after the twelfth week, it is reasonable to proceed with surgery even beyond this time point, as the alternative is certain liver failure. It is noteworthy that a significant number of patients have had favorable outcomes after undergoing portoenterostomy despite advanced age at time of diagnosis.

7▶

Bile drainage is anticipated when the operation is carried out early; however, bile flow does not necessarily imply cure. Approximately one third of patients remain symptom free after portoenterostomy; the remainder require liver transplantation due to progressive liver failure. Independent risk factors that predict failure of the procedure include bridging liver fibrosis at the time of surgery and postoperative cholangitic episodes. A review of the data of the Japanese Biliary Atresia Registry (JBAR), which includes the results of 1381 patients, showed that the 10-year survival rate was 53% without transplantation and 66.7% with transplantation. A common postoperative complication is cholangitis. There is no effective strategy to completely eliminate this complication, and the effectiveness of long-term prophylactic antibiotics has not been fully resolved. The Childhood Liver Research and Education Network (ChiLDREN, formerly the Biliary Atresia Research Consortium) is an active consortium of 15 children's hospitals in the United States, funded by the National Institutes of Health (NIH), which studies rare cholestatic liver diseases of infants and children (http://childrennetwork.org/). The primary disease of research interest is biliary atresia, as four of the seven active studies are dedicated to biliary atresia. Two of these four biliary atresia studies are therapeutic trials. Currently, enrollment for an NIH-funded, randomized, double-blind, placebo-controlled trial designed to determine if adjuvant steroids improves outcome of infants undergoing Kasai portoenterostomy has been completed. Treatment arms will be unblended, and outcomes of patients in this trial in terms of successful biliary drainage and survival with patients' native livers will be determined. Additionally, ChiLDREN is about to embark on a phase I trial looking at the safety and efficacy of adjuvant IV immunoglobulin (IVIg) given to infants with biliary atresia following Kasai portoenterostomy.

From this consortium, Superina and colleagues recently reported on the prospectively collected clinical, surgical, and outcomes data on 244 patients with biliary atresia. Notably, over 80% of infants manifested Ohi type III variant (atresia of the porta hepatis) compared with 10% with Ohi type I (atresia of the common bile duct) or 7% with Ohi type II (atresia of the hepatic duct). Outcomes analysis revealed a significantly greater survival with one's native liver for infants with type I compared with those with type II or III. Moreover, infants with Ohi distal subtype a (patent common bile duct) had significantly improved survival compared to those with Ohi distal subtypes b, c, or d (nonpatent common bile duct). Improved survival with the child's native liver was also observed in this study in patients less than 75 days old at time of Kasai portoenterostomy, no ascites at exploration, nonnodular liver, and low fibrosis score. Importantly, clearance of jaundice as defined by achieving a total bilirubin of less than 2 mg/dL within 3 months after portoenterostomy was highly predictive of survival with the native liver. The effect of hospital volume was not the focus of this publication. However, Davenport and colleagues recently reported on their experience in the United Kingdom where surgical care of infants with biliary atresia has been centralized to three hospitals. The authors report successful clearance of jaundice in 55% of patients, which is considerably better than clearance rates reported from the United States, France, or Switzerland and comparable to clearance rates reported from Taiwan where there is centralization of care.

Improved survival with one's native liver following Kasai portoenterostomy has previously been noted by numerous authors, as in the ChiLDREN consortium. Tseng and colleagues reported on improved rates of early diagnosis of biliary atresia (<60 days of age) following implementation of a national screening program for infant stool color in Taiwan. Given that early diagnosis of biliary atresia is associated with greater success of bile drainage, the authors reasonably speculate that higher rates of early diagnosis of biliary atresia nationally will translate into improved outcomes following the Kasai procedure.

Previous authors have published merits of revising the portoenterostomy in select patients if drainage of bile stops. Recently, Bondoc and colleagues reported on their experience with revision of portoenterostomies. Specifically, the authors reported on 183 patients who underwent Kasai portoenterostomy for biliary atresia, of whom 24 underwent revision for recurrence of nondrainage after successful bypass. Of the patients who underwent revision for nondrainage, 75% ultimately again achieved drainage after the second procedure, of whom nearly 50% survived long term with their native livers. The authors conclude that in selected patients in whom bile flow was established following the Kasai procedure and who then lost that flow, revision of the portoenterostomy is a reasonable treatment option with good success.

Choledochal Cyst

Classification. The term *choledochal cyst* refers to a spectrum of congenital biliary tract disorders that were previously grouped under the name *idiopathic dilation of the common bile duct*. After the classification system proposed by Alonso-Lej, five types of choledochal cyst are described. Type I cyst is characterized by fusiform dilatation of the bile duct. This is the most common type and is found in 80% to 90% of cases. A type II choledochal cyst appears as an isolated diverticulum protruding from the wall of the common bile duct. The cyst may be joined to the common bile duct by a narrow stalk. Type III choledochal cysts arise from the intraduodenal portion of the common bile duct and are also known as choledochoceles. Type IVA cysts consist of multiple dilatations of the intrahepatic and extrahepatic bile ducts. Type IVB choledochal cysts are multiple dilatations involving only the extrahepatic bile ducts. Type V (Caroli's disease) consists of multiple dilatations limited to the intrahepatic bile ducts.

Choledochal cyst is most appropriately considered the predominant feature in a constellation of pathologic abnormalities that can occur within the pancreato-biliary system. Frequently associated with choledochal cyst is an anomalous junction of the pancreatic and common bile ducts. The etiology of choledochal cyst is controversial. Babbit proposed an abnormal pancreatic and biliary duct junction, with the formation of a "common channel" into which pancreatic enzymes are secreted. This process results in weakening of the bile duct wall by gradual enzymatic destruction, leading to dilatation, inflammation, and finally cyst formation. Not all patients with choledochal cyst demonstrate an anatomic common channel, which raises questions regarding the accuracy of this model.

Clinical Presentation. Choledochal cyst is more common in females than in males (4:1). Typically these present in children beyond the toddler age group. The classic symptom triad consists of abdominal pain, mass, and jaundice. However, this complex is actually encountered in fewer than half of the patients. The more usual presentation is that of episodic abdominal pain, often recurring over the course of months or years and generally associated with only minimal jaundice that may escape detection. If left undiagnosed, patients may develop cholangitis or pancreatitis. Cholangitis may lead to the development of cirrhosis and portal hypertension. Choledochal cyst can present in the newborn period, where the symptoms are very similar to those of biliary atresia. Often neonates will have an abdominal mass at presentation.

Diagnosis. Choledochal cyst is frequently diagnosed in the fetus at a screening prenatal US. In the older child or adolescent, abdominal ultrasonography may reveal a cystic structure arising from the biliary tree. CT will confirm the diagnosis. These studies will demonstrate the dimensions of the cyst and define its relationship to the vascular structures in the porta hepatis, as well as the intrahepatic ductal configuration. Endoscopic retrograde cholangiopancreatography (ERCP) is reserved for patients in whom confusion remains after evaluation by less invasive imaging modalities. Magnetic resonance cholangiopancreatography may provide a more detailed depiction of the anatomy of the cyst and its relationship to the bifurcation of the hepatic ducts and into the pancreas.

Treatment. The cyst wall is composed of fibrous tissue and is devoid of mucosal lining. As a result, the treatment of choledochal cyst is surgical excision followed by biliary-enteric reconstruction. There is no role for internal drainage by cystoenterostomy, which leaves the cyst wall intact and leads to the inevitable development of cholangitis. Rarely, choledochal cyst can lead to the development of a biliary tract malignancy. This provides a further rationale for complete cyst excision.

Resection of the cyst requires circumferential dissection. The posterior plane between the cyst and portal vein must be carefully dissected to accomplish removal. The pancreatic duct, which may enter the distal cyst, is vulnerable to injury during distal cyst excision but can be avoided by avoiding

entry into the pancreatic parenchyma. In cases where the degree of pericystic inflammation is dense, it may be unsafe to attempt complete cyst removal. In this instance, it is reasonable to dissect within the posterior wall of the cyst, which allows the inner lining of the back wall to be dissected free from the outer layer that directly overlies the portal vascular structures. The lateral and anterior cyst, as well as the internal aspect of the back wall, is removed, yet the outer posterior wall remains behind. Cyst excision is accomplished, and the proximal bile duct is anastomosed to the intestinal tract typically via a Roux-en Y jejunal limb. More recently, laparoscopic-assisted resections of choledochal cysts have been described. In these cases, the end-to-side jejunojejunostomy is performed extracorporeally, but the remainder of the procedure is completed using minimally invasive techniques.

The prognosis for children who have undergone complete excision of choledochal cyst is excellent. Complications include anastomotic stricture, cholangitis, and intrahepatic stone formation. These complications may develop a long time after surgery has been completed.

DEFORMITIES OF THE ABDOMINAL WALL

Embryology of the Abdominal Wall

The abdominal wall is formed by four separate embryologic folds: cephalic, caudal, right, and left lateral folds. Each of these is composed of somatic and splanchnic layers and develops toward the anterior center portion of the coelomic cavity, joining to form a large umbilical ring that surrounds the two umbilical arteries, the vein, and the yolk sac or omphalomesenteric duct. These structures are covered by an outer layer of amnion, and the entire unit composes the umbilical cord. Between the fifth and tenth weeks of fetal development, the intestinal tract undergoes rapid growth outside the abdominal cavity within the proximal portion of the umbilical cord. As development is completed, the intestine gradually returns to the abdominal cavity. Contraction of the umbilical ring completes the process of abdominal wall formation.

Failure of the cephalic fold to close results in sternal defects such as congenital absence of the sternum. Failure of the caudal fold to close results in exstrophy of the bladder and, in more extreme cases, exstrophy of the cloaca. Interruption of central migration of the lateral folds results in omphalocele. Gastroschisis, originally thought to be a variant of omphalocele, possibly results from a fetal accident in the form of intrauterine rupture of a hernia of the umbilical cord, although other hypotheses have been advanced.

Umbilical Hernia

Failure of the umbilical ring to close results in a central defect in the linea alba. The resulting umbilical hernia is covered by normal umbilical skin and subcutaneous tissue, but the fascial defect allows protrusion of abdominal contents. Hernias less than a centimeter in size at the time of birth usually will close spontaneously by 4 to 5 years of life and, in most cases, should not undergo early repair. Sometimes the hernia is large enough that the protrusion is disfiguring and disturbing to both the child and the family. In such circumstances, early repair may be advisable (Fig. 39-28).

Umbilical hernias are generally asymptomatic protrusions of the abdominal wall. They are generally noted by parents or physicians shortly after birth. All families of patients with

Figure 39-28. Umbilical hernia in a 1-year-old female.

umbilical hernia should be counseled about signs of incarceration, which is rare in umbilical hernias and more common in smaller (≤1 cm) than larger defects. Incarceration presents with abdominal pain, bilious emesis, and a tender, hard mass protruding from the umbilicus. This constellation of symptoms mandates immediate exploration and repair of the hernia to avoid strangulation. More commonly, the child is asymptomatic and treatment is governed by the size of the defect, the age of the patient, and the concerns that the child and family have regarding the cosmetic appearance of the abdomen. When the defect is small and spontaneous closure is likely, most surgeons will delay surgical correction until 5 years of age. If closure does not occur by this time or a younger child has a very large or symptomatic hernia, it is reasonable to proceed to repair.

Repair of uncomplicated umbilical hernia is performed under general anesthesia as an outpatient procedure. A small curving incision that fits into the skin crease of the umbilicus is made, and the sac is dissected free from the overlying skin. The fascial defect is repaired with permanent or long-lasting absorbable, interrupted sutures that are placed in a transverse plane. The skin is closed using subcuticular sutures. The postoperative recovery is typically uneventful, and recurrence is rare, but more common in children with elevated intra-abdominal pressures such as those with a ventriculoperitoneal shunt.

Patent Urachus

During the development of the coelomic cavity, there is free communication between the urinary bladder and the abdominal wall through the urachus, which exits adjacent to the omphalomesenteric duct. Persistence of this tract results in a communication between the bladder and the umbilicus. The first sign of a patent urachus is moisture or urine flow from the umbilicus. Recurrent urinary tract infections can result. The urachus may be partially obliterated, with a remnant beneath the umbilicus in the extraperitoneal position as an isolated cyst that may be identified by US. A urachal cyst usually presents as an inflammatory mass inferior to the umbilicus. Initial treatment is drainage of the infected cyst followed by cyst excision as a separate procedure once the inflammation has resolved.

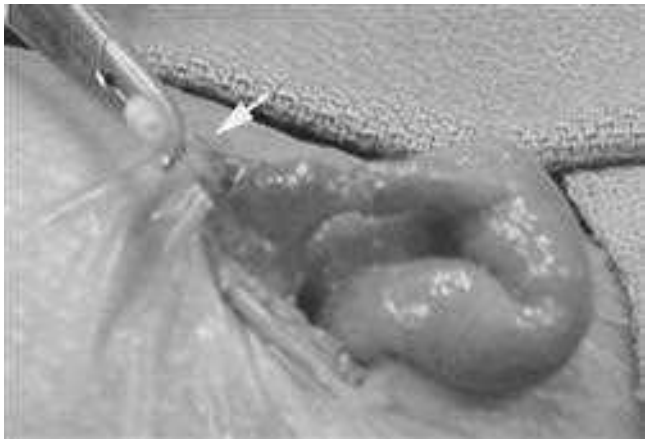

Figure 39-29. Patent vitelline duct. Note the communication between the umbilicus and the small bowel at the site of a Meckel's diverticulum.

In the child with a persistently draining umbilicus, a diagnosis of patent urachus should be considered. The differential diagnosis includes an umbilical granuloma, which generally responds to local application of silver nitrate. The diagnosis of patent urachus is confirmed by umbilical exploration. The urachal tract is excised and the bladder is closed with an absorbable suture. A patent vitelline duct may also present with umbilical drainage. In this circumstance, there is a communication with the small intestine, often at the site of a Meckel's diverticulum. Treatment includes umbilical exploration with resection of the duct remnant (Fig. 39-29).

Omphalocele

Presentation. Omphalocele refers to a congenital defect of the abdominal wall in which the bowel and solid viscera are covered by peritoneum and amniotic membrane (Fig. 39-30). The umbilical cord inserts into the sac. Omphalocele can vary from a small defect with intestinal contents to giant omphalocele in which the abdominal wall defect measures 4 cm or more in diameter and contains liver. The overall incidence is approximately 1 in 5000 live births, with 1 in 10,000 that are giant omphaloceles. Omphalocele occurs in association with special syndromes such as exstrophy of the cloaca (vesicointestinal fissure), the Beckwith-Wiedemann constellation of anomalies (macroglossia, macrosomia, hypoglycemia, and visceromegaly and omphalocele), and Cantrell's pentalogy (lower thoracic wall malformations [cleft sternum], ectopia cordis, epigastric omphalocele, anterior midline diaphragmatic hernia, and cardiac anomalies). There is a 60% to 70% incidence of associated anomalies, especially cardiac (20%–40% of cases) and chromosomal abnormalities. Chromosomal anomalies are more common in children with smaller defects. Omphalocele is associated with prematurity (10%–50% of cases) and intrauterine growth restriction (20% of cases).

8▶

Figure 39-30. Giant omphalocele in a newborn male.

Treatment. Immediate treatment of an infant with omphalocele consists of attending to the vital signs and maintaining the body temperature. A blood glucose should be evaluated because of the association with Beckwith-Wiedemann. The omphalocele should be covered to reduce fluid loss, but moist dressings may result in heat loss and are not indicated. No pressure should be placed on the omphalocele sac in an effort to reduce its contents, as this maneuver may increase the risk of rupture of the sac or may interfere with abdominal venous return. Prophylactic broad-spectrum antibiotics should be administered in case of rupture. The subsequent treatment and outcome are determined by the size of the omphalocele. In general terms, small to medium-sized defects have a significantly better prognosis than extremely large defects in which the liver is present. In these cases, not only is the management of the abdominal wall defect a significant challenge, but these patients often have concomitant pulmonary insufficiency that can lead to significant morbidity and mortality. If possible and if the pulmonary status will permit it, a primary repair of the omphalocele should be undertaken. This involves resection of the omphalocele membrane and closure of the fascia. A layer of prosthetic material may be required to achieve closure. In infants with a giant omphalocele, the defect cannot be closed primarily because there is not adequate intraperitoneal domain to reduce the viscera (see Fig. 39-30). Some infants may have associated congenital anomalies that complicate surgical repair, and because cardiac anomalies are common, an echocardiogram should be obtained prior to any procedure. If repair is contraindicated, a nonoperative approach can be used. The omphalocele sac can be treated with topical treatments. Various authors describe success with iodine-containing solutions, silver sulfadiazine, or saline, and some surgeons rotate these solutions because of the impact of iodine on the thyroid and the difficulty of cleaning off all of the silver sulfadiazine and its association with leukopenia. It typically takes 2 to 3 months before re-epithelialization occurs. In the past, mercury compounds were used, but they have been discontinued because of associated systemic toxicity. After epithelialization has occurred, attempts should be made to achieve closure of the anterior abdominal wall, but they may be delayed by associated pulmonary insufficiency. Such procedures typically require complex measures to achieve skin closure, including the use of biosynthetic materials or component separation. In cases of giant omphalocele, prolonged hospitalization is typical.

Figure 39-31. Gastroschisis in a newborn. Note the location of the umbilical cord and the edematous, thickened bowel.

Gastroschisis

Presentation. Gastroschisis represents a congenital anomaly characterized by a defect in the anterior abdominal wall through which the intestinal contents freely protrude. Unlike omphalocele, there is no overlying sac and the size of the defect is usually <4 cm. The abdominal wall defect is located at the junction of the umbilicus and normal skin and is almost always to the right of the umbilicus (Fig. 39-31). The umbilicus becomes partly detached, allowing free communication with the abdominal cavity. The appearance of the bowel provides some information with respect to the in utero timing of the defect. The intestine may be normal in appearance, suggesting that the rupture occurred relatively late during the pregnancy. More commonly, however, the intestine is thick, edematous, discolored, and covered with exudate, implying a more longstanding process. Progression to full enteral feeding is usually delayed, with diminished motility that may be related to these changes.

Unlike infants born with omphalocele, associated anomalies are not usually seen with gastroschisis except for a 10% rate of intestinal atresia. This defect can readily be diagnosed on prenatal US (Fig. 39-32). There is no advantage to performing a cesarean section instead of a vaginal delivery. In a decade-long retrospective review, early delivery did not affect the thickness of bowel peel, yet patients delivered before 36 weeks had significantly longer length of stay in the hospital and time to enteral feeds. Based on these findings, fetal well-being should be the primary determinant of the timing of delivery for gastroschisis.

Treatment. All infants born with gastroschisis require urgent surgical treatment. Of equal importance, these infants require vigorous fluid resuscitation in the range of 150 to 180 cc/kg/d to replace significant evaporative fluid losses. In many instances, the intestine can be returned to the abdominal cavity, and a primary surgical closure of the abdominal wall is performed. Some surgeons believe that they can facilitate primary closure with mechanical stretching of the abdominal wall, thorough orogastric suctioning with foregut decompression, rectal irrigation, and evacuation of meconium. Care must be taken to prevent markedly increased abdominal pressure during the reduction, which will lead to compression of the inferior vena cava, respiratory embarrassment, and abdominal compartment syndrome. To avoid this complication, it is helpful to monitor the bladder or airway pressures during reduction. In infants whose intestine has become thickened and edematous, it may be impossible to reduce the bowel into the peritoneal cavity in the immediate postnatal period. Under such circumstances, a plastic spring-loaded silo can be placed onto the bowel and secured beneath the fascia or a sutured silastic silo constructed. The silo covers the bowel and allows for graduated reduction on a daily basis as the edema in the bowel wall decreases (Fig. 39-33). It is important to ensure that the silo-fascia junction does not become a constricting point or "funnel" in which case the intestine will be injured upon return to the peritoneum. In this case, the fascial opening must be enlarged. Surgical closure can usually be accomplished within approximately 1 to 2 weeks. A prosthetic piece of material may be required to bring the edges of the fascia together. If an atresia is noted at the time of closure,

Figure 39-32. Prenatal ultrasound of a 30-week gestation fetus with a gastroschisis. *Arrows* point to the bowel outside within the amniotic fluid.

Figure 39-33. Use of a silo in a patient with gastroschisis to allow the bowel wall edema to resolve to facilitate subsequent closure of the abdominal wall.

it is prudent to reduce the bowel at the first operation, then to return after several weeks once the edema has resolved to correct the atresia. Intestinal function does not typically return for several weeks in patients with gastroschisis. This is especially true if the bowel is thickened and edematous. As a result, these patients will require central line placement and institution of TPN in order to grow. Feeding advancement should be slow and typically requires weeks to arrive at full enteral nutrition.

Prune-Belly Syndrome

Clinical Presentation. Prune-belly syndrome refers to a disorder that is characterized by extremely lax lower abdominal musculature, dilated urinary tract including the bladder, and bilateral undescended testes (Fig. 39-34). The term prune-belly syndrome appropriately describes the wrinkled appearance of the anterior abdominal wall that characterizes these patients. Prune-belly syndrome is also known as Eagle-Barrett syndrome and the triad syndrome, because of the three major manifestations. The incidence is significantly higher in males. Patients manifest a variety of comorbidities. The most significant is pulmonary hypoplasia, which is not survivable in the most severe cases. Skeletal abnormalities include dislocation or dysplasia of the hip and pectus excavatum.

The major genitourinary manifestation in prune-belly syndrome is ureteral dilation. The ureters are typically long and tortuous and become more dilated distally. Ureteric obstruction is rarely present, and the dilation may be caused by decreased smooth muscle and increased collagen in the ureters. Approximately 80% of these patients will have some degree of vesicoureteral reflux, which can predispose to urinary tract infection. Despite the marked dilatation of the urinary tract, most children with prune-belly syndrome have adequate renal parenchyma for growth and development. Factors associated with the development of long-term renal failure include the presence of abnormal kidneys on US or renal scan and persistent pyelonephritis.

Treatment. Despite the ureteric dilation, there is currently no role for ureteric surgery unless an area of obstruction develops. The testes are invariably intra-abdominal, and bilateral orchiopexy can be performed in conjunction with abdominal wall reconstruction at 6 to 12 months of age. Despite orchiopexy, fertility in a boy with prune-belly syndrome is unlikely as spermatogenesis over time is insufficient. Deficiencies in the production of prostatic fluid and a predisposition to retrograde ejaculation contribute to infertility. Abdominal wall repair is accomplished through an abdominoplasty, which typically requires a transverse incision in the lower abdomen extending into the flanks.

Figure 39-34. Eagle-Barrett (prune-belly) syndrome. Notice the lax, flaccid abdomen.

Inguinal Hernia

An understanding of the management of pediatric inguinal hernias is a central component of modern pediatric surgical practice. Inguinal hernia repair represents one of the most common operations performed in children. The presence of an inguinal hernia in a child is an indication for surgical repair. The operation is termed a herniorrhaphy because it involves closing off the patent processus vaginalis. This is to be contrasted with the hernioplasty that is performed in adults, which requires a reconstruction of the inguinal floor.

Embryology. In order to understand how to diagnose and treat inguinal hernias in children, it is critical to understand their embryologic origin. It is very useful to describe these events to the parents, who often are under the misconception that the hernia was somehow caused by their inability to console their crying child or by the child's high activity level. Inguinal hernia results from a failure of closure of the processus vaginalis, a finger-like projection of the peritoneum that accompanies the testicle as it descends into the scrotum. Closure of the processus vaginalis normally occurs a few months prior to birth. This explains the high incidence of inguinal hernias in premature infants. When the processus vaginalis remains completely patent, a communication persists between the peritoneal cavity and the groin, resulting in a hernia. Partial closure can result in entrapped fluid, which is known as a hydrocele. A communicating hydrocele refers to a hydrocele that is in communication with the peritoneal cavity and can therefore be thought of as a hernia. Using the classification system that is typically applied to adult hernias, all congenital hernias in children are by definition indirect inguinal hernias. Children also present with direct inguinal and femoral hernias, although these are much less common.

Clinical Manifestation. Inguinal hernias occur more commonly in males than females (10:1) and are more common on the right side than the left. Infants are at high risk for incarceration of an inguinal hernia because of the narrow inguinal ring. Patients most commonly present with a groin bulge that is noticed by the parents as they change the diaper (Fig. 39-35). Older children may notice the bulge themselves. On examination, the cord on the affected side will be thicker, and pressure

Figure 39-35. Right inguinal hernia in a 4-month-old male. The *arrows* point to the bulge in the right groin.

on the lower abdomen usually will display the hernia on the affected side. The presence of an incarcerated hernia is manifested by a firm bulge that does not spontaneously resolve and may be associated with fussiness and irritability in the child. The infant who has a strangulated inguinal hernia will manifest an edematous, tender bulge in the groin, occasionally with overlying skin changes. The child will eventually develop intestinal obstruction, peritonitis, and systemic toxicity.

Usually an incarcerated hernia can be reduced. Occasionally this may require light sedation. Gentle pressure is applied on the sac from below in the direction of the internal inguinal ring. Following reduction of the incarcerated hernia, the child may be admitted for observation, and herniorrhaphy is performed within the next 24 hours to prevent recurrent incarceration. Alternatively, the child may be scheduled for surgery at the next available time slot. If the hernia cannot be reduced or if evidence of strangulation is present, emergency operation is necessary. This may require a laparotomy and bowel resection.

When the diagnosis of inguinal hernia is made in an otherwise normal child, operative repair should be planned. Spontaneous resolution does not occur, and therefore, a nonoperative approach cannot ever be justified. An inguinal hernia in a female infant or child frequently contains an ovary rather than intestine. Although the gonad usually can be reduced into the abdomen by gentle pressure, it often prolapses in and out until surgical repair is carried out. In some patients, the ovary and fallopian tube constitute one wall of the hernia sac (sliding hernia), and in these patients, the ovary can be reduced effectively only at the time of operation. If the ovary is irreducible, prompt hernia repair is indicated to prevent ovarian torsion or strangulation.

When a hydrocele is diagnosed in infancy and there is no evidence of a hernia, observation is proper therapy until the child is older than 12 months. If the hydrocele has not disappeared by 12 months, invariably there is a patent processus vaginalis, and operative hydrocelectomy with excision of the processus vaginalis is indicated. When the first signs of a hydrocele are seen after 12 months of age, the patient should undergo elective hydrocelectomy, which in a child is always performed through a groin incision. Aspiration of hydroceles is discouraged, since almost all without a patent processus vaginalis will resorb spontaneously, and those with a communication to the peritoneum will recur and require operative repair eventually. Transillumination as a method to distinguish between hydrocele and hernia is nonspecific. A noncommunicating hydrocele is better identified by palpation of a nonreducible oval structure that appears to have a blunt end below the external ring, indicating an isolated fluid collection without a patent connection to the peritoneum.

Surgical Repair. The repair of a pediatric inguinal hernia can be extremely challenging, particularly in the premature child with incarceration. A small incision is made in a skin crease in the groin directly over the internal inguinal ring. Scarpa's fascia is seen and divided. The external oblique muscle is dissected free from overlying tissue, and the location of the external ring is confirmed. The external oblique aponeurosis is then opened along the direction of the external oblique fibers over the inguinal canal. The undersurface of the external oblique is then cleared from surrounding tissue. The cremasteric fibers are separated from the cord structures and hernia sac, and these are then elevated into the wound. Care is taken not to grasp the vas deferens. The hernia sac is then dissected up to the internal ring and doubly suture ligated. The distal part of the hernia sac is opened widely to drain any hydrocele fluid. When the hernia is very large and the patient very small, tightening of the internal inguinal ring or even formal repair of the inguinal floor may be necessary, although the vast majority of children do not require any treatment beyond high ligation of the hernia sac.

Controversy exists regarding the role for exploration of an asymptomatic opposite side in a child with an inguinal hernia. Several reports indicate that frequency of a patent processus vaginalis on the side opposite the obvious hernia is approximately 30%, although this figure decreases with increasing age of the child. Management options include never exploring the opposite side or exploring only under certain conditions such as in premature infants or in patients in whom incarceration is present. The opposite side may readily be explored laparoscopically. To do so, a blunt 3-mm trocar is placed into the hernia sac of the affected side. The abdominal cavity is insufflated, and the 2.7-mm 70° camera is placed through the trocar such that the opposite side is visualized. The status of the processes vaginalis on the opposite side can be visualized. However, the presence of a patent processus vaginalis by laparoscopy does not always imply the presence of a hernia.

Several authors have now reported a completely laparoscopic approach in the management of inguinal hernias in children. This technique requires insufflation through the umbilicus and the placement of an extraperitoneal suture to ligate the hernia sac. Proponents of this procedure emphasize the fact that no groin incision is used and there is a decreased chance of injuring cord structures. The long-term results of this technique remain to be established.

Inguinal hernias in children recur in less than 1% of patients, and recurrences usually result from missed hernia sacs at the first procedure, a direct hernia, or a missed femoral hernia. All children should have local anesthetic administered either by caudal injection or by direct injection into the wound. Spinal anesthesia in the preterm infant decreases the risk of postoperative apnea when compared with general anesthesia.

GENITALIA

Undescended Testis

Embryology. The term undescended testicle (cryptorchidism) refers to the interruption of the normal descent of the testis into the scrotum. The testicle may reside in the retroperineum, in the internal inguinal ring, in the inguinal canal, or even at the external ring. The testicle begins as a thickening on the urogenital ridge in the fifth to sixth week of embryologic life. In the seventh and eighth months, the testicle descends along the inguinal canal into the upper scrotum, and with its progress, the processus vaginalis is formed and pulled along with the migrating testicle. At birth, approximately 95% of infants have the testicle normally positioned in the scrotum.

A distinction should be made between an undescended testicle and an ectopic testicle. An ectopic testis, by definition, is one that has passed through the external ring in the normal pathway and then has come to rest in an abnormal location overlying either the rectus abdominis or external oblique muscle, or the soft tissue of the medial thigh, or behind the scrotum in the perineum. A congenitally absent testicle results from failure of normal development or an intrauterine accident leading to loss of blood supply to the developing testicle.

Clinical Presentation. The incidence of undescended testes is approximately 30% in preterm infants and 1% to 3% in term infants. For diagnosis, the child should be examined in the supine position, where visual inspection may reveal a hypoplastic or poorly rugated scrotum. Usually a unilateral undescended testicle can be palpated in the inguinal canal or in the upper scrotum. Occasionally, the testicle will be difficult or impossible to palpate, indicating either an abdominal testicle or congenital absence of the gonad. If the testicle is not palpable in the supine position, the child should be examined with his legs crossed while seated. This maneuver diminishes the cremasteric reflex and facilitates identification of the location of the testicle. If there is uncertainty regarding location of a testis, repeated evaluations over time may be helpful.

It is now established that cryptorchid testes demonstrate an increased predisposition to malignant degeneration. In addition, fertility is decreased when the testicle is not in the scrotum. For these reasons, surgical placement of the testicle in the scrotum (orchidopexy) is indicated. It should be emphasized that this procedure does improve the fertility potential, although it is never normal. Similarly, the testicle is still at risk of malignant change, although its location in the scrotum facilitates potentially earlier detection of a testicular malignancy. Other reasons to consider orchidopexy include the risk of trauma to the testicle located at the pubic tubercle and increased incidence of torsion, as well as the psychological impact of an empty scrotum in a developing male. The reason for malignant degeneration is not established, but the evidence points to an inherent abnormality of the testicle that predisposes it to incomplete descent and malignancy rather than malignancy as a result of an abnormal environment.

Treatment. Males with bilateral undescended testicles are often infertile. When the testicle is not within the scrotum, it is subjected to a higher temperature, resulting in decreased spermatogenesis. Mengel and coworkers studied 515 undescended testicles by histology and demonstrated a decreasing presence of spermatogonia after 2 years of age. Despite orchidopexy, the incidence of infertility is approximately two times higher in men with unilateral orchidopexy compared to men with normal testicular descent. Consequently, it is now recommended that the undescended testicle be surgically repositioned by 1 year of age.

The use of chorionic gonadotropin occasionally may be effective in patients with bilateral undescended testes, suggesting that these patients are more apt to have a hormone insufficiency than children with unilateral undescended testicle. The combination of micro-penis and bilateral undescended testes is an indication for hormonal evaluation and testosterone replacement if indicated. If there is no testicular descent after a month of endocrine therapy, operative correction should be undertaken. A child with unilateral cryptorchidism should have surgical correction of the problem. The operation is typically performed through a combined groin and scrotal incision. The cord vessels are fully mobilized, and the testicle is placed in a dartos pouch within the scrotum. An inguinal hernia often accompanies a cryptorchid testis. This should be repaired at the time of orchidopexy.

Patients with a nonpalpable testicle present a challenge in management. The current approach involves laparoscopy to identify the location of the testicle. If the spermatic cord is found to traverse the internal ring or the testis is found at the ring and can be delivered into the scrotum, a groin incision is made and an orchidopexy is performed. If an abdominal testis is identified that is too far to reach the scrotum, a two-stage Fowler-Stephens approach is used. In the first stage, the testicular vessels can be clipped via laparotomy or laparoscopically. This promotes neovasculogenesis along the vas deferens. Several months later, the second stage is performed during which the testis is mobilized intra-abdominally along with a swath of peritoneum with collateralized blood supply along the vas. This may be done laparoscopically as well. Preservation of the gubernacular attachments with its collaterals to the testicle may confer improved testicular survival following orchidopexy in over 90% of cases. It is, nonetheless, preferable to preserve the testicular vessels whenever possible and complete mobilization of the testicle with its vessels intact. Some surgeons advocate aggressive mobilization of testicular vessels up to the renal hilum if the intra-abdominal testis is within 1 or 2 cm of the internal ring. Other surgeons feel that the staged approach to orchidopexy is superior. To date, no large-scale trial has been performed to answer this question. In either case, meticulous mobilization of the intra-abdominal testis is critical for its survival and successful pexy.

Vaginal Anomalies

Surgical diseases of the vagina in children are either congenital or acquired. Congenital anomalies include a spectrum of diseases that range from simple defects (imperforate hymen) to more complex forms of vaginal atresia, including distal, proximal, and, most severe, complete. These defects are produced by abnormal development of müllerian ducts and/or urogenital sinus. The diagnosis is made most often by physical examination. Secretions into the obstructed vagina produce hydrocolpos, which may present as a large, painful abdominal mass. The anatomy may be defined using US. Pelvic MRI provides the most thorough and accurate assessment of the pelvic structures. Treatment is dependent on the extent of the defect. For an imperforate hymen, division of the hymen is curative. More complex forms of vaginal atresia require mobilization of the vaginal remnants and creation of an anastomosis at the perineum. Laparoscopy can be extremely useful in mobilizing the vagina, in draining hydrocolpos, and in evaluating the internal genitalia. Complete vaginal atresia requires the construction of skin flaps or the creation of a neovagina using a segment of colon.

The most common acquired disorder of the vagina is the straddle injury. This often occurs as young girls fall on blunt objects, which cause a direct injury to the perineum. Typical manifestations include vaginal bleeding and inability to void. Unless the injury is extremely superficial, patients should be examined in the operating room where the lighting is optimal and sedation can be administered. Vaginal lacerations are repaired using absorbable sutures, and the proximity to the urethra should be carefully assessed. Prior to hospital discharge, it is important that girls are able to void spontaneously. In all cases of vaginal trauma, it is essential that the patient be assessed for the presence of sexual abuse. In these cases, early contact with the sexual abuse service is necessary, so that the appropriate microbiologic and photographic evidence can be obtained.

Ovarian Cysts and Tumors

Pathologic Classification. Ovarian cysts and tumors may be classified as nonneoplastic or neoplastic. Nonneoplastic lesions include cysts (simple, follicular, inclusion, paraovarian, or corpus luteum), endometriosis, and inflammatory lesions. Neoplastic lesions are classified based on the three primordia

that contribute to the ovary: mesenchymal components of the urogenital ridge, germinal epithelium overlying the urogenital ridge, and germ cells migrating from the yolk sac. The most common variety is germ cell tumors. Germ cell tumors are classified based on the degree of differentiation and the cellular components involved. The least differentiated tumors are the dysgerminomas, which share features similar to the seminoma in males. Although these are malignant tumors, they are extremely sensitive to radiation and chemotherapy. The most common lesions are the teratomas, which may be mature, immature, or malignant. The degree of differentiation of the neural elements of the tumor determines the degree of immaturity. The sex cord stromal tumors arise from the mesenchymal components of the urogenital ridge. These include the granulosa-theca cell tumors and the Sertoli-Leydig cell tumors. These tumors often produce hormones that result in precocious puberty or hirsutism, respectively. Although rare, epithelial tumors do occur in children. These include serous and mucinous cystadenomas.

Clinical Presentation. Children with ovarian lesions usually present with abdominal pain. Other signs and symptoms include a palpable abdominal mass, evidence of urinary obstruction, symptoms of bowel obstruction, and endocrine imbalance. The surgical approach depends on the appearance of the mass at operation (i.e., whether it is benign-appearing or is suspicious for malignancy). In the case of a simple ovarian cyst, surgery depends on the size of the cyst and the degree of symptoms it causes. In general, large cysts (over 4–5 cm in size) should be resected, as they are unlikely to resolve, may be at risk of torsion, and may mask an underlying malignancy. Resection may be performed laparoscopically; ovarian tissue should be spared in all cases.

Surgical Management. For ovarian lesions that appear malignant, it is important to obtain tumor markers including α-fetoprotein (teratomas), lactate dehydrogenase (dysgerminoma), β-human chorionic gonadotropin (choriocarcinoma), and CA-125 (epithelial tumors). Although the diagnostic sensitivity of these markers is not always reliable, they provide material for postoperative follow-up and indicate the response to therapy. When a malignancy is suspected, the patient should undergo a formal cancer operation. This procedure is performed through either a midline incision or a Pfannenstiel approach. Ascites and peritoneal washings should be collected for cytologic study. The liver and diaphragm are inspected carefully for metastatic disease. An omentectomy is performed if there is any evidence of tumor present. Pelvic and para-aortic lymph nodes are biopsied, and the primary tumor is resected completely. Finally, the contralateral ovary is carefully inspected, and if a lesion is seen, it should be biopsied. Dysgerminomas and epithelial tumors may be bilateral in up to 15% of cases. It is occasionally possible to preserve the ipsilateral fallopian tube. More radical procedures are not indicated.

Ovarian Cysts in the Newborn. An increasing number of ovarian cysts are being detected by prenatal US. In the past, surgical excision was recommended for all cysts greater than 5 cm in diameter because of the perceived risk of ovarian torsion. More recently, it has become apparent from serial US examinations that many of these lesions will resolve spontaneously. Therefore, asymptomatic, simple cysts may be observed, and surgery can be performed only when they fail to decrease in size or become symptomatic. Typically, resolution occurs by approximately 6 months of age. A laparoscopic approach is preferable in these cases. By contrast, complex cysts of any size require surgical intervention at presentation.

Ambiguous Genitalia

Embryology. Normal sexual differentiation occurs in the sixth fetal week. In every fetus, wolffian (male) and müllerian (female) ducts are present until the onset of sexual differentiation. Normal sexual differentiation is directed by the sex-determining region of the Y chromosome (SRY). This is located on the distal end of the short arm of the Y chromosome. SRY provides a genetic switch that initiates gonadal differentiation in the mammalian urogenital ridge. Secretion of müllerian-inhibiting substance (MIS) by the Sertoli cells of the seminiferous tubules results in regression of the müllerian duct, the anlage of the uterus, fallopian tubes, and the upper vagina. Therefore, the result of MIS secretion is a phenotypic male. In the absence of SRY in the Y chromosome, MIS is not produced, and the müllerian duct derivatives are preserved. Thus, the female phenotype prevails.

In order for the male phenotype to develop, the embryo must have a Y chromosome, the SRY must be normal without point mutations or deletions, testosterone and MIS must be produced by the differentiated gonad, and the tissues must respond to these hormones. Any disruption of the orderly steps in sexual differentiation may result in disorders of sex development (DSDs), formerly known as intersex syndromes. DSDs are now classified as: (a) ovotesticular DSD or 46,XX testicular DSD (formerly referred to as true hermaphrodite), (b) 46,XY DSD (male pseudohermaphrodite), (c) 46,XX DSD (female pseudohermaphrodite), and (d) mixed gonadal dysgenesis (usually underdeveloped or imperfectly formed gonads).

Ovotesticular DSD or 46,XX Testicular DSD. This represents the rarest form of ambiguous genitalia. Patients have both normal male and female gonads, with an ovary on one side and a testis on the other. Occasionally, an ovotestis is present on one or both sides. The majority of these patients have a 46,XX karyotype. Both the testis and the testicular portion of the ovotestis should be removed.

46,XY DSD. This condition occurs in infants with an XY karyotype but deficient masculinization of the external genitalia. Bilateral testes are present, but the duct structures differentiate partly as phenotypic females. Causes include inadequate testosterone production due to biosynthetic error, inability to convert testosterone to dihydrotestosterone due to 5-α-reductase deficiency, or deficiencies in androgen receptors. The latter disorder is termed testicular feminization syndrome. Occasionally, the diagnosis in these children is made during routine inguinal herniorrhaphy in a phenotypic female at which time testes are found. The testes should be resected due to the risk of malignant degeneration, although this should be performed only after a full discussion with the family has occurred.

46,XX DSD. The most common cause of this disorder is congenital adrenal hyperplasia. These children have a 46,XX karyotype but have been exposed to excessive androgens in utero. Common enzyme deficiencies include 21-hydroxylase, 11-hydroxylase, and 3-β-hydroxysteroid dehydrogenase. These deficiencies result in overproduction of intermediary steroid hormones, which results in masculinization of the external genitalia of the XX fetus. These patients are unable to synthesize cortisol. In 90% of cases, deficiency of 21-hydroxylase causes adrenocorticotropic hormone (ACTH) to stimulate the secretion

Figure 39-36. Ambiguous genitalia manifest as enlarged clitoris and labioscrotal folds in a baby with the adrenogenital syndrome.

of excessive quantities of adrenal androgen, which masculinizes the developing female (Fig. 39-36). These infants are prone to salt loss and require cortisol replacement. Those with mineralocorticoid deficiency also require fludrocortisone replacement.

Mixed Gonadal Dysgenesis. This syndrome is associated with dysgenetic gonads and retained müllerian structures. The typical karyotype is mosaic, usually 45,XO/46,XY. There is a high incidence of malignant tumors in the dysgenetic gonads, most commonly gonadoblastoma. Therefore, they should be removed.

Management. In the differential diagnosis of patients with intersex anomalies, the following diagnostic steps are necessary: (a) evaluation of the genetic background and family history; (b) assessment of the anatomic structures by physical examination, US, and/or chromosome studies; (c) determination of biochemical factors in serum and urine to evaluate the presence of an enzyme defect; and (d) laparoscopy for gonadal biopsy. Treatment should include correction of electrolyte and volume losses in cases of congenital adrenal hyperplasia and replacement of hormone deficiency. Surgical assignment of gender should never be determined at the first operation. Although historically female gender had been assigned, there is abundant and convincing evidence that raising a genotypic male as a female has devastating consequences, not only anatomically but also psychosocially. This is particularly relevant given the role of pre- and postnatal hormones on gender imprinting and identity. In general terms, surgical reconstruction should be performed after a full genetic workup and with the involvement of pediatric endocrinologists, pediatric plastic surgeons, and ethicists with expertise in gender issues. Discussion with the family also plays an important role. This approach will serve to reduce the anxiety associated with these disorders and will help to ensure the normal physical and emotional development of these patients.

PEDIATRIC MALIGNANCY

Cancer is the second leading cause of death in children after trauma and accounts for approximately 11% of all pediatric deaths in the United States. Several features distinguish pediatric from adult cancers, including the presence of tumors that are predominantly seen in children, such as neuroblastoma and germ cell tumors, and the favorable response to chemotherapy observed for many pediatric solid malignancies, even in the presence of metastases.

Wilms' Tumor

Clinical Presentation. Wilms' tumor is the most common primary malignant tumor of the kidney in children. There are approximately 500 new cases annually in the United States, and most are diagnosed between 1 and 5 years with the peak incidence at age 3. Advances in the care of patients with Wilms' tumor have resulted in an overall cure rate of roughly 90%, even in the presence of metastatic spread. The tumor usually develops in otherwise healthy children as an asymptomatic mass in the flank or upper abdomen. Frequently, the mass is discovered by a parent while bathing or dressing the child. Other symptoms include hypertension, hematuria, obstipation, and weight loss. Occasionally the mass is discovered following blunt abdominal trauma.

Genetics of Wilms' Tumor. Wilms' tumor can arise from both germline and somatic mutations and can occur in the presence or absence of a family history. Nearly 97% of Wilms' tumors are sporadic, in that they occur in the absence of a heritable or congenital cause or risk factor. When a heritable risk factor is identified, the affected children often present at an earlier age and are frequently bilateral. Most of these tumors are associated with germline mutations. It is well established that there is a genetic predisposition to Wilms' tumor in the WAGR syndrome, which consists of *W*ilms' tumor, *a*niridia, *g*enitourinary abnormalities, and mental *r*etardation. In addition, there is an increased incidence of Wilms' tumor in certain overgrowth conditions, particularly Beckwith-Wiedemann syndrome and hemihypertrophy. The WAGR syndrome has been shown to result from the deletion of one copy each of the Wilms' tumor gene, *WT1*, and the adjacent aniridia gene, *PAX6*, on chromosome 11p13. Beckwith-Wiedemann syndrome is an overgrowth syndrome that is characterized by visceromegaly, macroglossia, and hyperinsulinemic hypoglycemia. It arises from mutations at the 11p15.5 locus. There is evidence to suggest that analysis of the methylation status of several genes in the 11p15 locus could predict the individual risk of developing Wilms' tumor. Importantly, most patients with Wilms' tumor do not have mutations at these genetic loci.

Surgical Treatment. Before operation, all patients suspected of having Wilms' tumor should undergo abdominal and chest CT. These studies characterize the mass, identify the presence of metastases, and provide information on the opposite kidney (Fig. 39-37). CT scanning also indicates the presence of nephrogenic rests, which are precursor lesions to Wilms' tumor. An abdominal US should be performed to evaluate the presence of renal vein or vena caval extension.

The management of patients with Wilms' tumor has been carefully analyzed within the context of large studies involving thousands of patients. These studies have been coordinated by the National Wilms' Tumor Study Group (NWTSG) in North America and the International Society of Paediatric Oncology (SIOP), mainly involving European countries. Significant differences in the approach to patients with Wilms' tumor have been highlighted by these studies. NWTSG supports a strategy of surgery followed by chemotherapy in most instances, whereas the SIOP approach is to shrink the tumor using preoperative chemotherapy. There are instances were preoperative chemotherapy is supported by both

Figure 39-37. Wilms' tumor of the right kidney (*arrow*) in a 3-year-old girl.

groups, including the presence of bilateral involvement or inferior vena cava involvement that extends above the hepatic veins and involvement of a solitary kidney by Wilms' tumor. The NWTSG proponents argue that preoperative therapy in other instances results in a loss of important staging information, and therefore places patients at higher risk for recurrence; alternatively, it may lead to overly aggressive treatment in some cases and greater morbidity. However, the overall survival rates are not different between the NWTSG and SIOP approaches.

The goal of surgery is complete removal of the tumor. It is crucial to avoid tumor rupture or injury to contiguous organs. A sampling of regional lymph nodes should be included, and all suspicious nodes should be sampled. Typically a transverse abdominal incision is made, and a transperitoneal approach is used. The opposite side is carefully inspected to ensure that there is no disease present. Although historically this involved the complete mobilization of the contralateral kidney, current evidence indicates that preoperative high-resolution CT scanning is of sufficient accuracy for the detection of clinically significant lesions if they are present. Provided only unilateral disease is present, a radical nephroureterectomy is then performed with control of the renal pedicle as an initial step. If there is spread above the hepatic veins, an intrathoracic approach may be required. If bilateral disease is encountered, both lesions are biopsied, and chemotherapy is administered followed by a nephron-sparing procedure.

Chemotherapy. Following nephroureterectomy for Wilms' tumor, the need for chemotherapy and/or radiation therapy is determined by the histology of the tumor and the clinical stage of the patient (Table 39-3). Essentially, patients who have disease confined to one kidney that is completely excised surgically receive a short course of chemotherapy and can expect a 97% 4-year survival, with tumor relapse rare after that time. Patients with more advanced disease or with unfavorable histology receive more intensive chemotherapy and radiation. Even in stage IV, cure rates of 80% are achieved. The survival rates are worse in the small percentage of patients considered to have unfavorable histology.

Table 39-3

Staging of Wilms' tumor

Stage I: Tumor limited to the kidney and completely excised.
Stage II: Tumor that extends beyond the kidney but is completely excised. No residual tumor is apparent at or beyond the margins of excision. The tumor was biopsied, or there was local spillage of tumor confined to the flank.
Stage III: Residual tumor confined to the abdomen. Lymph nodes in the renal hilus, the periaortic chains, or beyond contain tumor. Diffuse peritoneal contamination by the tumor, such as by spillage of tumor beyond the flank before or during surgery or by tumor growth that has penetrated through the peritoneal surface. Implants are found on the peritoneal surfaces. Tumor extends beyond the surgical margins either microscopically or grossly. Tumor is not completely resectable because of local infiltration into vital structures.
Stage IV: Hematogenous metastases
Stage V: Bilateral renal involvement

Neuroblastoma

Clinical Presentation. Neuroblastoma is the third most common pediatric malignancy and accounts for approximately 10% of all childhood cancers. The vast majority of patients have advanced disease at the time of presentation, and unlike Wilms' tumor, in which cure is expected in the vast majority of patients, the overall survival of patients with neuroblastoma is significantly lower. Over 80% of cases present before the age of 4 years, and the peak incidence is 2 years of age. Neuroblastomas arise from the neural crest cells and show different levels of differentiation. The tumor originates most frequently in the adrenal glands, posterior mediastinum, neck, or pelvis but can arise in any sympathetic ganglion. The clinical presentation depends on the site of the primary and the presence of metastases.

Two thirds of these tumors are first noted as an asymptomatic abdominal mass. The tumor may cross the midline, and a majority of patients will already show signs of metastatic disease. Occasionally, children may experience pain from the tumor mass or from bony metastases. Proptosis and periorbital ecchymosis may occur due to the presence of retrobulbar metastasis. Because they originate in paraspinal ganglia, neuroblastomas may invade through neural foramina and compress the spinal cord, causing muscle weakness or sensory changes. Rarely, children may have severe watery diarrhea due to the secretion of vasoactive intestinal peptide by the tumor or have paraneoplastic neurologic findings including cerebellar ataxia or opsoclonus/myoclonus.

Diagnostic Evaluation. Since these tumors derive from the sympathetic nervous system, catecholamines and their metabolites will be produced at increased levels. These include elevated levels of serum catecholamines (dopamine, norepinephrine) or urine catecholamine metabolites (vanillylmandelic acid [VMA] or homovanillic acid [HVA]). Measurement of VMA and HVA in serum and urine aids in the diagnosis and in monitoring adequacy of future treatment and recurrence. The minimum criterion for a diagnosis of neuroblastoma is based on one of the following: (a) an unequivocal pathologic diagnosis made from tumor tissue by light microscopy (with or without immunohistology, electron

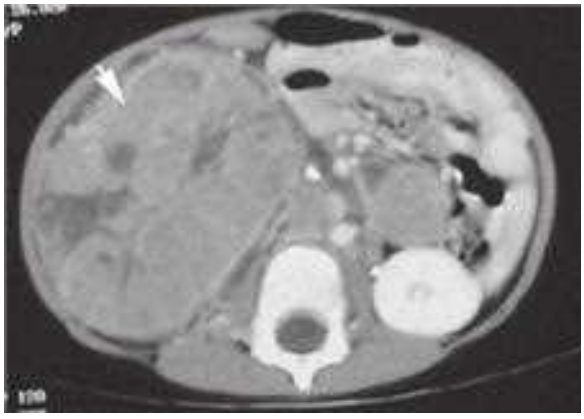

Figure 39-38. Abdominal neuroblastoma arising from the right retroperitoneum (*arrow*).

microscopy, or increased levels of serum catecholamines or urinary catecholamine metabolites); or (b) the combination of bone marrow aspirate or biopsy containing unequivocal tumor cells and increased levels of serum catecholamines or urinary catecholamine metabolites as described earlier.

The patient should be evaluated by abdominal CT, which may show displacement and occasionally obstruction of the ureter of an intact kidney (Fig. 39-38). Prior to the institution of therapy, a complete staging workup should be performed. This includes radiograph of the chest, bone marrow biopsy, and radionuclide scans to search for metastases. Any abnormality on chest x-ray should be followed up with CT of the chest.

Prognostic Indicators. A number of biologic variables have been studied in children with neuroblastoma. An open biopsy is required in order to provide tissue for this analysis. Hyperdiploid tumor DNA is associated with a favorable prognosis, and *N-myc* amplification is associated with a poor prognosis regardless of patient age. The Shimada classification describes tumors as either favorable or unfavorable histology based on the degree of differentiation, the mitosis-karyorrhexis index, and the presence or absence of schwannian stroma. In general, children of any age with localized neuroblastoma and infants younger than 1 year of age with advanced disease and favorable disease characteristics have a high likelihood of disease-free survival. By contrast, older children with advanced-stage disease have a significantly decreased chance for cure despite intensive therapy. For example, aggressive multiagent chemotherapy has resulted in a 2-year survival rate of approximately 20% in older children with stage IV disease. Neuroblastoma in the adolescent has a worse long-term prognosis regardless of stage or site and, in many cases, a more prolonged course.

Surgery. The goal of surgery is complete resection. However, this is often not possible at initial presentation due to the extensive locoregional spread of the tumor at the time of presentation. Under these circumstances, a biopsy is performed and preoperative chemotherapy is provided based on the stage of the tumor. After neoadjuvant treatment has been administered, surgical resection is performed. The principal goal of surgery is to obtain at least 95% resection, without compromising major structures. Abdominal tumors are approached through a transverse incision. Thoracic tumors may be approached through a posterolateral thoracotomy or through a thoracoscopic approach. These may have an intraspinal component. In all cases of intrathoracic neuroblastoma, particularly those at the thoracic inlet, it is important to be aware of the possibility of a Horner's syndrome (anhidrosis, ptosis, meiosis) developing. This typically resolves, although it may take many months to do so.

Neuroblastoma in Infants. Spontaneous regression of neuroblastoma has been well described in infants, especially in those with stage IVS disease. Regression generally occurs only in tumors with a near triploid number of chromosomes that also lack *N-myc* amplification and loss of chromosome 1p. Recent studies indicate that infants with asymptomatic, small, low-stage neuroblastoma detected by screening may have tumors that spontaneously regress. These patients may be observed safely without surgical intervention or tissue diagnosis.

Rhabdomyosarcoma

Rhabdomyosarcoma is a primitive soft tissue tumor that arises from mesenchymal tissues. The most common sites of origin include the head and neck (36%), extremities (19%), genitourinary tract (21%), and trunk (9%), although the tumor can arise virtually anywhere. The clinical presentation of the tumor depends on the site of origin. The diagnosis is confirmed with incisional or excisional biopsy after evaluation by MRI, CT scans of the affected area and the chest, and bone marrow biopsy. The tumor grows locally into surrounding structures and metastasizes widely to lung, regional lymph nodes, liver, brain, and bone marrow. The staging system for rhabdomyosarcoma is based on the TNM system, as established by the Soft Tissue Sarcoma Committee of the Children's Oncology Group. It is shown in Table 39-4. Surgery is an important component of the staging strategy and involves biopsy of the lesion and evaluation of lymphatics. Primary resection should be undertaken when complete excision can be performed without causing disability. If this is not possible, the lesion is biopsied, and intensive chemotherapy is administered. It is important to plan the biopsy so that it does not interfere with subsequent resection. After the tumor has decreased in size, resection of gross residual disease should be performed. Radiation therapy is effective in achieving local control when microscopic or gross residual disease exists

Table 39-4

Staging of rhabdomyosarcoma

Stage 1: Localized disease involving the orbit or head and neck (excluding parameningeal sites), genitourinary region (excluding bladder/prostate sites), or biliary tract (favorable sites).
Stage 2: Localized disease of any other primary site not included in the stage 1 category (unfavorable sites). Primary tumors must be ≤5 cm in diameter, and there must be no clinical regional lymph node involvement by tumor.
Stage 3: Localized disease of any other primary site. These patients differ from stage 2 patients by having primary tumors greater than 5 cm and/or regional node involvement.
Stage 4: Metastatic disease at diagnosis.

Sources: Lawrence W Jr, Gehan EA, Hays DM, et al. Prognostic significance of staging factors of the UICC staging system in childhood rhabdomyosarcoma: a report from the Intergroup Rhabdomyosarcoma Study (IRS-II). *J Clin Oncol.* 1987;5:46-54.
Lawrence W Jr, Anderson JR, Gehan EA, et al. Pretreatment TNM staging of childhood rhabdomyosarcoma: a report of the Intergroup Rhabdomyosarcoma Study Group. Children's Cancer Study Group. Pediatric Oncology Group. *Cancer.* 1997;80:1165-1170.

following initial treatment. Patients with completely resected tumors of embryonal histology do well without radiation therapy, but radiation therapy benefits patients with group I tumors with alveolar or undifferentiated histology.

Prognosis. The prognosis for rhabdomyosarcoma is related to the site of origin, resectability, presence of metastases, number of metastatic sites, and histopathology. Primary sites with more favorable prognoses include the orbit and nonparameningeal head and neck, paratestis and vagina (nonbladder, nonprostate genitourinary), and biliary tract. Patients with tumors less than 5 cm in size have improved survival compared to children with larger tumors, whereas children with metastatic disease at diagnosis have the poorest prognosis. Tumor histology influences prognosis. The embryonal variant is favorable, whereas the alveolar subtype has an unfavorable prognosis.

Teratoma

Teratomas are tumors composed of tissue from all three embryonic germ layers. They may be benign or malignant, may arise in any part of the body, and are usually found in midline structures. Thoracic teratomas usually present as an anterior mediastinal mass. Ovarian teratomas present as an abdominal mass often with symptoms of torsion, bleeding, or rupture. Retroperitoneal teratomas may present as a flank or abdominal mass.

Mature teratomas usually contain well-differentiated tissues and are benign, whereas immature teratomas contain varying degrees of immature neuroepithelium or blastemal tissues. Immature teratomas can be graded from 1 to 3 based on the amount of immature neuroglial tissue present. Tumors of higher grade are more likely to have foci of yolk sac tumor. Malignant germ cell tumors usually contain frankly neoplastic tissues of germ cell origin (i.e., yolk sac carcinoma, embryonal carcinoma, germinoma, or choriocarcinoma). Yolk sac carcinomas produce α-fetoprotein (AFP), whereas choriocarcinomas produce β-human chorionic gonadotropin (BHCG), resulting in elevation of these substances in the serum, which can serve as tumor markers. In addition, germinomas can also produce elevation of serum BHCG but not to the levels associated with choriocarcinoma.

Sacrococcygeal Teratoma. Sacrococcygeal teratoma usually presents as a large mass extending from the sacrum in the newborn period. Diagnosis may be established by prenatal US. In fetuses with evidence of hydrops and a large sacrococcygeal teratoma, prognosis is poor; thus, prenatal intervention has been advocated in such patients. The mass may be as small as a few centimeters in diameter or as massive as the size of the infant (Fig. 39-39). The tumor has been classified based on the location and degree of intrapelvic extension. Lesions that grow predominantly into the presacral space often present later in childhood. The differential diagnosis consists of neural tumors, lipoma, and myelomeningoceles.

Most tumors are identified at birth and are benign. Malignant yolk sac tumor histology occurs in a minority of these tumors. Complete resection of the tumor as early as possible is essential. The rectum and genital structures are often distorted by the tumor but usually can be preserved in the course of resection. Perioperative complications of hypothermia and hemorrhage can occur with massive tumors and may prove lethal. This is of particular concern in small, preterm infants with large tumors. The cure rate is excellent if the tumor is excised completely. The majority of patients who develop recurrent disease are salvageable with subsequent platinum-based chemotherapy.

Figure 39-39. Sacrococcygeal teratoma in a 2-day-old boy.

Liver Tumors

More than two thirds of all liver tumors in children are malignant. There are two major histologic subgroups: hepatoblastoma and hepatocellular carcinoma. The age of onset of liver cancer in children is related to the histology of the tumor. Hepatoblastoma is the most common malignancy of the liver in children, with most of these tumors diagnosed before 4 years of age. Hepatocellular carcinoma is the next most common, with a peak age incidence between 10 and 15 years. Malignant mesenchymomas and sarcomas are much less common but constitute the remainder of the malignancies. The finding of a liver mass does not necessarily imply that a malignancy is present. Nearly 50% of all masses are benign, and hemangiomas are the most common lesion.

Most children with a liver tumor present with an abdominal mass that is usually painless, which the parents note while changing the child's clothes or while bathing the child. The patients are rarely jaundiced but may complain of anorexia and weight loss. Most liver function tests are normal. AFP levels are increased in 90% of children with hepatoblastomas but much less commonly in other liver malignancies. Radiographic evaluation of these children should include an abdominal CT scan to identify the lesion and to determine the degree of local invasiveness (Fig. 39-40). For malignant-appearing lesions, a

Figure 39-40. Computed tomography of the abdomen showing a hepatocellular carcinoma in a 12-year-old boy.

Table 39-5

Staging of pediatric liver cancer

Stage I: No metastases, tumor completely resected
Stage II: No metastases, tumor grossly resected with microscopic residual disease (i.e., positive margins); or tumor rupture, or tumor spill at the time of surgery
Stage III: No distant metastases, tumor unresectable or resected with gross residual tumor, or positive lymph nodes
Stage IV: Distant metastases regardless of the extent of liver involvement

Source: Douglass E, Ortega J, Feusner J, et al. Hepatocellular carcinoma (HCA) in children and adolescents: results from the Pediatric Intergroup Hepatoma Study (CCG 8881/POG 8945). *Proc Am Soc Clin Oncol.* 1994;13:A-1439.

biopsy should be performed unless the lesion can be completely resected easily. Hepatoblastoma is most often unifocal, whereas hepatocellular carcinoma is often extensively invasive or multicentric. If a hepatoblastoma is completely removed, the majority of patients survive, but only a minority of patients have lesions amenable to complete resection at diagnosis.

A staging system based on postsurgical extent of tumor and surgical resectability is shown in Table 39-5. The overall survival rate for children with hepatoblastoma is 70%, but is only 25% for hepatocellular carcinoma. Children diagnosed with stage I and II hepatoblastoma have a cure rate of greater than 90% compared to 60% for stage III and approximately 20% for stage IV. In children diagnosed with hepatocellular carcinoma, those with stage I disease have a good outcome, whereas stages III and IV are usually fatal. The fibrolamellar variant of hepatocellular carcinoma may have a better prognosis.

Surgery. The abdominal CT scan usually will determine the resectability of the lesion, although occasionally this can only be determined at the time of exploration. Complete surgical resection of the tumor is the primary goal and is essential for cure. For tumors that are unresectable, preoperative chemotherapy should be administered to reduce the size of the tumor and improve the possibility for complete removal. Chemotherapy is more successful for hepatoblastoma than for hepatocellular carcinoma. Areas of locally invasive disease, such as the diaphragm, should be resected at the time of surgery. For unresectable tumors, liver transplantation may be offered in select patients. The fibrolamellar variant of hepatocellular carcinoma may have a better outcome with liver transplantation than other hepatocellular carcinomas.

TRAUMA IN CHILDREN

Injury is the leading cause of death among children older than 1 year. In fact, trauma accounts for almost half of all pediatric deaths, more than cancer, congenital anomalies, pneumonia, heart disease, homicide, and meningitis combined. Motor vehicle collisions are the leading cause of death in people age 1 to 19 years, followed by homicide or suicide (predominantly with firearms) and drowning. Unintentional injuries account for 65% of all injury-related deaths in children younger than 19 years. Each year, approximately 20,000 children and teenagers die as a result of injury in the United States. For every child who dies from an injury, it is calculated that 40 others are hospitalized and 1120 are treated in emergency departments. An estimated 50,000 children acquire permanent disabilities each year, most of which are the result of head injuries. Thus, the problem of pediatric trauma continues to be one of the major threats to the health and well-being of children.

Specific considerations apply to trauma in children that influence management and outcome. These relate to the mechanisms of injury, the anatomic variations in children compared to adults, and the physiologic responses.

Mechanisms of Injury

Most pediatric trauma is blunt. Penetrating injuries are seen in the setting of gun violence, falls onto sharp objects, or penetration by glass after falling through windows. Age and gender significantly influence the patterns of injury. Male children between 14 and 18 years of age are exposed to contact sports and gun violence and, in some jurisdictions, drive motor vehicles. As a result, they have a different pattern of injury than younger children, characterized by higher injury severity scores. In the infant and toddler age group, falls are a common cause of severe injury. Injuries in the home are extremely common. These include falls, near-drownings, caustic ingestion, and nonaccidental injuries.

10▸

Initial Management

The goals of managing the pediatric trauma patient are similar to those of adults and follow advanced trauma life support guidelines as established by the American College of Surgeons Committee on Trauma. Airway control is the first priority. In a child, respiratory arrest can proceed quickly to cardiac arrest. It is important to be aware of the anatomic differences between the airway of the child and the adult. The child has a large head, shorter neck, smaller and anterior larynx, floppy epiglottis, short trachea, and large tongue. The size of the endotracheal tube can be estimated by the formula (age + 16)/4. It is important to use uncuffed endotracheal tubes in children younger than 8 years in order to minimize tracheal trauma. After evaluation of the airway, breathing is assessed. It is important to consider that gastric distention from aerophagia can severely compromise respirations. A nasogastric tube should therefore be placed early during the resuscitation if there is no head injury suspected, or an orogastric tube should be placed in cases of head injury. Pneumothorax or hemothorax should be treated promptly. When evaluating the circulation, it is important to recognize that tachycardia is usually the earliest measurable response to hypovolemia. Other signs of impending hypovolemic shock in children include changes in mentation, delayed capillary refill, skin pallor, and hypothermia. IV access should be rapidly obtained once the patient arrives in the trauma bay. The first approach should be to use the antecubital fossa. If this is not possible, a cut-down into the saphenous at the groin can be performed quickly and safely. Intraosseous cannulation can provide temporary access in children up to 6 years old until IV access is established. Percutaneous neck lines should generally be avoided. Blood is drawn for cross-match and evaluation of liver enzymes, lipase, amylase, and hematologic profile after the IV lines are placed.

In patients who show signs of volume depletion, a 20 mL/kg bolus of saline or lactated Ringer's should be promptly given. If the patient does not respond to two boluses, blood should be transfused (10 mL/kg). The source of bleeding should be established. Common sites include the chest, abdomen, pelvis, extremity fractures, or large scalp wounds. These should be carefully sought. Care is taken to avoid hypothermia by infusing warmed fluids and using external warming devices.

Evaluation of Injury

All patients should receive an x-ray of the cervical spine, chest, and abdomen with pelvis. All extremities that are suspicious for fracture should also be evaluated by x-ray. Plain cervical spine films are preferable to performing routine neck CT scans in the child, as x-rays provide sufficient anatomic detail. But if a head CT is obtained, it may be reasonable to obtain images down to C2 since odontoid views in small children are difficult to obtain. In most children, it is possible to diagnose clinically significant cervical spine injuries using this approach while minimizing the degree of radiation exposure. Screening blood work that includes aspartate aminotransferase, alanine aminotransferase, and amylase/lipase is useful for the evaluation of liver and pancreatic injures. Significant elevation in these tests requires further evaluation by CT scanning. The child with significant abdominal tenderness and a mechanism of injury that could cause intra-abdominal injury should undergo abdominal CT scanning using IV and oral contrast in all cases. There is a limited role for diagnostic peritoneal lavage (DPL) in children as a screening test. Although focused abdominal US (FAST exam) is extremely useful in the evaluation of adult abdominal trauma, it is not widely accepted in the management of pediatric blunt abdominal trauma. In part this relates to the widespread use of nonoperative treatment for most solid-organ injuries. Thus a positive abdominal US scan would not alter this approach in a hemodynamically stable patient. However, FAST exam can be very useful in the child who needs to go emergently to the operating room for management of significant intracranial hemorrhage, to ensure that there is no intraabdominal source of bleeding.

Injuries to the Central Nervous System

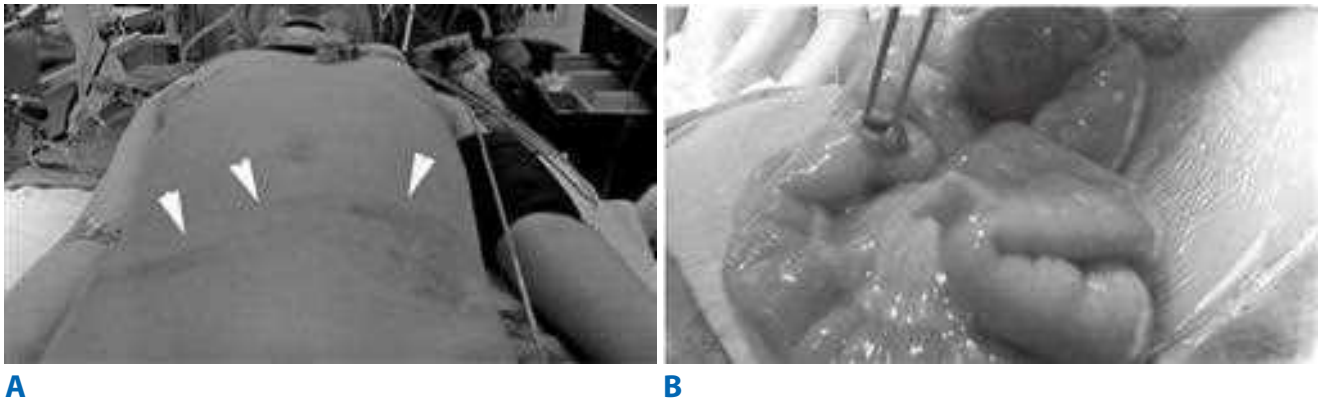
The central nervous system (CNS) is the most commonly injured organ system and is the leading cause of death among injured children. In the toddler age group, nonaccidental trauma is the most common cause of serious head injury. Findings suggestive of abuse include the presence of retinal hemorrhage on funduscopic evaluation, intracranial hemorrhage without evidence of external trauma (indicative of a shaking injury), and fractures at different stages of healing on skeletal survey. In older children, CNS injury occurs most commonly after falls and bicycle and motor vehicle collisions. The initial head CT can often underestimate the extent of injury in children. Criteria for head CT include any loss of consciousness or amnesia to the trauma or inability to assess the CNS status as in the intubated patient. Patients with mild, isolated head injury (Glasgow Coma Scale [GCS] 14–15) and negative CT scans can be discharged if their neurologic status is normal after 6 hours of observation. Young children and those in whom there is multisystem involvement should be admitted to the hospital for observation. Any change in the neurologic status warrants neurosurgical evaluation and repeat CT scanning. In patients with severe head injury (GCS ≤8), urgent neurosurgical consultation is required. These patients are evaluated for intracranial pressure monitoring and for the need to undergo craniotomy.

Thoracic Injuries

The pediatric thorax is pliable due to incomplete calcification of the ribs and cartilages. As a result, blunt chest injury commonly results in pulmonary contusion, although rib fractures are infrequent. Diagnosis is made by chest radiograph and may be associated with severe hypoxia requiring mechanical ventilation. Pulmonary contusion usually resolves with careful ventilator management and judicious volume resuscitation. Children who have sustained massive blunt thoracic injury may develop traumatic asphyxia. This is characterized by cervical and facial petechial hemorrhages or cyanosis associated with vascular engorgement and subconjunctival hemorrhage. Management includes ventilation and treatment of coexisting CNS or abdominal injuries. Penetrating thoracic injuries may result in damage to the lung or in major disruption of the bronchi or great vessels.

Abdominal Injuries

In children, the small rib cage and minimal muscular coverage of the abdomen can result in significant injury after seemingly minor trauma. The liver and spleen in particular are relatively unprotected and are often injured after direct abdominal trauma. Duodenal injuries are usually the result of blunt trauma, which may arise from child abuse or injury from a bicycle handlebar. Duodenal hematomas usually resolve without surgery. Small intestinal injury usually occurs in the jejunum in the area of fixation by the ligament of Treitz. These injuries are usually caused by rapid deceleration in the setting of a lap belt. There may be a hematoma on the anterior abdominal wall caused by a lap belt, the so-called "seat belt sign" (Fig. 39-41A). This should alert the caregiver to the possibility of an underlying small bowel injury (Fig. 39-41B), as well as to a potential lumbar spine injury (Chance fracture).



A B

Figure 39-41. Abdominal computed tomography of patient who sustained a lap belt injury. **A.** Bruising is noted across the abdomen from the lap belt. **B.** At laparotomy, a perforation of the small bowel is identified.

Table 39-6

Grading of splenic injuries

Grade I: Subcapsular hematoma, <10% surface area capsular tear, <1 cm in depth
Grade II: Subcapsular hematoma, nonexpanding, 10%–50% surface area; intraparenchymal hematoma, nonexpanding, <2 cm in diameter; capsular tear, active bleeding, 1–3 cm, does not involve trabecular vessel
Grade III: Subcapsular hematoma, >50% surface area or expanding; intraparenchymal hematoma, >2 cm or expanding; laceration >3 cm in depth or involving trabecular vessels
Grade IV: Ruptured intraparenchymal hematoma with active bleeding; laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
Grade V: Shattered spleen; hilar vascular injury which devascularizes spleen

The spleen is injured relatively commonly after blunt abdominal trauma in children. The extent of injury to the spleen is graded (Table 39-6), and the management is governed by the injury grade. Current treatment involves a nonoperative approach in most cases, even for grade IV injuries, assuming the patient is hemodynamically stable. This approach avoids surgery in most cases. All patients should be placed in a monitored unit, and type-specific blood should be available for transfusion. When nonoperative management is successful, as it is in most cases, an extended period of bed rest is prescribed. This optimizes the chance for healing and minimizes the likelihood of reinjury. A typical guideline is to keep the children on extremely restricted activity for 2 weeks longer than the grade of spleen injury (i.e., a child with a grade IV spleen injury receives 6 weeks of restricted activity). In children who have an ongoing fluid requirement or when a blood transfusion is required, exploration should not be delayed. At surgery, the spleen can often be salvaged. If a splenectomy is performed, prophylactic antibiotics and immunizations should be administered to protect against overwhelming postsplenectomy sepsis. The liver is also commonly injured after blunt abdominal trauma. A grading system is used to characterize hepatic injuries (Table 39-7), and nonoperative management is usually successful (Fig. 39-42). Recent studies have shown that associated injuries are more significant predictors of outcome in children with liver injuries than the actual injury grade. Criteria for surgery are similar to those for splenic injury and primarily involve hemodynamic instability. The intraoperative considerations in the management of massive hepatic injury are similar in children and adults. Renal contusions may occur after significant blunt abdominal trauma. Nonoperative management is usually successful, unless patients are unstable due to active renal bleeding. It is important to confirm the presence of a normal contralateral kidney at the time of surgery.

Table 39-7

Liver injury grading system

Grade I: Capsular tear <1 cm in depth
Grade II: Capsular tear 1–3 cm in depth, <10 cm length
Grade III: Capsular tear >3 cm in depth
Grade IV: Parenchymal disruption 25%–75% of hepatic lobe or 1–3 Couinaud's segments
Grade V: Parenchymal disruption >75% of hepatic lobe or >3 Couinaud's segments within a single lobe, injury to retrohepatic vena cava

FETAL INTERVENTION

One of the most exciting developments in the field of pediatric surgery has been the emergence of fetal therapy. In general terms, performance of a fetal intervention may be justified in the setting where a defect is present that would cause devastating consequences to the infant if left uncorrected. For the vast majority of congenital anomalies, postnatal surgery is the preferred modality. However, in specific circumstances, fetal surgery may offer the best possibility for a successful outcome. The decision to perform a fetal intervention requires careful patient selection, as well as a multidisciplinary center that is dedicated to the surgical care of the fetus and the mother. Patient selection is dependent in part on highly accurate prenatal imaging that includes US and MRI. Significant risks may be associated with the performance of a fetal surgical procedure, to both the mother and the fetus. From the maternal viewpoint, open fetal surgery may lead to uterine bleeding due to the uterine relaxation required during the procedure. The long-term effects on subsequent pregnancies remain to be established. For the fetus, in utero surgery carries the risk of premature labor and amniotic fluid leak. As a result, these procedures are performed only when the expected benefit of fetal intervention outweighs the risk to the fetus of standard postnatal care. Currently, open fetal intervention may be efficacious in certain instances of large congenital lung lesions with hydrops, large teratomas with hydrops, twin-twin transfusion syndrome, certain cases of congenital lower urinary tract obstruction, and *myelomeningocele*. This list of potential diagnoses that may benefit from a fetal intervention is significantly shorter than that of a decade ago, due in part to improvements in outcome of several diseases that are managed in the postnatal period, as well as the recognition of the relative lack of benefit of fetal surgery for many conditions.

Fetal Surgery for Lower Urinary Tract Obstruction

Lower urinary tract obstruction refers to a group of diseases characterized by obstruction of the distal urinary system. Common causes include the presence of posterior urethral valves and urethral atresia, as well as other anomalies of the urethra and bladder. The pathologic effects of lower urinary tract obstruction lie in the resultant massive bladder distention that occurs, which can lead to reflux hydronephrosis. This may result in oligohydramnios and cause limb contractures, facial anomalies (Potter sequence), and pulmonary hypoplasia. Carefully selected patients with lower urinary tract obstruction may benefit from vesicoamniotic shunting. By relieving the obstruction and improving renal function, fetal growth and lung development may be preserved.

Fetal Surgery for Congenital Diaphragmatic Hernia

Given the high mortality associated with the most severe cases of CDH, tremendous efforts have been undertaken to determine whether fetal intervention could improve the outcome of this disease. In 1990, Harrison and colleagues reported the first open fetal repair for CDH. The high morbidity of the open technique led to the development of fetal tracheal occlusion as a therapeutic approach. This was based on the observation that tracheal occlusion could lead to increased lung growth and reduction of the intrathoracic viscera in animal models. Tracheal occlusion can be achieved in utero by placement of clips that are removed at the time of delivery. Despite initial enthusiasm for this approach, a recent randomized trial that compared fetal tracheal occlusion with standard postnatal care for left-sided CDH showed no improvement in survival for patients treated with tracheal occlusion.

Fetal Surgery for Myelomeningocele

Myelomeningocele refers to a spectrum of anomalies in which portions of the spinal cord are uncovered by the spinal column. This leaves the neural tissue exposed to the injurious effects of the amniotic fluid, as well as to trauma from contact with the uterine wall. Nerve damage ensues, resulting in varying degrees of lower extremity paralysis as well as bowel and bladder dysfunction. Initial observations indicated that the extent of injury progressed throughout the pregnancy, which provided the rationale for fetal intervention. The current in utero approach for the fetus with myelomeningocele has focused on obtaining coverage of the exposed spinal cord. The efficacy of in utero treatment vs. postnatal repair was recently compared in a large multicenter trial and showed that prenatal surgery for myelomeningocele reduced the need for shunting and improved motor outcomes at 30 months but was associated with maternal and fetal risks. The results of this study have paved the way for the acceptance of in utero repair of myelomeningocele in certain centers with the experience and expertise to perform this procedure safely.

The EXIT Procedure

The EXIT procedure is an abbreviation for *e*x utero *i*ntrapartum *t*reatment. It is used in circumstances where airway obstruction is predicted at the time of delivery, due to the presence of a large neck mass, such as a cystic hygroma or teratoma (Fig. 39-43), or congenital tracheal stenosis. The success of the procedure is dependent on the maintenance of utero-placental perfusion for a sufficient duration to secure the airway. To achieve this, deep uterine relaxation is obtained during a cesarean section under general anesthesia. Uterine perfusion with warmed saline also promotes relaxation and blood flow to the placenta. On average, between 20 and 30 minutes of placental perfusion can be achieved. The fetal airway is secured either by placement of an orotracheal tube or performance of a tracheostomy. Once the airway is secured, the cord is cut and a definitive procedure may be performed to relieve the obstruction in the postnatal period. In general terms, cystic neck masses such as lymphangiomas have a more favorable response to an EXIT procedure as compared to solid tumors, such as teratomas, particularly in premature infants.

Figure 39-43. The EXIT procedure (ex utero intrapartum treatment) in a 34-week gestation age baby with a large cervical teratoma. Intubation is being performed while the fetus is on placental support.

chapter 40

Urology

Karim Chamie, Jeffrey La Rochelle, Brian Shuch, and Arie S. Belldegrun

ANATOMY

The anatomic structures that fall under the purview of genitourinary surgery are the adrenals, kidneys, ureters, bladder, prostate, seminal vesicles, urethra, vas deferens, penis, and testes. Some of these structures are situated outside the peritoneum, but urologic surgery frequently involves intraperitoneal approaches to the kidney, bladder, and retroperitoneal lymph nodes. Furthermore, urologists must be familiar with the techniques of intestinal surgery for the purposes of urinary diversion and bladder augmentation.

Kidney and Adrenal

The kidneys are paired retroperitoneal organs that are invested in a fibro-fatty layer: fascia of Zuckerkandl posteriorly and Gerota's fascia anteriorly. Posterolaterally, the kidneys are bordered by the quadratus lumborum and posteromedially by the psoas muscle. Anteriorly, they are confined by the posterior layer of the peritoneum. On the left, the spleen lies superolaterally, separated from the kidney and Gerota's fascia by the peritoneum. On the right, the liver is situated superiorly and anteriorly and also is separated by the peritoneum. The second portion of the duodenum is in close proximity to the right renal vessels, and during right renal surgery, it must be reflected anteromedially (Kocherized) to achieve vascular control. The renal arteries, in the typical configuration, are single vessels extending from the aorta that branch into several segmental arteries before entering the renal sinus. The right renal artery passes posterior to the vena cava and is significantly longer than the left renal artery. Occasionally, the kidney is supplied by a second renal artery, an accessory renal artery, typically to the lower pole. Within the kidney, there is essentially no anastomotic arterial flow, so the kidneys are prone to infarction when branch vessels are interrupted. The renal veins, which course anteriorly to the renal arteries, drain directly into the vena cava. The left renal vein passes anterior to the aorta and is much longer than the right renal vein. This explains why most surgeons prefer to take the left kidney for living donor transplantation. The left vein is in continuity with the left gonadal vein, the left inferior adrenal vein, and a lumbar vein. These veins provide adequate drainage for the left kidney in the event that drainage to the vena cava is interrupted. The right renal vein has no such collateral venous drainage.

The collecting system of the kidney is composed of several major and minor calyces that coalesce into the renal pelvis. The renal pelvis can have either a mainly intrarenal or extrarenal position. The renal pelvis tapers into the ureteropelvic junction (UPJ) where it joins with the ureter.

The adrenal glands lie superomedially to the kidneys within Gerota's fascia. There is a layer of Gerota's fascia between the adrenal and the kidney. However, in the presence of a tumor or inflammatory process, the adrenal can become very adherent to the kidney, and separation can be difficult. The arterial supply of the adrenals derives from the inferior phrenic, aorta, and small branches from the renal arteries. The venous drainage on the left is mainly through the inferior phrenic vein and through the left renal vein via the inferior adrenal vein. On the right, the adrenal is drained by a very short (<1 cm) vein to the vena cava. It can be avulsed by moderate traction and can be the source of troublesome bleeding.

Key Points

1. In the surgical treatment of invasive bladder cancer, a thorough lymph node dissection is essential.
2. Patients with testicular cancer without radiographic evidence of metastasis often harbor microscopic occult deposits of disease and require either adjuvant treatment or very close surveillance.
3. Partial nephrectomy is the mainstay of treatment for small renal masses, whereas radical nephrectomy provides a survival benefit in the setting of metastatic disease.
4. The vast majority of renal trauma can be treated conservatively, with early surgical intervention reserved for persistent bleeding, renal vascular, or ureteral injuries.
5. Distal ureteral injuries should only be treated with ureteroneocystostomy (bladder reimplantation) because of the high failure rate of distal uretero-ureterostomies.
6. Extraperitoneal bladder ruptures can be treated conservatively, but intraperitoneal ruptures typically require surgical repair.
7. Nearly all episodes of acute urinary retention can be treated with conservative measures such as decreasing narcotic usage and increasing ambulation.
8. Testicular torsion is an emergency where successful testicular salvage is inversely related to the delay in repair, so cases with a high degree of clinical suspicion should not wait for a radiologic diagnosis.
9. Fournier's gangrene is a potentially lethal condition that requires aggressive débridement and close follow-up due to the frequent need for repeat débridement.
10. Most small ureteral calculi will pass spontaneously or with the use of medical expulsive therapy, but larger stones (>6 mm) are better treated with ureteral stenting or lithotripsy.

Ureter

The ureters are muscular structures that course anterior to the psoas muscles from the renal pelvis to the bladder. The blood supply of the proximal ureter derives from the aorta and renal artery and comes mainly from the medial direction. However, once it crosses the iliac vessels at the pelvic brim near where the iliac vessels bifurcate, it derives its blood supply laterally from branches from the iliac arteries. The blood supply has implications for managing ureteral injuries. Mobilizing the distal ureter for anastomosis requires releasing its lateral attachments, which results in ischemia, so for this reason, distal ureteral injuries are typically managed by anastomosing the proximal ureter to the bladder.

The ureters course along the pelvic sidewall and pass under the uterine arteries in women, making them vulnerable to injury during hysterectomy, especially in the context of pelvic bleeding. They enter the bladder at the lateral aspect of the base. They course through the bladder musculature at an oblique angle and open into the bladder at the ureteral orifices that are relatively close to the bladder outlet.

Bladder and Prostate

The urinary bladder is situated in the retropubic space in an extraperitoneal position. A portion of the bladder dome is adjacent to the peritoneum, so ruptures at this point can result in intraperitoneal urine leakage. The anatomic relations of the bladder are dependent on the degree of filling. A very distended bladder can project above the umbilicus. At physiologic volumes (200–400 mL), the bladder projects modestly into the abdomen. The sigmoid colon lies superolaterally and may become adherent or fistulize to the bladder secondary to diverticulitis. The rectum lies posterior to the bladder in males, whereas the vagina and uterus are posterior in females.

In males, the prostate is in continuity with the bladder neck, and the urethra courses through it. The prostate has a significant component of smooth muscle and can provide urinary continence even in the absence of the external striated sphincter. The puboprostatic ligaments connect the prostate to the pubic symphysis, and pelvic fractures often result in proximal urethral injuries due to the traction that these ligaments provide. Between the prostate and the rectum lies Denonvilliers' fascia, which is the main anatomic barrier that prevents prostate cancer from regularly penetrating into the rectum. Just beyond the apex of the prostate is the external (voluntary) sphincter, which is part of the genitourinary diaphragm.

Penis

The penis is composed of three main bodies, along with fascia, neurovascular structures, and skin. The corpora cavernosum are the paired, cylinder-like structures that are the main erectile bodies of the penis. Proximally, they lie along the medial aspects of the inferior pubic rami in the perineum. Distally, they fuse along their medial aspects and form the pendulous penis. The corpora cavernosum consist of a tough outer layer called the *tunica albuginea* and spongy, sinusoidal tissue inside that fills with blood to result in erection. The two corpora cavernosum have numerous vascular interconnections, so they function as one compartment. The cavernosal arteries, which are branches of the penile artery, course through the center of the corporal sinusoidal tissue. The sinusoidal tissue is innervated by the cavernosal nerves, which are autonomic nerves that originate in the hypogastric plexus and play a critical role in erection. Before entering the penis, the cavernosal nerves travel immediately adjacent to the prostate, which explains why they often are damaged at radical prostatectomy. Injury or excess traction of these nerves may cause erectile dysfunction. On the underside of the penis lies the corpus spongiosum, which surrounds the urethra. The spongiosum does not have the same tunical layers as the corpora cavernosum, so it does not exhibit the same firmness during erection. The tip of the penis, called the glans, is in continuity with the corpus spongiosum. This highlights the point that when men develop priapism—persistent erection for greater than 4 hours unrelated to sexual stimulation—the two corpora cavernosum remain rigid while the glans (derived from the corpora spongiosum) can be soft.

Surrounding all three bodies of the penis are the outer dartos fascia and the inner Buck's fascia. The dorsal nerves of the penis, which provide sensation to the penile skin, derive from the pudendal nerves and, along with the dorsal penile arteries, travel along the dorsum of the penis within Buck's fascia. The neurovascular bundle of the penis must be avoided during surgical exploration of the penis for injuries or reconstruction, as injury may result in permanent erectile and/or ejaculatory dysfunction.

Scrotum and Testes

The scrotum is a capacious structure that contains the testes and epididymes. Because of its dependent position, significant edema can develop when a patient is fluid overloaded. Additionally, since the scrotum is capacious, any significant bleeding will result in the accumulation of large hematomas—even as large as a basketball. Beneath the skin, from superficial to deep, are the dartos, external spermatic, cremasteric, and internal spermatic fascias. These layers are not always distinct. Beneath the internal fascia are the parietal and visceral layers of the tunica vaginalis, between which hydroceles form. The visceral layer of the tunica vaginalis is adherent to the testis. The noncompliant outer testis layer is the tunica albuginea. Inside the tunica are the seminiferous tubules. The blood supply enters the testis at the superior pole by way of the spermatic cord. In addition to the vas deferens, the cord carries three separate sources of arterial blood flow—the testicular artery that arises from the aorta below the renal artery, the cremasteric artery, and the deferential artery. Interruption of one of the arteries during vasectomy or inguinal surgery will not result in ischemia to the testis. Some children are born with an undescended abdominal testicle. Often, it is difficult to derive enough length to place the testicles in the scrotum. In these instances, the testicular artery is ligated as a first-stage operation, and the testicle is then delivered into the scrotum as a second-stage procedure (i.e., Fowler-Stephens orchiopexy). Most of these testicles remain viable as a result of collaterals. However, if a patient has undergone a prior Fowler-Stephens procedure, any manipulation of the collaterals during inguinal surgery may compromise the testicle. Venous drainage parallels the arterial inflow except that the left gonadal vein drains into the renal vein rather than the vena cava. Dilation of spermatic veins is called a *varicocele* and may be palpable when a patient is standing or with Valsalva. They do not need to be treated unless they cause discomfort, are discovered on infertility workup, or are found in children.

UROLOGIC MALIGNANCIES

Bladder Cancer

The most common form of bladder cancer in the United States is urothelial carcinoma. Tobacco use is the most frequent risk factor, followed by occupational exposure to various carcinogenic materials such as automobile exhaust or industrial solvents. However, many patients develop bladder cancer without any identifiable risks.[1] Other forms of bladder cancer, such as adenocarcinoma and squamous cell carcinoma, occur in distinct patient populations. Patients with chronic irritation from catheters, bladder stones, or schistosomiasis infection are at risk for the squamous cell variant, whereas those with urachal remnants or bladder exstrophy have an increased risk of adenocarcinoma. However, the aforementioned variant histology should not be confused with urothelial carcinoma with variant transformation.

Bladder cancer can be categorized into invasive and noninvasive types. Management of urothelial carcinoma varies greatly, depending on the depth of invasion. A complete transurethral resection of the bladder tumor, which allows for staging of the tumor, is the first step. The tumor should be completely removed, if possible, along with a sampling of the muscular bladder wall underlying the tumor. An exam under anesthesia should be performed for all patients with newly diagnosed bladder tumors. The exam under anesthesia can help determine clinical staging and whether there is fixation of the bladder to adjacent structures. Radiologic imaging of most bladder tumors is of limited benefit in determining the presence, grade, or size/stage of a bladder tumor. However, in the presence of a known bladder tumor, unilateral or bilateral hydronephrosis is an ominous sign of locally advanced disease (at least muscle-invasive bladder cancer).[2] Computed tomography (CT) scans do provide valuable information regarding metastatic involvement of pelvic lymph nodes, liver, or lung. Historically, 25% of patients with preoperative CT scans demonstrating no evidence of lymphatic spread will actually have lymph node involvement during radical cystectomy and pelvic lymphadenectomy. The utility of a positron emission tomography (PET)-CT scan has emerged as an important imaging modality to minimize this rate to 5% to 10%. For patients who have disease invading into bladder muscle (T2), immediate (within 3 months of diagnosis) cystectomy with extended lymph node dissection offers the best chance of survival. Additionally, surgeons should send lymph node specimens in separate packets and not en bloc in an effort to increase nodal yield. Current long-term cure for those presenting with clinically localized disease has not significantly changed over the last two decades.[3] The addition of neoadjuvant or adjuvant chemotherapy in those without discernible metastatic spread is gaining increasing acceptance and does provide a survival benefit.[4] Patients with limited lymph node involvement may be cured with surgery alone, but those with extensive lymph node involvement have a dismal prognosis.

1▶

Patients have multiple reconstructive options, including continent and noncontinent urinary diversions. The orthotopic neobladder has emerged as a popular urinary diversion for patients without urethral involvement. This diversion type involves the detubularization of a segment of bowel, typically distal ileum, which is then refashioned into a pouch that is anastomosed to the proximal urethra (neobladder) or to the skin (continent cutaneous diversion). Detubularization decreases intrapouch filling pressure, which improves urinary storage capacity. In the case of a neobladder, the external sphincter is still intact, and voiding is achieved through sphincteric relaxation and a Valsalva maneuver. In the case of the continent cutaneous diversion, patients attain continence by utilizing a bowel segment (appendix or tapered small bowel) that has a high length-to-lumen ratio. The most common diversion is noncontinent, the ileal conduit, whereby a segment of distal ileum is isolated with one end brought out through the abdominal wall as a urostomy. Ileal conduits are preferred for renal insufficiency because urine is not "stored" and therefore has less time in contact with the absorptive surface of the ileal segment. Conduits are also used when the bladder is unresectable, but urinary diversion is necessary due to intractable bleeding, severe voiding pain, and hydronephrosis. Each segment of bowel that is used offers its own advantages and inherent complications.

Patients with non–muscle-invasive bladder cancer (confined to the bladder mucosa or submucosa) can be managed

with transurethral resection alone and adjuvant intravesical (instilled into the bladder) chemotherapy/immunotherapy. The use of these intravesical agents is critical since patients with non–muscle-invasive bladder cancer are at risk for tumor recurrence and progression. Tumor grade is extremely important in assessing the risk of disease progression. Those patients with high-grade disease or recurrent tumors can be treated with intravesical agents such as bacille Calmette-Guérin or mitomycin C. These agents decrease risk of progression and recurrence, by induction of an effective immunologic antitumor response in the case of bacille Calmette-Guérin and through direct cytotoxicity for mitomycin C. Those patients at high risk of progression who fail conservative therapy should be offered cystectomy. Because upper tract recurrence is fairly common (up to 17% of patients with carcinoma in situ), surveillance must be performed with retrograde pyelograms or CT urograms.

Surgical Approaches and Complications. The typical surgical approach for cystectomy is a lower midline incision from just above the umbilicus to the pubic symphysis. This allows adequate exposure of the pelvic contents, iliac vessels, and lower abdominal cavity. The peritoneum between the median umbilical ligaments (urachal remnant) also is taken with the specimen. In men, the prostate is removed with the bladder. In women, the uterus, ovaries (in postmenopausal women), and anterior wall of the vagina are removed with the bladder. The vagina may be spared, depending on the location and extent of the tumor, but significantly more operative bleeding results. Robotic approaches for cystectomy are increasingly used, but the urinary diversion is still usually performed through an open incision. The benefits of the robotic portion are decreased blood loss during the pelvic dissection (due to pneumoperitoneum) and the shortening of the time that the abdomen is open. However, recent evidence (randomized controlled trials of open versus robot-assisted radical cystectomy) did not demonstrate any difference in oncologic efficacy or complication rates.

Complications of bladder cancer surgery involve bladder perforation during transurethral resection of the bladder tumor, which requires catheter drainage for several days if small (common) or open repair if large and intraperitoneal (rare). Cystectomy and urinary diversion may result in prolonged ileus, bowel obstruction, intestinal anastomotic leak, urine leak, or rectal injury. A urine leak from the ureteroileal anastomoses is a common cause of ileus, intra-abdominal urinoma, abscess formation, and wound dehiscence. Deep venous thrombosis is common after cystectomy[5] due to the advanced age of most patients, proximity of the iliac veins to the resection and lymph node dissection, and the presence of malignancy. Pulmonary embolism is one of the leading causes of death in the perioperative period after radical cystectomy. The utility of subcutaneous heparin in the perioperative period can minimize the risk of venous thromboembolism.

Testicular Cancer

Testicular cancer is the most common solid malignancy in men age 15 to 35 years.[6] Most men are diagnosed with an asymptomatic enlarging mass (Fig. 40-1). A major risk for the development of testicular cancer is cryptorchidism. Although the debate continues over whether early surgical intervention to bring an undescended testis into the scrotum alters the future risk of cancer, it is generally accepted that doing so allows much easier monitoring for the development of a testicular mass.

Most neoplasms arise from the germ cells, although non–germ cell tumors arise from Leydig's or Sertoli's cells. The non–germ cell tumors are rare and generally follow a more benign course. Germ cell cancers are categorically divided into seminomatous and nonseminomatous forms that follow different treatment algorithms.

Figure 40-1. Testicular cancer. Patients often present with advanced disease despite scrotal enlargement for several months.

Since the vast majority of solid testicular masses are cancerous, any observed mass on physical examination and/or documented on ultrasound is malignant until proven otherwise. Initial studies must include tumor markers, including α-fetoprotein, β-human chorionic gonadotropin, and lactate dehydrogenase. Elevated tumor markers are found almost exclusively in nonseminomatous germ cell tumors, although up to 10% of patients with localized seminomas and 25% with metastatic seminomas will have a modest rise in β-human chorionic gonadotropin. Chest and abdominal imaging must be performed to evaluate for evidence of metastasis. The most common site of spread is the retroperitoneal lymph nodes extending from the common iliac vessels to the renal vessels, and abdominal imaging should be performed in all patients. There is no role for percutaneous biopsy of testicular masses due to (a) the risk of seeding the scrotal wall; (b) changing the natural retroperitoneal lymphatic drainage of the testicle (because the testes have a remarkably predictable pattern of lymphatic drainage); and (c) the propensity of a testicular mass being cancerous. In cases where metastatic disease to the testicle is suspected, an open testicular biopsy by delivery of the testicle through the inguinal canal is recommended. Lymphoma (especially among the elderly) may involve one or both testes. Often, evidence of lymphoma usually is present elsewhere in the body, although relapses may be isolated to the testes.

Even in the absence of enlarged lymph nodes on CT imaging (stage I), occult micrometastatic disease is often present (30% of the time), so adjuvant surgery, radiation, or chemotherapy is offered. However, active surveillance protocols have been gaining traction for both seminoma and nonseminomatous tumors. Retroperitoneal lymph node dissection

2▶

(RPLND) is potentially curative in the setting of limited lymph node involvement and has been the preferred adjuvant treatment of those with stage I nonseminomatous disease. Alternatively, patients with stage I nonseminomatous tumors can also choose to receive two cycles of chemotherapy. Pure seminoma is exquisitely radiosensitive, and stage I, IIa, and IIb disease can be treated with external-beam radiation to the retroperitoneal nodes. However, a single dose of carboplatin for stage I seminoma was found to be just as effective as radiation therapy. Both forms of germ cell tumors, in the setting of disseminated disease or large bulky lymph nodes, are best treated with four cycles of chemotherapy. However, teratoma frequently is a component of retroperitoneal lymph node metastasis, and it is not responsive to chemotherapy or radiation and can demonstrate aggressive malignant degeneration. Postchemotherapy RPLND for residual masses can be challenging. Large bulky metastases may encase the great vessels, and vascular graft placement after resection occasionally is required.

Surgical Approach and Complications. For orchiectomy, an inguinal incision is made over the external ring and carried laterally over the internal ring. It is important to not violate the scrotal skin during orchiectomy, for fear (mostly theoretical) of altering the lymphatic drainage of the testis. For RPLND, a midline incision usually is made from the xiphoid process to the umbilicus for most patients with stage I disease. If it is in a setting of a postchemotherapy residual mass, the incision is extended down to the pubic symphysis. The use of robotic-assisted RPLND is rarely used for stage I nonseminomatous disease, although with increasing demand for minimally invasive surgery, one would anticipate that it will be the happy compromise for those who wish to avoid a major incision but are not interested in active surveillance or systemic chemotherapy.

Complications of testicular cancer surgery include scrotal hematoma formation, which can be prevented by meticulous hemostasis. Complications after RPLND include bowel obstruction; excessive bleeding, particularly from retrocaval lumber veins; and chylous ascites. Patients who undergo a full, bilateral RPLND often suffer from ejaculatory dysfunction due to the interruption of the descending postganglionic sympathetic nerve fibers that are involved in seminal emission. For this reason, right and left templates have been developed that limit bilateral dissection (especially below the inferior mesenteric artery) and preserve some of these nerves with a low risk of leaving residual microscopic cancer.[7]

Figure 40-2. Complex renal cyst. A right kidney with a Bosniak type 3 renal cyst. Note the enhancing septum (*arrow*). This cyst was removed and found to be a high-grade papillary renal cell carcinoma.

Kidney Cancer

Renal cell carcinoma (RCC) is a malignancy of the renal epithelium that can arise from any component of the nephron (Fig. 40-2). In 2012, there were over 64,000 new cases in the United States, with over 13,000 deaths.[8] With the widespread use of imaging for many medical complaints, a stage migration has led to an increased incidence of small renal masses.[9] Surprisingly, this has not led to lower mortality rates. Various histologic subtypes include clear cell, papillary (types I and II), chromophobe, collecting duct, and unclassified forms. Collecting duct and unclassified forms have dismal prognoses and do not routinely respond to systemic therapy. Benign lesions, common in the setting of a small renal mass, include oncocytomas and angiomyolipomas. Renal tumors are usually solid, but they also can be cystic. Simple cysts are very common and are not malignant, but more complex cysts may be malignant. The Bosniak classification system, based on septations, calcifications, and enhancement, is used to assess the likelihood of malignancy (Table 40-1).[10]

Most cases of RCC are sporadic, but many hereditary forms have been described. These syndromes frequently involve

Table 40-1.

Bosniak renal cyst computed tomography classification

CATEGORY	DESCRIPTION	RISK OF MALIGNANCY/MANAGEMENT
I	Thin-walled cyst with water density with no septations or calcifications.	0%/nonsurgical
II	Thin-walled cyst with few hairline septa that may contain fine or very limited thick calcifications. Also includes homogeneously hyperdense cysts <3 cm.	0%/nonsurgical
II F (follow)	Multiple hairline or slightly thickened septa without measurable enhancement. May contain nodular calcification. Also includes hyperdense cysts >3 cm.	~5%/should be followed for progression
III	Irregular or smooth thickened walls or septa with measurable enhancement.	~50%/surgical
IV	Same as III, but with enhancing solid components.	~100%/surgical

a germline mutation in a tumor suppressor gene. von Hippel-Lindau disease is associated with multiple tumors including clear cell RCC (Fig. 40-3). The involved gene, *vhl*, also frequently is mutated or hypermethylated in sporadic RCC.[11] Other rare forms include Birt-Hogg-Dubé syndrome, where patients get oncocytomas or chromophobe tumors. Patients with hereditary papillary RCC and hereditary leiomyomatosis develop papillary RCC.

The most common sites of metastasis are the retroperitoneal lymph nodes and lungs, but liver, bone, and brain also are common sites of spread. Up to 20% to 30% of patients may present with metastatic disease, in which case, surgical debulking can improve survival, as shown in randomized controlled trials.[12,13] Patients with all but the smallest renal masses should undergo testing for the presence of metastatic disease including chest CT, bone scan, and liver function tests.

Patients with localized disease may be cured with either partial or radical nephrectomy (Fig. 40-4). The oncologic efficacy of partial nephrectomy (nephron sparing) appears to be similar to that of radical nephrectomy. However, patients

Figure 40-4. Partial nephrectomy. A kidney after partial resection for a small renal mass. Note the visible collecting system in the base of the defect (*arrow*).

with larger tumors or with a more central tumor location may be at increased risk for surgical complications. Nephron-sparing surgery should be considered in all patients, if feasible, as those patients undergoing a radical nephrectomy are at risk for future chronic kidney disease.[14] The lack of harm from nephrectomy due to malignancy has been extrapolated from the fact that kidney donors do not routinely develop renal insufficiency. However, kidney donors are a highly selected group, and patients with renal tumors are typically older and have more comorbidities. Additionally, the risk of contralateral RCC is 2% to 3% in most series,[15] and a partial nephrectomy may prevent the future need for dialysis in case of a contralateral kidney tumor. While we should all strive to preserve as many nephrons as possible, we do not have level 1 evidence that supports the use of partial nephrectomy over radical nephrectomy for patients with small renal masses. 3▶

Minimally invasive techniques for renal surgery have greatly changed the field of kidney cancer. Laparoscopic and robot-assisted laparoscopic renal surgery allows for more rapid convalescence and decreased narcotic requirements. While laparoscopic partial nephrectomy is challenging and is performed only in experienced hands due to its associated high rate of complications, the advent of robot-assisted surgery has changed the landscape. Surgeons are now capable of performing intracorporeal suturing with much greater ease. Ablative techniques such as cryoablation and radiofrequency ablation are also popular choices, especially among those who are poor surgical candidates. However, long-term results from these techniques are currently lacking due to their recent development. Active surveillance is another viable alternative for small renal masses, especially in patients with multiple comorbidities or advanced age. Most small renal masses are low grade with a slow growth rate, and patients very rarely progress to metastatic disease after limited follow-up of 2 to 3 years.[16]

Up to 10% of RCC invades the lumen of the renal vein or vena cava. The degree of venous extension directly impacts the surgical approach. Patients with thrombus below the level of the liver can be managed with cross-clamping above and below the thrombus and extraction from a cavotomy at the insertion of the renal vein (Fig. 40-5A). Usually, the thrombus is not adherent to the vessel wall. However, cross-clamping the vena cava above the hepatic veins can drastically reduce cardiac preload, and therefore, bypass techniques often are necessary. For thrombus above the hepatic veins, a multidisciplinary approach with either venovenous or cardiopulmonary bypass is necessary. In cases of invasion of the wall of the vena cava or atrium, deep hypothermic circulatory arrest may be used to give a completely bloodless field. Tumor thrombus embolization to the pulmonary artery is a rare but known complication during these cases and is associated with a high mortality rate (Fig. 40-5B). For cases of extensive tumor thrombus, intraoperative transesophageal echocardiography should be considered for monitoring and assessment of possible thrombus embolization. If a thrombus embolization occurs, a sternotomy/cardiopulmonary bypass with extraction of the thrombus may be life saving.

Patients undergoing resection of localized renal masses are at substantial risk of future recurrence. Many predictive features have been recognized, but the most widely accepted prognostic findings are tumor stage, grade, and size, each of which exerts an independent effect on recurrence. Isolated solitary recurrences,

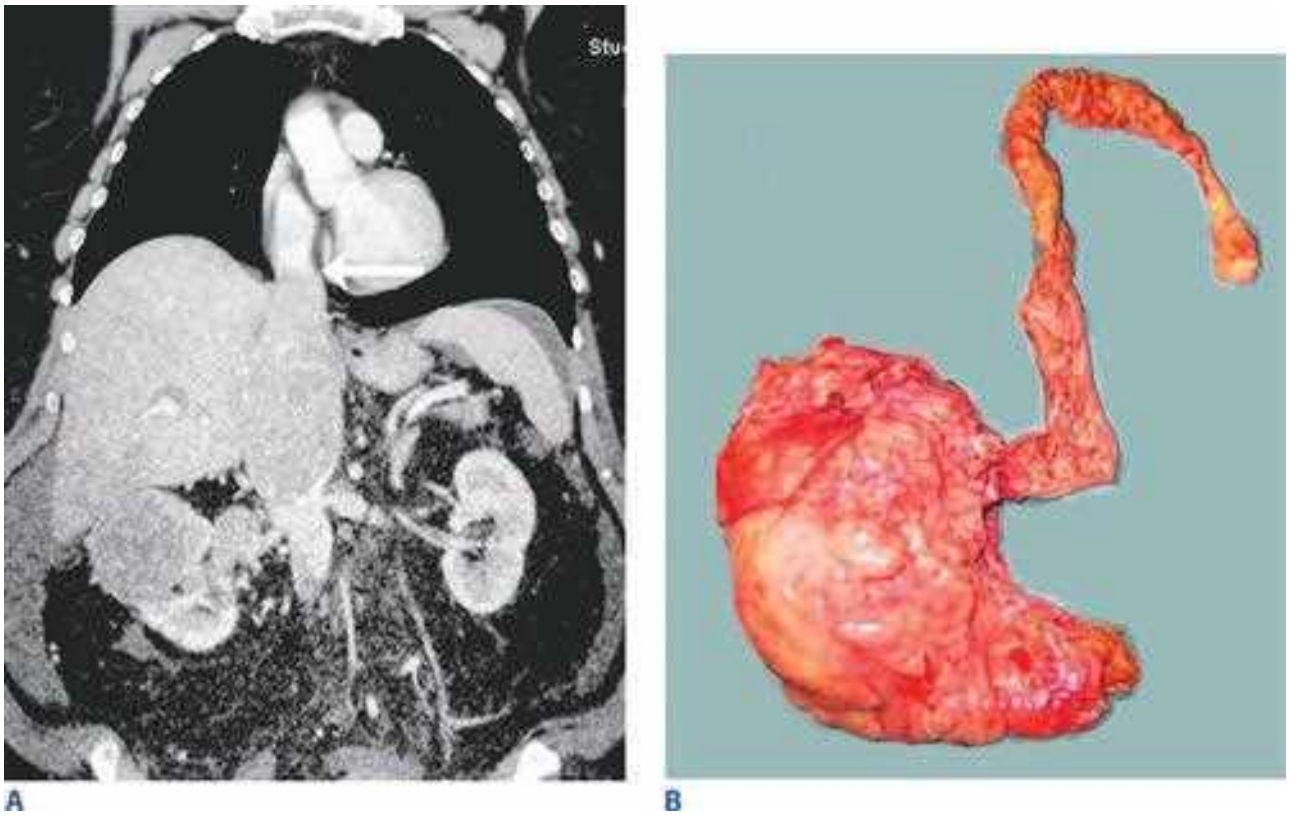

Figure 40-5. Inferior vena cava thrombus. **A.** A multidetector computed tomography image displaying a tumor thrombus extending above the diaphragm (*arrow*) arising from a right renal mass. **B.** An en bloc removal of a different right renal mass with a tumor thrombus that extended to the pulmonary artery. either local or distant, can be resected with long-term disease-free rates approaching 50%.[17]

Surgical Approach and Complications. Nephrectomy, either partial or radical, can be performed through a number of surgical approaches. Flank incisions over the eleventh or twelfth ribs from the anterior axillary line to the lateral border of the rectus muscle provide access to the kidney without entering the peritoneum. However, entry into the pleura is not uncommon. If small, the pleurotomy usually can be closed without need for a chest tube. The anterior subcostal approach also is used for nephrectomy. There is no risk for pleural entry, but this incision is transperitoneal, so ileus is somewhat more likely. Laparoscopic nephrectomy is now common, and robot-assisted laparoscopic partial nephrectomy is gaining significant traction in the management of small renal masses. For large tumors, particularly on the right side where the liver makes exposure of the tumor more difficult, a thoracoabdominal approach is very helpful. In these cases, the flank incision is made over the tenth rib and carried further posterior and anterior than a typical flank incision. The chest and abdominal cavities are intentionally entered for maximum exposure, and the diaphragm is partially divided in a circumferential fashion, which allows cephalad retraction of the liver. A chest tube is used postoperatively. The adrenal gland is no longer routinely removed unless the tumor is adherent to it. The benefit of lymph node dissection when the nodes are not clinically involved is uncertain.

Complications of radical nephrectomy include bleeding, pneumothorax, splenic injury, liver injury, and pancreatic tail injury. Partial nephrectomy has the added risks of delayed bleeding and urine leak. Ileus is not common when the peritoneal cavity is not entered.

Prostate Cancer

Prostate cancer is the most common nonskin malignancy in men, with an incidence of approximately 200,000 per year. Yearly screening consisting of digital rectal exam and serum prostate-specific antigen (PSA) testing has been a topic of much debate. The U.S. Preventive Services Task Force has advised against the routine use of prostate cancer screening. The American Urological Association has advised for screening for men 55 to 69 years of age. Patients of African American descent or those with a family history of prostate cancer should be considered for screening at an earlier age (as early as 40). Men with abnormal digital rectal exams or PSA elevation have an indication for prostate biopsy to determine the presence of the disease. With the advent of PSA screening, prostate cancer has experienced a stage migration, with most cases now discovered locally confined within the prostate. The majority of patients with prostate cancer will not die of the disease by 10 to 15 years, whether it is treated at diagnosis or not. However, those undergoing initial treatment have improved cancer-specific survival.[18]

Prostate cancer is graded according to the Gleason scoring system.[19] A primary and secondary score are assigned based on the most common and second most common histologic patterns. Grades range from 1 for the most differentiated to 5 for the least. The grades are added to give the Gleason score. In current practice, scores below 6 are almost never assigned. Gleason score, preoperative PSA level, and digital rectal exam are used

to estimate the likelihood of whether the cancer is localized, locally advanced, or metastatic. Prostate cancer with a high Gleason score (8 to 10) or a high PSA level (>20) is much more likely to have spread, often at a micrometastatic level. After definitive treatment, an increasing PSA is indicative of recurrent cancer.

The most common site of spread of prostate cancer is the pelvic lymph nodes and bone. For patients with high-risk disease based on clinical stage, grade on biopsy, and PSA level, staging includes bone scan and CT imaging to evaluate for bony metastases or pelvic lymphadenopathy. Multiple treatment options are available for men with localized disease, including radical prostatectomy (retropubic, perineal, or robotic-assisted laparoscopic approaches), brachytherapy, and external-beam radiation therapy. For low-risk disease, the efficacy of each treatment modality is thought to be similar. For low-risk disease, radical prostatectomy (open or robotic) can be performed with unilateral or bilateral cavernosal nerve sparing to limit postoperative erectile dysfunction (ED). For high-risk disease, either non–nerve-sparing surgery or external-beam radiation therapy plus androgen deprivation may be performed. The associated morbidity of each treatment differs, and it is important to discuss the side effects with patients. Irritative voiding and bowel symptoms are common after radiation therapy, with ED being a late side effect. Radical prostatectomy is associated with early incontinence and ED (depending on nerve sparing). Incontinence improves significantly with time, with <1% of men in experienced hands suffering severe long-term problems with urinary control. Likewise, ED improves with time. The large majority of younger men (<55 years of age) regain erectile function, often with the aid of oral medications, if both cavernosal nerves are spared.[20] Older men or those with no nerves or one nerve spared have lower rates of erectile function.

Active surveillance has emerged as a safe and viable option for men with anticipated survival of <10 years, low Gleason score (6), early-stage disease (cT1c), and small-volume disease as determined by biopsy. Patients should be monitored closely with digital rectal exam, PSA testing, and repeat biopsy at 1 to 2 years to assess the possible progression of disease. Once prostate cancer has spread, it is no longer curable. Medications that lower serum testosterone or that block the androgen receptor are able to control the disease, often for years, but the cancer inevitably becomes resistant to this treatment. Nevertheless, patients with noncurable prostate cancer can live many years, and a large number die of causes other than prostate cancer.

Surgical Approach and Complications. The approach for an open radical retropubic prostatectomy uses a lower midline incision from the pubic symphysis to approximately 5 cm below the umbilicus. The peritoneum is not entered. Lymph nodes are removed between the external iliac vein and obturator vessels bilaterally, although this may be omitted in cases where the probability of involvement is very low. Some regularly perform a wider dissection that may improve staging, although any therapeutic benefit is uncertain. The cavernosal nerves lay immediately posterolateral to the prostatic capsule. They may be spared if the cancer is not likely to penetrate the capsule on that side, which is a function of preoperative parameters such as biopsy results, PSA, and clinical examination. Robot-assisted laparoscopic radical prostatectomy has superseded laparoscopic prostatectomy due to the learning curve and increased agility that facilitates intracorporeal suturing. Benefits over open radical retropubic prostatectomy include lower blood loss and faster convalescence. Some claim faster return of continence and lower ED rates, but these findings have not yet been widely demonstrated.

Complications of prostatectomy depend on approach. Retropubic approaches may result in urine leaks, lymphocele, and very rarely, rectal or ureteral injury. Robotic prostatectomy uses a transperitoneal approach that can occasionally result in ileus, particularly in cases of a urine leak from the vesicourethral anastomosis. All approaches carry a small risk of urinary incontinence and a more substantial risk of ED.

TRAUMA

Kidney

Renal injuries are more common during blunt trauma, accounting for 90% of injuries to the kidney. Any patient with a major deceleration injury, shock, or gross hematuria should undergo radiographic imaging of the kidneys. All patients with penetrating injuries to the flank or abdomen must undergo imaging unless unstable and requiring immediate exploration.

Renal injuries are classified by extent of damage (Table 40-2). Blunt traumatic injuries usually can be managed conservatively, while penetrating renal injuries usually require exploration. Urinary extravasation alone does not require exploration, but reimaging is necessary and, if persistent leakage is

Table 40-2.

American Association for the Surgery of Trauma renal injury scale

GRADE	INJURY TYPE	DESCRIPTION
1	Contusion	Microscopic or gross hematuria with normal imaging
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
2	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum
		<1 cm in depth without urinary extravasation
3	Laceration	>1 cm in depth without collecting system rupture or urinary extravasation
4	Laceration	Parenchymal laceration through cortex, medulla, and collecting system
4	Vascular	Main renal artery or vein injury with contained hemorrhage
5	Laceration	Completely shattered kidney
5	Laceration	Avulsion of renal hilum leading to devascularized kidney

present, a stent or nephrostomy tube is indicated. All grade V vascular injuries should be considered for immediate exploration, as a delay of several hours greatly decreases the risk of renal salvage. High-grade renal injuries are associated with significant bleeding, but patients who are stable and without a pulsatile or expanding hematoma can be observed. Even in expert hands, the risk of renal loss at surgery is significant and must be considered before opening the retroperitoneum. Additionally, most grade IV injuries can be managed nonoperatively (Fig. 40-6).[21] Patients typically are placed on restricted activity until hematuria resolves. Table 40-3 lists indications for assessing surgical intervention in renal trauma patients.

If immediate operative exploration for other injuries is required, renal injury staging can be performed while in the operating room. If concern exists over renal injury or the presence of a retroperitoneal hematoma, a single-shot, 10-minute delayed intravenous pyelogram (IVP) (2 mL/kg contrast) is useful at assessing the presence of two functional kidneys and

Table 40-3.

Indications for surgical intervention for renal trauma

Absolute indications
1. Persistent, life-threatening hemorrhage from probable renal injury 2. Renal pedicle avulsion (grade 5 injury) 3. Expanding, pulsatile, or uncontained retroperitoneal hematoma
Relative indications
1. Large laceration of the renal pelvis or avulsion of the ureteropelvic junction 2. Coexisting bowel or pancreatic injuries 3. Persistent urinary leakage, postinjury urinoma, or perinephric abscess with failed percutaneous or endoscopic management 4. Abnormal intraoperative one-shot intravenous urogram 5. Devitalized parenchymal segment with associated urine leak 6. Complete renal artery thrombosis of both kidneys or of a solitary kidney when renal perfusion appears preserved 7. Renal vascular injuries after failed angiographic management 8. Renovascular hypertension

extent of injury. If the IVP is abnormal or the hematoma is pulsatile, renal exploration should be performed.

Renal exploration should begin once the renal hilum is controlled. Although rarely necessary, temporary control of the renal hilum may decrease the need for nephrectomy when a significant injury is found on exploration. Complete exposure is necessary to evaluate the extent of injury. All nonviable tissue should be débrided and segmental and intralobar arteries ligated with 4-0 chromic or polydioxanone sutures. If the collecting system is injured, it should be repaired at this time. A stent and percutaneous drain should be considered to prevent urinoma formation. A partial vascular injury to the renal vein or artery can be repaired with 5-0 or 6-0 Prolene sutures. A complete injury may require débridement, and if an end-to-end anastomosis cannot be performed, a vascular graft may be required.

Ureter

The retroperitoneal location of the ureter protects it from external trauma, and blunt injury is rare but can occur with rapid deceleration injuries. Penetrating trauma may occur, but a high index of clinical suspicion is required to make the appropriate diagnosis. Any penetrating trauma involving the retroperitoneum should undergo evaluation with intraoperative inspection, IVP, or CT urogram. A retrograde pyelogram is the most sensitive test for ureteral injury, and a stent can be placed if a partial transection is observed. The ureter also is frequently injured intraoperatively, most commonly from open and laparoscopic surgical procedures including hysterectomy, low anterior colonic resections, or aortic surgery. Endoscopic procedures such as ureteroscopy also can lead to ureteral injury such as perforation and avulsion.

Surgical repair depends on location and extent of injury. A briefly misplaced suture may be removed usually without consequence. Partial injuries can be primarily repaired, although all devitalized tissue must be débrided to avoid delayed tissue breakdown and urinoma formation. Ureteral stents should be placed in this situation to facilitate healing without stricture. Lower ureteral injuries (below the iliac vessels) are best treated with ureteral reimplantation, as the blood supply can be tenuous, and strictures are more common with a distal uretero-ureterostomy. Midureteral level injuries can be treated with a uretero-ureterostomy if a spatulated, tension-free repair can be achieved. For longer defects, the bladder can be mobilized and brought up to the psoas muscle (psoas hitch). For additional length, a tubularized flap of bladder (Boari flap) can be created and anastomosed to the remaining ureter. Renal mobilization with nephropexy by anchoring to the psoas muscle can provide additional length. Autotransplantation, transuretero-ureterostomy, and ileal ureter are rarely needed in the acute setting.

5▶

Bladder

Bladder injury can occur from penetrating and blunt trauma. The diagnosis should be entertained for any lower abdominal or pelvic trauma. Intraperitoneal ruptures are less common than retroperitoneal injuries but may be seen in the setting of a full bladder before injury. Bladder injuries often are associated with pelvic fractures and may frequently occur in conjunction with urethral injuries. Nearly all patients present with gross hematuria, although occasionally microscopic hematuria is present. A delayed presentation can be associated with intoxication, but it also may occur as a result of iatrogenic injury. These patients often have electrolyte abnormalities such as metabolic derangements, azotemia, and leukocytosis from urine absorption. Patients clinically present with fevers or a prolonged ileus.

Radiographic evaluation begins with either a fluoroscopic or CT cystogram. It is vital to avoid underfilling, as it may lead to a false-negative study. A preset amount can be instilled based on age calculations, which is typically approximately 300 to 400 mL in adults. The bladder can be filled under gravity by raising the Foley catheter to 15 cm above the pubic ramus. The contrast material should be allowed to fill to the natural capacity of the bladder. It is important to have a postdrainage film to assess for persistent contrast, which may indicate a rupture.

Extraperitoneal bladder injuries can typically be managed with catheter drainage for 7 to 10 days. If intraoperative exploration is to occur for other injuries, repair can be performed at that time. For patients with pelvic injuries that require placement of metal hardware, repair of the bladder rupture should be performed concurrently. Intraperitoneal bladder injuries should be explored immediately and repaired. However, in cases of a missed intraperitoneal injury, patients often do well with catheter drainage only. For large ruptures after repair, a suprapubic tube is recommended, but a large urethral catheter is sufficient for smaller injuries. All injuries, especially those managed nonoperatively, should be followed up by a cystogram to document healing before catheter removal.

6▶

Urethra

Urethral injuries can be divided by anterior (penile and bulbar urethra) and posterior (membranous and prostatic) location. Any patient with blunt pelvic trauma, blood present at the urethral meatus, hematuria, inability to void, or perineal hematoma should be considered to have a urethral injury until proven otherwise. Urethral injuries should be anticipated with pubic ramus fractures and occur in 10% of unilateral ramus and 20% of bilateral rami injuries.[22]

Staging is performed by retrograde urethrography. This study can be easily performed in the trauma suite with the patient in an oblique position and a 12F catheter placed in the urethral meatus. With the penis placed on traction, 30 mL of contrast is instilled while an x-ray is obtained during filling. The addition of fluoroscopy is a valuable addition to the procedure but can be omitted if not available. A partial or complete disruption can be diagnosed based on extravasation or filling of the proximal urethra. Catheter placement can be attempted in patients with partial urethral injuries. Those with complete disruptions should have placement of a suprapubic tube.

Anterior injuries often are related to blunt straddle injuries and penetrating trauma. Blunt anterior urethral injury can be managed in multiple ways, and only small series are available in the literature to compare methods. Immediate surgical repair is not recommended in the acute setting with the exception of low-velocity penetrating injuries. If the patient is stable with minimal hematoma formation, repair should be considered. In the setting of a 1- to 2-cm defect, the urethra can be débrided, spatulated, and anastomosed in an end-to-end, watertight fashion. Large defects should have treatment deferred, as grafts or flaps may be required for repair and the success may diminish with infections. For most cases, catheter drainage is recommended. Many advocate avoiding placement of a urethral catheter, as it may convert a partial tear to a complete dissection. However, a single gentle passage performed by a urologist is safe. For a complete disruption, the placement of a suprapubic tube is recommended; however, a stricture at the site of injury may ensue.

Posterior urethral injuries usually result from pelvic crush injuries and shearing forces causing a prostatomembranous disruption. The patient's other injuries dictate urologic management. Initial open surgical exploration of the urethral injury should be avoided due to altered anatomy, risk of bleeding, and high likelihood of incontinence and ED from injury of adjacent nerves. Patients can be managed with suprapubic tube and delayed repair or with delayed primary realignment. Primary endoscopic realignment, when possible, leads to decreased rates of strictures without increasing adverse outcomes.[23,24]

Urethral strictures can be caused by trauma or inflammatory conditions. They should be staged with either a retrograde urethrography or voiding cystourethrogram (VCUG). Patients with short defects may be amenable to dilatation or cystoscopic urethrotomy. Depending on location, length, and severity, open repairs may be required. Long defects may require grafting to avoid significant penile shortening. Young patients should be considered for open surgical management to definitely repair the stricture due to the tendency of strictures to recur when treated with simple dilation.

Testes

Testicular injury most commonly occurs with blunt injuries when the testicle is forcibly compressed against the thigh or pubic bone with enough force to rupture the tunica albuginea. For patients with scrotal trauma, ultrasound is the preferred modality for staging the extent of injury. Ultrasound can evaluate the testicular blood flow, the presence of testicular

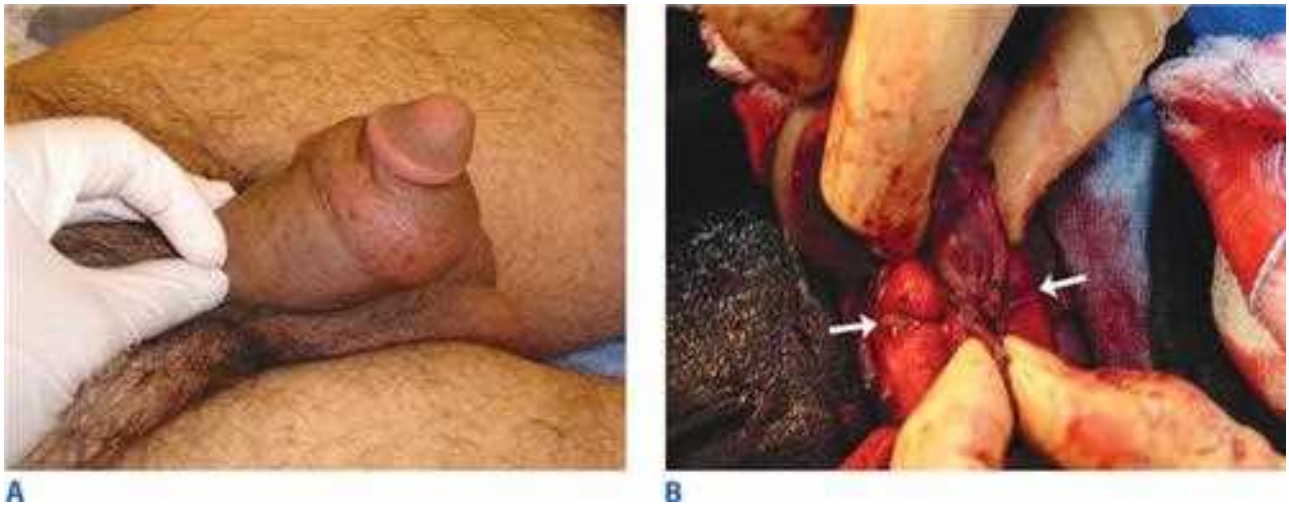

Figure 40-7. Penile fracture. **A.** A patient with a penile fracture that was suspected based on history and examination. Note the lack of skin discoloration that is often present. **B.** Intraoperative finding of bilateral corporal body ruptures (*arrows*) along the ventral penile surface. The urethra, which is between the surgeon's fingers, surprisingly escaped injury.

contusions, intratesticular hematomas, hematoceles, or a disrupted tunica albuginea. The presence of a hematocele should increase suspicion for testicular rupture because ultrasound may not detect the tunical defect in this setting.[25]

The goal of surgery is to salvage as much parenchyma as possible and to avoid delayed complications such as ischemic atrophy or abscess formation. A large hematocele, if not evacuated, could lead to ischemic atrophy, and drainage should be considered. A ruptured tunica albuginea can be repaired primarily, and nonviable parenchyma may need to be débrided. For penetrating trauma, immediate exploration is recommended for accurate staging and repair. Frequently, these injuries result in major devascularization and nonviable tissue (especially gunshot wounds). Although salvage may be possible, an orchiectomy usually is required.

Penis

Penile fractures are injuries that involve a traumatic rupture of the tunica albuginea, usually occurring during sexual intercourse—usually with the female partner on top. The engorged penile corporal bodies can rupture if sufficient force is generated against the partner's pubic symphysis or perineum (Fig. 40-7). Men may notice an immediate audible "pop" and experience rapid penile detumescence. Immediate swelling develops. If Buck's fascia is disrupted, swelling and ecchymosis can be noted throughout the perineum ("butterfly sign"). At presentation, a classic "eggplant" appearance of the penis is often, although not always, seen. Exploration by a circumcising (degloving) incision and repair of the defect offers the best chance at avoiding permanent ED and penile deformity while also minimizing the risk of infection.[26] A retrograde urethrogram should be performed to rule out urethral injury at the time of surgery. Alternatively, the urethra can be manually occluded intraoperatively at the penoscrotal junction and a dilute methylene blue solution injected under pressure into the urethral meatus with a catheter-tip syringe. Leakage should be visualized if there is a urethral disruption. If present, the urethra should be repaired, taking care not to significantly narrow the lumen. A Foley catheter is left in place for several days after surgery. Any penetrating injury to the penis must undergo exploration to repair any injuries to the corporal bodies or the urethra.

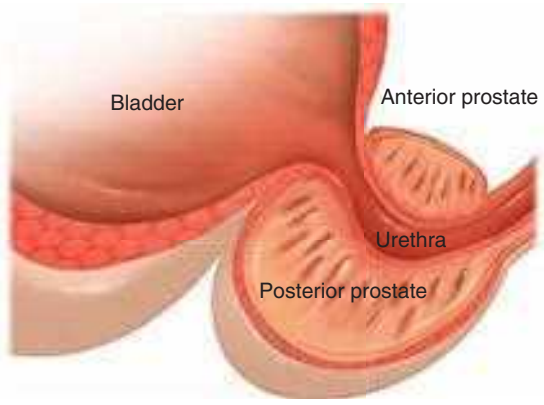
EMERGENCIES

Acute Urinary Retention

Acute urinary retention (AUR) can happen in men or women and results from a variety of causes, although it most commonly occurs in men with benign prostatic hyperplasia (BPH). Other chronic causes of poor bladder emptying, such as diabetic neuropathy, urethral stricture, multiple sclerosis, or Parkinson's disease, can result in episodes of complete urinary retention, often when the bladder becomes overdistended. This frequently occurs in the hospital setting when patients have limited mobility and are receiving medications that decrease bladder contractility, including opiates or anticholinergics. Constipation, a common side effect of those medications, can itself worsen urinary retention. Significant hematuria can result in the formation of blood clots, which may block the urethra and cause retention.

7▶

Although some patients receiving large doses of narcotics or those with chronically decompensated bladders may not experience discomfort, most patients with AUR have significant pain. If the urinary retention has lasted several days (often accompanied by overflow incontinence), patients may develop acute renal failure. Treatment should include placement of a urethral catheter as quickly as possible. However, BPH or urethral strictures often make the placement of a catheter difficult. For men with BPH, a coude (French for *curved*) catheter is helpful in negotiating past the angulation in the prostatic urethra (Fig. 40-8A). The curved portion (which is angled in line with the balloon port) is maintained at the 12 o'clock position as it is passed through the urethra (Fig. 40-8B). A common mistake is to use a smaller catheter to bypass the enlarged prostate. However, a larger (18F to 20F) catheter is less flexible and is more likely to push into the bladder rather than curl in the prostatic urethra. Smaller catheters are useful for bypassing a urethral stricture. A urethral stricture should be suspected when the catheter meets resistance closer to the meatus, as many strictures occur in the distal urethra, which is narrower than the proximal portion. Using a 12F or 14F catheter often will allow the passage of the catheter into the bladder. If catheter placement is not successful, a urologic consultation should be requested. The urologist can either choose to (a) use a cystoscope, guidewire,



A

B

Figure 40-8. Coude catheter. **A.** A schematic drawing of a lateral view of the prostatic urethra showing the upward angulation at the bladder neck, which a coude catheter is helpful in negotiating. **B.** The tip of a coude catheter. Note the curved tip, which should always point to 12 o'clock when inserted.

and urethral dilators to dilate the stricture and place a Counseltip catheter via Seldinger technique; or (b) place a suprapubic tube approximately two fingerbreadths above the pubic symphysis. With regard to the suprapubic tube, aspiration with a finder needle should be used first to localize the bladder and avoid intra-abdominal contents, although bowel injury is unlikely with a distended bladder filling the pelvis. If hematuria is the cause of retention, continuous bladder irrigation often is necessary to prevent clot formation. This is done through a large three-way catheter that has an additional port for fluid inflow. Fluid is infused by gravity only because the use of higher pressure may result in bladder rupture if outflow is occluded.

A urinalysis should be checked because a poorly emptying bladder is prone to infection. Renal function also should be assessed for those in AUR by checking the creatinine level. An elevated creatinine level suggests that AUR has resulted in renal dysfunction, and these patients are at risk for postobstructive diuresis. These patients must be closely watched for excessive urine output, often caused by an osmotic diuresis due to retained nitrogenous waste products or a temporary renal concentrating defect. Fluid and electrolytes must be replaced if the urine output exceeds 200 mL/h, especially if hemodynamic instability or electrolyte imbalances are seen. Fluid replacement typically is 0.5 mL of 0.45 normal saline for every 1 mL of urine output above 200 mL in 1 hour, although sodium and potassium supplementation requirements depend on the electrolyte status of the patient.

Once the bladder is adequately drained, the cause of AUR should be addressed. For men with suspected BPH, an α-blocker such as tamsulosin should be started. Although finasteride and dutasteride (5α-reductase inhibitors) have been shown to reduce the incidence of urinary retention by 50%, they require a few months to take effect and, hence, will not provide significant benefit in the short term. Narcotics should be tapered as tolerated, and constipation should be treated. Acute spinal cord compression, which is accompanied by saddle paresthesias, is a neurologic emergency that requires neurosurgical or orthopedic consultation. In most cases, except severe neurologic injuries, patients will be able to resume voiding, and the catheter can be removed after 1 to 2 days. Postvoid residuals should be checked with a portable ultrasound device (bladder scanner) or by "straight" catheterization to determine the residual amount of urine left after the patient tries to empty his or her bladder. In patients with severe liver dysfunction, the bladder scanner may inadvertently misinterpret ascites for urine. The inability to void or the presence of a postvoid residual over 200 mL is concerning for development of another episode of AUR. Patients may be given the option of an indwelling catheter for another few days with a subsequent voiding trial, or learning to clean intermittent catheterization (CIC), whereby, after predetermined intervals (4–6 hours) or after voiding attempts, the patient passes a catheter into the bladder and empties it. This is the preferred method, because it reduces the likelihood of infections from indwelling catheters and may improve bladder functionality. However, most patients are resistant to this approach.

Testicular Torsion

The differential diagnosis of acute scrotal pain includes testicular torsion. This usually occurs in neonates or adolescent males but may be observed in other age groups. The blood supply to the testicle is compromised due to twisting of the spermatic cord within the tunica vaginalis, resulting in ischemia to the epididymis and the testis. In newborns, an extravaginal torsion also can occur with twisting of the tunica vaginalis and spermatic cord together. Risk factors for torsion include undescended testis, testicular tumor, and a "bell-clapper" deformity—poor gubernacular fixation of the testicles to the scrotal wall.

Clinical history is vital for diagnosis. Patients describe a sudden onset of pain at a distinct point in time, with subsequent swelling. Physical examination may demonstrate a swollen, asymmetric scrotum with a tender, high-riding testicle. Children normally have a brisk cremasteric reflex that usually is lost in the setting of torsion. The diagnosis is made by clinical history and examination, but can be supported by a Doppler ultrasound, which typically shows decreased intratesticular blood flow relative to the contralateral testis. If an ultrasound is not promptly available, timely surgical exploration should ensue if there is reasonable suspicion of torsion. However, besides ruling out other pathologies, an ultrasound can rule out an associated testicular neoplasm that would necessitate tumor serum marker evaluation and an inguinal, rather than a scrotal, incision.

Immediate surgical exploration can salvage an ischemic testis. More than 80% of testes can be salvaged if surgery is performed within 6 hours; this rate decreases to <20% as time lapses beyond 12 hours.[27] At the time of surgery, the

8▶ contralateral testes also must be explored and fixed to the dartos fascia due to the possibility that the same anatomic defect allowing torsion exists on the contralateral side. Midline (along the median raphe) or bilateral transverse scrotal incisions are made. Once the testis is detorsed, it should be assessed for viability after being given time for normal blood flow to resume. One can assess for blood flow by intraoperative Doppler or by incising the tunica vaginalis and examining for blood. The testes are fixed to the dartos fascia with a small, nonabsorbable suture on their medial, lateral, and dependent aspects, taking care to ensure that the spermatic cord is not twisted before doing so. An orchiectomy should be performed to avoid later risk of abscess formation only if the testis is clearly necrotic because overall testicular function may be improved with testicular preservation in cases of moderately delayed (15 hours) presentation.[28]

Fournier's Gangrene

Fournier's gangrene is a necrotizing fasciitis of the male genitalia and perineum that can be rapidly progressing and fatal if not treated promptly (Fig. 40-9A). The mortality rate has been reported to be as high as 30% to 40%.[29] Risk factors for Fournier's gangrene include urethral strictures, perirectal abscesses, poor perineal hygiene, diabetes, cancer, human immunodeficiency virus (HIV), and other immunocompromised states.[30] The infection spreads along the dartos, Scarpa's, and Colles' fascias. Clinical signs include fevers, perineal and scrotal pain, and associated indurated tissue. Cellulitis, eschars, necrosis, flaking skin, and crepitus may all be observed. The diagnosis is largely made on clinical suspicion, and significantly less often made on laboratory or radiographic findings. Classically, the patient describes pain out of proportion to the physical findings.

Prompt débridement of nonviable tissue and broad-spectrum antibiotics are necessary to prevent further spread (Fig. 40-9B). If there is damage to the external anal sphincter, patients may require a colostomy.[30] Because the testes have a 9▶ separate blood supply, they are usually not threatened and do not need to be removed. They may be tucked subcutaneously into the thigh ("thigh pouch") to ease postoperative management. Patients frequently require return trips to the operating room for further débridement. Tight glucose control and adequate nutrition are necessary to facilitate wound healing. The large tissue defect should be initially treated with frequent dressing changes. Reconstructive strategies involving skin grafting are needed when large tissue defects result from extensive tissue damage.

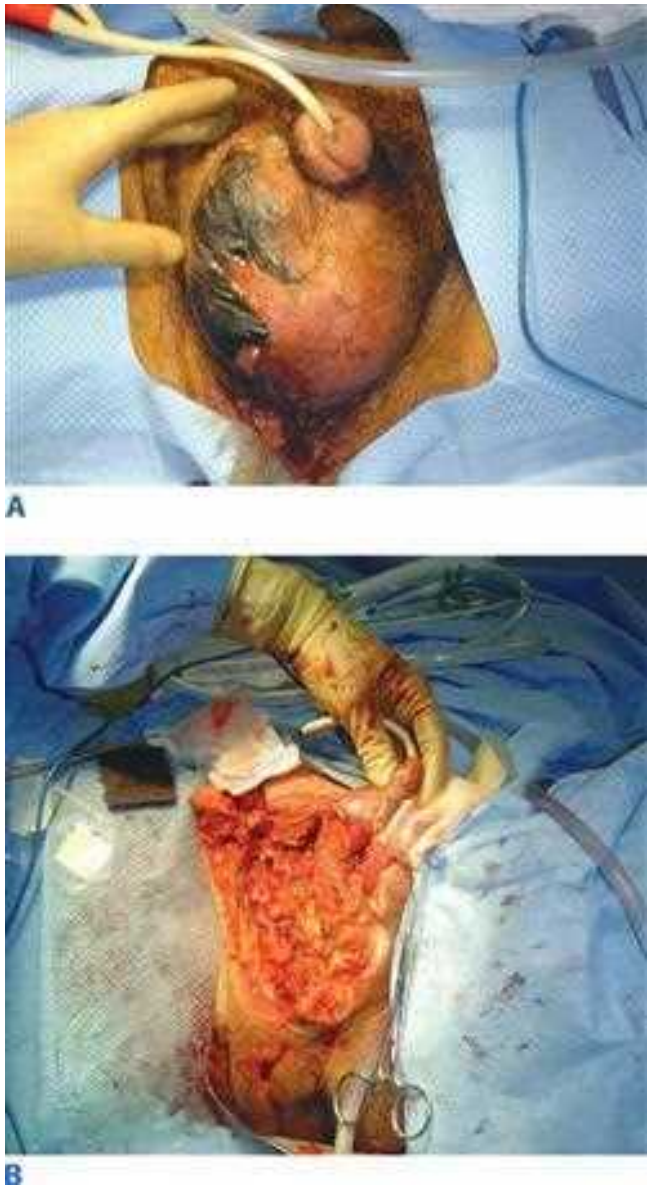


Figure 40-9. Fournier's gangrene. **A.** Necrotic scrotal skin from Fournier's gangrene. **B.** Débridement of gangrenous tissue. Note the extensive débridement, which is commonly required. The right testicle required removal in this case (the left is wrapped in gauze), but typically the testes are not involved with the necrotic process.

Priapism

Priapism is a persistent erection for greater than 4 hours unrelated to sexual stimulation. Priapism is divided into two types, based on the underlying pathophysiology. The most common type—low-flow/ischemic priapism—is a medical emergency. On examination, the penis is very tender, and both cavernosal bodies will be rigid while the glans will be flaccid. Decreased venous outflow with persistent inflow results in increased intracorporeal pressure and tumescence, which is the normal process of erection. Diminished arterial inflow due to elevated intrapenile pressure usually is brief under normal circumstances. Priapism is essentially a compartment syndrome.[30] With prolonged erection (priapism), the sustained decrease in arterial inflow ultimately causes tissue hypoxia, acidosis, and edema and results in long-term fibrosis and impotence, and sometimes frank necrosis. Risk factors include sickle cell disease or trait, malignancy, medications, cocaine abuse, certain antidepressants, and total parenteral nutrition.[32-34] If a cause is not identified, a hematologic workup is necessary to rule out malignancy or blood dyscrasias.

The management of priapism is rapid detumescence with the goal of preservation of future erectile function. The ability to achieve normal erections is directly related to length of the episode of priapism.[30] Low-flow priapism can be confirmed with a penile blood gas of the cavernosal bodies demonstrating hypoxic, acidotic blood. Initial management can include oral agents such as pseudoephedrine or baclofen, but more aggressive measures usually are necessary to achieve rapid detumescence. Insertion of a large-gauge needle (18-gauge) into the lateral aspect of one corporal body allows thorough aspiration and irrigation of both corporal bodies because of widely communicating channels. Injection of phenylephrine (up to 200 mg in 20 mL normal saline) into the corporal bodies may be required. For those with sickle cell disease, hydration and

oxygen administration should be performed first, because these are sometimes successful in this group.[35]

A surgical shunt is sometimes necessary to resolve the episode. Distal shunts should be performed first, because they can be done quickly in the emergency room with a True-Cut needle (Winter shunt). If this fails, an operative distal shunt can be performed (Al-Ghorab). Proximal shunts such as Grayhack (corporal-saphenous vein) or Quackel (proximal cavernosum-spongiosum) shunts may be required in refractory cases.

The other form, high-flow/traumatic priapism, is rare and is related to penile or perineal trauma resulting in a cavernous artery–corporal body fistula. This form is not painful because it is not related to ischemia and can be managed conservatively. Many cases will resolve with time; those that do not can undergo selective arterial embolization.[36]

Paraphimosis

Foreskin emergencies occur in uncircumcised men. Paraphimosis is a common problem that represents a true medical emergency. When foreskin is retracted for prolonged periods, constriction of the glans penis may ensue. This is particularly likely in hospitalized patients who are confined to bed or who have altered mentation. Edema often forms in the genitals of supine patients due to the dependent position of that area. Patients with diminished consciousness will not be aware of the penile pain from paraphimosis, which may delay recognition of the problem until too late. Delay can be catastrophic as penile necrosis may occur due to ischemia.[37] Penile blocks, pain medication, and sedation are sometimes necessary before manual reduction. It is useful to apply firm pressure to the edematous distal penis for several minutes. Although painful, this reduction in penile edema can be the key to success. With the fingers pulling the constricting band distally, the thumbs can push the glans penis back into normal location. If the foreskin cannot be manually reduced, surgical intervention is required.

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a life-threatening infection that results from complicated pyelonephritis by gas-producing organisms. It is an acute necrotizing infection of the kidney that occurs predominantly in diabetic patients.[38] Patients frequently present with sepsis and ketoacidosis. *Escherichia coli* appears to be the most frequent organism responsible for this infection.[39]

Patients require supportive care, intravenous (IV) antibiotics, and relief of any urinary tract obstruction. Emphysematous pyelonephritis can be subdivided based on extent of infection. Those with gas confined to the parenchyma frequently can be managed conservatively with placement of a nephrostomy tube to allow drainage of purulent material. Patients with extensive involvement of the perirenal tissue may not respond to conservative management, and strong consideration should be given to expeditious nephrectomy, particularly if the patient is displaying signs of sepsis.[40]

INFECTIONS

Cystitis

Cystitis is an infection in the bladder with common symptoms of dysuria, urinary frequency, and urgency. Urinary culture (10^5 colony-forming units) is necessary to make a definitive diagnosis, although lower thresholds are meaningful if clinical suspicion is high. Urinalysis can assist with the diagnosis, as leukocyte esterase is a marker of inflammation, and nitrites are formed from bacterial reduction of nitrates. Risk factors include female gender, urinary instrumentation, urinary obstruction, diabetes, and neurologic bladder dysfunction.

An uncomplicated episode of cystitis requires a 3-day course of antibiotics. Those with complicated cystitis require 7 days of antibiotics and possible imaging studies. Asymptomatic bacteriuria does not necessarily need to be treated except if found in a pregnant woman, before a planned urinary tract surgery, or with associated urinary tract obstruction. Patients undergoing nonurologic surgery also should be considered for treatment, especially in surgery involving cardiac valves or orthopedic hardware.

Pyelonephritis

Pyelonephritis is a bacterial infection of the kidney that usually manifests itself by fevers and flank tenderness. It is frequently attributed to ascending bacteria along the path of the ureters and is rarely due to hematogenous bacterial spread. Patients typically present with flank pain and fevers. However, very young or elderly patients may not demonstrate these symptoms but rather irritability, poor appetite, or altered mental status. Urinary tract imaging is not required unless urinary obstruction or stones are suspected or the patient is not responding to antibiotics. Patients who are not septic and can tolerate fluids can be discharged home on a 2-week course of oral antibiotics. Otherwise, they should be hospitalized for IV antibiotics. Fevers from pyelonephritis may take 24 to 48 hours to subside in the setting of effective antibiotic therapy. Pyelonephritis can result in renal scarring that is accelerated in the setting of urinary obstruction. Emphysematous pyelonephritis can be a life-threatening condition with a mortality of up to 30% (see Emphysematous Pyelonephritis in the Emergencies section).

Occasionally, pyelonephritis can develop into an abscess that can be located within the renal parenchyma (renal abscess) or between the capsule and Gerota's fascia (perinephric abscess). Any patient who is not properly responding to antibiotic therapy after 72 hours should undergo CT imaging to rule out an abscess or obstruction. Treatment consists of broad-spectrum IV antibiotics and percutaneous drainage.

Prostatitis

Acute prostatitis is a bacterial infection in the prostate gland, most commonly by urinary pathogens. Patients present with fevers, dysuria, and perineal or back discomfort. A digital rectal examination may indicate an indurated and tender gland. However, a brisk digital rectal examination should be avoided, as it is extremely uncomfortable for patients and is thought to cause bacteremia. Patients require a 4- to 6-week course of antibiotic therapy, typically a quinolone. Those who continue to have no improvement after 48 hours should be considered for imaging to rule out a prostatic abscess. If present, large abscesses can be managed with transurethral unroofing or percutaneous drainage.

Chronic prostatitis presents with continued lower urinary tract symptoms and pelvic pain. Chronic prostatitis may be bacterial or nonbacterial, which can be distinguished by culturing pre- and postprostatic massage urine. The bacterial form is a frequent cause of recurrent urinary tract infections in men and can be treated with a prolonged course of antibiotics. Chronic nonbacterial prostatitis does not respond to antibiotics or most other medications. Biofeedback, physical therapy, and other non–prostate-specific treatments may be effective in the treatment of this challenging clinical entity.[41]

Epididymo-orchitis

Epididymo-orchitis is typically the result of bacterial infection originating in the urinary tract. However, most men will not show evidence of urinary tract infection. Symptoms consist of unilateral painful swelling of the epididymis and/or testis, often with fever. The scrotum may be erythematous on the side of involvement. The white blood cell (WBC) count often is elevated. The onset is fairly rapid, but not as sudden as torsion. An ultrasound may provide supporting evidence such as increased blood flow to the epididymis. A reactive hydrocele may be present. Intratesticular infection can result in ischemic orchitis, and reduced testicular blood flow can be seen on ultrasound. Although the clinical history of gradual onset may point to an infectious etiology, scrotal exploration is necessary when blood flow is reduced to rule out torsion unless other signs such as pyuria, elevated WBC count, or fevers are present.

Treatment is with oral antibiotics if the patient is not markedly febrile and is otherwise stable. Hospitalization and parenteral antibiotics are required if the patient has high fevers or significantly elevated WBC or is hemodynamic unstable, as sepsis from epididymo-orchitis is possible. Intratesticular abscesses may form and usually result in orchiectomy. The tunica albuginea of the testis is not compliant, so elevated pressures from intratesticular inflammation can result in ischemic necrosis of the parenchyma.

LOWER URINARY TRACT OBSTRUCTION

Benign Prostatic Hyperplasia

BPH is a clinical diagnosis describing urinary symptoms attributable to obstruction by the prostate, although some patients with BPH have minimally enlarged glands, and some with large prostates have no symptoms. The symptoms of BPH are urinary frequency, urgency, hesitancy, slow stream, and/or nocturia. These symptoms are not specific and may be caused by infection, urethral strictures, or neurologic dysfunction from diabetes, Parkinson's disease, multiple sclerosis, stroke, or spinal cord injury. Besides voiding symptoms, consequences of BPH include gross hematuria, infections due to incomplete emptying, bladder calculi, and urinary retention. Over time, incomplete emptying may lead to chronic bladder overdistension that can result in a defunctionalized bladder.

Medical treatment of BPH is usually the first step. α-Blockers act on α receptors in the smooth muscle of the prostate and decrease its tone. 5α-Reductase inhibitors, which block the conversion of testosterone to the more potent Z, shrink the prostate over several months. Both are used either singly or in combination as medical therapy for BPH. If medications are ineffective at alleviating urinary symptoms or other consequences of BPH, surgical intervention is indicated. Transurethral resection of the prostate is the mainstay of endoscopic surgical BPH treatment. It is extremely effective at improving flow and decreasing residual urine. Complications are rare but include incontinence and excessive fluid absorption of the hypotonic irrigating solution used during resection, resulting in the transurethral resection syndrome. It is due to hyponatremia and fluid overload, and although rare, can result in death. Mental status changes and pulmonary edema are managed by diuresis and sodium supplementation with hypertonic saline in severe cases. Because of these rare, but potentially dangerous side effects, laser or electrovaporization of the prostate has grown popular. It is associated with very limited fluid absorption, and saline can be used because there is no monopolar electrocautery. There also is less bleeding. Urinary outcomes appear to be similar to transurethral resection of the prostate.[42] When the prostate is very enlarged (>100 g), endoscopic management is less effective and open surgical procedures can be used. Suprapubic (simple) prostatectomy involves enucleation of the majority of the prostate, but the capsule is left so there is minimal effect on continence and erectile function.

Urethral Stricture

The voiding symptoms of urethral stricture are very similar to BPH. Strictures may result from scarring due to infectious urethritis, prior instrumentation, trauma, or cancer. Urethral carcinoma is very rare, particularly in males, so most strictures are due to benign causes. Diagnosis is by retrograde urethrogram or cystoscopy. They may be treated with dilation or transurethral incision, but they have a tendency to recur after treatment. Open surgical excision is preferred for long or recalcitrant strictures, and long-term success rates are excellent.[43]

UPPER URINARY TRACT OBSTRUCTION

The hallmark of partial or complete upper urinary tract obstruction is hydroureteronephrosis (HN), with the ureteral dilation extending to the level of the obstruction (Fig. 40-10). HN may be seen on CT imaging or ultrasound, and it may range from very mild to severe, with associated parenchymal thinning in chronic cases. In the acute setting, the degree of HN does not necessarily correlate with the degree of obstruction, as it may take time for severe HN to develop. The obstruction may be intrinsic, as with calculi or ureteral tumors, or due to extrinsic

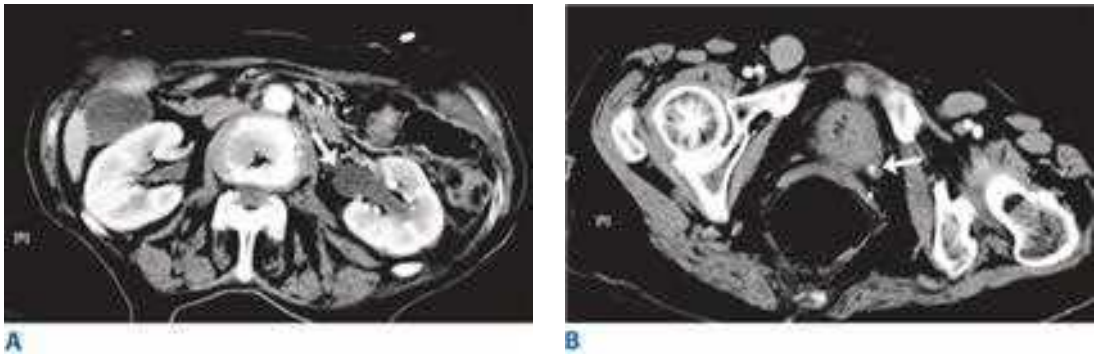

Figure 40-10. Hydronephrosis and ureteral calculus. **A.** Left hydronephrosis from distal obstruction (*arrow*). **B.** A 4-mm calculus at the ureterovesical junction (*arrow*).

compression due to varied causes, such as an intra-abdominal tumor, iliac aneurysm, or gravid uterus. Serum creatinine may be elevated, but the contralateral kidney will compensate so serum chemistries may not indicate renal impairment. Normal renal function makes intervention less urgent, but even partial obstruction may result in permanent loss of function on the affected side if not alleviated within several weeks.[44] Complete occlusion can cause permanent dysfunction within 2 weeks.[45]

Treatment of ureteral obstruction is by endoscopic placement of a ureteral stent, which is a temporary plastic tube with curls on each end to prevent migration. Stents allow flow both through the lumen and around it. When chronic stenting is required, it must be changed every 3 months to prevent severe encrustation with urinary sediments. Stents commonly become colonized with bacteria, but symptomatic infections are less common.[46] Once a stent is in place, mild residual HN often will persist due to ureteral aperistalsis and urinary reflux, but unless severe, it does not represent residual obstruction.

When stent placement is unsuccessful or fails to provide adequate drainage due to severe extrinsic compression, a percutaneous nephrostomy (PCN) should be placed. This is the preferred approach when a patient is unstable because it requires less anesthesia and provides more rapid and reliable decompression of the renal collecting system.

Urolithiasis

Urolithiasis, or urinary calculus disease, may affect up to 10% of the population over the course of a lifetime.[47] Calculi are crystalline aggregates of one or more components, most commonly calcium oxalate. They also may contain calcium phosphate, magnesium ammonium phosphate (struvite), uric acid, or cystine. Calcium- and struvite-containing stones often are visible on plain radiographs, but CT scans will demonstrate all calculi except those composed of crystalline-excreted indinavir, an antiretroviral medication.[48] For this reason, noncontrast CT scans have become the study of choice to evaluate for urolithiasis.

Several underlying causes exist for the formation of urinary calculi. Hypercalciuria due to hyperparathyroidism, sarcoidosis, "renal leaks," or idiopathic overabsorption can lead to calcium-containing stones. Patients often will develop calculi after gastric bypass, which has been attributed to increased oxalate excretion in the urine.[49] After bypass, dietary calcium is bound by unabsorbed dietary fats (saponification), preventing it from binding dietary oxalate, thereby making oxalate more available for intestinal absorption. Patients with gout are at risk for uric acid stones due to increased urinary uric acid and decreased urine pH, which diminishes uric acid solubility.

Urinary calculi may occur anywhere in the urinary tract. They usually are asymptomatic in the renal pelvis or bladder, but they are a very common cause of symptomatic ureteral obstruction. The obstruction may be partial or complete. Smaller stones (up to 6 mm) may cause severe symptoms, such as flank pain and nausea, but typically pass without intervention beyond supportive care.[50] α-Blockers, which relax the distal ureter, may be given to reduce renal colic.[51] Calculi ≥7 mm are more likely to become impacted or to have a prolonged passage through the ureter. For this reason, intervention at the time of presentation is preferred for larger stones (except in cases where the calculus is in the very distal ureter) due to the likelihood of repeat emergency room visits for severe symptoms.

10▶

Several methods for treating urinary calculi are available, depending on location. Obstructing stones often are temporized with stent placement, which allows proximal collecting system decompression. When urinary infection coexists with an obstructing stone, a stent can be placed, but a PCN is preferable if the patient demonstrates any instability. Definitive treatment of renal or ureteral calculi (lithotripsy) is through ureteroscopy, percutaneous nephrostolithotomy (PCNL), or extracorporeal shock wave lithotripsy (ESWL). Ureteroscopy is performed with a flexible or semirigid device that is passed to the level of the calculus. Under direct visualization, a laser fiber is passed through the scope, and energy is delivered to fragment the calculus. Fragments are extracted, although they usually will pass spontaneously. PCNL is performed through a percutaneous tract into the kidney, where a larger scope and various energy sources (laser, ultrasound) are used to fragment and aspirate large renal calculi. This approach is well suited to staghorn calculi. ESWL is completely noninvasive and uses a device that delivers convergent shockwave energy to the calculus under fluoroscopic guidance. However, the lower efficacy rate of ESWL, when compared with ureteroscopy or PCNL, highlights the point that despite ESWL being less invasive, patients will often undergo multiple procedures to be rendered stone free.

Complications of lithotripsy are specific to the technique used. Ureteroscopy may occasionally lead to strictures due to scarring from trauma to the ureter. If performed in the setting of infection, endoscopic irrigation can force bacteria into the renal parenchyma and result in sepsis. PCNL can cause significant bleeding, and if the tract used to access the kidney traverses the lower aspect of the pleura, large amounts of irrigating fluid can result in a significant hydrothorax. ESWL can occasionally cause renal hematomas, and splenic rupture has been seen after the treatment of a left-sided stone.[52,53]

Patients with recurrent stones will benefit from examination of stone composition and 24-hour urine metabolic workup to determine the underlying etiology. Better hydration is useful for all etiologies. Additionally, most patients will benefit from alkalization of the urine (e.g., potassium citrate). Patients with calcium-containing stones do not benefit from a reduction in dietary calcium unless they have absorptive hypercalciuria, which most do not. In fact, patients with higher dietary calcium have, on average, fewer episodes of urolithiasis.[54]

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is a process resulting in encasement of the ureters, along with the great vessels, in a dense fibrotic mass. Many patients present in acute renal failure, and imaging demonstrates medially displaced ureters with a homogeneous, plaque-like mass in the retroperitoneum. The cause may occasionally be a neoplastic process such as histiocytosis or lymphoma—which must be ruled out—but most are idiopathic.[55] Many medications such as the ergot derivative methysergide, methyldopa, and β-blockers have been implicated as precipitating factors for the inflammatory process.[56]

Bilateral ureteral stent or PCN placement provides temporary relief of the obstruction. Corticosteroids may be given to reverse the inflammatory process, but surgical ureterolysis still usually is required to free the ureters from retroperitoneal encasement. They are brought into the peritoneum and wrapped in omentum to prevent re-entrapment.

Ureteropelvic Junction Obstruction

UPJ obstruction is the most common cause of hydronephrosis found on prenatal ultrasound. UPJ obstruction also is commonly observed in children and young adults. Intrinsic and extrinsic causes of UPJ obstruction exist and can be determined by presentation. Intrinsic UPJ obstruction occurs in neonates due to an adynamic or stenotic segment of proximal ureter. This impairs flow of urine into the ureter, particularly during times of high flow, and causes dilatation of the collecting system. Over time, elevated renal pelvic pressures and recurrent infections can injure renal parenchyma. Abnormal lower pole (i.e., accessory) renal arteries may be a secondary cause of UPJ obstruction by kinking the proximal ureter. Nuclear scans (mercaptoacetyltriglycine or ^{99m}Tc diethylene-triamine-penta-acetic acid) have replaced the IVP as the diagnostic modality of choice. Delayed clearance of contrast or radiotracer implies obstruction. Invasive pressure-flow examinations (Whitaker test) rarely are performed.

Not every case of UPJ obstruction requires operative intervention. Many children with hydronephrosis due to an apparent UPJ obstruction are not highly obstructed and will improve with time. However, patients with infections or impaired renal function require repair to improve drainage. Open dismembered pyeloplasty is considered the gold standard approach, especially in infants. In older children or adults, laparoscopic or robotic approaches for pyeloplasty can expedite convalescence and diminish postoperative pain. An endoscopic approach, endopyelotomy, is also an option in older children and adults. However, it is not as effective as a dismembered pyeloplasty. Surgery involves ureteroscopy and a full-thickness lateral incision into the affected ureteral segment with a laser or knife taking care not to injure the renal hilar vessels (or accessory vessels in cases of a crossing vessel).

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) is the second most common cause of hydronephrosis after UPJ obstruction. Up to two thirds of infants presenting with urinary tract infections have VUR.[57] VUR is significantly more common among white children (10 times as common) than black children. Although VUR is more prevalent in male newborns, among children older than 1 year of age, girls are five to six times more likely to have VUR than boys. The incidence of VUR decreases with advancing age. Primary reflux is a congenital anomaly caused by insufficient intramural tunneling of the distal ureter, although bladder outlet obstruction may cause unilateral or bilateral secondary reflux when the ureters are anatomically normal. The primary danger of VUR is reflux of infected urine that results in recurrent episodes of pyelonephritis, which can cause scarring and cumulative renal damage.

Neonates with hydronephrosis detected on prenatal ultrasound or infants/children experiencing a urinary tract infection should be evaluated for VUR with a voiding cystourethrogram (VCUG). VUR is graded according to the International Classification System. Spontaneous resolution of VUR, which is the norm, is a function of the grade of VUR.[58] The large majority of low-grade (1–2) reflux cases will spontaneously resolve, whereas 30% to 50% of grade 3 and 4 reflux cases and 9% of grade 5 reflux cases will resolve.[58,59] The initial management of VUR is controversial, particularly for moderate degrees. Surgical repair with ureteral reimplantation is effective, but may be overtreatment for those destined to resolve spontaneously. However, conservative management, consisting of antibiotic prophylaxis, may result in breakthrough infections with resistant organisms. Submucosal injection of bulking agents at the ureteral orifice (Deflux^{-}) is being used with increasing frequency. Although patients with high-grade VUR still undergo ureteral reimplantation, those with low-grade VUR are increasingly more likely to undergo submucosal injection of bulking agents instead of being managed conservatively. It is a minimally invasive technique that may, in some patients, obviate the need for long-term suppressive antibiotics. Submucosal bulking is not effective in every case, and patients with severe reflux will likely need reimplantation.

Ureteroceles

A ureterocele is a cystic dilation of the terminal ureter thought to result from a persistent membrane between the ureteral bud and the urogenital sinus. Most patients will have associated genitourinary anomalies such as duplicated collecting systems or an ectopic ureteral location. Patients frequently present during childhood and can present in multiple ways depending on size and degree of obstruction. Patients may have hydronephrosis and pyelonephritis. A large, prolapsing ureterocele can cause bladder outlet obstruction, and rarely, a large ureterocele can present as an intralabial mass in a newborn child. Diagnosis can be confirmed with cystoscopy, VCUG, or IVP.

Patients with a functioning renal moiety can undergo endoscopic incision of the ureterocele; however, VUR is common postoperatively. A ureterocele in a nonfunctioning duplicated system may require a heminephrectomy to avoid infections.

Posterior Urethral Valve

Posterior urethral valves can be a particularly damaging cause of bilateral hydronephrosis in a newborn boy. The "valves," which are tissue folds located in the prostatic urethra, cause bladder outlet obstruction. Diagnosis is established with a VCUG, which may show poor bladder emptying and a dilated posterior urethra. A Foley catheter should be placed in the bladder to decompress the urinary system in the hopes of facilitating recovery of renal function. Treatment involves cystoscopic ablation or resection of the valve. Even after ablation of the valves and elimination of the urethral obstruction, patients with posterior urethral valves are at significant risk of renal failure, depending on the degree of prenatal obstruction.[60] Bladders frequently suffer damage and become partially defunctionalized from prolonged prenatal obstruction, and normal voiding patterns often are not established. The most serious outcome of posterior urethral valves is pulmonary hypoplasia due to intrauterine oligohydramnios, and efforts have been made prenatally to transplacentally decompress the urinary bladder and prevent this dreaded development.

chapter 41

Gynecology

Chad Hamilton, Michael Stany, W. Thomas Gregory, and Elise C. Kohn

PATHOPHYSIOLOGY AND MECHANISMS OF DISEASE

The female reproductive tract is a unique component of the body with a multitude of tightly regulated functions. Many of the activities normally ongoing, such as angiogenesis and physiologic invasion, are necessary in order for the reproductive organs to fulfill their purpose and are usurped in disease. Immune surveillance is modified by multiple mechanisms under investigation and regulated in a different fashion, in order to allow implantation, placentation, and development of the fetus. How this potential disruption of normal immune barriers is involved in pathologic events is incompletely understood.

The pelvis is a very complex area, with a multitude of spatially and temporally varied functions. It is a site where pathologies ranging from mechanical events, such as ovarian torsion or ruptured ectopic pregnancy, to infection, such as pelvic inflammatory disease, to mass effects, including leiomyomata and malignancy, can present with similar and even overlapping symptoms and signs. An acute abdomen presentation in a woman of child-bearing potential can range from pregnancy-related catastrophes to appendicitis.

The ongoing rupture, healing, angiogenesis, and regrowth of the ovarian capsule and endometrium during the menstrual cycle uses the same series of biological and biochemical events that are also active in pathologic events such as endometriosis and endometriomas, mature teratomas, dysgerminomas, and progression to malignancy. Genetic abnormalities, both germline and somatic, that may cause competence and/or promote disease are now being uncovered, especially in the progression to malignancy, in pharmacogenomics, and in surgical risks such as bleeding and clotting. Incorporation of genetic and genomic information in disease diagnosis and assessment is a wave for the near future and may alter how we diagnose and follow disease, in whom we increase our diligence in searching for disease, and ultimately how we use the drug and other therapeutic armamentarium available to the treating physician.

These points will be incorporated with surgical approaches into discussions of anatomy, diagnostic workup, infection, surgical and medical aspects of the obstetric patient, pelvic floor dysfunction, and neoplasms.

ANATOMY

Clinical gynecologic anatomy centers on the pelvis (from Latin meaning *basin*). Aptly named, the bowl-shaped pelvis houses the confluence and intersection of multiple organ systems. Understanding those structural and functional relationships is essential for the surgeon and allows an appreciation for the interplay of sexual function and reproduction and a context for understanding gynecologic pathology.

Structure and Support of the Pelvis and Genitalia

The bony pelvis is comprised by the *sacrum* posteriorly and the *ischium*, *ilium*, and *pubic* bones anteromedially. It supports the upper body and transmits the stresses of weight bearing to the

Key Points

1. Gynecologic causes of acute abdomen include pelvic inflammatory disease, tubo-ovarian abcess, ovarian torsion, ruptured ectopic pregnancy, and septic abortion. Pregnancy must be ruled out early in assessment of reproductive-age patients presenting with abdominal or pelvic pain.
2. The general gynecology exam must incorporate the whole physical examination in order to adequately diagnosis and treat gynecologic disorders.
3. Benign gynecologic pathologies that are encountered at the time of surgery include endometriosis, endometriomas, fibroids, and ovarian cysts.
4. It is critical that abnormal lesions of the vulva, vagina, and cervix are biopsied for diagnosis before any treatment is planned; postmenopausal bleeding should always be investigated to rule out malignancy.
5. Early-stage cervical cancer is managed surgically, whereas chemoradiation is preferred for stage IB2 and above.
6. Pregnancy confers important changes to both the cardiovascular system and the coagulation cascade. Trauma in pregnancy must be managed with these changes in mind.
7. Pelvic floor dysfunction (pelvic organ prolapse, urinary and fecal incontinence) is common; 11% of women will undergo a reconstructive surgical procedure at some point in their lives.
8. Radical hysterectomy has unique risks of ureteral fistula and bowel dysfunction.
9. Risk-reducing salpingo-oophorectomy (RRSO) should be considered in women with *BRCA1* or *BRCA2* mutations; RRSO and complete hysterectomy should be considered in women with Lynch syndrome.
10. Optimal debulking for epithelial ovarian cancer is a critical element in patient response and survival. The preferred primary therapy for optimally debulked advanced-stage ovarian epithelial ovarian cancer is intraperitoneal chemotherapy.

lower limbs in addition to providing anchors for the supporting tissues of the pelvic floor.[1] The opening of the pelvis is spanned by the muscles of the pelvic diaphragm (Fig. 41-1). The muscles of the pelvic sidewall include the *iliacus*, the *psoas*, and the *obturator internus* muscle (Fig. 41-2). These muscles contract tonically and include, from anterior to posterior, bilaterally, the *pubococcygeus, puborectalis, iliococcygeus*, and *coccygeus* muscles. The first two of these muscles contribute fibers to the fibromuscular perineal body. The *urogenital hiatus* is bordered laterally by the pubococcygeus muscles and anteriorly by the *symphysis pubis*. It is through this muscular defect that the urethra and vagina pass, and it is the focal point for the study of disorders of pelvic support such as cystocele, rectocele, and uterine prolapse.

Vasculature and Nerves of the Pelvis

The rich blood supply to the pelvis arises largely from the *internal iliac* arteries except for the *middle sacral* artery originating at the aortic bifurcation and the ovarian arteries originating from the abdominal aorta. The internal iliac, or hypogastric, arteries divide into anterior and posterior branches. The latter supply lumbar and gluteal branches. From the anterior division of

 Figure 41-1. Deeper muscles of the pelvic floor.

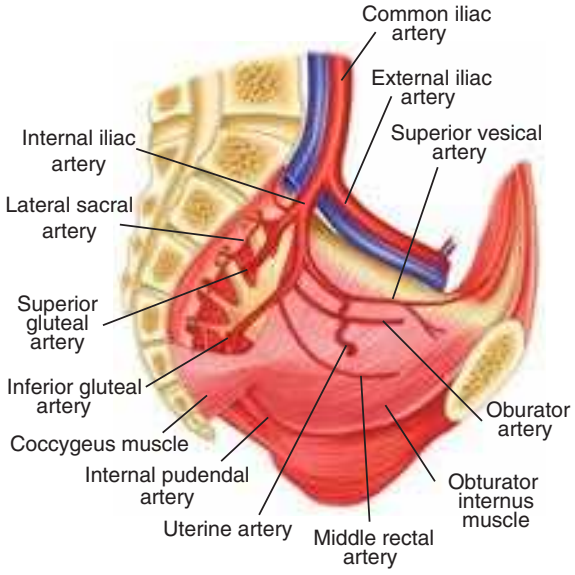

Figure 41-2. The muscles and vasculature of the pelvis.

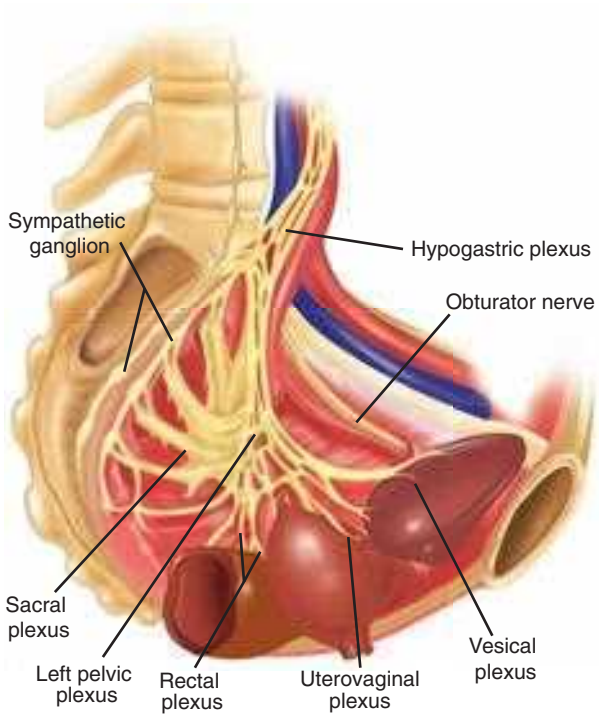

Figure 41-3. The nerve supply of the female pelvis.

the hypogastric arteries arise the *obturator*, *uterine*, *pudendal*, *middle rectal*, *inferior gluteal*, and *superior and middle vesical* arteries (see Fig. 41-2).

The major nerves found in the pelvis are the *sciatic*, *obturator*, and *femoral* nerves. Sympathetic fibers course along the major arteries, and parasympathetics form the superior and inferior *pelvic plexus* (Fig. 41-3). The *pudendal* nerve arises from S2-S4 and travels laterally, exiting the greater sciatic foramen, hooking around the ischial spine and *sacrospinous ligament*, and returning via the greater sciatic foramen. It travels through Alcock's canal and becomes the sensory and motor nerve of the perineum (see Figs. 41-1 and 41-3). The motor neurons serve the tonically contracting urethral and anal sphincter, and direct branches from the S2-S4 nerves serve the *levator ani* muscles. During childbirth and other excessive straining, this tethered nerve (along with the levator ani muscles) is subject to stretch injury and at least partially responsible for many female pelvic floor disorders.

Vulva

The *labia majora* form the cutaneous boundaries of the lateral vulva and represent the female homologue of the male scrotum (Fig. 41-4). The labia majora are fatty folds covered by hair-bearing

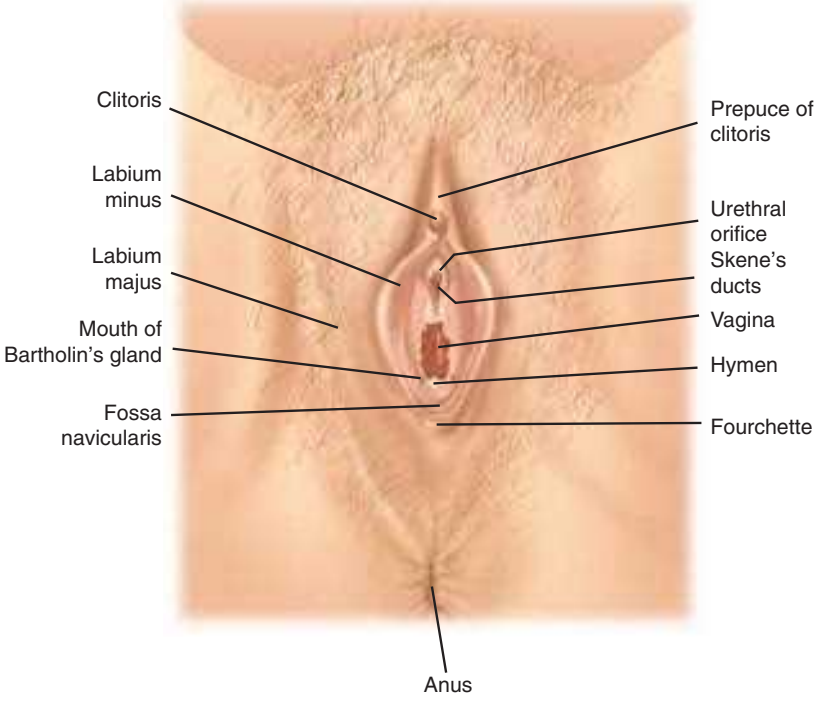

Figure 41-4. External genitalia. *(Reproduced with permission from Rock J, Jones HW.* TeLinde's Operative Gynecology. *9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003, Fig. 5-1, p. 70.)*

skin in the adult. They fuse anteriorly over the anterior prominence of the *symphysis pubis,* the *mons pubis*. The deeper portions of the adipose layers are called Colles' fascia and insert onto the inferior margin of the perineal membrane, limiting spread of superficial hematomas inferiorly. Adjacent and medial to the labia majora are the *labia minora*, smaller folds of connective tissue covered laterally by non–hair-bearing skin and medially by vaginal mucosa. The anterior fusion of the labia minora forms the *prepuce and frenulum of the clitoris;* posteriorly, the labia minora fuse to create the *fossa navicularis* and *posterior fourchette*. The term *vestibule* refers to the area medial to the labia minora bounded by the *fossa navicularis* and the clitoris. Both the urethra and the vagina open into the vestibule. Skene's glands lie lateral and inferior to the urethral meatus. Cysts, abscesses, and neoplasms may arise in these glands.

Erectile tissues and associated muscles are in the space between the perineal membrane and the vulvar subcutaneous tissues (see Fig. 41-1). The clitoris is formed by two crura and is suspended from the pubis. Overlying the crura are *ischiocavernosus* muscles, which run along the inferior surfaces of the *ischiopubic rami*. Extending medially from the inferior end of the ischiocavernosus muscles are the *superficial transverse perinei* muscles. These terminate in the midline in the perineal body, caudal and deep to the posterior fourchette. *Vestibular bulbs* lie just deep to the vestibule and are covered laterally by *bulbocavernosus* muscles. These originate from the perineal body and insert into the body of the clitoris. At the inferior end of the vestibular bulbs are Bartholin's glands, which connect to the vestibular skin by ducts.

Vagina

The vagina is an elastic fibromuscular tube opening from the vestibule running superiorly and posteriorly, passing through the *perineal membrane*. The lower third is invested by the superficial and deep perineal muscles; it incorporates the urethra in its anterior wall and has a rich blood supply from the vaginal branches of the *external and internal pudendal* arteries. The upper two thirds of the vagina are not are not invested by muscles. This portion lies in opposition to the bladder base anteriorly and the rectum and posterior pelvic cul-de-sac superiorly. The cervix opens into the posterior vaginal wall bulging into the vaginal lumen.

Fibrovascular Ligaments and Avascular Tissue Planes

Figure 41-5 is a view of the internal genitalia as one would approach the pelvis from a midline abdominal incision. The central uterus and uterine cervix are supported by the pelvic floor muscles. They are suspended by the lateral fibrous cardinal, or *Mackenrodt's ligament*, and the *uterosacral ligaments*, which insert into the *paracervical fascia* medially and into the muscular sidewalls of the pelvis laterally. Posteriorly, the uterosacral ligaments provide support for the vagina and cervix as they course from the sacrum lateral to the rectum and insert into the paracervical fascia. Emanating from the *uterine cornu* and traveling through the inguinal canal are the *round ligaments*, eventually attaching to the subcutaneous tissue of the mons pubis. The peritoneum enfolding the *adnexa* (tube, round ligament, and ovary) is referred to as the *broad ligament*, which separates the pelvic cavity into an anterior and posterior component.

The peritoneal recesses in the pelvis anterior and posterior to the uterus are referred to as the *anterior* and *posterior*

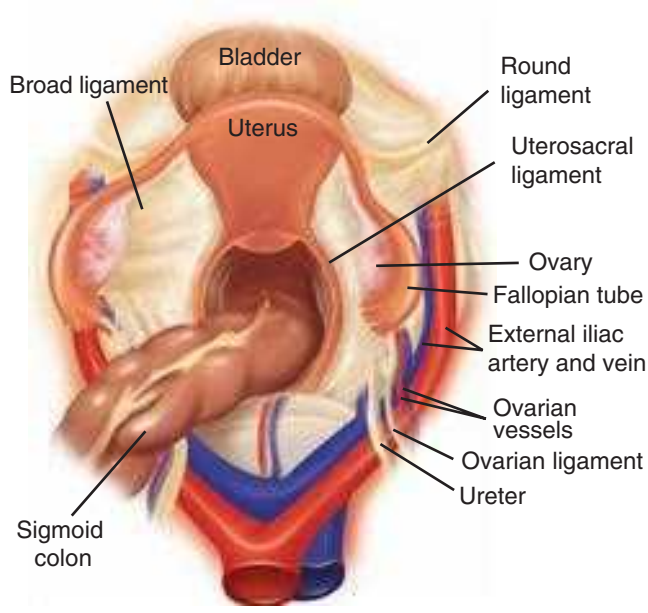

Figure 41-5. Internal pelvic anatomy, from above.

cul-de-sacs. The latter is also called the *pouch* or *cul-de-sac of Douglas*. On transverse section, several avascular, and therefore important, surgical planes can be identified (Fig. 41-6). These include the lateral paravesical and pararectal spaces and, from anterior to posterior, the retropubic or prevesical space of Retzius and the vesicovaginal, rectovaginal, and retrorectal or presacral spaces.

These avascular tissue planes are often preserved and provide safe surgical access when the intraperitoneal pelvic anatomy is distorted by tumor, endometriosis, adhesions, or infection. As an example, the ureter is at significant risk of iatrogenic injury in the context of such pathology. Using the avascular retroperitoneal planes, the ureter can be traced into the pelvis as it crosses the distal common iliac arteries laterally into the pararectal space and then courses inferior to the ovarian arteries and veins until crossing under the uterine arteries into the paravesical space just lateral to the cervix. After traveling to the cervix, the ureters course downward and medially over the anterior surface of the vagina before entering the base of the bladder in the vesicovaginal space.

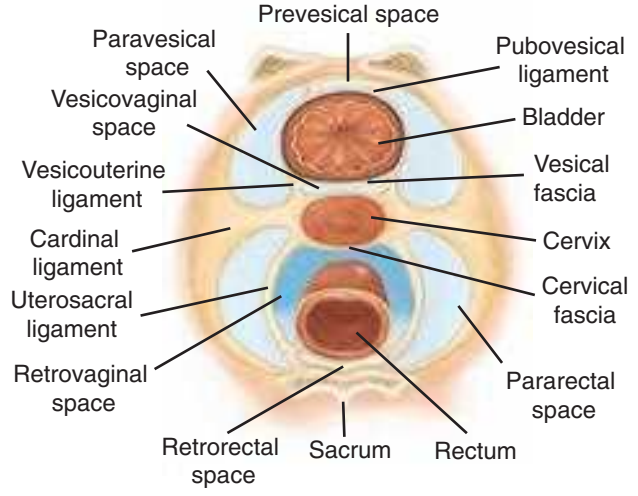

Figure 41-6. The avascular spaces of the female pelvis.

Uterus

The typically pear-shaped uterus consists of a fundus, cornua, body, and cervix. It lies between the bladder anteriorly and the rectosigmoid posteriorly. The *endometrium* lines the cavity and has a superficial functional layer that is shed with menstruation and a basal layer from which the new functional layer is formed. Sustained estrogenic stimulation can lead to hyperplastic changes or carcinoma. Adenomyosis is a condition in which benign endometrial glands infiltrate into the muscle or myometrium of the uterus. The *myometrium* is composed of smooth muscle, and the contraction of myometrium is a factor in menstrual pain and is essential in childbirth. The myometrium can develop benign smooth muscle neoplasms known as leiomyoma or fibroids.

Cervix

The cervix connects the uterus and vagina and projects into the upper vagina. The vagina forms an arched ring around the cervix described as the *vaginal fornices*—lateral, anterior, and posterior. The cervix is about 2.5 cm long with a fusiform endocervical canal lined by columnar epithelium lying between an *internal and external os*, or opening. The vaginal surface of the cervix is covered with stratified squamous epithelium, similar to that lining the vagina. The squamocolumnar junction, also referred to as the *transformation zone*, migrates at different stages of life and is influenced by estrogenic stimulation. The transformation zone develops as the columnar epithelium is replaced by squamous metaplasia. This transformation zone is vulnerable to human papillomavirus (HPV) infection and resultant dysplastic changes. These changes can be detected by microscopic assessment of a cervical cytologic (or Pap) smear. If the duct of a cervical gland becomes occluded, the gland distends to form a retention cyst or Nabothian follicle.

Fallopian Tubes

The bilateral fallopian tubes arise from the upper lateral *cornua* of the uterus and course posterolaterally within the upper border of the broad ligament. The tubes can be divided into four parts. The *interstitial* part forms a passage through the myometrium. The *isthmus* is the narrow portion extending out about 3 cm from the myometrium. The *ampulla* is thin-walled and tortuous with its lateral end free of the broad ligament. The *infundibulum* is the distal end fringed by a ring of delicate fronds or *fimbriae*. The fallopian tubes receive the ovum after ovulation. Peristalsis carries the ovum to the ampulla where fertilization occurs. The zygote transits the tube over the course of 3 to 4 days to the uterus. Abnormal implantation in the fallopian tube is the most common site of ectopic pregnancies. The tubes may also be infected by ascending organisms, resulting in tubo-ovarian abscesses.

Ovaries

The ovaries are attached to the uterine cornu by the *proper ovarian ligaments,* or the *utero-ovarian ligaments*. The ovaries are suspended from the lateral pelvis by their vascular pedicles, the *infundibulopelvic (IP) ligaments* or *ovarian arteries.* The IP ligaments are paired branches from the abdominal aorta arising just below the renal arteries. They merge with the peritoneum over the psoas major muscle and pass over the pelvic brim and the external iliac vessels. The ovarian veins ascend at first with the ovarian arteries, and then track more laterally. The right ovarian vein ascends to drain directly into the inferior vena cava, whereas the left vein drains into the left renal vein. Lymphatic drainage follows the arteries to the para-aortic lymph nodes. The ovaries are covered by a single layer of cells that is continuous with the mesothelium of the peritoneum. Beneath this is a fibrous stroma within which are embedded germ cells. At ovulation, an ovarian follicle ruptures through the ovarian epithelium.

EVALUATION AND DIAGNOSIS

Elements of a Gynecologic History

A complete history is a seminal part of any assessment (Table 41-1). Many gynecologic diseases can present with broad constitutional symptoms, occur secondary to other conditions, or be related to medications. A full history should include particular attention to family history; organ system history, including breast, gastrointestinal, and urinary tract symptoms; and a careful medication, anesthesia, and surgical history. The key elements of a focused gynecologic history include the following:

- Date of last menstrual period, if premenopausal
- History of contraceptive and postmenopausal hormone use
- Obstetrical history
- Age at menarche and menopause (method of menopause, e.g., drug, surgical)
- Menstrual bleeding pattern
- History of pelvic assessments, including cervical smear results
- History of pelvic infections, including HPV, and human immunodeficiency virus (HIV) status
- Sexual history (number of lifetime partners)
- Prior gynecologic surgery(s)

The Gynecologic Examination

For many women, their gynecologist is their primary care physician. When that is the case, it is necessary that a full medical and surgical history be taken and that, in addition to the pelvic examination, the minimum additional examination should include assessment of the thyroid, breasts, and cardiopulmonary system. The pelvic examination starts with a full abdominal examination. Inguinal node evaluation is performed before placing the patient's legs in the dorsal lithotomy position (in stirrups). A flexible, focused light source is essential, and vaginal instruments including speculums of variable sizes and shapes including pediatric sizes (Graves and Pederson) are required to assure that the patient's anatomy can be fully and comfortably viewed.

2▶

The external genitalia are inspected, noting the distribution of pubic hair, the skin color and contour, the Bartholin and Skene's glands, and perianal area. Abnormalities are documented, and a map with measurements of abnormalities is drawn. A warmed lubricated speculum is inserted into the vagina and gently opened to identify the cervix if present, or the vaginal apex if not. If there is a concern that a malignancy is present, careful digital assessment of a vaginal mass and location may be addressed prior to speculum placement in order to avoid abrading a vascular lesion and inducing hemorrhage. The speculum would then be inserted just short of the length to the mass in order to view that area directly before advancing. An uncomplicated speculum exam includes examination of the vaginal sidewalls; assessment of secretions, including culture if necessary; and collection of the cervical cytologic specimen if indicated (see later section, Common Screening and Testing).

Table 41-1

Key elements of the gynecologic history

ISSUE	ELEMENTS TO EXPLORE	ASSOCIATED ISSUES
Menstrual history	Age at menarche, menopause. Bleeding pattern, postmenopausal bleeding, spotting between periods Any medications (warfarin, heparin, aspirin, herbals, others) or personal or family history that might lead to prolonged bleeding times	Identifies abnormal patterns related to endocrine, structural, infectious, and oncologic etiologies
Obstetrical history	Number of pregnancies, dates, type of deliveries, pregnancy loss, abortion, complications	Identifies potential surgical complications due to previous cesarean sections
Infectious diseases	Sexually transmitted diseases (STDs) and treatment and/or testing for these	Also need to explore history of other gastrointestinal diseases that may mimic STD (Crohn's, diverticulitis)
Contraceptive history	Present contraception if appropriate, prior use, type and duration	Concurrent pregnancy with procedure or complications of contraceptives
Cytologic screening	Frequency, results (normal, prior abnormal Pap), any prior surgery or diagnoses, human papillomavirus testing history	Prolonged intervals increase risk of cervical cancer Relationship to anal, vaginal, vulvar cancers
Prior gynecologic surgery	Type (laparoscopy, vaginal, abdominal); diagnosis (endometriosis?, ovarian cysts?, tubo-ovarian abscess?); actual pathology if possible	Assess present history against this background (for example, granulosa cell pathology; is it now recurrent?)
Pain history	Site, location, relationship (with urination, with menses, with intercourse at initiation or deep penetration, with bowel movements), referral	Assesses relationship to other organ systems and potential involvement of these with process Common examples presenting as pelvic pain, ureteral stone, endometriosis with bowel involvement, etc.

A bimanual examination is performed by placing two fingers in the vaginal canal; one finger may be used if patient has significant vaginal atrophy or has had prior radiation with stenosis (Fig. 41-7). Carefully and sequentially assess the size and shape of the uterus by moving it against the abdominal hand, and assess the adnexa by carefully sweeping the abdominal hand down the side of the uterus. The rectovaginal examination, consisting of one finger in the vagina and one in the rectal vault, is used to further examine and characterize the location, shape, fixation, size, and complexity of the uterus, adnexa, cervix, and anterior and posterior cul-de-sacs. The rectovaginal exam also allows examination of the uterosacral ligaments from the back of the uterus sweeping laterally to the rectal finger and the sacrum, and a stool sample for occult blood can be obtained during this exam.

It is critical that presurgical assessments include a full general examination. This is particularly important with potential oncologic diagnoses or infectious issues, in order to assure that the proposed surgery is both safe and appropriate. Complications such as sites of metastatic cancer or infection, associated bleeding and/or clotting issues and history, and drug exposure, allergies, and current medications must be addressed.

Common Screening and Testing

Cervical Preinvasive and Invasive Disease Screening.

The most recent cervical cytology guidelines by the U.S. Preventative Services Task Force has increased the intervals for most women given the known natural history of HPV-related cervical dysplasia progression to cancer.[2] The very high negative predictive value of the HPV test allows for this change. The current recommendations call for cervical smear screening every 3 years in women age 21 to 65 years. If an HPV test

Figure 41-7. Bimanual abdominovaginal palpation of the uterus.

Table 41-2

Features of common causes of vaginitis

	BACTERIAL VAGINOSIS	VULVOVAGINAL CANDIDIASIS	TRICHOMONIASIS
Pathogen	Anaerobic organisms	*Candida albicans*	*Trichomonas vaginalis*
% of vaginitis	40	30	20
pH	>4.5	<4.5	>4.5
Signs and symptoms	Malodorous, adherent discharge	White discharge, vulvar erythema, pruritus, dyspareunia	Malodorous purulent discharge, vulvovaginal erythema, dyspareunia
Wet mount	Clue cells	Pseudohyphae or budding yeasts in 40% of cases	Motile trichomonads
KOH mount		Pseudohyphae or budding yeasts in 70% of cases	
Amine test	+	–	–
Treatment	Metronidazole 500 mg bid × 7 d or 2 g single dose, metronidazole or clindamycin vaginal cream	Oral fluconazole 150 mg single dose, vaginal antifungal preparations	Metronidazole 2 g single dose and treatment of partner

+ = positive; – = negative; bid = twice a day; KOH = potassium hydroxide.

performed at the same time also is negative, a Pap and HPV test combination does not need to be repeated in women age 30 to 65 for 5 years. HPV testing should not be performed as a screening test in women under age 30 due to the high prevalence of HPV, as well as the high likelihood of resolution of infection. Women with a history of cervical dysplasia or cancer need more frequent screening based on their diagnosis.

Microscopy of Vaginal Discharge. During a speculum exam, a cotton-tipped applicator is used to collect the vaginal discharge; it is smeared on a slide with several drops of 0.9% normal saline to create a saline wet mount. A cover slide is placed and the slide is evaluated microscopically for the presence of mobile trichomonads (*Trichomonas vaginalis*) or clue cells (epithelial cells studded with bacteria, seen in bacterial vaginosis; Table 41-2). A potassium hydroxide (KOH) wet mount is the slide application of the collected vaginal discharge with 10% KOH; this destroys cellular elements. The test is positive for vaginal candidiasis when pseudohyphae are seen (Table 41-2).

Chlamydia/Gonorrhea Testing. Nucleic acid amplification testing (NAAT) has emerged as the diagnostic test of choice for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. A vaginal swab, endocervical swab, and/or urine sample can be used for this test. The test can be completed within hours and has been found to be more sensitive than cultures.

β-Human Chorionic Gonadotropin (β-hCG) Testing. Qualitative urinary pregnancy tests for β-hCG are standard prior to any surgery in a woman of reproductive age and potential, regardless of contraception history. In addition, serum quantitative β-hCG testing is appropriate for evaluation of suspected ectopic pregnancy, gestational trophoblastic disease, or ovarian mass in a young woman. In the case of ectopic pregnancy, serial levels are required when a pregnancy cannot be identified in the uterine cavity. As a general rule, 85% of viable intrauterine pregnancies will have at least a 66% rise in the β-hCG level over 48 hours.

Common Office Procedures for Diagnosis

Vulvar/Vaginal Biopsy. Any abnormal vulvar or vaginal lesion including skin color changes, raised lesions, or ulcerations should be biopsied. Local infiltration with local anesthetic is followed by a 3- to 5-mm punch biopsy appropriate to the lesion. The specimen is elevated with Adson forceps and cut from its base with scissors. The vaginal biopsy can sometimes be difficult to perform because of the angle of the lesion. After injection with local anesthetic, traction of the area with Allis forceps and direct resection of the lesion with scissors or cervical biopsy instrument (Schubert, Kevorkian, etc.) can achieve an adequate biopsy.

Colposcopy and Cervical Biopsy. In cases of an abnormal Pap smear cytology, a colposcopy is performed for a histologic evaluation. A colposcope is used to achieve 2× to 15× magnification of the cervix. Once the cervix is visualized, cervical mucus, if present, is removed, and then 3% acetic acid is applied to the cervix for 1 minute. This application dehydrates cells and causes dysplastic cells with dense nuclei to appear white. The entire squamocolumnar junction is visualized during an adequate colposcopy. This area is seen as the transition from the smooth-appearing squamous ectocervix to the pink endocervical tissue. Acetowhite areas or areas with punctation, mosaicism, or atypical blood vessels seen during colposcopy may represent dysplasia or cancer and should be biopsied.

Endometrial Biopsy. Endometrial sampling should be performed before planned hysterectomy if there is a history of bleeding between periods, heavy and/or frequent menstrual periods, or postmenopausal bleeding. A patient with the potential for pregnancy should have a pregnancy test before the procedure. An endometrial pipelle is inserted after cervical cleaning, and the depth of the uterine cavity is noted. The endometrial specimen is obtained by pulling on the plunger within the pipelle, creating a small amount of suction. The pipelle is rotated and pulled back from the fundus to the lower uterine segment within

the cavity to access all sides.[3] Additional passes may be needed in order to acquire an adequate amount of tissue.

Evaluation for Fistula. When a patient presents with copious vaginal discharge, the provider must be concerned about a fistula with the urinary or gastrointestinal tract. A simple office procedure can be performed when there is a concern for a vesicovaginal fistula. A vaginal tampon is placed, followed by instillation of sterile blue dye through a transurethral catheter into the bladder; a positive test is blue staining of the tampon. If the test is negative, one can evaluate for a ureterovaginal fistula. The patient is given phenazopyridine, which changes the color of urine to orange. If a tampon placed in the vagina stains orange, the test is positive. Alternatively, the patient can be given an intravenous injection of indigo carmine.

Rectal fistula must be considered when a patient reports stool evacuation per vagina. It can be identified in a similar fashion using a large Foley catheter placed in the distal rectum through which dye may be injected or with the use of an oral charcoal slurry and timed examination. Common areas for fistulae are at the vaginal apex, at the site of a surgical incision, or around the site of a prior episiotomy or perineal repair after a vaginal delivery.

BENIGN GYNECOLOGIC CONDITIONS

Vulvar Lesions

Many women suffer with undiagnosed symptoms of vulvar disease. Patients presenting with chronic vulvar symptoms should be carefully interviewed, examined, and a vulvar biopsy obtained whenever the diagnosis is in question, the patient is not responding to treatment, or premalignant or malignant disease is suspected. Vulvar conditions such as contact dermatitis, atrophic vulvovaginitis, lichen sclerosis, lichen planus, lichen chronicus simplex, Paget's disease, Bowen's disease, and invasive vulvar cancer are not uncommon. Systemic diseases like psoriasis, eczema, Crohn's disease, Behçet's disease, vitiligo, and seborrheic dermatitis may also involve the vulvar skin.

3▶

Vulvar Contact Dermatitis. This dermatitis is a common cause of acute or chronic vulvar pruritus and can be irritant or allergic.[4] Irritant dermatitis usually results from overzealous hygiene habits, such as the use of harsh soaps and frequent douching. It is also common in patients with urinary or fecal incontinence, especially the elderly and the disabled. Allergic vulvar dermatitis is caused by a variety of allergens, such as fragrances and topical antibiotics. The mainstay of treatment is to identify and discontinue the offending agent or practice or providing a skin barrier in the case of incontinence.

Leukoplakias. There are three types of leukoplakia, a flat white abnormality. Lichen sclerosis is the most common cause of leukoplakia.[4] It affects women 30 to 40 years of age. Classically, it results in a figure-of-eight pattern of white epithelium around the anus and vulva resulting in variable scaring and itching and, less commonly, pain. Diagnosis is confirmed with biopsy, and treatment consists of topical steroids. Lichen planus is a cause of leukoplakia with an onset in the fifth and sixth decades of life. Lichen planus, in contrast to lichen sclerosis, which is limited to the vulva and perianal skin, can involve the vagina and oral mucosa, and erosions occur in the majority of patients, leading to a variable degree of scaring. Patients usually have a history and dysuria and dyspareunia and complain of a burning vulvar pain. Histology is not specific, and biopsy is recommended. Treatment is with steroid ointments. Systemic steroids are indicated for severe and/or unresponsive cases. Lichen simplex chronicus is the third cause of leukoplakia but is distinguished from the other lichen diseases by epidermal thickening, absence of scaring, and a severe intolerable itch.[4] Intense scratching is not uncommon and contributes to the severity of the symptoms and predisposes the cracked skin to infections. Treatment consists of cessation of the scratching, which sometimes requires sedation; elimination of any allergen or irritant; suppression of inflammation with potent steroid ointments; and treatment of any coexisting infections.

Bartholin's Cyst or Abscess. Bartholin's glands, great vestibular glands, are located at the vaginal orifice at the four and eight o'clock positions; they are rarely palpable in normal patients. They are lined with cuboidal epithelium and secrete mucoid material to keep the vulva moist. Their ducts are lined with transitional epithelium, and their obstruction secondary to inflammation may lead to the development of a Bartholin's cyst or abscess. Bartholin's cysts range in size from 1 to 3 cm and are detected on exam or are recognized by the patient. They occasionally result in discomfort and dyspareunia and require treatment. Cysts and ducts can become infected and form abscesses. Infections are often polymicrobial; however, sexually transmitted *N. gonorrhoeae* and *C. trachomatis* are sometimes implicated. Treatment consists of incision and drainage and placement of a Word catheter, a small catheter with a balloon tip, for 2 to 3 weeks to allow for formation and epithelialization of a new duct. Appropriate antibiotic therapy should be instituted. Recurrent cysts or abscesses are usually marsupialized, but on occasion necessitate excision of the whole gland. Marsupialization is done by incising the cyst or abscess wall and securing its lining to the skin edges with interrupted sutures.[5] Cysts or abscesses that fail to resolve after drainage and those occurring in patients over age 40 should be biopsied to exclude malignancy.

Molluscum Contagiosum. Molluscum contagiosum presents with dome-shaped papules and is caused by the poxvirus. The papules are usually 2 to 5 mm in diameter and classically have a central umbilication. They are spread by direct skin contact and present on the vulva, as well as abdomen, trunk, arms, and thighs. Lesions typically clear in several months but can be treated with cryotherapy, curettage, or cantharidin, a topical blistering agent.

Genital Ulcer Syndromes. The frequency of the infectious etiologies of genital ulcers varies by geographic location. The most common causes of sexually transmitted genital ulcers in young adults in the United States are, in descending order of prevalence, herpes simplex virus (HSV), syphilis, and chancroid.[6] Others infectious causes of genital ulcers include lymphogranuloma venereum and granuloma inguinale. Noninfectious etiologies include Behçet's disease, neoplasms, and trauma. Table 41-3 outlines a rational approach to their evaluation and diagnosis.

Vulvar Condyloma. Condylomata acuminata (anogenital warts) are viral infections caused by HPV.[7] Genital infection with HPV is the most common sexually transmitted infection in the United States today. HPV types 6 and 11 are the most common low-risk types and are implicated in 90% of cases of genital warts.[8] High-risk types can be found in association

Table 41-3

Clinical features of genital ulcers syndromes

	HERPES	SYPHILIS	CHANCROID	LYMPHOGRANULOMA VENEREUM	GRANULOMA INGUINALE (DONOVANOSIS)
Pathogen	Herpes simplex virus (HSV) type II and less commonly HSV type I	*Treponema palladium*	*Haemophilus ducreyi*	*Chlamydia trachomatis* L1-L3	*Calymmatobacterium granulomatis*
Incubation period	2–7 days	2–4 weeks (1–12 weeks)	1–14 days	3 days–6 weeks	1–4 weeks (up to 6 months)
Primary lesion	Vesicle	Papule	Papule or pustule	Papule, pustule, or vesicle	Papule
Number of lesions	Multiple, may coalesce	Usually one	Usually multiple, may coalesce	Usually one	Variable
Diameter (mm)	1–2	5–15	2–20	2–10	Variable
Edges	Erythematous	Sharply demarcated, elevated, round, or oval	Undermined, ragged, irregular	Elevated, round, or oval	Elevated, irregular
Depth	Superficial	Superficial or deep	Excavated	Superficial or deep	Elevated
Base	Serous, erythematous	Smooth, nonpurulent	Purulent	Variable	Red and rough ("beefy")
Induration	None	Firm	Soft	Occasionally firm	Firm
Pain	Common	Unusual	Usually very tender	Variable	Uncommon
Lymphadenopathy	Firm, tender, often bilateral	Firm, nontender, bilateral	Tender, may suppurate, usually unilateral	Tender, may suppurate, loculated, usually unilateral	Pseudo-adenopathy
Treatment	Acyclovir (ACV) 400 mg PO tid for 7–10 days for primary infection and 400 mg PO tid for 5 days for episodic management	Primary, secondary, and early latent (<1 year): penicillin G (PCN-G) benzathine 2.4 million U IM × 1 Late latent (>1 year) and latent of unknown duration: PCN-G benzathine 2.4 million U IM every week × 3	Azithromycin 1 g PO or ceftriaxone 250 mg IM × 1 *or* ciprofloxacin 500 mg PO bid for 3 days Erythromycin base 500 mg PO tid for 7 days	Doxycycline 100 mg PO bid for 21 days *or* erythromycin base 500 mg PO qid for 21 days	Doxycycline 100 mg PO bid for 3 weeks until all lesions have healed
Suppression	ACV 400 mg PO bid for those with frequent outbreaks				

bid = twice a day; IM = intramuscular; PO = oral; qid = four times a day; tid = twice a day.
Data from Stenchever M, Droegemueller W, Herbst A, et al. *Comprehensive Gynecology*. 4th ed. St. Louis: Mosby; 2001.

with invasive cancers. Genital warts are skin-colored or pink and range from smooth flattened papules to verrucous papilliform lesions. Lesions may be single or multiple and extensive. Diagnosis should be confirmed with biopsy because verrucous vulvar cancers can be mistaken for condylomata.[9] Treatment modalities range from patient-applied ointments to physician-applied agents and office procedures. If small, self-administered topical imiquimod 5% cream or trichloroacetic acid for in-office applications may be tried. Extensive lesions may require surgical modalities that include cryotherapy, laser ablation, cauterization, and surgical excision.

Paget's Disease of the Vulva. Paget's disease of the vulva is an intraepithelial disease of unknown etiology that affects mostly white postmenopausal women in their sixth decade of life. It causes chronic vulvar itching and is sometimes associated with an underlying invasive vulvar adenocarcinoma or invasive cancers of the breast, cervix, or gastrointestinal tract. Grossly, the lesion is variable but usually confluent, raised, erythematous to violet, and waxy in appearance. Biopsy is required for diagnosis; the disease is intraepithelial and characterized by Paget's cells with large pale cytoplasm. Treatment is assessment for other potential concurrent adenocarcinomas, and then surgical removal by wide local resection of the involved area with a 2-cm margin. Free margins are difficult to obtain because the disease usually extends beyond the clinically visible area.[10,11] Intraoperative frozen section of the margins can be done; however, Paget's vulvar lesions have a high likelihood of recurrence even after securing negative resection margins.

Vulvar Intraepithelial Neoplasia (VIN). VIN is similar to its cervical intraepithelial neoplasia (CIN) counterpart and is graded on the degree of epithelial involvement as mild (VIN I), moderate (VIN II), severe (VIN III), or vulvar carcinoma in situ (Bowen's disease).[12] Risk factors include HPV infection, prior VIN, HIV infection, immunosuppression, smoking, vulvar dermatoses such as lichen sclerosis, CIN, and cervical cancer. VIN can be unifocal or multifocal. Unifocal lesions commonly affect postmenopausal women and lack a clear association with HPV, while multifocal disease mostly affects younger reproductive-age females and has a strong association with HPV infection. Fifty percent of patients are asymptomatic, with vulvar pruritus being the most common complaint in those with symptoms. Lesions may be vague or raised and velvety with sharply demarcated borders. Diagnosis is made with a vulvar skin biopsy, and multiple biopsies are sometimes necessary. Colposcopy with application of 5% acetic acid and identification of the acetowhite lesions of VIN is a valuable diagnostic tool for subtle lesions and will help guide the biopsy. Evaluation of the perianal and anal area is important as the disease may involve these areas, particularly in immunocompromised and/or nicotine-addicted women. Once invasive disease is ruled out, treatment usually involves wide surgical excision; however, the initial treatment approach may include 5% imiquimod cream, CO_2 laser ablation, or cavitational ultrasonic surgical aspiration, and depends on the number of lesions and their severity. When laser ablation is used, a 1-mm depth in hair-free areas is usually sufficient, whereas hairy lesions require ablation to a 3-mm depth because the hair follicles' roots can reach a depth of 2.5 mm. Unfortunately, VIN tends to recur in up to 30% of cases, and high-grade lesions (VIN III, carcinoma in situ) progress to invasive disease in approximately 10% of patients if left untreated.[13]

4▶

Vaginal Lesions

Vaginitis (see Table 41-2). Vulvovaginal symptoms are extremely common, accounting for over 10 million office visits per year in the United States. The causes of vaginal complaints are commonly infectious in origin, but they include a number of noninfectious causes, such as chemicals or irritants, hormone deficiency, foreign bodies, systemic diseases, and malignancy. Symptoms are commonly nonspecific and include abnormal vaginal discharge, pruritus, irritation, burning, odor, dyspareunia, bleeding, and ulcers. A purulent discharge from the cervix should always raise suspicion of these infections even in the absence of pelvic pain or other signs.

Normal vaginal discharge is white or transparent, thick, and mostly odorless. It increases during pregnancy, with use of estrogen-progestin contraceptives, or at mid-cycle around the time of ovulation. Complaints of foul odor and abnormal vaginal discharge should be investigated. Candidiasis, bacterial vaginosis, and trichomoniasis account for 90% of vaginitis cases. The initial workup includes pelvic examination, vaginal pH testing, microscopy, vaginal cultures if microscopy is normal, and gonorrhea/chlamydia NAAT (see earlier section, Common Screening and Testing).[14] The pH of normal vaginal secretions is 3.8 to 4.4, which is hostile to growth of pathogens. A pH greater than or equal to 4.9 is indicative of a bacterial or protozoal infection. Treatment of vaginal infection before anticipated surgery is appropriate, particularly for bacterial vaginosis, which may be associated with a higher risk for vaginal cuff infections (Fig. 41-8).

Bacterial Vaginosis (BV). BV accounts for 50% of vaginal infections. It results from reduction in concentration of the normally dominant lactobacilli and increase in concentration of anaerobic organisms like *Gardnerella vaginalis*, *Mycoplasma hominis*, *Bacteroides* species, and others.[15] Diagnosis is made by microscopic demonstration of clue cells. The discharge typically produces a fishy odor upon addition of KOH (amine or Whiff test). Initial treatment is usually a 7-day course of metronidazole.

Vulvovaginal Candidiasis (VVC). VVC is the most common cause of vulvar pruritus. It is generally caused by *Candida albicans* and occasionally by other *Candida* species. It is common in pregnant women, diabetics, patients taking antibiotics, and immunocompromised hosts. Initial treatment is usually with topical antifungals, although single-dose oral antifungal treatments are also common.

Trichomonas vaginalis. Trichomoniasis is a sexually transmitted infection of a flagellated protozoan and can present with malodorous, purulent discharge. It is typically diagnosed with visualization of the trichomonads during saline wet mount microscopy. Initial treatment is usually a 7-day course of metronidazole.

Gartner's Duct Cyst. A Gartner's duct cyst is a remnant of the Wolffian tract; it is typically found on the lateral vaginal walls. Patients can be asymptomatic or present with complaints of dyspareunia or difficulty inserting a tampon. If symptomatic, these cysts may be surgically excised or marsupialized. If surgery is planned, a preoperative magnetic resonance imaging (MRI) scan should be obtained to determine the extent of the cyst.

Vaginal Condyloma. The etiology and treatment of vaginal condyloma is similar to vulvar condyloma (see earlier section, Vulvar Condyloma).

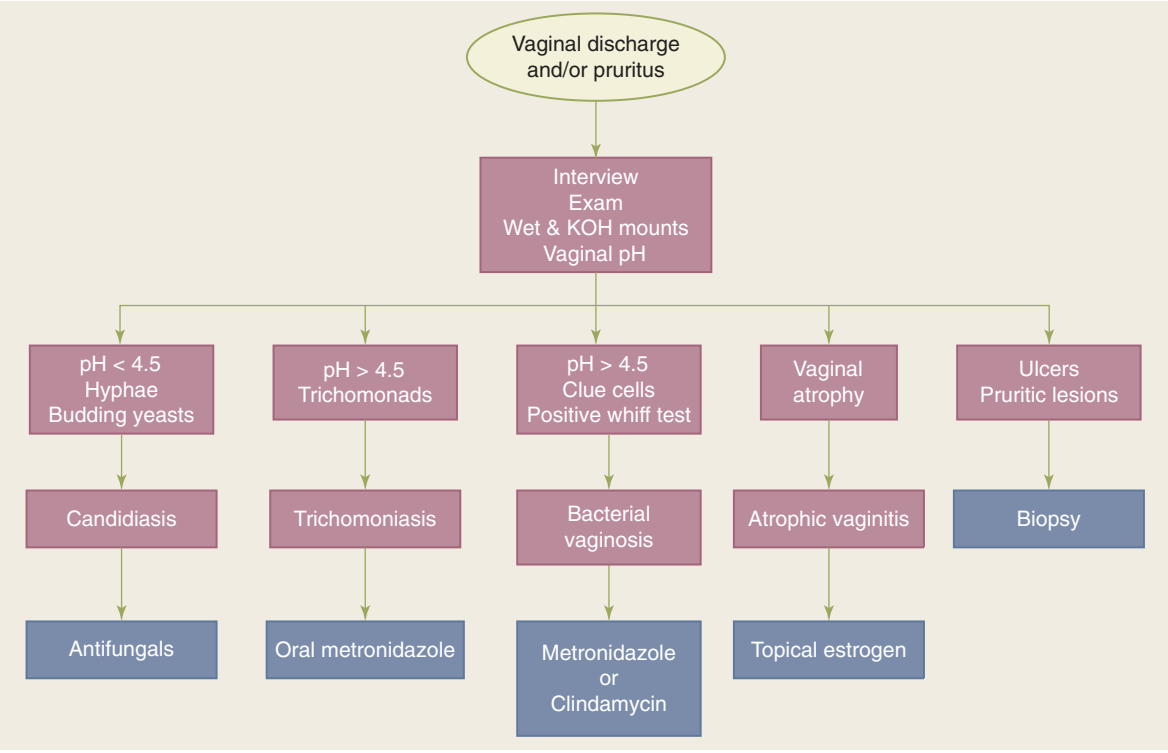

Figure 41-8. Treatment algorithm for vulvovaginitis.

Vaginal Intraepithelial Neoplasia. Vaginal intraepithelial neoplasia, or VaIN, is similar to VIN and is classified based on the degree of epithelial involvement as mild (I), moderate (II), severe (III), or carcinoma in situ.[12] Sixty-five percent to 80% of VaIN or vaginal cancers are associated with HPV infection. The majority of lesions are located in the upper one third of the vagina. Lesions are usually asymptomatic and found incidentally on cytologic screening. Diagnosis is made via guided biopsy of acetowhite lesions at the time of colposcopy. Lesions may appear flat or raised and white with sharply demarcated borders and may show vascular changes. The presence of aberrant vessels with marked branching is suggestive of invasive disease. VaIN is treated with laser ablation, surgical excision, or topical 5-fluorouracil therapy.

Cervical Lesions

Benign Cervical Lesions. Benign lesions of the cervix include endocervical polyps, Nabothian cysts (clear, fluid-filled cysts with smooth surfaces), trauma (such as delivery-related cervical tear or prior cervical surgery), malformation of the cervix, and cervical condyloma. For endocervical polyps, exploration of the base of the polyp with a cotton swab tip to identify that it is cervical and not uterine and to identify the stalk characteristics can help identify the appropriate surgical approach. Small polyps with identifiable base can be removed by grasping the polyp with ring forceps and slowly rotating it until separated from its base. Use of loop electro-excisional procedure (LEEP) is appropriate for larger lesions. Laser or other ablative procedures are appropriate for condyloma proven by biopsy.

Cervical Intraepithelial Neoplasia (CIN). High-grade cervical dysplasia (CIN II or III) has a high chance of persistent HPV infection with risk of transformation to malignancy; thus an excisional procedure is usually indicated. This serves a therapeutic purpose by removal of dysplastic cells and a diagnostic purpose for histologic review to rule out concomitant early-stage cervical cancer. Either a LEEP or cold knife conization (CKC) may be used for surgical excision of the squamocolumnar junction (SCJ) and outer endocervical canal. Risks of both procedures include bleeding, postprocedure infection, cervical stenosis, and risk of preterm delivery with subsequent pregnancies. A looped wire attachment for a standard monopolar electrosurgical unit is used to perform a LEEP excision. Loops range in a variety of shapes and sizes to accommodate different sizes of cervix. Optimally, one pass of the loop should excise the entire SCJ. Hemostasis of the remaining cervix is achieved with the ball electrode and ferrous sulfate paste (Monsel's solution).

Different from a LEEP, a cervical CKC does not use energy to excise the specimen. The advantage of this procedure is that the margin status is not obscured by cauterized artifact. This is important in cases of adenocarcinoma in situ and microinvasive squamous cell carcinoma, where margin status dictates the type of and indication for future therapy. During a CKC, a #11 blade is used to circumferentially excise the conical biopsy. Hemostasis is achieved with the ball electrode, Monsel's solution, or suture.

HPV Vaccine. Two HPV vaccines have been developed and approved by the U.S. Food and Drug Administration (FDA).[16] Gardasil is a quadrivalent vaccine that targets HPV genotypes 16 and 18, which cause approximately 70% of cervical cancers and about 50% of precancerous lesions (CIN II/III) worldwide, and HPV genotypes 6 and 11, which cause 90% of genital warts. Cervarix is a bivalent vaccine that targets HPV genotypes 16 and 18. In contrast to natural infection, the vaccine is highly immunogenic, activating both humoral and cellular immune responses. Vaccination generates high concentrations of neutralizing antibodies to HPV L1 protein, the antigen in both

vaccines. It is thought that vaccination may provide protection against HPV infection through neutralization of virus by serum immunoglobulin that diffuses from capillaries to the genital mucosal epithelium.[17]

Several randomized clinical trials[18-20] involving approximately 35,000 young women have shown that both Gardasil and Cervarix prevent nearly 100% of the HPV subtype-specific precancerous cervical cell changes for up to 4 years after vaccination among women who were not infected at the time of vaccination; vaccination occurred before sexual debut. These major clinical trials have used prevention of CIN II/III and carcinoma in situ as the efficacy endpoints. Vaccination has not yet been shown to protect women who are already infected with HPV-16 or HPV-18 at the time of vaccination.

Current FDA approval applies to use in women who are between 9 and 26 years of age for the prevention of the following: cervical, vulvar, and vaginal cancer caused by HPV-16 or -18, genital warts caused by HPV-6 or -11, and lesions caused by HPV-6, -11, -16, or -18 (CIN I, II, and III; cervical carcinoma in situ; VIN; or VaIN II/III). The Advisory Committee on Immunization Practices (ACIP) recommends routine vaccination for females 11 to 12 years of age, maybe starting at age 9; catch-up vaccination is recommended for females 13 to 26 years of age who did not get all three doses when they were younger. Studies to evaluate the efficacy of the vaccine in healthy women 26 years of age and older with no prior exposure to HPV is ongoing, and additional information on the length of protection is forthcoming. In 2009, the FDA approved the quadrivalent vaccine for use to prevent genital warts in men and boys, and in 2011, the ACIP recommended that all males 11 to 12 years of age be vaccinated, stating that this may reduce some of the HPV-related burden suffered by women.

Immunocompromised women may receive the quadrivalent vaccine. Although the safety and immunogenicity of HPV vaccination in this population are not well established, the vaccine could be beneficial in these women since they are at increased risk for HPV-related cancers. Vaccination is not recommended for pregnant women, although neither vaccine has been shown to be causally associated with adverse outcomes in pregnant women or their fetuses. If pregnant women are vaccinated inadvertently, completion of the series should be delayed until after the pregnancy.

Cervical cancer screening continues to play an important role in detection and treatment of CIN II/III and prevention of cervical cancer in these high-risk patients. Cervical cancer screening continues to be of great importance since HPV immunization will not prevent approximately 25% to 30% of cervical cancers in HPV-naïve women and does not protect against the development of cancer in women already infected with carcinogenic HPV types.

Uterine Corpus

The average age of menarche, or first menstrual period, in the United States is 12 years and 5 months. Duration of normal menstruation is between 2 and 7 days, with a flow of less than 80 mL, cycling every 21 to 35 days.[21] Nonpregnant patients, who present with heavy bleeding and are 35 years of age and older or have risk factors for endometrial cancer, must be ruled out for malignancy as the first step in their management (see earlier section, Endometrial Biopsy).

Abnormal Uterine Bleeding (AUB). Abnormal uterine bleeding is described based on the bleeding pattern. Menorrhagia is prolonged (>7 days) or excessive (>80 mL daily) menstrual cycles occurring at regular intervals, and metrorrhagia is bleeding between menstrual periods. Menometrorrhagia is the occurrence of both. Intermenstrual bleeding, also known as spotting, is bleeding of variable amounts occurring between regular menstrual cycles. Poly-, oligo-, and amenorrhea are menstrual cycles of less than 21 days, longer than 35 days, or the absence of uterine bleeding for 6 months or a period equivalent to three missed cycles, respectively. Because there are many causes of AUB, they are divided into two categories: structural causes and nonstructural causes.[22] Structural causes include polyps, adenomyosis, leiomyomata, and malignancy. Nonstructural causes can include coagulopathy, ovulatory dysfunction, endometrial effects, and iatrogenic causes.

Endometrial Polyps. Endometrial polyps are localized hyperplastic growth of endometrial glands and stroma around a vascular core forming sessile or pedunculated projections from the surface of the endometrium.[23] Endometrial polyps are rarely neoplastic (<1%) and may be single or multiple. Many are asymptomatic; however, they are responsible for about 25% of cases of abnormal uterine bleeding, usually metrorrhagia. Polyps are common in patients on tamoxifen therapy and in peri- and postmenopausal women. Up to 2.5% of patients with a polyp may harbor foci of endometrial carcinoma.[24] Diagnosis can be made with saline-infused hysterosonography, hysterosalpingogram, or direct visualization at the time of hysteroscopy. Definitive treatment, in the absence of malignancy, involves resection with an operative hysteroscope or by sharp curettage.

Adenomyosis. Adenomyosis refers to ectopic endometrial glands and stroma situated within the myometrium. When diffuse, it results in globular uterine enlargement secondary to hyperplasia and hypertrophy of the surrounding myometrium. Adenomyosis is very common, tends to occur in parous women, and is frequently an incidental finding at the time of surgery. Diagnosis is suspected in a parous woman with menorrhagia, dysmenorrhea, and diffuse globular uterine enlargement. MRI may reveal islands within the myometrium with increased signal intensity.[25] Hysterectomy is the only treatment, providing material for definitive pathologic diagnosis.

Uterine Leiomyomas. Leiomyomas, also known colloquially as fibroids, are the most common female pelvic tumor and occur in response to growth of the uterine smooth muscle cells (myometrium). They are common in the reproductive years, and by age 50, at least 60% of white and up to 80% of black women are or have been affected. Leiomyomas are described according to their anatomic location (Fig. 41-9) as intramural, subserosal, submucosal, pedunculated, cervical, and rarely ectopic.[21] Most are asymptomatic; however, abnormal uterine bleeding caused by leiomyomas is the most common indication for hysterectomy in the United States. Other manifestations include pain, pregnancy complications, and infertility. Pain generally results from degenerating myomas that outgrew their blood supply or from compression of other pelvic organs such as the bowel, bladder, and ureters. High levels of pregnancy hormones frequently cause significant enlargement of pre-existing myomas, which may lead to significant distortion of the uterine cavity resulting in recurrent miscarriages, fetal malpresentations, intrauterine growth restriction, obstruction of the birth canal and the subsequent need for cesarean delivery, abruption, preterm labor, and pain from degeneration.

Bleeding is usually heavy and irregular (menometrorrhagia) and can be severe at times, requiring hospitalization. Examination

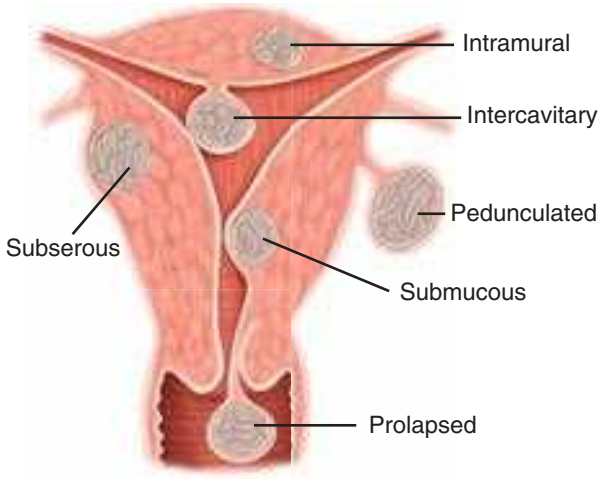

Figure 41-9. Types of uterine myomas.

reveals an enlarged irregular uterus and, in severe cases, a large solid pelvic mass extending to the upper abdomen. Diagnosis is usually made by transvaginal ultrasonography. Other diagnostic modalities, including MRI, computed tomography (CT), and hysterosalpingogram or saline-infused hysterosalpingography, are especially useful in the cases of submucosal and intrauterine myomas. Most are benign; malignant degeneration occurs in less than 1% of cases and is usually encountered in the menopausal years. Management options of leiomyomas are tailored to the individual patient depending on her age and desire for fertility and the size, location, and symptoms of the myomas. Conservative management options include oral contraceptive pills, medroxyprogesterone acetate, gonadotropin-releasing hormone (GnRH) agonists, uterine artery embolization, and myomectomy.[26-28] Uterine artery embolization is contraindicated in patients planning future pregnancy and frequently results in acute degeneration of myomas requiring hospitalization for pain control. Myomectomy is indicated in patients with infertility and those who wish to preserve their reproductive capacity. Hysterectomy is the only curative therapy. Treatment with GnRH agonists for 3 months prior to surgery is recommended in anemic patients and may allow them time to normalize their hematocrit, avoiding transfusions; GnRH also decreases blood loss at hysterectomy and shrinks the myomas by an average of 30%. The latter may make the preferred vaginal surgical approach more feasible.

Endometrial Hyperplasia. Endometrial hyperplasia is caused by chronic unopposed hyperestrogenic state (relative absence of progesterone) and is characterized by proliferation of endometrial glands resulting in increased gland-to-stroma ratio. It can be asymptomatic or, more commonly, result in abnormal vaginal bleeding. Hyperplasia can be either simple or complex, based on the architecture of the glands. Of greater importance is the presence or absence of nuclear atypia, described by the World Health Organization (WHO) classification.[29] Untreated endometrial hyperplasia progresses to malignancy in 1%, 3%, 8%, and 29% of cases of simple, complex, simple with atypia, and complex hyperplasia with atypia, respectively.[30] Simple and complex hyperplasias can be treated with progestins, and women should have repeat endometrial sampling in 3 to 6 months. Atypical hyperplasia is considered a premalignant condition and is treated ideally with simple hysterectomy. When a patient has a preoperative diagnosis of complex atypical hyperplasia, the likelihood of a concomitant endometrial cancer at hysterectomy is 38% to 60%.[31] If preservation of fertility is desired or surgery contraindicated, treatment with high-dose progestins such as megestrol acetate 40 to 160 mg/d usually reverses these lesions. Close follow-up and repeated sampling are necessary.

Procedures Performed for Structural Causes of Abnormal Uterine Bleeding

Dilation and Curettage. The patient is placed on the operating table in a lithotomy position, and the vagina and cervix are prepared as for any vaginal operation. The cervix is grasped on the anterior lip with a tenaculum. Some traction on the cervix is necessary to straighten the cervical canal and the uterine cavity. A uterine sound is inserted into the uterine cavity, and the depth of the uterus is noted. The cervical canal is then systematically dilated beginning with a small cervical dilator. Most operations can be performed after the cervix is dilated to accommodate a number 8 or 9 Hegar dilator or its equivalent. Dilatation is accomplished by firm, constant pressure with a dilator directed in the axis of the uterus (Fig. 41-10). After the cervix is dilated to admit the curette, the endocervical canal should be curetted and the sample submitted separately from the endometrial curettings. The endometrial cavity is then systemically scraped with a uterine curette. Uterine perforation is the major complication of dilatation and curettage, diagnosed when the operator finds no resistance to a dilator or curette. Laparoscopy to identify any damage to vessels or bowel may be required. Curettage of the postabortal uterus must be approached carefully because the uterus is extremely soft and perforation can occur with very little warning. Using the largest curette available or suction curettage is a safer choice than a small curette, which tends to cause perforation with less pressure.

Hysteroscopy. Hysteroscopy, like laparoscopy, has gained widespread support for use both for diagnosis and treatment of intrauterine pathology and for ablation of the endometrium as an alternative to hysterectomy for the treatment of abnormal uterine bleeding. Scopes can have an objective lens that is offset from the long axis from 0° to 30°. The diagnostic hysteroscope usually has an external diameter of 5 mm. Some diagnostic sheaths allow passage of flexible instruments for biopsy and cutting. An operative hysteroscope is wider and usually has an integral unipolar or bipolar resecting loop identical to a urologic resectoscope. The loop can be replaced with a roller ball for endometrial ablation.

Several types of distention media exist and vary by electrolyte composition and osmolarity. High-viscosity (e.g., dextran 70), low-viscosity/electrolyte-poor (e.g., glycine and sorbitol), and low-viscosity/electrolyte-containing (e.g., normal saline and lactated Ringer's solution) medias are commonly used for distension of the uterus during hysteroscopy.[32] The use and safety profiles of these medias vary, however. Dextran 70 allows excellent visibility, but the manufacturer recommends that no more than 250 mL be absorbed because of the concern for pulmonary edema. Anaphylactic reactions and coagulopathy are rare complications that have been described.[33] Glycine and sorbitol allow the use of monopolar cautery during operative hysteroscopy. Large volume deficits have been associated with secondary hyponatremic hypervolemia due to their metabolism to free water after intravasation.[33] When fluid deficits reach 1000 to 1500 mL, the procedure should be terminated, and the patient's serum electrolytes assessed. Patients who have excessive intravasation experience

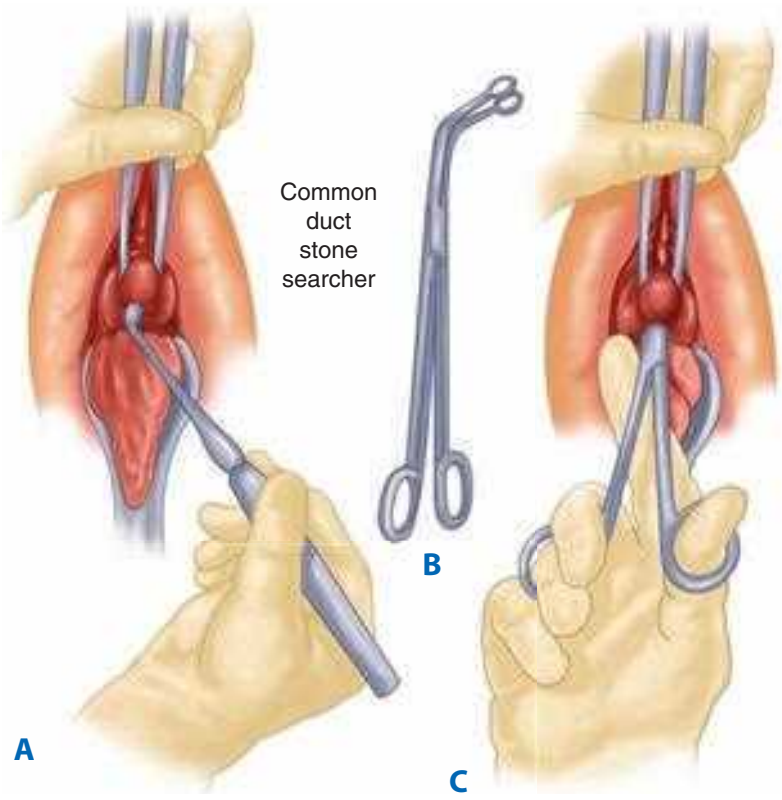

Figure 41-10. **A** through **C.** Dilatation and curettage of the uterus.

headache, nausea, vomiting, and agitation.[34] This manifestation can progress to pulmonary and cerebral edema. These patients require close monitoring and diuretic administration.

Unlike glycine and sorbitol, normal saline and lactated Ringer's solution have physiologic osmolarity and contain sodium. Although excessive intravasation does not lead to hyponatremia, it can lead to volume overload. Media deficits of greater than 2500 mL should prompt conclusion of the procedure and assessment of electrolytes.[35] Fluid-management systems are available to monitor the amount of distension media lost during hysteroscopy. Media intravasation can be lessened by using the minimum intrauterine pressure needed to perform the hysteroscopy and by minimizing operating time. The physician must be aware that certain procedures such as endometrial ablation and resection of myomas open vascular channels and place the patient at increased risk for fluid overload.[33]

Diagnostic Hysteroscopy. Following dilation of the cervix, a diagnostic hysteroscope is placed and the uterine cavity distended with the media of choice. Inspection of the cavity includes identifying the uterine fundus, cornua, and any other anomalies to include polyps, leiomyomas, or uterine septum.

Hysteroscopic Polypectomy or Myomectomy. If an intrauterine polyp is discovered, the base of the polyp is incised with hysteroscopic scissors, and the polyp is grasped with grasping forceps. The hysteroscope, sleeve, and polyp are removed simultaneously, because most polyps will not fit through the operating channel. Extremely large polyps may have to be removed piecemeal. Any residual base of the polyp may be removed with biopsy forceps. Pedunculated or submucosal leiomyoma can be removed safely hysteroscopically. Because myoma tissue is relatively dense, a power cutting instrument is required. The most common method is use of electrosurgery. A monopolar device may be used with an electrolyte-poor distention medium. Only bipolar devices may be used with normal saline or lactated Ringer's solution. Both pedunculated and submucosal fibroids are shaved into small pieces with the hysteroresectoscope. Stalk resection should only be done to release a pedunculated fibroid if it is 10 mm or less in size; larger fibroids are difficult to remove in one piece without excessive cervical dilatation. Morcellation is much easier when the stalk is still attached for stability. Hysteroscopes with a morcellation attachment have been recently developed.[36]

Endometrial Ablation. A common treatment for abnormal uterine bleeding in the absence of endometrial hyperplasia is ablation of the endometrium. Historically, this was performed with an operative hysteroscope using an electrosurgical "roller ball," where the endometrium was destroyed down to the myometrium in a systematic fashion. Currently, hysteroscopic endometrial ablation has been widely supplanted by various devices, including heated free fluid, cryotherapy, thermal balloon, microwave, and radiofrequency electricity. Most ablation techniques result in amenorrhea in approximately half the patients and decreased menstruation in another third of the patients over the first year of therapy.[37]

Myomectomy. Myomectomy (Fig. 41-11) is the removal of fibroids, and it can be treatment for abnormal uterine bleeding, bulk symptoms, or infertility. Hemostasis during myomectomy can be aided medically by direct injection of dilute vasopressin at the site of the intended uterine incision (10 U in 50 mL). It can be aided further through the placement of a Penrose drain around the base of the uterus, pulled through small perforations in the broad ligament lateral to the uterine blood supply on either

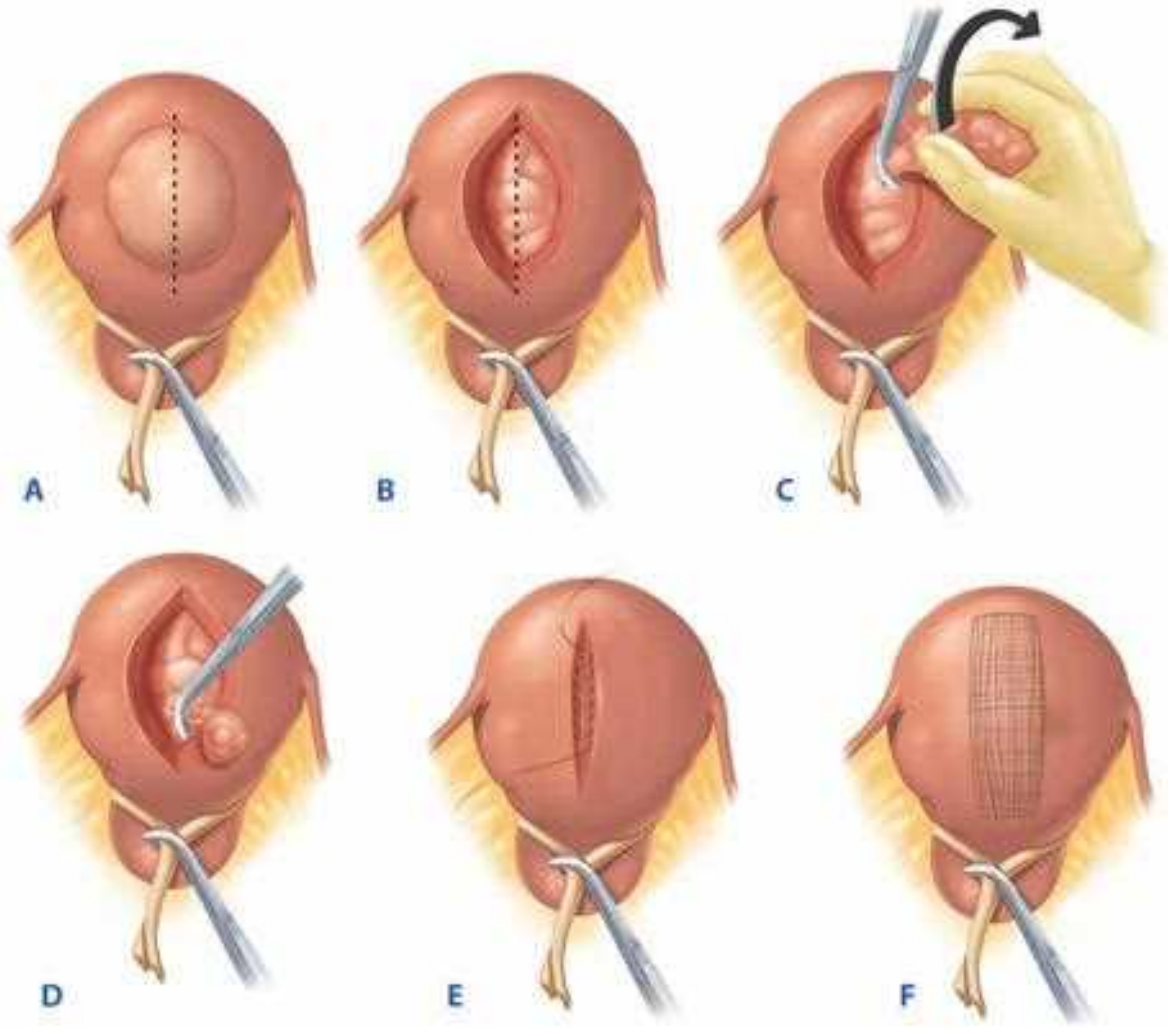

Figure 41-11. Myomectomy. **A.** Hemostatic "tourniquet'" in place before myomectomy. **B.** Uterine incision for myomectomy. **C.** Removal of myoma. **D.** Several myomas may be removed through a single incision. **E.** The uterine wound is closed with an absorbable suture. **F.** The uterine wound covered with mesh to retard adhesions.

side and clamped to form a tourniquet for uterine blood flow. An incision is then made through the uterine serosa into the myoma. The pseudocapsule surrounding the tumor is identified and the tumor is bluntly dissected out with scissors, or bluntly if open. Vessels to the myoma are dessicated with the electrosurgical unit. Several myomas may be removed through a single incision, depending on size. The uterine wounds are closed with absorbable sutures to obliterate the dead space and provide hemostasis. The uterine serosa is closed with a 3-0 absorbable suture, placed subserosally if possible. Because myomectomies are associated with considerable postoperative adhesion formation, barrier techniques are used to decrease adhesion formation.

During a laparoscopic myomectomy, hemostasis is assisted by intrauterine injection of dilute vasopressin (10 U in 50 mL) at the site of incision, similar to an open procedure. This is usually performed percutaneously with a spinal needle. Pedunculated leiomyomas can be excised at the base using scissors or a power instrument. Intramural leiomyomas require deep dissection into the uterine tissue, which must be closed subsequently with laparoscopic suturing techniques. Removing the specimen often requires morcellation, and power morcellators have been developed that significantly expedite this technique. Adhesion barriers are placed laparoscopically.

Total Abdominal Hysterectomy (Fig. 41-12). After the abdomen is entered, the upper abdomen is examined for evidence of extrapelvic disease, and a suitable retractor is placed in the abdominal incision. The uterus is grasped at either cornu with clamps and pulled up into the incision. The round ligament is identified and divided. The peritoneal incision is extended from the round ligament to just past the ovarian hilum, lateral to the infundibulopelvic ligament, if the ovaries are to be removed. The retroperitoneal space is bluntly opened, the ureter identified on the medial leaf of the broad ligament, and the infundibulopelvic ligament isolated, clamped, cut, and suture-ligated; a similar procedure is carried out on the opposite side. If the ovaries are to be left in situ, the ureter is identified and an opening below the utero-ovarian ligament and fallopian tube created. The fallopian tube and utero-ovarian ligament are clamped, cut, and ligated. The bladder is mobilized by sharply dissecting it free of the anterior surface of the uterus and cervix. Clamps are placed on the uterine vessels at the cervicouterine junction, and they are cut and suture-ligated. The cardinal ligaments are then serially clamped, cut, and ligated. Following division of the remaining cardinal ligaments, the uterus is elevated and the vagina clamped. The cervix is amputated from the vagina with scissors or a knife. Sutures are placed at each lateral angle of the

Hysterectomy. **A.** The uterus grasped at the cornua. **B.** The round ligament is cut. **C.** The ovarian ligament and fallopian tube are isolated. **D.** The bladder is mobilized. **E.** The uterine vessels are clamped. **F.** The cardinal ligaments are clamped. **G.** The vagina is entered. **H.** The cardinal ligaments are sutured to the vagina. **I.** The vagina is "closed open."

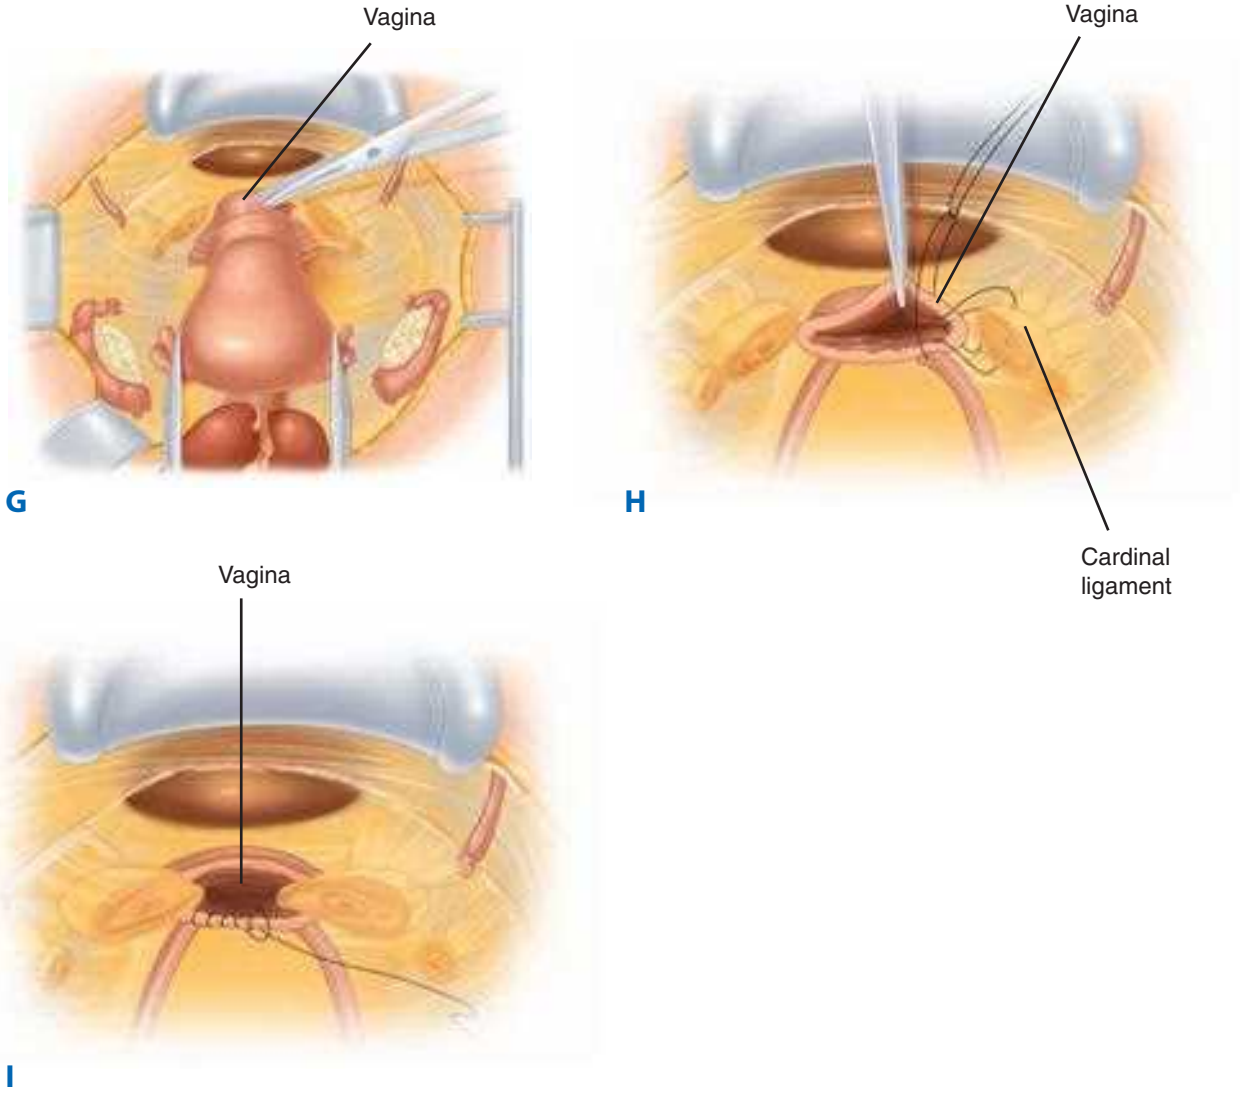

Figure 41-12. (*Continued*)

vagina, and the remainder of the vagina is closed with a running absorbable suture. Pelvic reperitonealization is not necessary.

Transvaginal Hysterectomy (Fig. 41-13). Vaginal hysterectomy is the preferred approach in patients in whom the uterus descends and the pubic arch allows enough space for a vaginal operation. A bladder catheter can be placed before the procedure, and the patient is placed in a lithotomy position. A weighted vaginal speculum is placed in the vagina, and the cervix is grasped with a tenaculum and pulled in the axis of the vagina. Injection of the cervix and paracervical tissue with analgesic with epinephrine may be helpful in defining planes and decreasing obscuring bleeding. A circumferential incision may be made with a scalpel or scissors. The posterior cul-de-sac is identified and entered with scissors. A long weighted speculum is then placed through this opening into the peritoneal cavity. Metzenbaum scissors are used to dissect anteriorly on the cervix down to the pubocervical-vesical fascia, reflecting the bladder off the lower uterine segment. When the peritoneum of the anterior cul-de-sac is identified, it is entered with the scissors, and a retractor is placed in the defect. The uterosacral ligaments are identified, doubly clamped, cut, and ligated. Serial clamps are placed on the parametrial structures above the uterosacral ligament; these pedicles are cut and ligated. At the cornu of the uterus, the tube, round ligament, and utero-ovarian ligament of the ovary are doubly clamped and cut. The procedure is carried out usually concurrently on the opposite side, and the uterus is removed. The pelvis is inspected for hemostasis; all bleeding must be meticulously controlled at this point.

The pelvic peritoneum is closed with a running purse-string suture incorporating the uterosacral and ovarian pedicles, those that were held. This exteriorizes those areas that might tend to bleed. The sutures attached to the ovarian pedicles are cut. The vagina may be closed with interrupted mattress stitches, incorporating the uterosacral ligaments into the corner of the vagina with each lateral stitch. On occasion, the uterus, which is initially too large to remove vaginally, may be reduced in size by morcellation (Fig. 41-14). After the uterine vessels have been clamped and ligated, serial wedges are taken from the central portion of the uterus in order to reduce the uterine mass. This procedure will allow the vaginal delivery of even very large uterine leiomyomas.

Laparoscopic Hysterectomy. Laparoscopy has been used to augment vaginal hysterectomy to avoid laparotomy in patients with known pelvic adhesions, with endometriosis, or in whom the uterus is enlarged by leiomyoma. Although multiple variations in technique exist, there are three basic laparoscopic

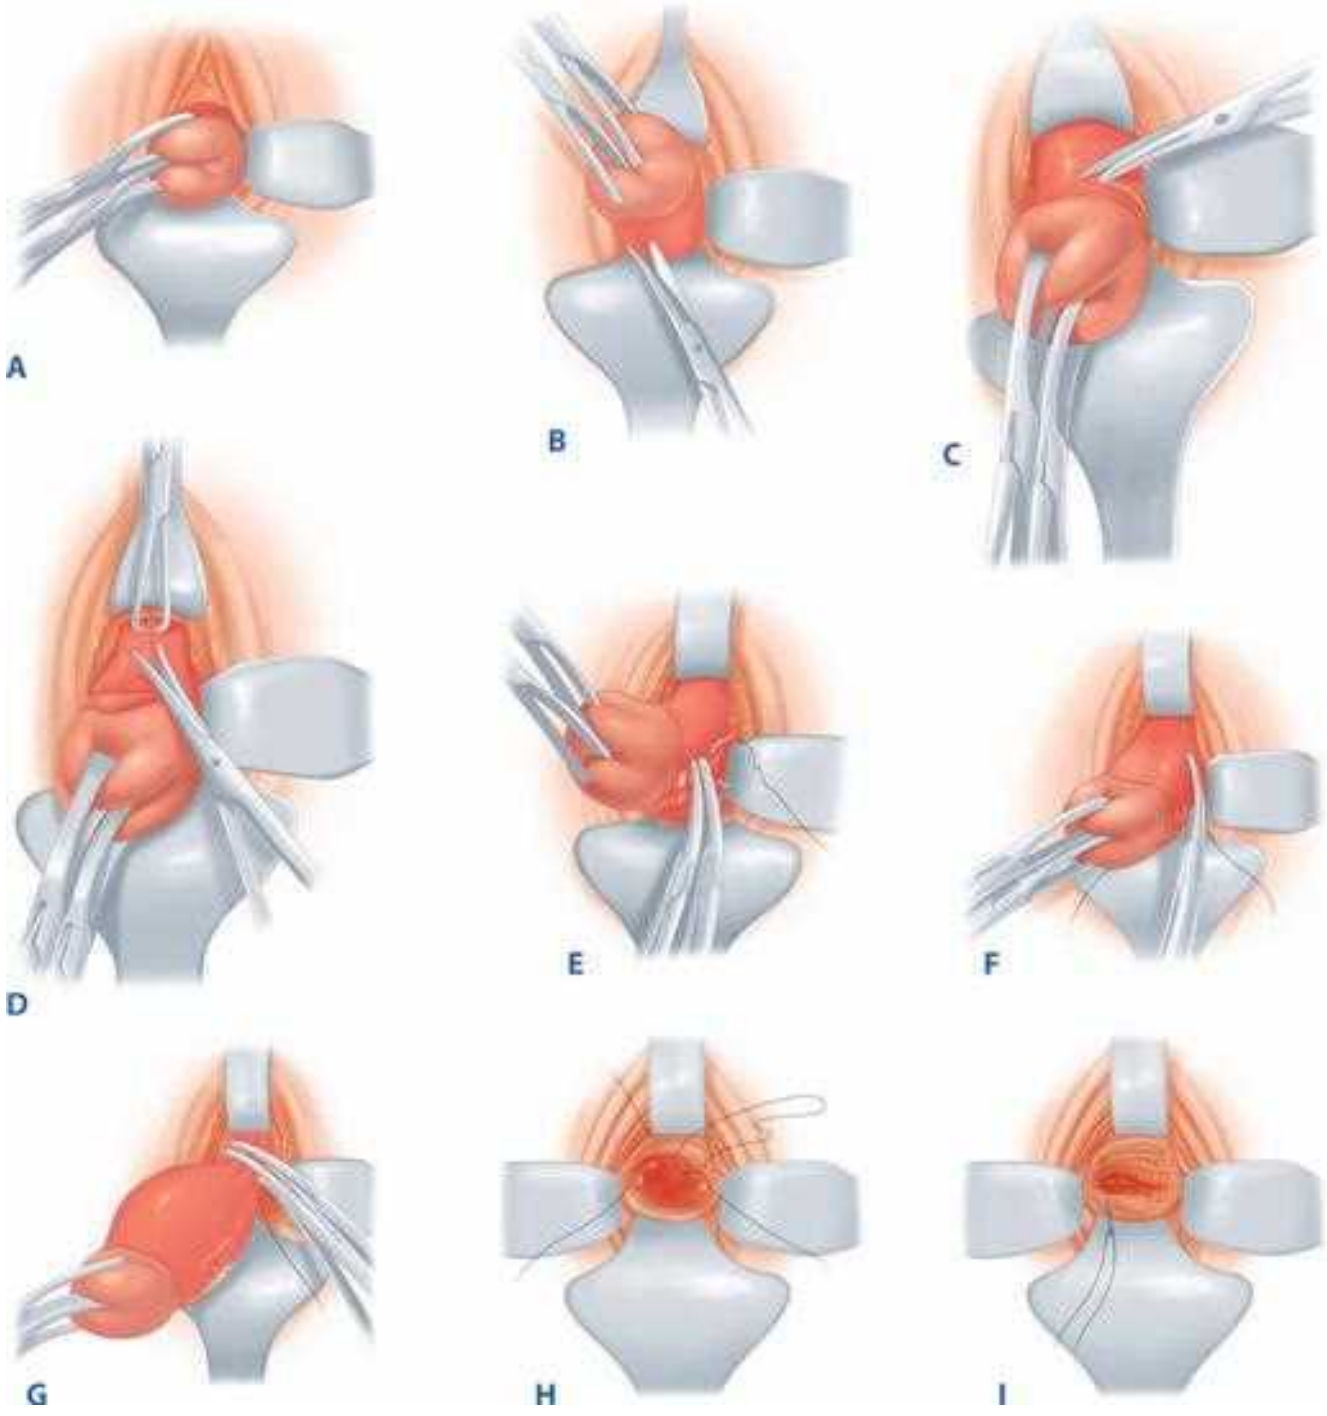

Figure 41-13. Vaginal hysterectomy. **A.** Traction is placed on the uterus. **B.** The posterior cul-de-sac is entered. **C.** The vaginal mucosa is circumcised. **D.** The anterior cul-de-sac is entered. **E.** The uterosacral ligaments are clamped. **F.** The uterosacral ligaments are tied. **G.** The fallopian tube, round ligament, and ovarian ligament are ligated. **H.** The peritoneum is closed. **I.** The vaginal mucosa is closed.

approaches for hysterectomy: laparoscopic-assisted vaginal hysterectomy (LAVH), total laparoscopic hysterectomy (TLH), and laparoscopic supracervical hysterectomy (LSH). The technically simplest is the LAVH. A multiple-port approach is used to survey the peritoneal cavity, and any pelvic adhesions are lysed. The round ligaments are then occluded and divided, and the uterovesical peritoneum and peritoneum lateral to the ovarian ligament are incised. The course of the ureter and any adhesions or implants, such as endometriosis that might place the ureter in the way of the surgical dissection, are carefully dissected. Next, the proximal uterine blood supply is dissected for identification and then occluded with a laparoscopic energy device. When the ovaries are removed, the infundibulopelvic ligaments containing the ovarian vessels are divided. If the ovaries are conserved, the utero-ovarian ligament and blood vessels are divided and occluded. In many cases, the posterior cul-de-sac is also incised laparoscopically and the uterosacral ligaments separated with an energy device. The amount of dissection that is done prior to the vaginal portion depends on individual patient characteristics and may include as little as ovarian and adhesion management to full dissection including bladder dissection, with only the last vaginal incision done by the vaginal approach. During a

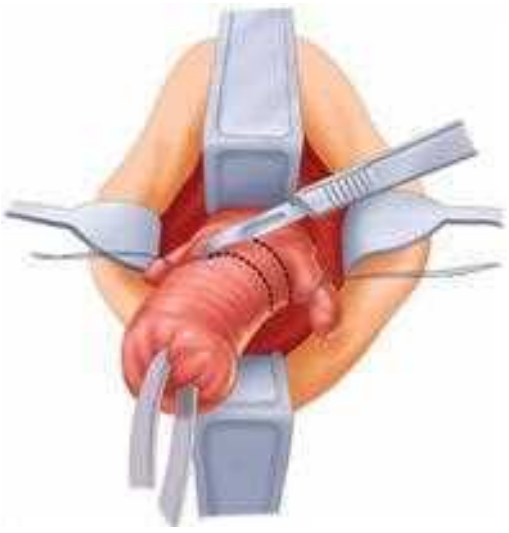

Figure 41-14. Uterine morcellation through the vagina.

TLH, the vaginal incision is performed laparoscopically, and the vaginal incision may be closed with laparoscopic suturing. This procedure is used for the indications listed earlier and also when lack of uterine descent makes the vaginal approach impossible.

During an LSH, the uterine vessels are divided after the bladder is dissected from the anterior uterus. The ascending branches of the uterine arteries are occluded, and the entire uterine fundus is amputated from the cervix. The endocervix is either cauterized or cored out. The fundus is then morcellated and removed through a 12-mm abdominal port or through a special transcervical morcellator. The end result is an intact cervix, with no surgical dissection performed below the uterine artery. This approach avoids both a large abdominal incision and a vaginal incision. According to its advocates, this approach minimizes operating time, recovery time, and risk of both infection and ureteral injury. LSH has yet to be widely applied, in part out of concern for the subsequent risk of developing cancer in the residual cervical stump. In addition, women may develop bleeding from the remaining lower uterine segment that can be bothersome, even if preventive measures had been taken.

Benign Ovarian and Fallopian Tube Lesions

The most common ovarian benign findings include functional follicular cysts, endometriomas (due to ovarian endometriosis), and serous cystadenomas or cystadenofibromas. These can present with varying degrees or pelvic pain, or sometimes be completely asymptomatic. Ultrasound is the best initial imaging modality for evaluating ovarian abnormalities.

Ovarian Cystectomy. When a cystic lesion persists or causes pelvic pain, surgical intervention is usually justified. Performing a cystectomy with ovarian preservation is recommended in women who desire future fertility. Whether the cystectomy is performed laparoscopically or by laparotomy, the procedure is initiated with inspection of the peritoneal cavity, peritoneum, diaphragm, liver, and pelvis. In the absence of signs of malignancy, pelvic washings are obtained and the ovarian capsule is incised superficially sharply or with the electrosurgical unit. The cyst is shelled out carefully through the incision. During laparoscopy, it is placed in a bag, intact if possible, and the bag opening is brought through a 10-mm port. If a cyst should rupture before removal, contents are aspirated thoroughly, and the cyst wall is removed and sent for pathologic evaluation. The peritoneal cavity is copiously rinsed with Ringer's lactate solution. This is especially important when a dermoid cyst is ruptured, because the sebaceous material can cause a chemical peritonitis unless all the visible oily substance is carefully removed. A cyst may need to be drained to facilitate removal, but only after bag edges are firmly out of the abdomen assuring no leakage within the abdomen. Hemostasis of the ovary is achieved with bipolar electrocoagulation, but the ovary is usually not closed. If there are solid growths within the cyst, it should be sent for frozen section to verify the absence of the malignancy. If malignancy is detected, immediate definitive surgery is recommended.

Removal of Adnexa. Indications for removal of adnexa include persistent ovarian cyst, pelvic pain, concern for malignancy, and risk reduction surgery in women with genetic predisposition for ovarian or endometrial cancers (*BRCA1/2* mutation carrier, Lynch syndrome). In general, the peritoneum lateral to the infundibulopelvic (IP) ligament is incised in a parallel fashion to allow retroperitoneal dissection and identification of the ureter. Once this has been accomplished, the IP ligament is ligated with suture or an energy source (ultrasonic or bipolar). The remaining posterior leaf of the broad ligament is incised toward the uterus in a direction parallel to the utero-ovarian ligament, to avoid ureteral injury. The fallopian tube and utero-ovarian ligaments are then ligated with either suture or an energy source. If performed laparoscopically, the specimen or specimens are removed in a bag as described earlier.

Tubal Sterilization. As in diagnostic laparoscopy, a one- or two-port technique can be used. Fallopian tubes are occluded in the mid-isthmic section, approximately 3 cm from the cornua, using clips, elastic bands, or bipolar electrosurgery. With electrosurgery, approximately 2 cm of tube should be desiccated. Pregnancy rates after any of these techniques have been reported in the range of 3 per 1000 women.

Other Pelvic Pathology

Chronic Pelvic Pain. Chronic pelvic pain is defined as pain below the umbilicus that has lasted at least 6 months or causes functional disability, requiring treatment. While there can be gastrointestinal and urologic causes of chronic pelvic pain, gynecologic causes are frequently identified. Often, a surgical evaluation is needed for diagnosis and/or intervention. The most common gynecologic causes of chronic pelvic pain include endometriosis, adenomyosis, uterine leiomyomas, and adhesive disease.

Endometriosis. Endometriosis is the finding of ectopic endometrial glands and stroma outside the uterus. It affects 10% of the general population and is an incidental finding at the time of laparoscopy in more than 20% of asymptomatic women. It is especially prevalent in patients suffering from chronic pelvic pain (80%) and infertility (20%–50%).[21] The pathophysiology of endometriosis is poorly understood; etiologic theories explaining dissemination of endometrial glands include retrograde menstruation, lymphatic and vascular spread of endometrial glands, and coelomic metaplasia. Endometriosis commonly involves the ovaries, pelvic peritoneal surfaces, and uterosacral ligaments. Other possible sites include the rectovaginal septum, sigmoid colon, intraperitoneal organs, retroperitoneal space, ureters, incisional scars, umbilicus, and even the thoracic cavity. Involvement of the fallopian tubes may lead to scarring,

blockage, and subsequent infertility. Ovarian involvement varies from superficial implants to large complex ovarian masses called endometriomas or "chocolate cysts." Endometriomas are found in approximately one third of women with endometriosis and are often bilateral.

While endometriosis can be totally asymptomatic, more commonly, women are symptomatic, and complaints vary from mild dyspareunia and cyclic dysmenorrhea to debilitating chronic pelvic pain with acute exacerbations at the time of menses. Less common manifestations include painful defecation, hematochezia, and hematuria if there is bowel and/or bladder involvement. Pelvic examination in symptomatic patients typically demonstrates generalized pelvic tenderness and nodularity of the uterosacral ligaments, and at times, a pelvic mass may be appreciated if an endometrioma is present. The severity of symptoms does not correlate with the degree of clinical disease present. Endometriosis can also cause increases in serum cancer antigen 125 (CA-125). Definitive diagnosis usually requires laparoscopy and visualization of the pathognomonic endometriotic implants. These appear as blue, brown, black, white, or yellow lesions that can be raised and at times puckered, giving them a "gunpowder" appearance. Biopsy is not routinely done but should be obtained if the diagnosis is in doubt.

Treatment is guided by severity of the symptoms and whether preservation of fertility is desired and varies from expectant, to medical, to surgical.[38,39] Expectant management is appropriate in asymptomatic patients. Those with mild symptoms can be managed with oral contraceptive pills and/or nonsteroidal anti-inflammatory analgesia; moderate symptoms are treated with medroxyprogesterone acetate. Severe symptoms are treated with GnRH agonists to induce medical pseudo-menopause.

Surgical management for endometriosis varies depending on the age and fertility desires of the patient. A diagnostic laparoscopy with biopsies may be indicated to confirm the diagnosis of endometriosis. If endometriosis is suspected, an operative laparoscopy with ablation of endometriotic implants usually decreases the severity of pelvic pain. Ablation of endometriotic implants can be performed with CO_2 laser or electrocautery and/or resection of deep endometriotic implants.[38] Endometriomas can cause pain and, if found, should be treated by ovarian cystectomy. Complete resection of the cyst wall is required because recurrence of the endometrioma is common after partial removal. Conservative surgical therapy in endometriosis patients with patent fallopian tubes results in pregnancy in about 50% of cases. Unfortunately, endometriosis is a chronic disease and conservative therapy, medical or surgical, provides only temporary relief, with the majority of patients relapsing with 1 to 2 years. Patients with severe debilitating symptoms who do not desire future fertility and have not responded to conservative management can undergo extirpative surgery to remove the uterus, ovaries, and fallopian tubes; this intervention is curative and should be considered.

Pelvic Adhesive Disease. Pelvic adhesions usually are related to previous surgery, endometriosis, or infection, the latter of which can be either genital (i.e., pelvic inflammatory disease) or extra-genital (e.g., ruptured appendix) in origin. Adhesions can be lysed mechanically with scissors if not vascular, harmonic scissors, or any of the power techniques as discussed elsewhere in this text. Postoperatively, adhesion barrier methods have been shown to decrease adhesion formation in both animal and human studies but have not been demonstrated to improve outcome in terms of either subsequent pregnancies or pain relief.

Pelvic Inflammatory Disease. Pelvic inflammatory disease (PID) is an infection of the upper female genital tract involving the uterus, fallopian tubes, and ovaries resulting in endometritis, salpingitis, and oophoritis. It often involves contiguous pelvic organs, resulting in peritonitis, tubo-ovarian abscesses, and occasionally perihepatitis (Fitz-Hugh-Curtis syndrome). Long-term sequelae can include infertility, chronic pelvic pain, and increased risk of ectopic pregnancy.[40,41] PID is mostly a sexually transmitted ascending infection caused by *N. gonorrhoeae* and/or *C. trachomatis*, but numerous other organisms have been implicated, including normal vaginal flora. Screening for concomitant HIV infection is strongly recommended. Less commonly, PID may result from extension of other pelvic and abdominal infections, such as appendicitis and diverticulitis, or may be precipitated by a medical procedure, such as hysterosalpingography, endometrial biopsy, or dilation and curettage.

Differential diagnosis includes appendicitis, cholecystitis, inflammatory bowel disease, pyelonephritis, nephrolithiasis, ectopic pregnancy, and ovarian torsion.[40,41] The Centers for Disease Control and Prevention recommend treatment of suspected PID in patients with pelvic or lower abdominal pain who also exhibit cervical motion tenderness, uterine tenderness, or adnexal tenderness (Table 41-4). Transvaginal ultrasound may

Table 41-4

CDC recommended treatment of PID (2010)[42]

ORAL REGIMENS
Ceftriaxone 250 mg IM in a single dose *plus* doxycycline 100 mg PO bid for 14 days *with or without* metronidazole 500 mg PO bid for 14 days OR Cefoxitin 2 g IM in a single dose and probenecid 1 g PO administered concurrently in a single dose *plus* doxycycline 100 mg PO bid for 14 days *with or without* metronidazole 500 mg PO bid for 14 days OR Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime) *plus* doxycycline 100 mg PO bid for 14 days *with or without* metronidazole 500 mg PO bid for 14 days
PARENTERAL REGIMENS
Recommended Regimen A
Cefotetan 2 g IV every 12 hours *or* cefoxitin 2 g IV every 6 hours *plus* doxycycline 100 mg PO or IV every 12 hours
Recommended Regimen B
Clindamycin 900 mg IV every 8 hours *plus* gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) every 8 hours; single daily dosing may be substituted
Alternative Parenteral Regimen
Ampicillin/sulbactam 3 g IV every 6 hours *plus* doxycycline 100 mg PO or IV every 12 hours

bid = twice a day; CDC = Centers for Disease Control and Prevention; IM = intramuscular; IV = intravenous; PID = pelvic inflammatory disease; PO = oral.

reveal thickened fluid-filled tubes with or without free pelvic fluid. Laparoscopic findings include swollen erythematous tubes with exudates. Criteria for hospitalization and intravenous antibiotic treatment include the following[42]: surgical emergencies (e.g., appendicitis), infection during pregnancy, failure to respond to or inability to follow or tolerate outpatient oral medication regimens, severe illness with nausea and vomiting or high fever, and tubo-ovarian abscess.

First-line treatment for tubo-ovarian abscess includes broad-spectrum antibiotics and, sometimes, percutaneous drainage. Surgical intervention becomes necessary if medical therapy fails or if the abscess ruptures. Rupture is a surgical emergency with a high mortality rate if not recognized and managed promptly. In addition to management of the septic shock state, hysterectomy and bilateral salpingo-oophorectomy is the procedure of choice; however, conservative surgery must be considered in young patients desiring future fertility. The abdomen should be explored for metastatic abscesses, and special attention must be paid to bowel, bladder, and ureteral safety due to the friability of the infected tissue and the adhesions commonly encountered at the time of surgery. Placement of an intraperitoneal drain and mass closure of the peritoneum, muscle, and fascia with delayed-absorbable or permanent sutures is advised. Closure of the skin and subcutaneous layer should be avoided in patients with frank pus, and delayed primary closure or closure by secondary intention is recommended because of the high rate of wound infections. Conservative surgery, when feasible, may be attempted by laparoscopy and may involve unilateral salpingo-oophorectomy or drainage of the abscess and liberal irrigation of the abdomen and pelvis.

PREGNANCY-RELATED SURGICAL CONDITIONS

Many pregnant women will undergo invasive diagnostic procedures for prenatal diagnosis, and in the United States, nearly one third of all births are cesarean deliveries.[43] About 1 in 500 pregnant women will require surgery for nonobstetrical issues.[44,45] Diagnostic challenges and physiologic changes due to pregnancy, as well as the unique anesthesia risks and potential risks to the pregnancy, should be kept in mind whether the primary surgeon is an obstetrician gynecologist or a general surgeon (Table 41-5).[45]

6▶

Trauma in the obstetric patient requires stabilization of the mother while considering the fetal compartment.[45,46] Trauma-related hypovolemia may be compounded by pregnancy-induced decreases in systemic vascular resistance and, when supine, the weight of the gravid uterus on the vena cava. When feasible, a left lateral tilt should be instituted to improve venous return to the right heart. Later in pregnancy, the small bowel is displaced into the upper abdomen, making it vulnerable to complex injury from penetrating upper abdominal trauma. Although the small bowel is displaced from the pelvis, the dramatic increase in pelvic blood flow can lead to rapid blood loss due to penetrating pelvic trauma, fractures, or avulsion of pelvic vessels. Gastric motility is decreased, increasing the risk of aspiration. Peritoneal signs may be attenuated by the stretching of the abdominal wall. Several coagulation factors are also increased in pregnancy, increasing the likelihood for thromboembolic events, but also giving the unsuspecting surgeon false security when low-normal levels are observed during resuscitative efforts. Although treating the maternal compartment is the primary concern, it should also be recognized that the fetus will be impacted significantly by maternal hypotension, as blood may be shunted away from the uterus. Only the third-trimester fetus has any ability to autoregulate in the context of decreased uterine blood flow and oxygen delivery.

Table 41-5

Physiologic changes due to pregnancy[45]

Cardiovascular changes	
	Increased cardiac output
	Increased blood volume
	Increased heart rate
	Decreased blood pressure
	Decreased systemic vascular resistance
	Decreased venous return from lower extremities
Respiratory changes	
	Increased minute ventilation
	Decreased functional residual capacity
Gastrointestinal changes	
	Decreased gastric motility
	Delayed gastric emptying
Coagulation changes	
	Increased clotting factors (II, VII, VIII, IX, X)
	Increased fibrinogen
	Increased risk for venous thromboembolism
Renal changes	
	Increased renal plasma flow and glomerular filtration rate
	Ureteral dilation

Conditions and Procedures Performed Before Viability

Amniocentesis/Chorionic Villus Sampling. Amniocentesis is a procedure in which amniotic fluid is aspirated from the uterine cavity, typically under ultrasound guidance with a 20- to 22-gauge needle. Common indications include prenatal genetic testing, assessment of fetal lung maturity, and evaluation for intrauterine infection. Chorionic villus sampling (CVS) is performed for prenatal genetic testing. During the procedure, placental villi are obtained through transcervical or transabdominal access to the placenta. CVS is typically performed after 9 completed weeks of gestation, while genetic amniocentesis is offered between 15 and 20 weeks. Pregnancy loss attributable to genetic amniocentesis is 1 in 300 to 500. The rate is slightly higher after CVS due in large part to the higher background spontaneous pregnancy loss between 9 and 16 weeks of gestation.[47]

Pregnancy Terminations. Although legal nonsurgical options are now available for early pregnancy termination, the safest and most commonly performed termination procedure is a cervical dilation and suction curettage. The uterine cervix is grasped with a tenaculum and then mechanically dilated with tapered rods occasionally using adjunctive prostaglandins, and an appropriately sized vacuum cannula is inserted into the uterus and rotated on its axis to remove the products of conception. Additional forceps can be used as needed and will be necessary in later

second-trimester dilation and extractions. The most common complications are infection, hemorrhage due to uterine atony, cervical lacerations, uterine perforations, and inadvertent bowel injury from the vacuum cannula or forceps.

Cerclage. Cervical insufficiency is defined as painless cervical dilation leading to recurrent second-trimester pregnancy loss, or shortened cervical length as determined by transvaginal ultrasound, or advanced cervical change before 24 weeks gestation in a woman with either prior preterm birth/loss or significant risk factors for insufficiency. A cervical cerclage refers to a procedure in which suture or synthetic tape is used to circumferentially reinforce the cervix to improve pregnancy outcome in at-risk patients.[48] Shirodkar and McDonald techniques have been described[49,50]; both involve transvaginally placing a nonabsorbable suture at the uterocervical junction to lengthen and close the cervix. A laparotomy can access the abdominal portion of the lower uterine segment for an abdominal cerclage for a patient with a severely shortened or absent cervix.

Ectopic Pregnancies. Extrauterine pregnancies are most commonly located along the fallopian tubes and on the ovary. Rarely, implantation can occur primarily on other abdominal organs or surfaces. A high index of suspicion and early diagnosis, typically using sensitive β-hCG assays and ultrasound, are the key to minimizing maternal morbidity and mortality. Early ectopic pregnancies can be managed medically with methotrexate, whereas advanced ectopic pregnancies and unstable women are managed by laparoscopy or laparotomy. Linear salpingostomy along the antimesenteric border and removal of the products of conception is a reasonable option. The tube should be removed (salpingectomy) if the oviduct has already ruptured and a large hemoperitoneum already exists.[51]

Conditions and Procedures Performed After Viability

Fetal Surgery. The Management of Myelomeningocele (MOMs) trial tested the safety and efficacy of fetal surgery for myelomeningocele between 2003 and 2010. During this procedure, surgeons expose the gravid uterus via low transverse or vertical incision and position the fetus manually within the uterus under ultrasound guidance with the myelomeningocele sac centered at the proposed hysterotomy site. The uterus is entered sharply between two full-thickness stay sutures, and the hysterotomy is extended 6 to 8 cm with a uterine stapling device. The myelomeningocele is closed in standard fashion under magnification. Early outcomes data revealed that fetal surgery reduced the risk of death or need for shunt placement during the first year of life and also improved mental development and motor function at 30 months of age. These outcomes in the fetal surgery arm were despite higher preterm delivery rates, and the trial was stopped early because of efficacy.[52]

Obstetric Lacerations and Repair. The mean biparietal diameter of a term infant approaches 10 cm. The measured hiatus of the nulliparous vaginal introitus is approximately 2 cm. As a result, at the time of vaginal delivery, perineal lacerations and, with decreasing frequency, episiotomies are quite common. These lacerations involve, in varying degrees, the vaginal mucosa, the muscular elements inserting onto the perineal body, the levator ani, and in 4% to 5% of vaginal deliveries, the anal sphincter or anorectal mucosa.

Episiotomies and Perineal Laceration. First-degree tears involve only the perineal skin and may or may not need to be reapproximated. Second-degree tears involve the perineal body and can generally be repaired with some variation using a single continuous, nonlocking suture technique, typically a 2-0 or 3-0 synthetic delayed absorbable suture. The apex of the vaginal epithelial is approximated first including epithelium and underlying tissue to build up the rectovaginal septum. Upon reaching the hymenal ring, the perineal body and bulbocavernosus muscle are reapproximated, and a transition stitch is placed from the vaginal mucosa, which was repaired along a horizontal plane, to the deep perineal layer, which lies in a vertically oriented plane. A running closure is then completed incorporating the deep perineal tissues from the introitus to the extent of the perineal defect. At this point, the perineal skin is closed from inferior to superior in a subcuticular fashion and tied just inside the introitus.

Third-degree lacerations extend through the perineal body and involve the external anal sphincter, whereas fourth-degree lacerations involve the internal anal sphincter and rectal mucosa. When present, third- and fourth-degree lacerations should be repaired first before proceeding with the second-degree repair. This is accomplished by first closing the anal mucosa and then identifying and closing the internal anal sphincter in a second layer. The external anal sphincter is then identified, and the muscular cylinder is reconstructed by suturing the severed ends together using either an end-to-end or overlapping technique. Although these are typically straightforward layered closures, knowledge of the anatomy is important. Incomplete reconstruction, particularly of third- or fourth-degree lacerations, can contribute to future pelvic floor disorders, as well as the development of fistulae or incontinence.

Cervical and Vaginal Lacerations. Significant lacerations to the cervix or vagina may also occur during childbirth, particularly with instrumented deliveries or macrosomic infants. These lacerations may present as persistent bleeding, not readily recognized due to their location, and often in association with a firmly contracted uterus. Vaginal lacerations may be repaired primarily but should only be closed after deeper tissues are inspected to ensure no active bleeding. Cervical lacerations can be repaired in a running, locking fashion, ensuring that the apex of the laceration is incorporated in the closure. If the apex is challenging to reach, the closure can be started more distally using the suture to apply traction so that the apex may be closed.

Puerperal Hematoma. Trauma during childbirth can occasionally result in significant hematoma formation with or without a visible laceration. These hematomas may hide significant blood loss and most commonly occur in the vulva, paravaginal, and pelvic retroperitoneum. Typical presentation is pain and mass effect. Small hematomas can be managed conservatively with close observation and patient monitoring. Although there are no evidence-based size criteria, an unstable patient or expanding hematomas should prompt surgical intervention. After the hematoma is incised and drained, diffuse venous oozing is usually encountered rather than a single bleeding vessel. Hemostasis can be achieved using electrosurgery or fine absorbable suture, although caution must be used due to the proximity of bowel, bladder, and ureters to some hematomas. Pressure on the vulva or packing the vagina, rather than the hematoma cavity, may prevent further bleeding.

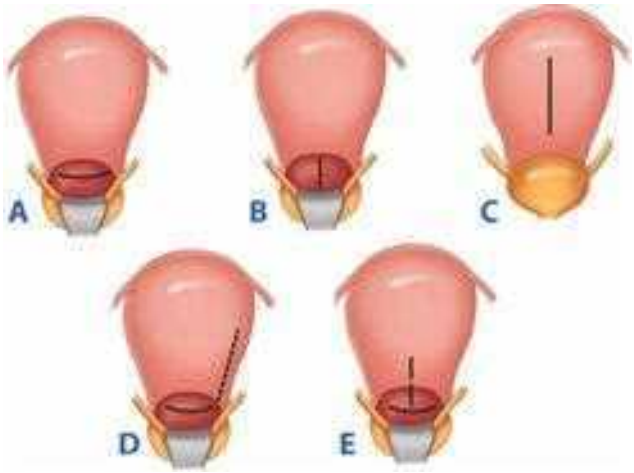

Figure 41-15. Uterine incisions for cesarean delivery. **A.** Low transverse incision. **B.** Low vertical incision. **C.** Classical incision. **D.** J incision. **E.** T incision. *(Reproduced from Gabbe S, Niebyl J, Simpson J.* Obstetrics: Normal and Problem Pregnancies. *5th ed. Philadelphia: Churchill Livingstone; 2007, Fig. 19-3. Copyright Elsevier.)*

Cesarean Deliveries. Typical indications for cesarean delivery include nonreassuring fetal status, breech or other malpresentations, triplet and higher order gestations, cephalopelvic disproportion, failure to progress, placenta previa, and active genital herpes. Previous low transverse cesarean delivery is not a contraindication to subsequent vaginal birth after cesarean; however, much of the increase in cesarean delivery in the past decade is attributable to planned repeat cesareans. Cesarean deliveries typically are performed via a lower anterior (caudal) uterine transverse incision because there is decreased blood loss, and the uterine rupture rate with future pregnancies is about 0.5% (Fig. 41-15). A prior classical cesarean delivery is an absolute indication for a planned repeat cesarean delivery because of a high rate of uterine rupture during labor, unlike with the lower anterior uterine transverse incision. Abdominal access is obtained by a Pfannenstiel or Maylard incision. Once the abdomen is entered, a vesicouterine reflection is created if a low transverse uterine incision is planned. The uterine incision is then made and extended laterally, avoiding the uterine vessels. After amniotomy, the baby is delivered, and the uterus closed. Approximately 1000 mL of blood is typically lost during a cesarean delivery. Along with rapid closure of the uterine incision, uterotonics, such as intravenous oxytocin, are administered. A classical, vertical, uterine incision is made in certain very early viable gestations or in the case of certain transverse lies. Infection, excessive blood loss due to uterine atony, and urinary tract and bowel injuries are potential complications at the time of cesarean delivery. The risk of those injuries, as well as abnormal placentation (placenta accreta, increta, and percreta), rises with each subsequent cesarean delivery. Bleeding can only be controlled in some instances by performing a cesarean hysterectomy.

Postpartum Hemorrhage. Postpartum hemorrhage is an obstetrical emergency that can follow either vaginal or cesarean delivery. Hemorrhage is usually caused by uterine atony, trauma to the genital tract, or rarely, coagulation disorders. Management consists of mitigating potential obstetric causes while simultaneously acting to avert or treat hypovolemic shock. In the absence of atony, the genital tract should be thoroughly evaluated for trauma. Atony is the most common cause of postpartum hemorrhage. It is typically treated with fundal massage and uterotonics such as oxytocin, methylergonovine, carboprost tromethamine, and misoprostol. When aggressive medical management fails, surgical management may be necessary and lifesaving.[53]

Uterine Curettage. Retained products of conception may result in uterine atony. It may be possible to remove retained products via manual extraction or with ring forceps. Bedside ultrasound may be helpful in localization. When clinical suspicion is high, uterine curettage is indicated. A blunt, large curette, the banjo curette, is introduced, and removal of retained tissue typically results in contraction of the myometrium and cessation of bleeding.

Procedures Short of Hysterectomy. As bleeding from postpartum hemorrhage becomes increasingly acute, interventions short of hysterectomy should be carried out expeditiously while supporting the hemodynamic status of the patient and preparing for possible definitive surgery. A number of techniques for packing and tamponade of the uterus have been described, including a balloon device reported by Bakri and colleagues.[54] These are typically left in place for 24 to 36 hours and appear to be safe and often effective conservative measures short of laparotomy and hysterectomy. The B-Lynch compression suture may control bleeding of atony at the time of cesarean section. A suture is placed through the hysterotomy, around the fundus of the uterus anterior to posterior, and then through the posterior lower uterine segment, to the contralateral side. At this point, the steps are reversed, with the suture brought around the fundus posterior to anterior, through the contralateral side of the hysterotomy, and then tied in the midline to compress the uterus. Additional procedures described include the O'Leary uterine artery ligation and the hypogastric artery ligation. "O'Leary stitches" are a series of sutures placed around the branches of the uterine artery and through the myometrium, resulting in compression of the vessels against the uterus. Hypogastric artery ligation entails the isolation of the internal iliac artery at its bifurcation with the external iliac artery. The hypogastric artery is ligated at least 3 cm distal to the bifurcation to avoid compromising the posterior division.

Hysterectomy. A cesarean or postpartum (absent a prior cesarean delivery) hysterectomy involves the same steps as in a nonpregnant patient, but is distinctly different due to the engorged vessels and the pliability of the tissues. If a cesarean section has been performed, occasionally the incision can be used for traction to keep the vessels and tissues attenuated. Vascular pedicles should be secured with clamps, but not ligated until both uterine arteries have been secured, to fully control bleeding. Lack of typical anatomic landmarks requires careful identification of the ureters and the dilated cervix visually or by palpation, to separate them from the bladder and vagina (Fig. 41-16). This procedure is often done for life-threatening hemorrhage; thus, appropriate blood products, including packed red blood cells, fresh frozen plasma, platelets, and fibrinogen, should be on call and are usually required. Fibrinogen is typically elevated in a pregnant woman, such that a low-normal fibrinogen level can be a cause for alarm, and further fibrinogen may be required before consumptive coagulopathy reverses. A massive transfusion protocol is often helpful.

Gestational Trophoblastic Disease. Gestational trophoblastic disease (GTD) is characterized by abnormal trophoblastic proliferations most commonly related to a pregnancy event.

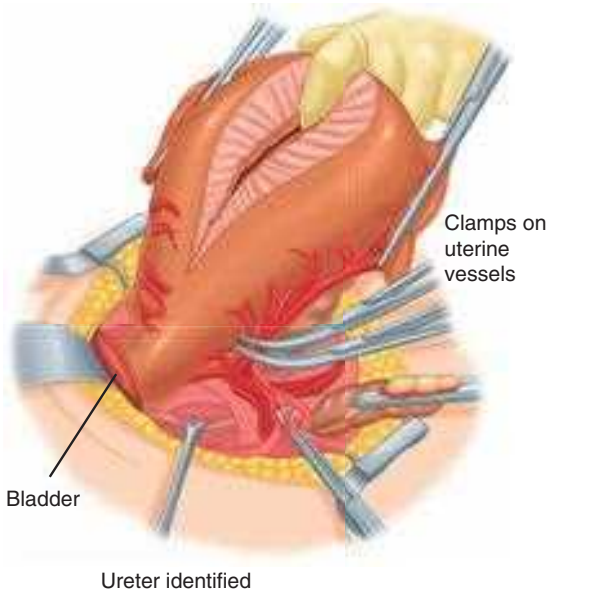

Figure 41-16. Demonstration of location of distal ureter and bladder and their relationship to uterine vessels. *(Reproduced from Nichols DH.* Gynecologic and Obstetric Surgery, *Vol. 1, 1993, Fig. 68-5, p. 1130. Copyright Elsevier.)*

Histologic types include hydatidiform moles, invasive moles, choriocarcinoma, and placental site trophoblastic tumors. It is an important gynecologic entity to consider when uterine size is significantly greater than expected for date in pregnancy, when bleeding occurs in pregnancy, or with abnormal bleeding after pregnancy loss, abortion, or full-term delivery. Diagnosis is usually made by ultrasound and measurement of serum β-hCG, followed by pathologic examination of curettage specimens. There are two subtypes of hydatidiform moles. Complete moles contain no fetal tissue and have a diploid karyotype. Partial moles contain fetal tissue and have triploid karyotypes. The chromosome pattern suggests paternal origin. These can be associated with theca lutein ovarian cysts often greater than 6 cm in diameter that are fragile; they should generally be followed without surgical intervention as they resolve with removal or treatment of the GTD. Metastatic GTD can present on the cervix, vagina, liver, or lung, and should not be managed surgically. Chemotherapy is primary therapy, and the incidence of bleeding complications is significant.

Primary surgery for diagnosis and initial therapy is a suction dilatation and curettage. Oxytocin is started either prior to anesthesia or immediately as the cervix is being dilated. The largest suction catheter possible (12 mm preferred) is gently inserted through the cervix and suction turned on, to allow the tissue to be removed and the uterus to rapidly decrease with less blood loss. Following this, a careful sharp curettage of the uterus is done acknowledging the increased risk for perforation. β-hCG is then followed weekly until normal for 3 weeks, then monthly for at least 6 months. Any increase in β-hCG should trigger further evaluation and consideration of chemotherapy.[55,56]

PELVIC FLOOR DYSFUNCTION

Pelvic floor disorders can be categorized, from a urogynecologic perspective, into three main topics: female urinary incontinence and voiding dysfunction, pelvic organ prolapse, and disorders of defecation.[57] Approximately 11% of women will undergo surgery for incontinence or prolapse.[58] The normal functions of support, storage, and evacuation can be altered by derangements in neuromuscular function both centrally and peripherally and through acquired changes in connective tissue. Reconstructive surgeons aim to repair or compensate for many of these losses.

Evaluation

Diagnostic evaluations, in addition to the history and examinations described earlier, can aid in the diagnosis of many pelvic floor disorders. Cystoscopy, multichannel urodynamics, and/or fluoroscopic evaluation of the urinary tract can be obtained for patients with urinary incontinence or voiding dysfunction.[59] Defecography, anal manometry, and endorectal ultrasound may be useful for diagnosis of defecatory dysfunction. A standardized examination called the pelvic organ prolapse quantification (POP-Q)[59] helps to clarify which vaginal compartment, and therefore which specific structure, has lost its anatomic integrity in women with uterovaginal prolapse. Finally, dynamic MRI and pelvic floor electromyography have demonstrated growing utility for all three disorders.

Surgery for Pelvic Organ Prolapse

Many factors are important in determining which reconstructive operation is optimal for a given patient with pelvic organ prolapse. Surgical decisions are often based on case series and expert opinions that may not have universal applicability. However, the few reports with the highest level of evidence suggest that failure rates for prolapse reconstruction may be twice as high using the vaginal approach when compared with the abdominal route.[60,61]

Colporrhaphy. Anterior colporrhaphy, also known as an "anterior repair," is performed for a symptomatic cystocele. The procedure begins with incision of the anterior vaginal epithelium in a midline sagittal direction. The epithelium is dissected away from the underlying vaginal muscularis. The vaginal muscularis is plicated with interrupted delayed absorbable stitches, after which the epithelium is trimmed and reapproximated. The vaginal canal is therefore shortened and narrowed proportionate to the amount of removed epithelium. Posterior colporrhaphy is performed for a symptomatic rectocele. This procedure is performed in a similar manner, often including the distal pubococcygeus muscles in the plication. Recently, in attempts to decrease surgical failures alluded to earlier, many surgeons have opted to use grafts and meshes to augment these vaginally performed procedures. Unfortunately the apparent number of postoperative complications, including mesh erosion, pelvic pain and dyspareunia, prompted the FDA to publish a warning encouraging a much more limited use of vaginal mesh for prolapse repair until greater surveillance and more rigorous studies could be completed.[62]

Sacrospinous and Uterosacral Ligament Fixations. Both the sacrospinous ligament fixation (SSLF) and uterosacral ligament fixation (USLF) procedures are vaginal procedures that suspend the apex of the vagina using native tissue for treatment of apical prolapse. The sacrospinous ligament is found embedded in and continuous with the coccygeus muscle, which extends from the ischial spine to the lateral surface of the sacrum. The procedure begins with entry into the rectovaginal space, usually by incising the posterior vaginal wall at its attachment to the perineal body. The space is developed to the level of the vaginal apex, and the rectal pillar is penetrated to gain access to the pararectal space. A long-ligature carrier is used to

7▶

place sutures medial to the ischial spine, through the substance of the ligament-muscle complex. Structures at risk in this procedure include the pudendal neurovascular bundle, the inferior gluteal neurovascular bundle, lumbosacral plexus, and sciatic nerve. After the stitches are placed, the free ends are sewn to the undersurface of the vaginal cuff. The sacrospinous stitches are tied to firmly approximate the vagina to the ligament without suture bridging.

When using the uterosacral ligaments for repair of prolapse, it is important to recall that these structures are not "ligaments" in the true sense of the word, but rather condensations of smooth muscle, collagen, and elastin. Several support sutures are placed from the lateral-most portion of the vaginal cuff to the distal-most part of the ligament, and from the medial vaginal cuff to the proximal ligament. Intraoperative evaluation of the lower urinary tract is important to confirm the absence of ureteral compromise.

Colpocleisis. Colpocleisis is reserved for patients who are elderly, who do not wish to retain coital ability, and for whom there is good reason not to perform a more extensive reconstructive operation. A colpocleisis removes of part or all of the vaginal epithelium, obliterating the vaginal vault and leaving the external genitalia unchanged. The procedure can be performed with or without a hysterectomy. Successive purse-string sutures through the vaginal muscularis are used to reduce the prolapsed organs to above the level of the levator plate.

Sacrocolpopexy. The best procedure for patient with prolapse of the vaginal apex is an abdominal sacrocolpopexy. In these patients, the natural apical support structure, the cardinal-uterosacral ligament complex, is often damaged and attenuated. The abdominal placement, as opposed to vaginal placement, of graft material to compensate for defective vaginal support structures is well described.[63] Apical support defects rarely exist in isolation, and the sacrocolpopexy may be modified to include the anterior and posterior vaginal walls as well as the perineal body in the suspension. Sacrocolpopexies can be performed via laparotomy as well as via laparoscopy. Like rectopexies and low anterior resections, deep pelvic access is needed. Significant suturing at varied angles is required. The advent of the DaVinci robotic laparoscopic system has made visualization and adequate placement of the mesh and sutures easier to perform when using the minimally invasive approach.

During a sacrocolpopexy, a rigid stent (usually an EEA sizer) is placed into the vagina to facilitate its dissection from the overlying bladder and rectum and to allow the graft material to be spread evenly over its surface. A strip of synthetic mesh is fixed to the anterior and posterior vaginal walls. The peritoneum overlying the presacral area is opened, extending to the posterior cul-de-sac. The sigmoid colon is retracted medially, and the anterior surface of the sacrum is skeletonized. Two to four permanent sutures are placed through the anterior longitudinal ligament in the midline, starting at the S2 level and proceeding distally. The sutures are passed through the graft at an appropriate location to support the vaginal vault without tension. The peritoneum is then closed with an absorbable running suture. The most dangerous potential complication of sacrocolpopexy is sacral hemorrhage.

Surgery for Stress Urinary Incontinence

Stress incontinence is believed to be caused by lack of urethrovaginal support (urethral hypermobility) or intrinsic sphincter deficiency (ISD). ISD is a term applied to a subset of stress-incontinent patients who have particularly severe symptoms, including urine leakage with minimal exertion. This condition is often recognized clinically as the low pressure or "drainpipe" urethra. The urethral sphincter mechanism in these patients is severely damaged, limiting coaptation of the urethra. Standard surgical procedures used to correct stress incontinence share a common feature: partial urethral obstruction that achieves urethral closure under stress.

Burch Procedure. The most quoted description of this procedure is that of Tanagho in 1976.[64] The space of Retzius is approached extraperitoneally, from an abdominal approach, allowing the bladder to be mobilized from the surrounding adipose tissue and lateral pelvis. Overlying fat and blood vessels in the area of the vesical neck are cleared away. Two pairs of large-caliber nonabsorbable sutures, although the original description advocated delayed absorbable sutures, are placed through the periurethral vaginal wall, one pair at the midurethra and one at the urethrovesical junction. Each stitch is then anchored to the ipsilateral Cooper's (iliopectineal) ligament. The sutures are tied with the operator's nondominant hand placed vaginally to give preferential support to the urethrovesical junction relative to the anterior vaginal wall without overcorrection. Long-term outcome studies up to 10 years have shown that the Burch procedure yields cure rates of 80% to 85%.

Tensionless Sling. The tension-free vaginal tape (TVT) is a modified sling that uses a strip of polypropylene mesh. Unlike traditional sling procedures, the mesh is positioned at the midurethra, not the urethrovesical junction, and is not sutured or otherwise fixed into place. Advantages of TVT include the ability to perform the procedure under local anesthesia on an outpatient basis. Small subepithelial tunnels are made bilaterally to the descending pubic rami through an anterior vaginal wall incision. A specialized conical metal needle coupled to a handle is used to drive one end of the sling through the perineal membrane, space of Retzius, and through one of two small suprapubic stab incisions. The tape is set in place without any tension after bringing up the other end of the tape through the other side. Recently, multiple modifications have been made to carry the tape through the bilateral medial portions of the obturator space. Risks of the procedure include visceral injury from blind introduction of the needle, bleeding, and nerve and muscle injury in the obturator space. Additionally, voiding dysfunction and delayed erosion of mesh into the bladder or urethra have been seen.

Urethral Bulking Injections. A transurethral or periurethral injection of bulking agents is indicated for patients with intrinsic sphincter deficiency. Several synthetic injectable agents (e.g., polydimethylsiloxane, calcium hydroxylapatite) are now used because glutaraldehyde cross-linked (GAX) bovine dermal collagen is no longer commercially available.[65] Anesthesia is easily obtained by using intraurethral 2% lidocaine jelly and/or transvaginal injection of the periurethral tissues with 5 mL of 1% lidocaine. The material is injected underneath the urethral mucosa at the bladder neck and proximal urethra at multiple positions, until mucosal bulk has improved. Patients must demonstrate a negative reaction to a collagen skin test prior to injection. The long-term cure rate is 20% to 30%, with an additional 50% to 60% of patients demonstrating improvement.[57] Repeat injections are frequently necessary because of migration and dissolution of the collagen material.

Vulvar Cancer

Vulvar cancer is the fourth most common gynecologic cancer. The mean age at diagnosis is 65, although this has trended down over the last several decades.[66] Evidence supports an HPV-dependent pathway of carcinogenesis with risks factors similar to VIN in the majority of cases. A second pathway independent of HPV is associated with chronic inflammation and vulvar dystrophy.[67] Patients usually present with a vulvar ulcer or mass. Pruritus is a common complaint, and vulvar bleeding or enlarged inguinal lymph nodes are signs of advanced disease. Careful evaluation of the patient is necessary to rule out concurrent lesions of the vagina and cervix. Biopsy is required and should be sufficient to allow evaluation of the extent of stromal invasion. Vulvar carcinomas are squamous in 90% of cases. Other less common histologies include melanoma (5%), basal cell carcinoma (2%), and soft tissue sarcomas (1%–2%).

Spread of vulvar carcinoma is by direct local extension and via lymphatic microembolization. Hematogenous spread is uncommon except for vulvar melanoma. Lymphatic spread seems to follow a stepwise, predictable pattern traveling from superficial, above the cribriform fascia, to deep inguinofemoral nodes and ultimately to the pelvic and external iliac nodal basins (Fig. 41-17).[68,69] The node of Cloquet is an important sentinel node situated in the route of spread to the pelvic lymph nodes.

Staging and primary surgical treatment are typically preformed as a single procedure and tailored to the individual patient (Table 41-6). Surgical staging accounts for the most important prognostic factors including tumor size, depth of invasion, inguinofemoral node status, and distant spread. The most conservative procedure should be performed in view of the high morbidity of aggressive surgical management. This typically involves radical resection of the vulvar tumor targeting a 1- to 2-cm margin around the lesion, and carried to the deep perineal fascia of the urogenital diaphragm with an ipsilateral or bilateral inguinofemoral lymphadenectomy (Fig. 41-18). For tumors ≤2 cm in size with ≤1 mm invasion (International Federation of Gynecology and Obstetrics [FIGO] stage IA), lymphadenectomy may be safely omitted, and wide local or radical local excision is adequate. Patients with stage IB tumors have deeper invasion but negative nodes and therefore carry an excellent prognosis. Stage II includes patients with local extension and negative nodes, and therefore, these patients have a prognosis similar to other node-negative patients.

Stage III disease includes patients with lymph node metastases, and stage IV disease is either locally advanced or distant metastasis. Treatment options for stage III and IV disease include: (a) chemoradiation followed by limited resection if needed; (b) radical vulvectomy; and (c) radical vulvectomy coupled with pelvic exenteration. External-beam radiotherapy combined with radiosensitizing chemotherapy of cisplatin and 5-fluorouracil is emerging as the preferred initial management

Table 41-6

2009 International Federation of Gynecology and Obstetrics staging of vulvar carcinoma[78]

IA	Tumor confined to the vulva or perineum, ≤2 cm in size with stromal invasion ≤1 mm, negative nodes
1B	Tumor confined to the vulva or perineum, >2 cm in size or with stromal invasion >1 mm, negative nodes
II	Tumor of any size with adjacent spread (1/3 lower urethra, 1/3 lower vagina, anus), negative nodes
IIIA	Tumor of any size with positive inguinofemoral lymph nodes
(i)	1 lymph node metastasis ≥5 mm
(ii)	1–2 lymph node metastasis(es) of <5 mm
IIIB	(i) 2 or more lymph nodes metastases ≥5 mm
(ii)	3 or more lymph nodes metastases <5 mm
IIIC	Positive node(s) with extracapsular spread
IVA	(i) Tumor invades other regional structures (2/3 upper urethra, 2/3 upper vagina), bladder mucosa, rectal mucosa, or fixed to pelvic bone
(ii)	Fixed or ulcerated inguinofemoral lymph nodes
IVB	Any distant metastasis including pelvic lymph nodes

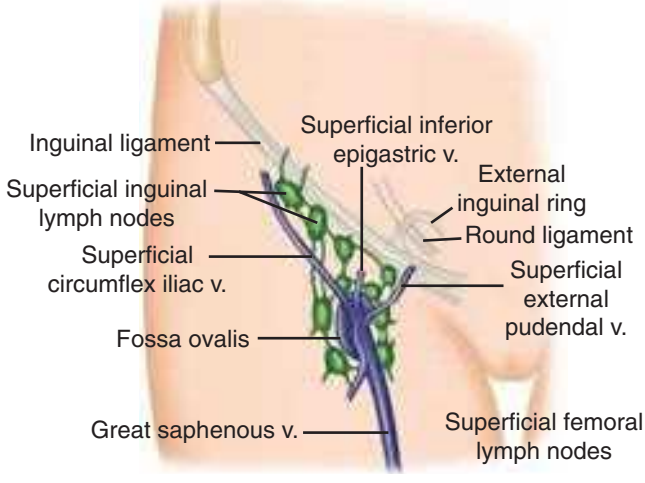

Figure 41-17. Lymphatic drainage of the vulva delineated by Stanley Way.

of advanced disease followed by limited surgical resection of residual disease.[70-72] Reconstruction of the vulva and groin, if needed, can be accomplished using grafts and rotational or myocutaneous flaps depending on the size and type of defect.

Inguinofemoral lymphadenectomy is indicated beyond clinical stage IA. Unilateral lymphadenectomy is recommended for lateralized lesions, and bilateral lymphadenectomy is recommended for central lesions that cross the midline or those involving the periclitoral area (Figs. 41-19 and 41-20). The role of vulvar sentinel lymph node biopsy is under investigation by the Gynecologic Oncology Group (GOG) and is in use by a growing number of gynecologic oncologists. Preliminary data are encouraging and may allow patients with negative sentinel nodes to avoid complete groin dissection and its attendant morbidity such as lower extremity lymphedema.

Nodal failure in the groin and pelvis is difficult to treat successfully, and attention to primary management of these areas is key. Postoperative adjuvant inguinal and pelvic radiotherapy is indicated when inguinal lymph nodes are positive and is superior to pelvic lymphadenectomy, which has been largely abandoned. It is also indicated when the vulvectomy margins are positive or close positive for disease and further surgical management is not anatomically feasible.

Vaginal Cancer

Vaginal carcinoma is a rare gynecologic malignancy and accounts for about 3% of cancers affecting the female reproductive system.[66] Squamous cell carcinomas account for 85% to 90% of cases; more than two thirds of vaginal cancers are diagnosed in women 60 years of age or older. Risk factors are similar to other HPV-related cervical and vulvar cancers. Rare clear cell carcinoma of the vagina is associated with in utero exposure to diethylstilbestrol (DES), which is now largely of historical interest due to aging of the exposed cohort.[73] Patients with vaginal cancer usually present with postmenopausal and/or postcoital bleeding and may also complain of vaginal discharge, vaginal mass, dysuria, hematuria, rectal bleeding, or pelvic pain, which may be indicative of advanced disease. Diagnosis is made via biopsy of suspicious lesions, which may require colposcopic guidance.[67]

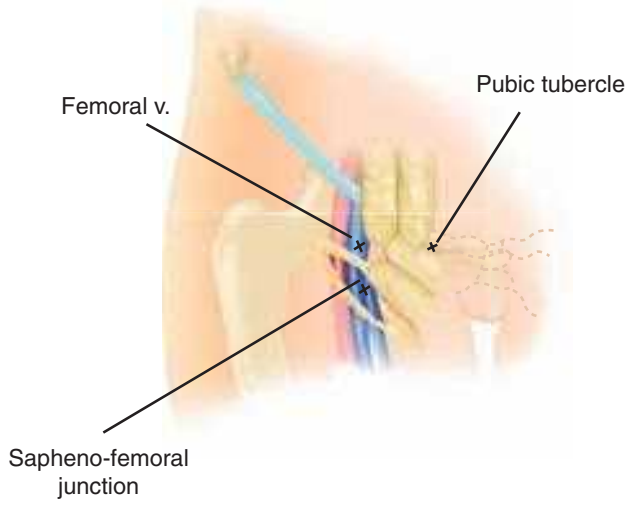

Figure 41-20. Incision recommended for superficial inguinal lymphadenectomy. v. = vein.

Table 41-7

International Federation of Gynecology and Obstetrics staging of vaginal carcinoma

0	Carcinoma in situ; intraepithelial neoplasia grade 3
I	Tumor limited to the vaginal wall
II	Tumor has involved the subvaginal tissue but has not extended to the pelvic wall
III	Tumor extends to the pelvic wall
IV	Tumor has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis
IVB	Distant metastasis

Vaginal cancer is staged clinically by pelvic exam, chest x-ray, cystoscopy, and proctoscopy (Table 41-7).[74] Vaginal cancer spreads by local extension to adjacent pelvic structures, by lymphatic embolization to regional lymph nodes, and less commonly via the hematogenous route. Lymphatic drainage is complex, but in general, lesions in the upper vagina drain to the pelvic lymph nodes, while lesions involving the lower third drain to the inguinofemoral lymph nodes.

Stage I disease, involving the upper vagina, may be treated surgically or with intracavitary radiation therapy.[68,69,75] Surgery consists of a radical hysterectomy, upper vaginectomy, and bilateral pelvic lymphadenectomy. Stage I disease in the mid to lower vagina is usually treated with radiation and concurrent chemotherapy. External-beam pelvic radiation is the mainstay of treatment for stage II to IV disease and may be followed by intracavitary and/or interstitial brachytherapy. Prognosis for treated early-stage disease is excellent, with 5-year survival rates greater than 90%. Advanced-stage disease, however, carries a poor prognosis, with 5-year survival rates of only 15% to 40%.

Cervical Cancer

General Principles. There are over 12,000 new cases of cervical cancer and over 4000 cervical cancer deaths annually in the United States. It is a major killer worldwide, causing 275,000 deaths annually.[76] Risk factors for cervical squamous cell carcinoma and adenocarcinoma, the two most common histologies, are largely related to acquisition of and immune response to carcinogenic subtypes of the HPV virus. The presence of inherited genetic variations that increase the likelihood of developing cervical cancer when exposed to oncogenic subtypes of HPV is under active investigation. Cervical screening is correlated with

Table 41-8

2009 International Federation of Gynecology and Obstetrics cervical cancer staging and management options[78]

STAGE	DESCRIPTION	OPTIONS FOR MANAGEMENT
0	Carcinoma in situ	Adenocarcinoma in situ: hysterectomy, although some may be followed for preservation if all margins negative on cone Squamous in situ: local excision with LEEP or cone or laser ablation
I	Confined to the cervix A1: Confined to the cervix, diagnosed only by microscopy with invasion of ≤3 mm in depth and lateral spread ≤7 mm A2: Confined to the cervix, diagnosed with microscopy with invasion of >3 mm and <5 mm with lateral spread ≤7 mm B1: Clinically visible lesion or greater than A2, ≤4 cm in greatest dimension B2: Clinically visible lesion, >4 cm in greatest dimension	A1 and some A2: fertility preservation through large cone followed by close monitoring, followed by hysterectomy B1 and B2: radical hysterectomy or chemoradiation; radical trachelectomy with uterine preservation for childbearing is under investigation for highly selected patients
II	A1: Involvement of the upper two thirds of the vagina, without parametrial invasion, ≤4 cm in greatest dimension A2: >4 cm in greatest dimension B: Parametrial involvement	For some IIA, radical hysterectomy may be considered IIA and IIB: chemoradiation is preferred
III	A: Involvement of the lower third of the vagina B: Involvement of a parametria to the sidewall or obstruction of one or both ureters on imaging	Chemoradiation
IV	A: Local involvement of the bladder or rectum B: Distant metastases	A: Chemoradiation B: Chemotherapy with palliative radiation as indicated

LEEP = loop electro-excisional procedure.

early identification and treatment of preinvasive disease.[77] Cervical cancer is most commonly identified in women with long intervals between screening or with no prior screening.

Early cervical cancer is usually asymptomatic, although irregular or postcoital bleeding may be present, particularly in more advanced disease. The diagnosis of cervical cancer is made by cervical biopsy, either of a gross lesion or a colposcopically identified lesion. Cervical cancer is staged clinically.[78] Staging and management options are outlined in Table 41-8.

Procedures for Cervical Cancer Treatment

Radical Hysterectomy. This procedure may be performed via laparotomy or, increasingly, via a minimally invasive (laparoscopic or robotic) approach.[79] The key elements are dissection of the pelvic and periaortic nodes and the dissection of the parametrium from the pelvic sidewall to allow en bloc removal with the uterus. The principle steps of an open procedure are demonstrated in Fig. 41-21. In contrast to a typical simple hysterectomy, the radical hysterectomy involves dissection much closer to the bowel, bladder, ureters, and great vessels, resulting in a higher complication rate to these organs. Additionally, disruption of the nerves supplying the bladder and the rectum, which traverse the cardinal and uterosacral ligaments, may result in temporary or long-term bladder and bowel dysfunction. Radical hysterectomies allow for the maintenance of the ovaries since the incidence of metastases to this area is very low, providing a clear advantage of surgery over radiation therapy in the younger patient.

Radical Trachelectomy. Interest in fertility preservation with stage IA1 and IA2 and stage IB1 lesions has led to the development of methods of radical trachelectomy with uterine preservation. This procedure depends on an adequate blood supply to the uterus from the ovarian anastomoses, as the cervical portion is removed. The lower uterine segment is closed with a cerclage and attached directly to the vaginal cuff. The rates of recurrence, pregnancy outcomes, and the best surgical candidates for this surgery are still under study.[80]

Pelvic Exenteration for Recurrent Disease (Fig. 41-22). Cervical cancer recurrences after primary surgical management are treated with radiation. Surgery may be a consideration in selected patients with recurrent cervical cancer who have received maximal radiation therapy. If the recurrence is locally confined with no evidence of spread or metastatic disease, then pelvic exenteration may be considered. Attempted exenteration procedures are aborted intraoperatively if metastatic disease is found. Exenteration is tailored to the disease size and location and may be supralevator or extend below the levator ani muscle and require vulvar resection. Reconstruction of the pelvis may require a continent urinary pouch (if radiation enteritis is limited) or ileal conduit and colostomy, as well as rebuilding of the pelvic floor and vagina with grafts or myocutaneous flaps.

Uterine Cancer

Endometrial Cancer. Endometrial cancer is the most common gynecologic malignancy and fourth most common cancer in

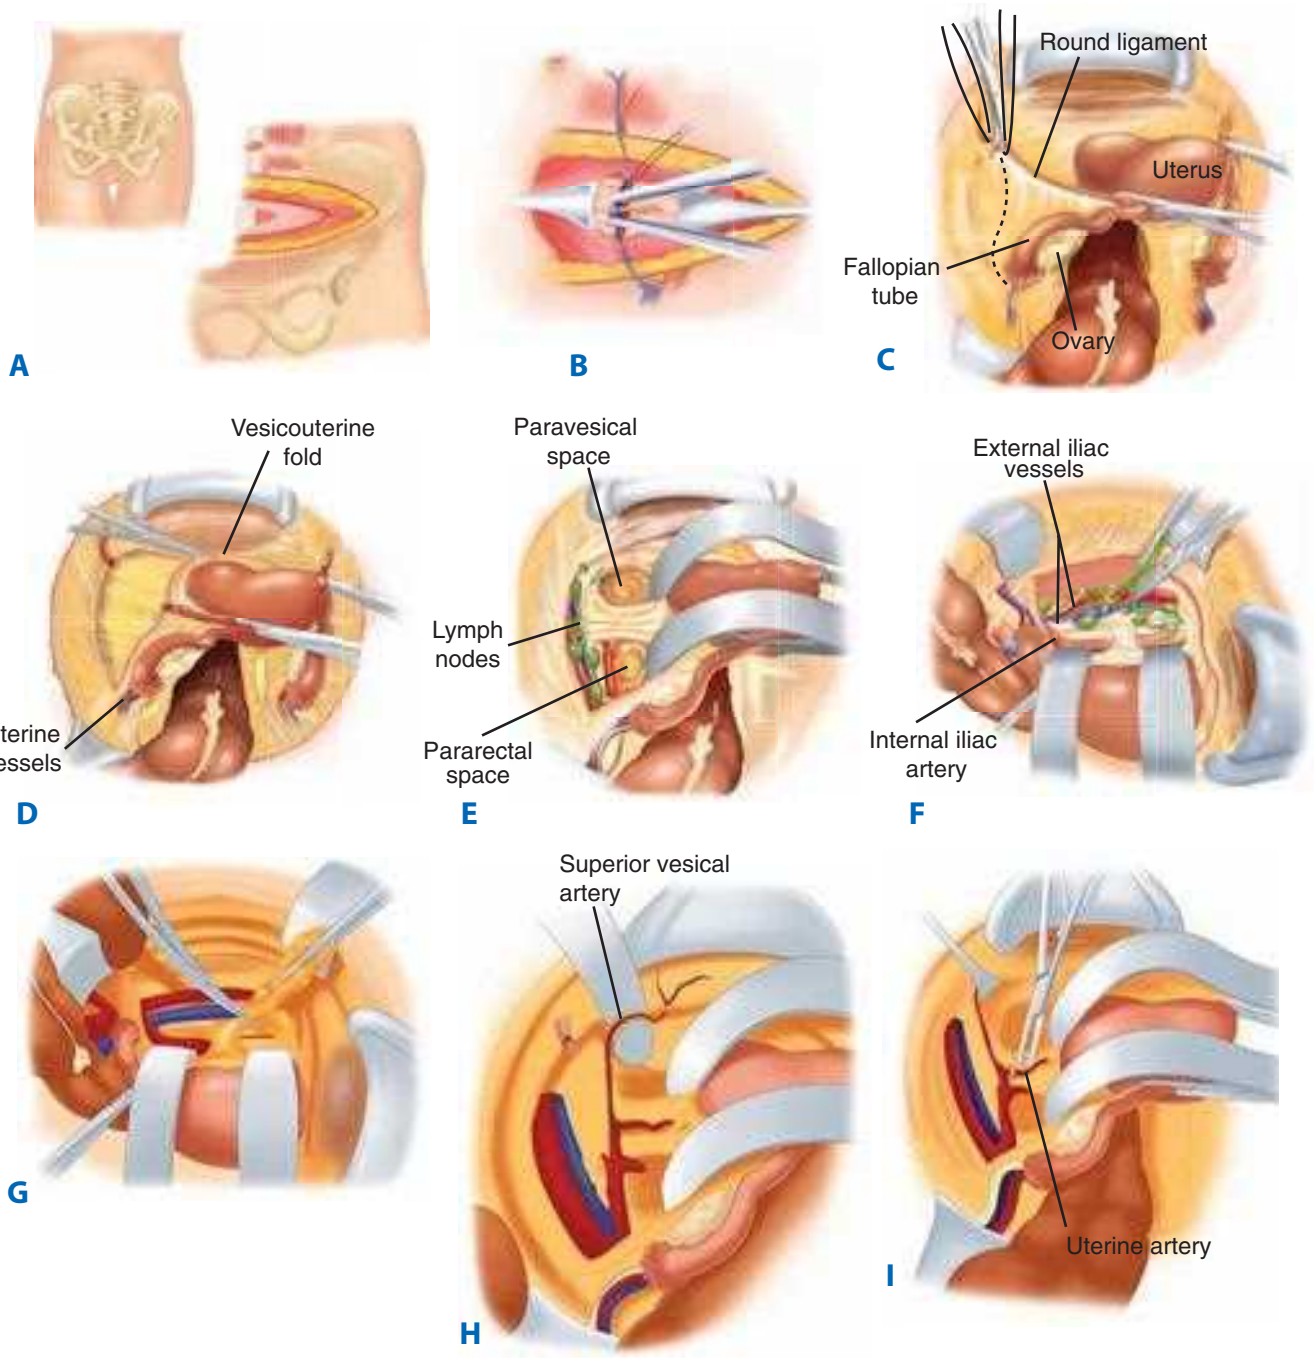

Figure 41-21. Radical hysterectomy. **A.** Exposure of the inferior epigastric vessels before transection of the rectus muscles. **B.** Ligation of the inferior epigastric vessels before transection of the rectus muscles. **C.** Ligation and division of the round ligaments opens the pelvic retroperitoneum. **D.** First peritoneal incision lateral to the ovarian vessels and across the vesicouterine fold. **E.** Narrow malleable retractors (Indiana retractors) are placed into the paravesical and pararectal spaces to provide excellent access to the lateral pelvic sidewall and pelvic lymph nodes. **F.** Pelvic lymphadenectomy (external and internal iliac vessels). **G.** Pelvic lymphadenectomy (obturator fossa). **H.** Development of the uterine and superior vesical arteries. **I.** The uterine artery has been clipped and divided near its origin. **J.** The proper ovarian ligament and proximal fallopian tube are clamped and divided if the ovary is to be preserved. **K.** The ureters have been detached from the posterior peritoneum of the broad ligament and are retracted laterally. The rectovaginal space is developed using blunt finger dissection. **L.** Transection of the uterosacral ligaments. **M.** Clamps are placed on the lateral vagina, taking care to remove 3 to 4 cm of the upper vagina.

women.[66] It is most common in menopausal women in the fifth decade of life; up to 15% to 25% of cases occur prior to menopause, and 1% to 5% occur before age 40. Risk factors for the most common type of endometrial cancer include increased exposure to estrogen without adequate opposition by progesterone, either endogenous (obesity, chronic anovulation) or exogenous (hormone replacement). Additional risk factors include diabetes, Lynch II syndrome (hereditary nonpolyposis colorectal cancer), and prolonged use of tamoxifen. Tamoxifen is a mixed agonist/antagonist ligand for the estrogen receptor. It is an agonistic in the uterus and an antagonistic to the breast and ovary. Protective factors for endometrial cancer include smoking and use of combination oral contraceptive pills. Adenocarcinomas are the most prevalent histologic type.

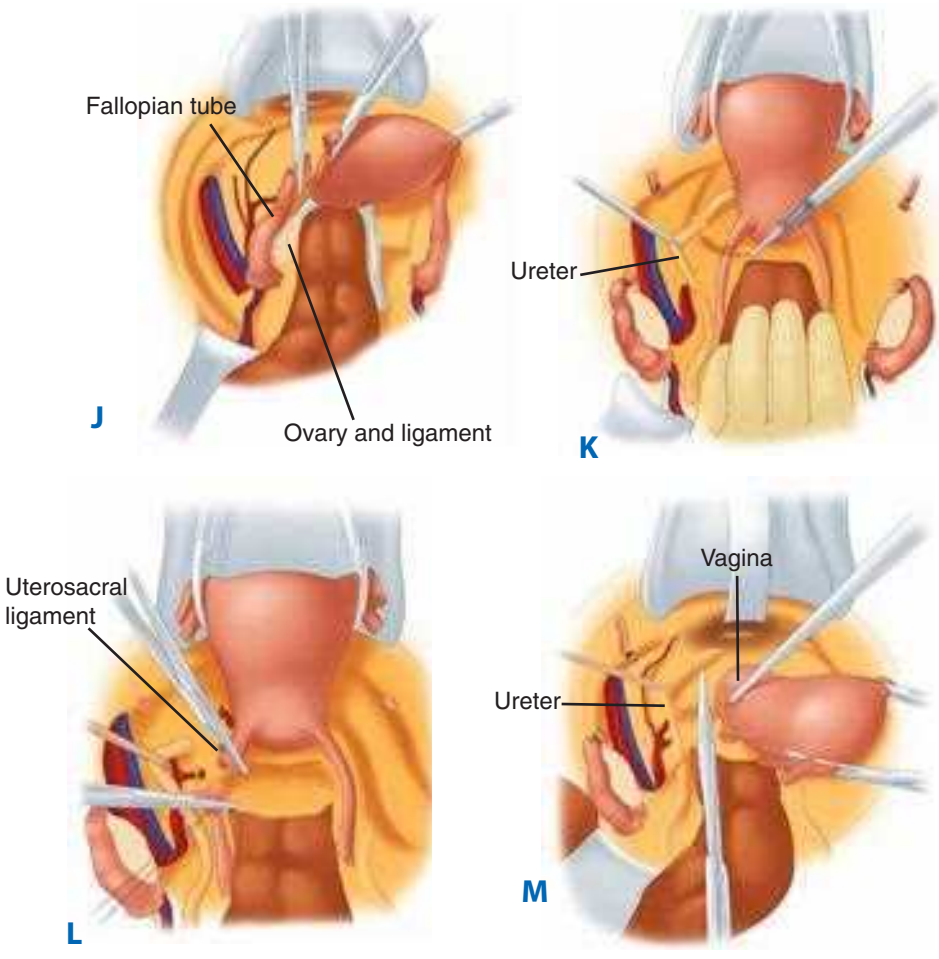

Figure 41-21. (*Continued*)

Endometrial adenocarcinomas are divided into type I and type II, although there is a trend to return to histology as a divider. Type I tumors are estrogen-dependent endometrioid histology and have a relatively favorable prognosis. Type II endometrial cancers are estrogen-independent, aggressive, and characterized by nonendometrioid, serous, or clear cell histology.[81] Postmenopausal bleeding is the most common presentation of type I disease and often permits early-stage diagnosis, resulting in a favorable prognosis. Abnormal bleeding should prompt endometrial evaluation and sampling, which is usually done with an office endometrial biopsy, although at times, it requires operative curettage or diagnostic hysteroscopy. Transvaginal ultrasonography (TVUS) often reveals a thickened endometrial stripe. An endometrial stripe measuring 5 mm or more in a postmenopausal patient raises concern and should be followed by endometrial sampling; patients with stripe of 4 mm

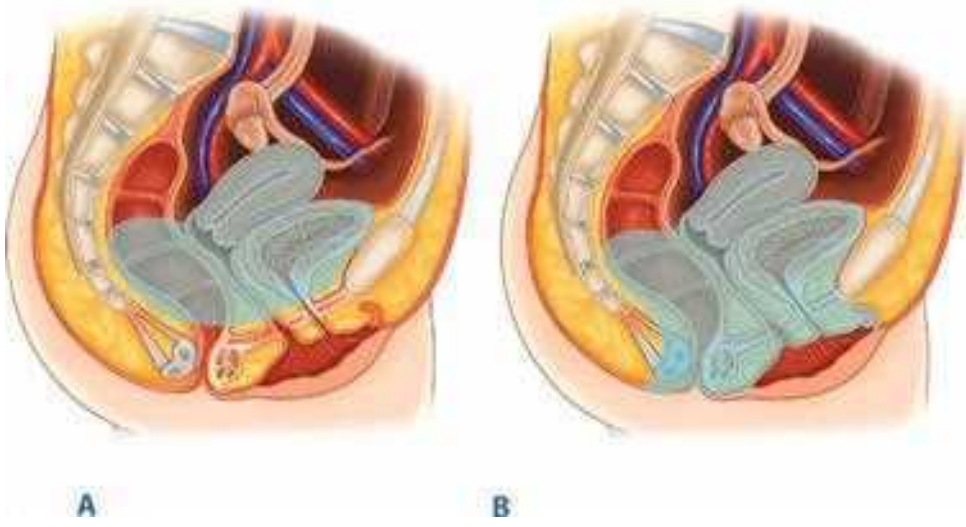

Figure 41-22. Pelvic exenteration may be limited to the supralevator space (**A**) or can extend below the levator ani muscle (*shaded area*) (**B**).

Table 41-9

2009 International Federation of Gynecology and Obstetrics staging of carcinoma of the uterine corpus[78]

IA	Tumor confined to the uterus, no or <½ myometrial invasion
IB	Tumor confined to the uterus, >½ myometrial invasion
II	Cervical stromal invasion, but not beyond uterus
IIIA	Tumor invades serosa or adnexa
IIIB	Vaginal and/or parametrial involvement

IIIC2	Para-aortic involvement
IVA	Tumor invasion bladder and/or bowel mucosa
IVB	Distant metastases including abdominal metastases and/or inguinal lymph nodes

or less rarely have occult malignancy, and TVUS may thus be used to triage patients before invasive endometrial sampling. Uterine cancer is surgically staged and is graded based on the degree of histologic differentiation of the glandular components (Table 41-9).[78] Grade is an important prognostic factor, independent of stage.

Treatment is surgical and most commonly involves hysterectomy, bilateral salpingo-oophorectomy, peritoneal cytology, pelvic and para-aortic lymphadenectomy, and resection of any gross disease.[68,69,75] Evidence supports equivalent oncologic outcomes with minimally invasive approaches.[82] The utility of lymphadenectomy is an area of great controversy. The need for postoperative adjuvant radiation or chemotherapy is individualized based on the histology, stage, and risk factors such as age, lymphovascular space invasion, and histology. Early-stage patients are typically cured with surgery alone, whereas patients with high- or intermediate-risk factors, as defined by collaborative trials groups, commonly receive intracavitary brachytherapy to decrease local recurrence.[83,84] Patients with advanced disease and adverse histologies commonly receive platinum-based chemotherapy with or without radiation.

Lynch Syndrome. Lynch syndrome, a cancer family syndrome, also known as hereditary nonpolyposis colorectal cancer (HNPCC), is an autosomal dominant inherited predisposition to develop colorectal carcinoma and extracolonic cancers, predominantly including tumors of the uterus and ovaries, with rare but defined inclusion of breast cancer.[85] Genes involved in HNPCC are those required for proper single-strand DNA repair via the mismatch repair pathway; most commonly involved are *MLH1*, *MSH2*, and *MSH6*. The risk of colorectal carcinoma is as high as 75% by age 75. Affected female patients have a 40% and 10% lifetime risk of developing uterine and ovarian cancers, respectively. Surveillance has not been proven to identify early-stage disease in these patients, although it is recommended and should include annual cervical cytology, mammography, transvaginal ultrasonography, CA-125 measurements, and an endometrial biopsy. Risk reduction salpingo-oophorectomy with hysterectomy is now being recommended for women who have completed childbearing, ideally 5 to 10 years earlier than the first case of endometrial or ovarian cancer in the family.

Uterine Sarcomas. Uterine sarcomas arise from the uterine muscle and connective tissue elements and are typically aggressive tumors with a poorer prognosis compared to the more common endometrial carcinomas. The most common histopathologic types are endometrial stromal sarcomas, undifferentiated endometrial sarcomas, and leiomyosarcomas. Risk factors are challenging to assess but may include African American race, pelvic radiation, and tamoxifen exposure. Patients typically present with bleeding or mass effects, although some are discovered incidentally at the time of hysterectomy for other indications. Leiomyosarcoma is the most common uterine sarcoma, and hysterectomy with salpingo-oophorectomy is the treatment of choice. Lymph node metastases are rare in sarcomas in general, and in uterine sarcomas in the absence of palpable nodes or extrauterine disease. There are limited data to support cytoreduction when extrauterine disease is present. Benefits of adjuvant therapy are unknown. Advanced disease is typically treated with systemic chemotherapy.[86]

Ovarian, Tubal, and Primary Peritoneal Cancer

Epithelial Ovarian, Tubal, and Primary Peritoneal Cancer. There were an estimated 22,280 new cases and 15,500 deaths due to ovarian cancers in 2012, yielding a fractional death rate of 70% and making ovarian cancer the most deadly of all women's cancers.[66] One in 60 to 70 women in the United States will develop ovarian cancer during her lifetime, with a median age at diagnosis of 63 years. Symptoms for either benign or malignant ovarian tumors are nonspecific but frequent. Goff and colleagues, in a 2007 publication, described symptoms of bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary symptoms of urgency or frequency,[87] which form the basis of an ovarian cancer symptom index (Table 41-10), the use of which is endorsed by the Ovarian Cancer National Alliance, the Gynecologic Cancer Foundation, the Society of Gynecologic Oncologists, and the American Cancer Society. These symptoms, when newly developed and persistent or when representing a distinct change from a personal norm, should prompt an evaluation specifically targeted for identification of gynecologic malignancy.

High-grade, particularly serous epithelial cancers of the ovary, fallopian tube, and peritoneum are clinically similar and often combined under the rubric of epithelial ovarian cancer (EOC) in clinical practice, as well as in research and clinical trials. Risk factors for development of EOC include events that appear to increase the number of lifetime ovulations (e.g., early menarche, late menopause, nulliparity), whereas events that decrease the number of ovulations decrease risk (e.g., pregnancy, breastfeeding, oral contraceptives). Additionally, a history of tubal ligation or hysterectomy also decreases EOC risk. Family history of breast cancer and/or EOC is one of the strongest factors for lifetime risk of having breast cancer or EOC. Approximately 85% of ovarian cancer is sporadic; of the remaining 10% of cases, 75% of hereditary ovarian cancer has been attributed to mutations in the *BRCA1* and *BRCA2* genes, 7% to HNPCC, and the remainder to familial cancer of undefined genetic origin.[88] The lifetime risk of ovarian cancer in *BRCA1* mutation carriers has been estimated at 40% to 60%, and it is 15% to 45% in *BRCA2* carriers. The only confirmed 9▶ prevention is risk-reducing salpingo-oophorectomy (RRSO).[89,90] The lifetime risk of ovarian or tubal malignancy is reduced to approximately 5% with RRSO, with the resultant cancer presenting as a primary peritoneal cancer.

Physical examination of patients with EOC may reveal evidence of metastatic disease, whereas a pelvic mass may be

Table 41-10

Ovarian cancer symptom index (2007) and ACOG guidelines for patient referral to gynecologic oncology[87, 104]

OVARIAN CANCER SYMPTOM INDEX	ACOG GUIDELINES FOR REFERRAL OF PREMENOPAUSAL WOMEN WITH MASS SUSPICIOUS FOR OVARIAN CANCER	ACOG GUIDELINES FOR REFERRAL OF POSTMENOPAUSAL WOMEN WITH MASS SUSPICIOUS FOR OVARIAN CANCER
Development of, change in, and/or persistence in:	*1 or more of:*	*1 or more of:*
Bloating	CA-125 >200 U/mL	Elevated CA-125
Pelvic or abdominal pain	Ascites	Ascites
Difficulty eating or feeling full quickly	Evidence of abdominal or distant metastasis	Nodular or fixed pelvic mass
Urinary symptoms of urgency or frequency	Family hx of 1 or more first-degree relatives with ovarian or breast cancer	Evidence of abdominal or distant metastasis
		Family hx of 1 or more first-degree relatives with ovarian or breast cancer

ACOG = American Congress of Obstetricians and Gynecologists; hx = history.

appreciated on exam. Ultrasound is particularly useful in the evaluation of a pelvic mass, whereas CT scan may detect evidence of metastatic disease. In the presence of a radiographically complex mass, CA-125 may provide further evidence for or against a possible ovarian malignancy. Concerning physical or radiographic exam findings should prompt referral to a gynecologic oncologist (see Table 41-10), as studies demonstrate inferior patient outcomes for women who have had primary surgery by nongynecologic oncologists.

The objectives of surgery in EOC are threefold. The first is to make the histologic diagnosis. The second is to assess the extent of disease through complete surgical staging (Tables 41-11 and 41-12). The third objective is (complete when feasible) surgical cytoreduction or debulking. An optimal cytoreduction is defined as no gross residual lesion greater than 1 cm, although outcomes are improved with complete resection of all gross disease. The extent of disease upon entering the abdomen and the residual disease upon completion of the debulking surgery are independent prognostic variables for patient outcome. When EOC is identified on frozen section and disease is grossly limited to the pelvis, complete staging with node dissection will upstage nearly one third of patients.[91] Decisions about the benefits and risks of radical debulking for individual presentations and diverse pathology depend on the age and medical stability of the patient, as well as the pathologic type of the cancer. Conservative, fertility-sparing surgery can be considered for likely stage I, grade 1 EOC. In a patient who is medically compromised or in whom complete primary cytoreduction is unlikely, neoadjuvant chemotherapy followed by interval debulking may be more appropriate and is supported by a recent randomized controlled trial.[92] Patients usually receive three cycles of platinum-based chemotherapy prior to debulking, and then three additional cycles after surgery.

10▶

Early-stage EOC has an excellent outcome. Low-grade, stage IA and IB disease can be cured in up to 90% to 95% of cases by a complete surgical procedure. The prevailing position in the United States is that such patients do not benefit from

Table 41-11

Risk and protective factors for epithelial ovarian and fallopian tube cancers

PROTECTIVE FACTORS	RISKS
Oral contraceptive use, especially >5 years	Primary and secondary infertility
Tubal ligation	Nulliparity

chemotherapy.[93] The standard of care for women with stages IC and II and all women with grade 3 or clear cell histology is adjuvant chemotherapy with three to six cycles of cisplatin or carboplatin in combination with paclitaxel or docetaxel.[94]

Since GOG-111[95] was published in 1996, and through much of the subsequent decade, standard-of-care adjuvant therapy of advanced-stage EOC has been intravenous (IV) platinum and taxane. More recent trials have sustained that chemotherapy backbone but prompt an individualized, more nuanced approach. In 2006, the National Cancer Institute issued a Clinical Alert indicating that inclusion of intraperitoneal chemotherapy administration in adjuvant therapy should be considered first line for women with optimally cytoreduced (defined as no residual lesions >1 cm in diameter) EOC. This was the result of completion and analysis of three independent randomized clinical trials showing a significant survival advantage for intraperitoneal therapy.[96,97] It is unclear whether it is the site of drug administration and/or the doses and dose density used that contributed to the improved outcomes. The intraperitoneal port is usually a 9.6-French venous catheter, with the port placed over the right or left costal margin. The catheter is tunneled caudad with insertion through the fascia in the lower abdomen and the tip in the pelvis.

Patients who have suboptimally debulked advanced-stage disease and/or who are not candidates for intraperitoneal therapy should receive IV adjuvant chemotherapy. Interest has increased in both dose-dense IV chemotherapy dosing as well as incorporation of biologic agents. The Japanese Gynecologic Oncology Group phase III trial of carboplatin and weekly, dose-dense paclitaxel demonstrated significant improvement in both progression-free and overall survival[98]; the U.S. study of this regimen is now maturing. Addition of the angiogenesis inhibitor, bevacizumab, to the standard carboplatin-paclitaxel backbone and its continuance in maintenance therapy provided a modest increase in progression-free survival without an overall survival advantage. Patients with bulky disease after primary surgery appeared to derive the greatest benefit in post-hoc analysis.[99,100]

Secondary cytoreduction upon recurrence can be considered (Table 41-13). Patients who have had a disease-free period of at least 12 months, following an initial complete clinical response to surgery and initial chemotherapy, who have no evidence of carcinomatosis on imaging, and who have disease that can be completely resected are considered optimal candidates. A randomized controlled trial is ongoing to validate that current state of treatment. Debulking surgery done after subsequent relapses or in women with early recurrence has not been shown to result in an outcome benefit. Finally, surgery is used to palliate disease complications. The most common cause of palliative surgery is bypass of bowel obstruction.

Chemotherapy is the mainstay of therapy for recurrent EOC. Treatment approaches are based on platinum sensitivity[101] (Table 41-14). Referral to an oncologist with specific expertise in chemotherapeutic treatment of ovarian cancer and access to clinical trials is important. In determining secondary and subsequent therapy, consideration of prior therapies, sites of disease, organs at risk from cancer, organs sustaining injury from prior therapy, and quality of life desires of the patient should be taken into consideration.

Ovarian Germ Cell Tumors. Ovarian germ cell tumors occur most commonly in women under age 30. Malignant forms often grow and disseminate rapidly and are symptomatic. The rapid growth may be accompanied by torsion producing an acute abdomen and need for emergent intervention. Because they are derived from primordial germ cells, many produce characteristic tumor markers. The most common benign germ cell neoplasm is the mature cystic teratoma; approximately 1% of teratomas contain a secondary malignancy arising from one of the components, most commonly squamous cell cancer. Immature teratomas comprise a significant proportion of malignant germ cell tumors and may be associated with elevated lactate dehydrogenase (LDH) or α-fetoprotein (AFP). Excluding teratomas, the most common malignant germ cell tumor is dysgerminoma, made up of pure undifferentiated germ cells. Bilaterality occurs in up to 15% of patients; lactate dehydrogenase is commonly elevated, and elevated β-hCG may occur. Staging, including removal of the involved ovary, biopsy of any suspicious areas, node dissection, and omentectomy, should be done initially but does not require hysterectomy or removal of the second ovary if fertility preservation is of concern and no extension of disease is observed. Evidence of extraovarian spread, such

Table 41-13

Guidelines for secondary debulking of epithelial ovarian cancer

TIME FROM COMPLETION OF PRIMARY THERAPY	DEFINITION	INTERVENTION
Progression on therapy	Platinum-refractory	No value of secondary debulking unless remediating complication such as bowel obstruction Nonplatinum-based chemotherapy Platinum with gemcitabine (class I) Nonplatinum-based chemotherapy

PLATINUM SENSITIVITY	DEFINITION	INTERVENTION
Refractory	Progression while receiving a platinum	Nonplatinum-based chemotherapy Platinum with gemcitabine
Resistant	Progression within 6 months of completing treatment	Nonplatinum-based chemotherapy Platinum with gemcitabine
Sensitive	Progression after 6 months of completing treatment	Consider secondary debulking if >12 months since treatment Consider platinum ± taxane Nonplatinum-based chemotherapy

as nodal metastases, requires adjuvant chemotherapy. The cure rate remains high, near 90% with metastatic disease; recurrent disease is more difficult to eradicate.[102]

Less common are malignant germ cell tumors, including endodermal sinus or yolk sac tumors, embryonal carcinomas, mixed germ cell neoplasms, polyembryomas, and choriocarcinomas. Endodermal sinus tumors may have elevated AFP levels in the blood, whereas embryonal and mixed germ cell tumors may have elevated β-hCG, LDH, or AFP. Tumor markers are useful to follow during definitive therapy. Early spread of these tumors occurs, and other than completely resected stage I, grade 1 immature teratoma, all others require adjuvant therapy with a platinum-containing regimen.[103]

Ovarian Sex Cord-Stromal Tumors. Although rare, sex cord-stromal cell tumors are derived from cells that support and surround the oocyte and can present with symptoms referable to endocrine activity of the tumor. These include granulosa cell tumors (female differentiated), fibroma-thecomas, and Sertoli-Leydig cell tumors (male differentiated). Granulosa cell tumors are the most common in this group and are a low-grade malignancy with less than 3% bilaterality. They are treated with conservative surgery, similar to germ cell tumors in young women.[103] Hysterectomy and bilateral salpingo-oophorectomy are recommended for women who have completed childbearing. Nodal staging can be safely omitted in the absence of grossly involved nodes, and fertility preservation is possible in disease limited to one ovary, the most common presentation. Debulking surgery is recommended for more extensive disease. These tumors and the thecomas in the same class often stimulate estrogen production and can be found in association with endometrial hyperplasia and cancer (5%). Granulosa cell tumors can recur over a prolonged period given their low rate of proliferation and tendency for local or intraperitoneal recurrence. Inhibin has been shown to be elaborated by these tumors and often is followed to identify recurrence of the disease. The Sertoli-Leydig cell tumors can present with virilization as a primary symptom. Evaluation of the ovary when this symptom is found is always of value.

MINIMALLY INVASIVE GYNECOLOGIC SURGERY

Hysteroscopy

See earlier section, Hysteroscopy, under Procedures Performed for Structural Causes of Abnormal Uterine Bleeding.

Laparoscopy

The standard method for gynecologic laparoscopy follows the same methods as all minimally invasive surgery. In general, a camera port is placed near the umbilicus. Sometimes it must be placed more cephalad if the patient has a larger fibroid uterus. Two additional ports are placed laterally, usually just superior and medial to the anterior superior iliac spines (ASIS). Sometimes one additional suprapubic port is placed for extra traction or instrumentation as described elsewhere in this text.

Complications Related to Gynecologic Surgery

Abdominal Wall Vessels. The vessel at greatest risk of injury during the lateral trocar placement is the inferior epigastric artery. The superficial epigastric vessels and the superficial circumflex iliac vessels can be injured as well (Fig. 41-23). The primary methods to avoid vessel injury are knowledge of the vessels at risk and their visualization prior to trocar placement, when possible. The superficial vessels often can be seen and avoided by transillumination of the abdominal wall with the laparoscope. In contrast, the larger inferior epigastric vessels cannot be seen by transillumination because of their deeper location; these vessels often can be seen laparoscopically and avoided as they course along the peritoneum between the lateral umbilical fold of the bladder and the insertion of the round

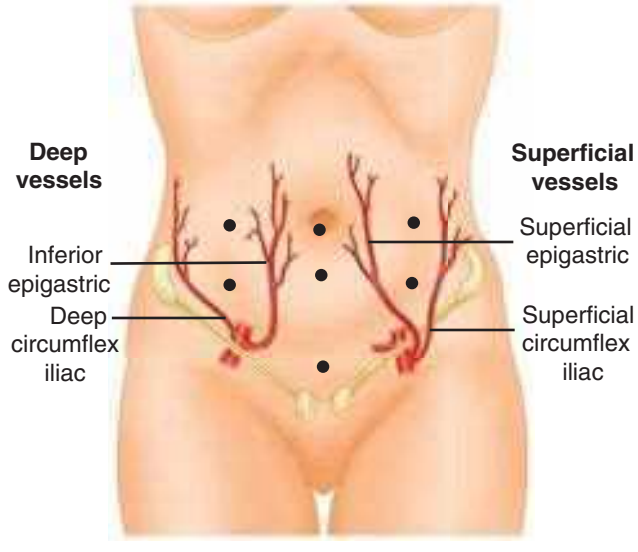

Figure 41-23. Location of anterior abdominal wall blood vessels.

ligament into the inguinal canal. Anatomic variation and anastomoses between vessels make it impossible to know the exact location of all the abdominal wall vessels. For this reason, other strategies also should be used to avoid vessel injury, including the use of trocars with conical tips rather than pyramid tips and the use of the smallest trocars possible lateral to the midline.

Intestinal Injury. Another potentially serious complication of laparoscopic surgery is injury to either small or large intestines. An unrecognized bowel injury may occur at the time of trocar insertion, especially if the patient has had previous abdominal procedures that often result in bowel adhesions to the anterior abdominal wall peritoneum. An open technique for placement of the first port is advocated to minimize the risk of bowel injury in patients who have undergone previous laparotomy. Some bowel injuries may not be seen during surgery because of the limited field of view. These injuries usually manifest 1 to 3 days after surgery, well after the patient has been released following these primarily outpatient procedures, and any patient concerns in this time period should be addressed seriously and rapidly.

Urologic Injuries. Bladder injury is an uncommon laparoscopic injury, occurring as a result of retroperitoneal perforation during lower trocar placement or during sharp dissection of the bladder from the lower uterine segment during hysterectomy. The latter of these two situations is usually recognized intraoperatively; the first sign of the former may be postoperative hematuria or lower-port incisional drainage. Once diagnosed, large defects require layered closure, whereas smaller defects usually close spontaneously within days or weeks with the aid of transurethral catheter drainage. Ureteral injury may occur as a result of any procedure that requires dissection or ligation of sidewall vessels, such as removal of adnexa, because the ureter is adjacent to the pelvic peritoneum in the area of the ovarian fossa (see Fig. 41-5). This complication also has been reported after fulguration of endometriosis on the pelvic sidewall. Another common cause of ureteral injury is hysterectomy, because the ureter is often located less than 2 cm from the cervix. This type of injury appears to be increased during laparoscopic hysterectomy, compared to abdominal or vaginal approaches. Ureteral injuries, including complete ligation, partial resection, or thermal injuries, usually will manifest within hours to days of surgery. Complete obstruction most often manifests as flank pain, whereas the first sign of partial or complete transection may be symptoms of intra-abdominal irritation caused by urine leakage. Transperitoneal thermal injuries resulting from fulguration of endometriosis may be similar to those after transection, but the appearance of symptoms may be delayed several days until tissue necrosis occurs.

Robotic Surgery

Over the last decade, there has been increased use of robotics for gynecologic surgery. With the DaVinci robotic system, the surgeon sits at a console and visualizes the operative field with three-dimensional optics. The laparoscopic instruments are "wristed" and move as the surgeon's hands/fingers move the actuators at the console. Robotic surgery uses a camera port, two to three robotic ports, and an accessory port. More meticulous dissection, improved visualization, and ability to operate with lower intra-abdominal pressures make the robotic platform advantageous, especially in obese patients. Longer set-up time and increased cost, however, are distinct disadvantages. The use of robotic surgery has been described for virtually every gynecologic procedure that has been performed abdominally or laparoscopically.

chapter 42

Neurosurgery

Casey H. Halpern and
M. Sean Grady

OVERVIEW

Neurologic surgery provides the operative and nonoperative management (i.e., prevention, diagnosis, evaluation, treatment, critical care, and rehabilitation) of disorders of the central, peripheral, and autonomic nervous systems (ANSs) . Such disorders include those of the brain, meninges, skull and skull base, and their blood supply, including surgical and endovascular treatment of disorders of the intracranial and extracranial vasculature supplying the brain and spinal cord; disorders of the pituitary gland; disorders of the spinal cord, meninges, and vertebral column, including those that may require treatment by fusion, instrumentation, or endovascular techniques; and disorders of the cranial and spinal nerves throughout their distribution.

1▶

An accurate history is the first step toward neurologic diagnosis. A history of trauma or of neurologic symptoms is of obvious interest, but general constitutional symptoms are also important. Neurologic disease may have systemic effects, while diseases of other systems may affect neurologic function. The patient's general medical ability to withstand the physiologic stress of anesthesia and surgery should be understood. A detailed history from the patient and/or family, along with a reliable physical examination, will clarify these issues.

NEUROANATOMY

An understanding of neuroanatomy is the foundation of comprehensive neurologic examination and diagnosis. Salient features will be considered, from cephalad to caudad. The cerebral hemispheres (or telencephalon) consist of the cerebral cortex, underlying white matter, the basal ganglia, hippocampus, and amygdala. The cerebral cortex is the most recently evolved part of the nervous system. Its functions are mapped to discrete anatomic areas. The frontal areas are involved in executive function, decision making, and restraint of emotions. The motor strip, or precentral gyrus, is the most posterior component of the frontal lobes, and is arranged along a homunculus with the head inferior and lateral to the lower extremities superiorly and medially. The motor speech area (Broca's area) lies in the left posterior inferior frontal lobe in almost all right-handed people and in up to 90% of left-handed people. The parietal lobe lies between the central sulcus anteriorly and the occipital lobe posteriorly. The postcentral gyrus is the sensory strip, also arranged along a homunculus. The rest of the parietal lobe is involved with awareness of one's body in space and relative to the immediate environment, body orientation, and spatial relationships. The occipital lobes are most posterior. The visual cortex is arrayed along the apposing medial surfaces of the occipital lobes. The left occipital lobe

Key Points

1. Neurologic surgery specializes in primarily surgical management of central, peripheral, and autonomic nervous system disorders.
2. Although clinical examination is paramount, neurosurgical diagnosis and treatment are aided largely by a variety of modalities, such as MRI and intracranial pressure monitoring.
3. The common treatment goals for traumatic brain and spinal injury are aimed at preventing secondary insults of hypoxia and hypotension.
4. Aneurysmal subarachnoid hemorrhage remains one of the most morbid and intensive neurosurgical diseases. Endovascular therapy is a growing technology that allows for safer securing of ruptured aneurysms.
5. Brain tumors can arise from primary or metastatic tissues. Treatment typically involves resection, followed by radiation and/or chemotherapy, depending on the type and grade of tumor.
6. Spinal instrumentation is used for surgical stabilization of many types of spinal instability, including traumatic, infectious, oncologic, and degenerative.
7. Infection of the nervous system is a serious and prevalent medical problem. Operative management is indicated for most conditions in which there is symptomatic compression of neural structures.
8. Functional neurosurgery via device implantation is a rapidly evolving discipline that has already become the standard of care in treating medically refractory Parkinson's disease and essential tremor. A wider variety of deep brain stimulation targets will treat additional neuropsychiatric diseases.
9. Stereotactic radiosurgery is a powerful treatment option for intracranial disease, whether it is primary or adjunct. Gamma knife surgery can be used to treat tumors, vascular malformations, and cranial neuralgias.

receives and integrates data from the left half of each retina. A left occipital lesion would therefore result in an inability to see objects right of center. The temporal lobes lie below the sylvian fissures. The hippocampus, amygdala, and lower optic radiations (Meyer's loops) are important components of the temporal lobe and are involved in memory, emotion, and vision, respectively. The receptive speech area (Wernicke's area) typically is found in the area of the left posterior superior temporal lobe and inferior parietal lobe. The basal ganglia include the caudate, putamen, globus pallidus, subthalamic nucleus, substantia nigra, and nucleus accumbens. These structures are involved in the selection, activation and termination of movement, and facilitate learning of appropriate context-dependent motor behaviors.

Lying deep to the cerebral hemispheres is the diencephalon, which includes the thalamus and hypothalamus. The thalamus is a key processor and relay circuit for most motor and sensory information traveling to or from cortex. The hypothalamus regulates homeostasis via the autonomic and neuroendocrine systems.

The brain stem consists of the midbrain (mesencephalon), pons (metencephalon), and medulla (myelencephalon). Longitudinal fibers run through the brain stem, carrying motor and sensory information between the cerebral hemispheres and spinal cord. The corticospinal tract is the major motor tract, while the medial lemniscus and spinothalamic tracts are the major sensory tracts. The nuclei of cranial nerves III through XII are also located within the brain stem. These nerves relay the motor, sensory, and special sense functions of the eye, face, mouth, and throat.

The cerebellum arises from the dorsal aspect of the brain stem. It integrates somatosensory, vestibular, and motor information for coordination and timing of movement. Midline, or vermian, lesions lead to truncal ataxia. Lateral, or hemispheric, lesions lead to tremor and dyscoordination in the extremities.

The ventricular system is the cerebrospinal fluid (CSF)–containing contiguous space inside the brain, continuous with the subarachnoid space outside the brain. The paired lateral ventricles consist of temporal, occipital, and frontal horns, as well as the main body. CSF travels from each lateral ventricle through the foramina of Monroe to the third ventricle, located between the left and right thalami. CSF then drains through the cerebral aqueduct to the fourth ventricle within the brain stem. The foramen of Magendie (midline) and paired foramina of Luschka (lateral) drain to the subarachnoid space. The approximate CSF volume in an average adult is 150 mL, and the choroid plexus produces approximately 500 mL of CSF per day.

The spinal cord starts at the bottom of the medulla and extends caudally through the spinal canal to the first lumbar vertebra, approximately. Motor tracts (efferent pathways) continue from the brain stem down via the lateral and anterior corticospinal tracts to anterior horn cells, and then exit via ventral nerve roots. Sensory information (afferent pathways) enters via dorsal nerve roots, travels cranially via the dorsal columns (proprioception and fine touch) or spinothalamic tract (pain and temperature), and into the brain stem. Paired nerves exit the spinal cord at each level. There are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal.

The dorsal and ventral nerve roots at each level fuse to form mixed motor-sensory spinal nerves and spread through the body to provide innervation to muscles and sensory organs. The C5–T1 spinal nerves intersect in the brachial plexus and divide to form the main nerve branches to the arm, including the median, ulnar, and radial nerves. The L2–S4 spinal nerves intersect in the lumbosacral plexus, and divide to form the main nerve branches to the leg, including the femoral and sciatic nerves.

The principal motor tract of the spinal cord is the corticospinal tract. It is a two-neuron path, including an upper motor neuron and a lower motor neuron. The upper motor neuron cell body is located within the motor strip of the cerebral cortex. The axon travels through the internal capsule to the brain stem, decussates at the brain stem–spinal cord junction, and travels down the contralateral corticospinal tract to the lower motor neuron in the anterior horn at the appropriate level. The lower motor neuron axon then travels via peripheral nerves to its target muscle. Damage to upper motor neurons typically results in hyperreflexia and mild atrophy Damage to lower motor neurons results in flaccidity and significant atrophy.

The two major sensory tracts are three-neuron pathways. Fine touch and proprioceptive signals enter the spinal cord via the dorsal root ganglia and then ascend ipsilaterally via the dorsal columns. Then they synapse and decussate in the lower medulla, travel up the contralateral medial lemniscus to make a second synapse in the thalamus, and then finally ascend to the sensory cortex. Pain and temperature fibers first synapse in the dorsal horn of the spinal cord

at their entry level, decussate, and then travel up the contralateral spinothalamic tracts to the thalamus. The second synapse occurs in the thalamus, and the output axons ascend to the sensory cortex.

The aforementioned motor and sensory tracts together constitute the somatic nervous system. In addition to this system, the ANS is the other constituent of the nervous system. The ANS carries messages for homeostasis and visceral regulation from the central nervous system (CNS) to target structures such as arteries, veins, the heart, sweat glands, and the digestive tract.[1] CNS control of the ANS arises particularly from the hypothalamus and the nucleus of the tractus solitarius. The ANS is divided into the sympathetic, parasympathetic, and enteric systems. The sympathetic system drives the "fight or flight" response, using epinephrine to increase heart rate, blood pressure, blood glucose, and temperature, as well as to dilate the pupils. It arises from the thoracolumbar spinal segments. The parasympathetic system promotes the "rest and digest" state, and uses acetylcholine to maintain basal metabolic function under nonstressful conditions. Parasympathetic fibers arise from cranial nerves III, VII, IX, and X, and from the second to fourth sacral segments. The enteric nervous system controls the complex synchronization of the digestive tract, especially the pancreas, gallbladder, and small and large bowels. It can run autonomously but is regulated by the sympathetic and parasympathetic systems.

NEUROLOGIC EXAMINATION

The neurologic examination is divided into several components, and generally is done from head to toe. First, one must assess mental status. A patient may be awake, lethargic (will follow commands and answer questions, but then returns to sleep), stuporous (difficult to arouse), or comatose (no purposeful response to voice or pain). Cranial nerves may be thoroughly tested in the awake patient, but pupil reactivity, eye movement, facial symmetry, and gag are the most relevant measures when mental status is impaired. Motor testing is based on maximal effort of major muscle groups in those able to follow commands, while assessing for amplitude and symmetry of movement to deep central pain may be all that is possible for stuporous patients. Table 42-1 details scoring for motor assessment tests. Characteristic motor reactions to pain in patients with depressed mental status include withdrawal from stimulus, localization to stimulus, flexor (decorticate) posturing, extensor (decerebrate) posturing, or no reaction (in order of worsening pathology). Figure 42-1 diagrams the clinical patterns of posturing. This forms the basis of determining the Glasgow Coma Scale (GCS) motor

Table 42-1

Motor scoring system

GRADE	DESCRIPTION
0	No muscle contraction
1	Visible muscle contraction without movement across the joint
2	Movement in the horizontal plane, unable to overcome gravity
3	Movement against gravity
4	Movement against some resistance
5	Normal strength

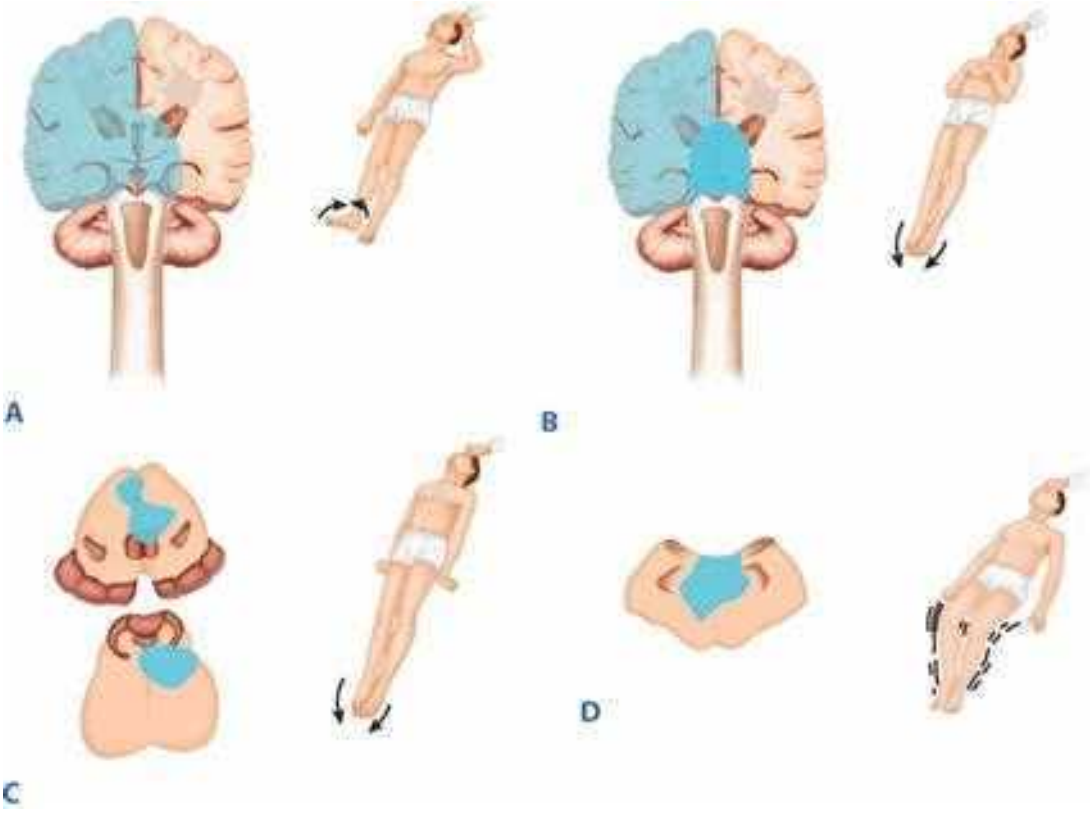

Figure 42-1. Patterns of motor responses associated with various lesions. **A.** Left hemispheric lesion with right hemiplegia and left localization. **B**. Deep cerebral/thalamic lesion with bilateral flexor posturing. **C**. Midbrain or pontine lesion with bilateral extensor posturing. **D**. Medullary lesion with general flaccidity. Copyright Elsevier.*)

Table 42-2

The Glasgow Coma Scale score[a]

MOTOR RESPONSE		VERBAL RESPONSE		EYE-OPENING RESPONSE	
Obeys commands	6	Oriented	5	Opens spontaneously	4
Localizes to pain	5	Confused	4	Opens to speech	3
Withdraws from pain	4	Inappropriate words	3	Opens to pain	2
Flexor posturing	3	Unintelligible sounds	2	No eye opening	1
Extensor posturing	2	No sounds	1		
No movement	1				

[a]Add the three scores to obtain the Glasgow Coma Scale (GCS) score, which can range from 3 to 15. Add "T" after the GCS if intubated and no verbal score is possible. For these patients, the GCS can range from 3T to 10T.

score, as detailed in Table 42-2. Light touch, proprioception, temperature, and pain testing may be useful in awake patients but is often impossible without good cooperation. It is critical to document sensory patterns in spinal cord injury (SCI) patients. Muscle stretch reflexes should be examined. Often comparing left to right or upper extremity to lower extremity reflexes for symmetry is the most useful for localizing a lesion. Check for ankle-jerk clonus or up-going toes (Babinski's test). Presence of either is pathologic and signifies upper motor neuron disease.

Diagnostic Studies

Plain Films. Plain X-rays of the skull may demonstrate fractures, osteolytic or osteoblastic lesions, or pneumocephaly (air in the head). The use of skull plain films has decreased given the rapid availability and significantly increased detail of head computed tomography (CT) scans. Plain films of the cervical, thoracic, and lumbar spine are used to assess for evidence of bony trauma or soft tissue swelling suggesting fracture. Spinal deformities and osteolytic or osteoblastic pathologic processes also will be apparent. The shoulder girdle usually poses problems in visualizing the cervicothoracic junction clearly.

Computed Tomography. The noncontrast CT scan of the head is an extremely useful diagnostic tool in the setting of new focal neurologic deficit, decreased mental status, or trauma. It is rapid and almost universally available in hospitals in the United States. Its sensitivity allows for the detection of acute hemorrhage. A contrast-enhanced CT scan will help show neoplastic or infectious processes. In the current era, contrast CT generally is used for those patients who cannot undergo magnetic resonance imaging (MRI) scanning due to pacemakers or metal in the orbits. Fine-slice CT scanning of the spine is helpful for defining bony anatomy and pathology, and is usually done after an abnormality is seen on plain films, or because plain films are inadequate (especially to visualize C7 and T1 vertebrae). Finally, high-speed multislice scanners, combined with timed-bolus contrast injections, allow CT angiography. A thin-slice axial scan is obtained during the passage of contrast through the cerebral arteries and reconstructed in three dimensions to assess for vascular lesions. CT angiography does not reliably detect lesions, such as cerebral aneurysms <3 mm across, but can provide detailed morphologic data of larger lesions. Newer, multislice scanner technology is approaching the resolution of conventional angiography.

Magnetic Resonance Imaging. MRI provides excellent imaging of soft tissue structures in the head and spine . It is a complex and evolving science. Several of the most clinically useful MRI sequences are worth describing. T1 sequences made before and after gadolinium administration are useful for detecting neoplastic and infectious processes. T2 sequences facilitate assessment of lesion-associated edema in the brain and neural compression in the spine by the presence or absence of bright T2 CSF signals. Diffusion-weighted images can detect ischemic stroke earlier than CT. Fine-slice time-of-flight axial images can be reformatted in three dimensions to build MRI angiograms and MRI venograms. MRI angiograms can detect stenosis of the cervical carotid arteries or intracranial aneurysms >3 mm in diameter. MRI venograms can assess the dural venous sinuses for patency or thrombosis.

Angiography. Transarterial catheter-based angiography remains the gold standard for evaluation of vascular pathology of the brain and spine. The current state of the art is biplanar imaging to reduce dye load and facilitate interventional procedures. Digital subtraction technologies minimize bony interference in the resultant images. Bilateral carotid arteries and bilateral vertebral arteries may be injected and followed through arterial, capillary, and venous phases for a complete cerebral angiogram.

Electromyography and Nerve Conduction Studies. Electromyography and nerve conduction studies (EMG/NCS) are useful for assessing the function of peripheral nerves. EMG records muscle activity in response to a proximal stimulation of the motor nerve. NCS record the velocity and amplitude of the nerve action potential. EMG/NCS typically is performed approximately 3 to 4 weeks after an acute injury, as nerves distal to the injury continue to transmit electrical impulses normally until degeneration of the distal nerve progresses.

Invasive Monitoring. The most reliable monitor, *always*, is an alert patient with a reliable neurologic examination. If a reliable neurologic examination is not possible due to the presence of brain injury, sedatives, or paralytics, or if there is active and unstable intracranial pathology, invasive monitoring is required. There are several methods of monitoring intracranial physiology. The three described below are bedside intensive care unit (ICU) procedures that allow for continuous monitoring. All three procedures involve making a small hole in the skull with a hand-held drill. They generally are placed in the right frontal

region to minimize the neurologic impact of possible complications such as hemorrhage.

External Ventricular Drain. An external ventricular drain is also known as a *ventriculostomy*. A perforated plastic catheter is inserted into the frontal horn of the lateral ventricle. An uninterrupted fluid column through a rigid tube allows transduction of intracranial pressure (ICP). CSF also can be drained to reduce ICP or sampled for laboratory studies.

Intraparenchymal Fiber-Optic Pressure Transducer. An intraparenchymal fiber-optic pressure transducer is commonly referred to as a *bolt*. A threaded post locks securely into the hole made in the skull, and holds the fiber-optic catheter in place. A bolt allows ICP monitoring only, but it is smaller and less invasive than a ventriculostomy, and may be associated with fewer complications, although the data do not clearly support this.

Brain Tissue Oxygen Sensors. The brain tissue oxygen sensor is a recent development that has already demonstrated a mortality benefit in traumatic brain injury patients.[2] This sensor is part of a bolt, which is screwed into the skull in the same manner as the bolt described previously, however, is engineered to hold a pressure sensor, oxygen sensor, and brain temperature sensor. The oxygen sensor catheter has an electrochemical oxygen–tension sensitive membrane. Patients with severe brain injury due to trauma or aneurysmal hemorrhage may benefit from placement of these three sensors in addition to a ventriculostomy to drain CSF for control of ICP. Such monitoring requires two twist-drill holes, which may be placed on adjacent or opposite sides of the head.

Figure 42-2. Head computed tomography scan demonstrating hydrocephalus. The third ventricle (*3rd*) is widened and rounded, the anterior horns of the lateral ventricles are plump, and pressure-driven flow of cerebrospinal fluid into brain parenchyma adjacent to the ventricles is seen (*arrowhead*). This is known as *transependymal flow of cerebrospinal fluid*.

NEUROLOGIC AND NEUROSURGICAL EMERGENCIES

Raised Intracranial Pressure

ICP normally varies between 4 and 14 mmHg. Sustained ICP levels above 20 mmHg can injure the brain. The Monro-Kellie doctrine states that the cranial vault is a rigid structure, and therefore, the total volume of the contents determines ICP. The three normal contents of the cranial vault are brain tissue, blood, and CSF. The brain's contents can expand due to swelling from traumatic brain injury (TBI), stroke, or reactive edema. Blood volume can increase by extravasation to form a hematoma, or by reactive vasodilation in a hypoventilating, hypercarbic patient. CSF volume increases in the setting of hydrocephalus. Figure 42-2 demonstrates the classic CT findings of hydrocephalus. The addition of a lesion, such as a tumor or abscess, also will increase ICP. The pressure-volume curve depicted in Fig. 42-3 demonstrates a compensated region with a small $\Delta P/\Delta V$, and an uncompensated region with large $\Delta P/\Delta V$. In the compensated region, increased volume is offset by decreased volume of CSF and blood.

Increased ICP can injure the brain in several ways. Focal mass lesions cause shift and herniation. Temporal lesions push the uncus medially and compress the midbrain. This phenomenon is known as *uncal herniation*. The posterior cerebral artery (PCA) passes between the uncus and midbrain and may be occluded, leading to an occipital infarct. Masses higher up in the hemisphere can push the cingulate gyrus under the falx cerebri. This process is known as *subfalcine herniation*. The anterior cerebral artery (ACA) branches run along the medial surface of the cingulate gyrus and may be occluded in this case, leading to medial frontal and parietal infarcts. Diffuse increases in pressure in the cerebral hemispheres can lead to central, or transtentorial, herniation. Increased pressure in the posterior fossa can lead to upward central herniation or downward tonsillar herniation through the foramen magnum. Uncal, transtentorial, and tonsillar herniation can cause direct damage to the brain stem. Figure 42-4 diagrams patterns of herniation.

Patients with increased ICP, or intracranial hypertension, often will present with headache, nausea, vomiting, and progressive mental status decline. Cushing's triad is the classic presentation of intracranial hypertension, bradycardia, and irregular respirations. Focal neurologic deficits such as hemiparesis may be present if there is a focal mass lesion causing the problem. Patients with these symptoms should undergo an immediate head CT and rapid neurosurgical evaluation.

Initial management of intracranial hypertension includes airway protection and adequate ventilation. A bolus of mannitol up to 1 g/kg causes free water diuresis, increased serum osmolality, and extraction of water from the brain. The effect is delayed by about 20 minutes and has a transient benefit. Driving serum osmolality above 300 mOsm/L is of indeterminate benefit and can have deleterious cardiovascular side effects, such as hypovolemia that leads to hypotension and decreased brain perfusion. A ventriculostomy and/or craniectomy may be needed for definitive decompression.

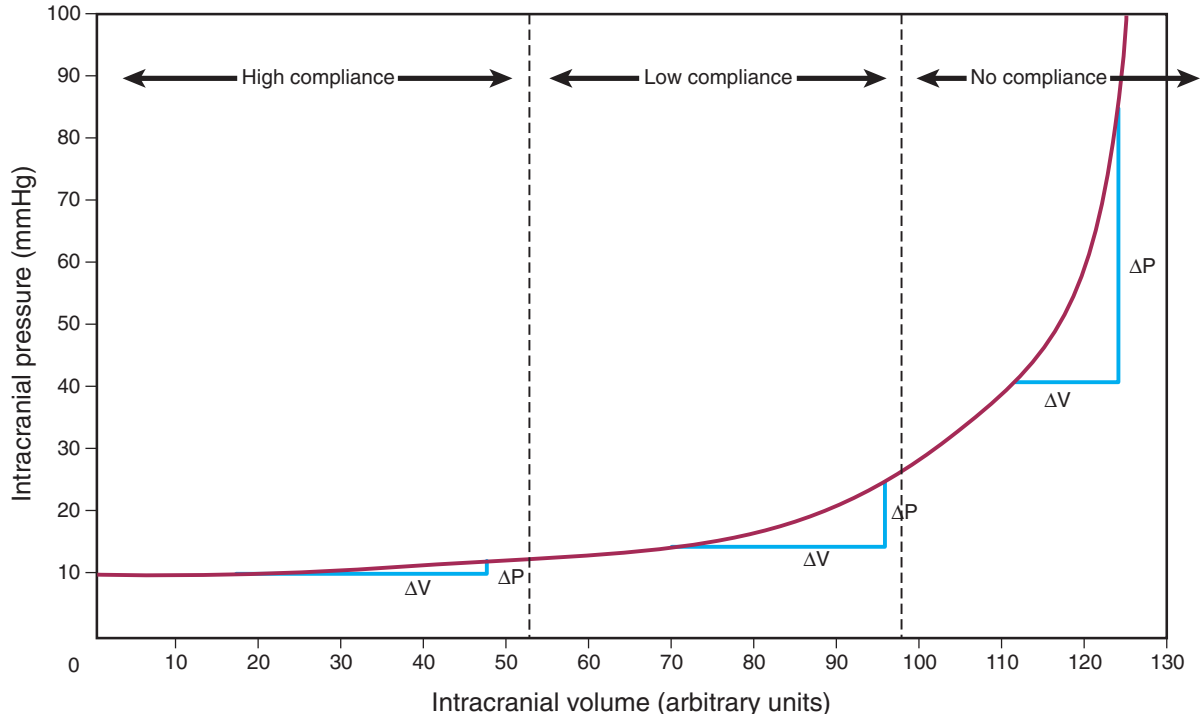

Figure 42-3. Pressure-volume curve demonstrating the effect of changing the volume of intracranial contents on intracranial pressure. Note the compensated zone, with little change of pressure with change of volume, and the uncompensated zone, with significant change of pressure with change of volume. *(Adapted with permission from Morton R, Ellenbogen RG: Intracranial consciousness, in Ellenbogen RG et al (eds):* Principles of Neurosurgery, *3rd ed. Philadelphia: Elsevier Saunders, 2012, p 313. Copyright Elsevier.)*

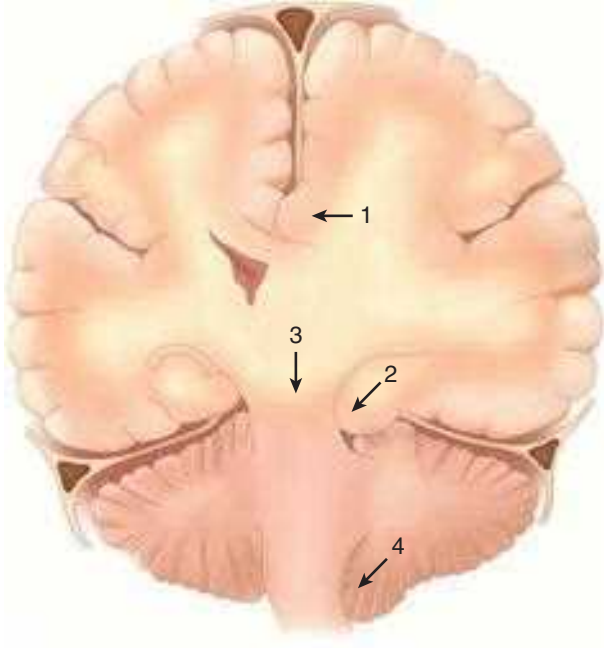

Figure 42-4. Schematic drawing of brain herniation patterns. *1*. Subfalcine herniation. The cingulate gyrus shifts across midline under the falx cerebri. *2*. Uncal herniation. The uncus (medial temporal lobe gyrus) shifts medially and compresses the midbrain and cerebral peduncle. *3*. Central transtentorial herniation. The diencephalon and midbrain shift caudally through the tentorial incisura. *4*. Tonsillar herniation. The cerebellar tonsil shifts caudally through the foramen magnum. (*Reproduced with permission from Cohen DS, Quest DO: Increased intracranial pressure, brain herniation and their control, in Wilkins RH, Rengachary SS* [*eds*]*: Neurosurgery, 2nd ed. New York: McGraw Hill, 1996, p 349.*)

It is critical to note that lethargic or obtunded patients often have decreased respiratory drive. This causes the partial pressure of arterial carbon dioxide ($Paco_2$) to increase, resulting in cerebral vasodilation and worsening of intracranial hypertension. This cycle causes a characteristic "crashing patient," who rapidly loses airway protection, becomes apneic, and herniates. Emergent intubation and ventilation to reduce $Paco_2$ to roughly 35 mmHg can reverse this process.

Brain Stem Compression

The posterior fossa (brain stem and cerebellum) requires special consideration because the volume of the posterior fossa within the cranial vault is small. Posterior fossa lesions such as tumors, hemorrhage or stroke can cause mass effect that can rapidly kill the patient in two ways. Occlusion of the fourth ventricle can lead to acute obstructive hydrocephalus, raised ICP, herniation, and eventually death. This mass effect can also lead directly to brain stem compression (Fig. 42-5). Symptoms of brain stem compression include hypertension, agitation, and progressive obtundation, followed rapidly by brain death. A patient exhibiting any of these symptoms needs an emergent neurosurgical evaluation for possible ventriculostomy or suboccipital craniectomy (removal of the bone covering the cerebellum). This situation is especially critical, as expeditious decompression can lead to significant functional recovery.

Stroke

Patients presenting with acute focal neurologic deficits at a clearly defined time of onset (i.e., when the patient was last seen in a normal state of health) must be evaluated as rapidly as possible. An emergent head CT scan should be done.

Figure 42-5. Maturing cerebellar stroke seen as a hypodense area in the right cerebellar hemisphere (*arrowhead*) on head computed tomography in a patient with rapidly progressing obtundation 2 days after the initial onset of symptoms. Swelling of the infarcted tissue causes posterior fossa mass effect. The fourth ventricle is obliterated and not visible, and the brain stem is being compressed.

The study is often normal, because CT changes from ischemic stroke may take up to 24 hours to appear (Fig. 42-6). A patient with a clinical diagnosis of acute stroke <3 hours old, without hemorrhage on CT, may be a candidate for thrombolytic therapy with tissue plasminogen activator (tPA). An emergent MRI is helpful but not always diagnostically necessary.

Seizure

A seizure is defined as an uncontrolled synchronous organization of neuronal electrical activity. A new-onset seizure often signifies an irritative mass lesion in the brain, particularly in adults, in whom tumors commonly present with seizure. Patients with traumatic intracranial hemorrhage are at risk for seizure. In addition to airway and ventilatory problems, a seizing patient is also at risk for neural excitotoxicity if the activity is prolonged, such as in *status epilepticus*. Any patient with a new-onset seizure should have imaging of the brain after the seizure is controlled and the patient is resuscitated.

TRAUMA

Trauma is the leading cause of death in children and young adults; however, the incidence of death and disability from trauma has been slowly decreasing. This decline is partly attributable to increased awareness of safety devices such as seat belts and motorist helmets. Nonetheless, trauma remains a major cause of morbidity and mortality, and it can affect every major organ system in the body. The three main areas of neurosurgical focus are: traumatic brain injury (TBI), spinal cord injury (SCI), and peripheral nerve injury.

Head Trauma

Glasgow Coma Scale Score. The initial assessment of the trauma patient includes the primary survey, resuscitation, secondary survey, and definitive care. Neurosurgical evaluation begins during the primary survey with the determination of the GCS score (usually referred to simply as the *GCS*) for the patient. The GCS is determined by adding the scores of the best responses of the patient in each of three categories. The motor score ranges from 1 to 6, verbal from 1 to 5, and eyes from 1 to 4. The GCS therefore ranges from 3 to 15, as detailed in Table 42-2. Tracheal intubation or severe facial or eye swelling can impede verbal and eye responses. In these circumstances, the patient is given the score of 1 with a modifier, such as verbal "1T" where T = tube.

Scalp Injury. Blunt or penetrating trauma to the head can cause injury to the densely vascularized scalp, and significant blood loss can result. Direct pressure initially controls the bleeding, allowing close inspection of the injury. If a simple laceration is found, it should be copiously irrigated and closed primarily. If the laceration is short, a single-layer, percutaneous suture closure will suffice. If the laceration is long or has multiple arms, the patient may need debridement and closure in the operating room, with its superior lighting and wider selection of instruments and suture materials. Careful reapproximation of the galea will provide a more secure closure and better hemostasis. Blunt trauma also can cause crush injury with subsequent tissue necrosis. These wounds require debridement and consideration of advancement flaps to cover the defect.

Skull Fractures. The usual classification system for bony fractures may be applied to the skull. The fracture may be characterized by skull X-rays or head CT.[3] A closed fracture is covered by intact skin. An open, or compound, fracture is associated with disrupted overlying skin. The fracture lines may be single (linear); multiple and radiating from a point (stellate); or multiple, creating fragments of bone (comminuted). Closed skull fractures do not normally require specific treatment. Open fractures require repair of the scalp and operative debridement. Indications for craniotomy include depression greater than the cranial thickness, intracranial hematoma, and frontal sinus involvement.[4] Skull fractures generally indicate that a significant amount of force was transmitted to the head and should increase the suspicion for intracranial injury. Fractures that cross meningeal arteries can cause rupture of the underlying vessels and subsequent epidural hematoma (EDH) formation.

Depressed skull fractures may result from a focal injury of significant force. The inner and outer cortices of the skull are disrupted, and a fragment of bone is pressed in toward the brain in relation to adjacent intact skull. The fragment may overlap the edge of intact bone, or may plunge completely below the level of adjacent normal skull. The inner cortex of the bone fragments often has multiple sharp edges that can lacerate dura, brain, and vessels. Craniotomy is required to elevate the fracture, repair dural disruption, and obtain hemostasis in these cases (Fig. 42-7). However, fractures overlying dural venous sinuses require restraint. Surgical exploration can lead to life-threatening hemorrhage from the lacerated sinus.

Fractures of the skull base are common in head-injured patients, and they indicate significant impact. They are generally apparent on routine head CT, but should be evaluated with

A

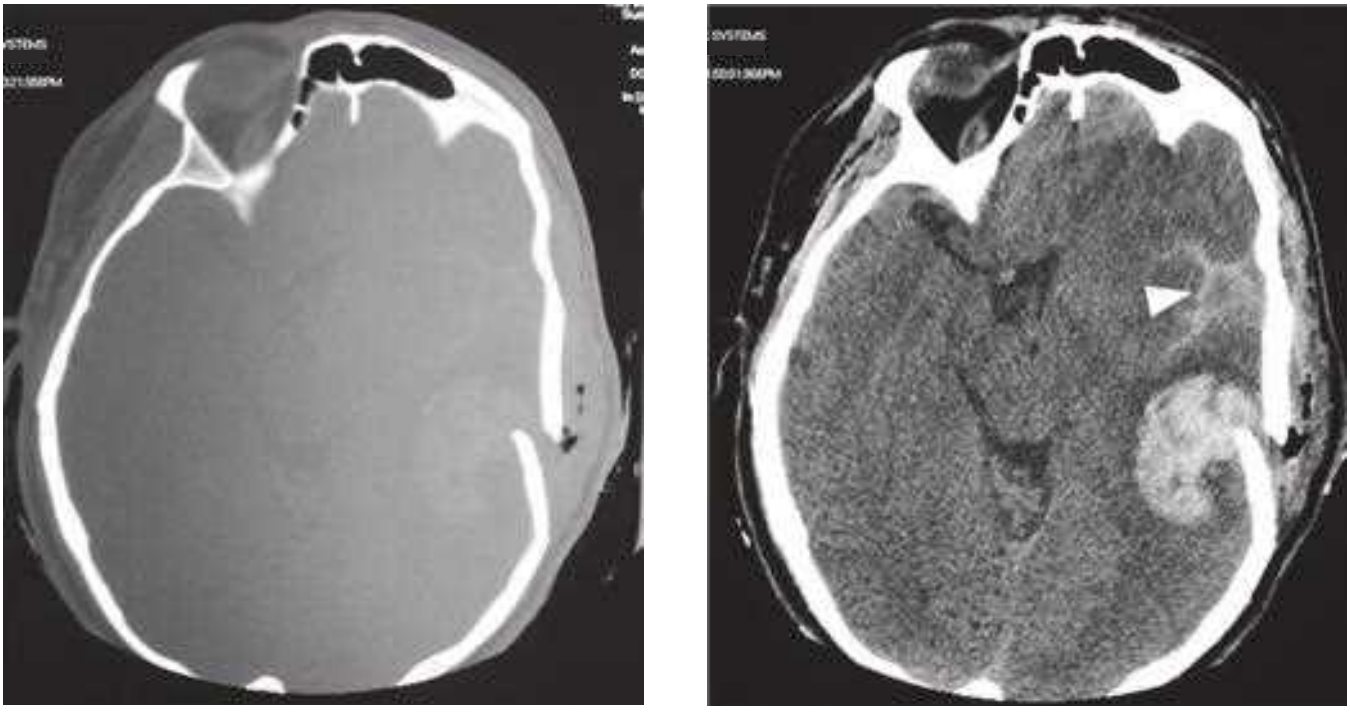
B

C

Figure 42-6. **A.** Head computed tomography scan of a patient with a 4-day-old stroke that occluded the right middle cerebral and posterior cerebral arteries. The infarcted tissue is the hypodense (*dark*) area indicated by the *arrowheads*. The patient presented with left-sided weakness and left visual field loss, but then became less responsive, prompting this head computed tomography. Note the right-to-left midline shift. **B.** Same patient status post decompressive right hemicraniectomy. Note the free expansion of swollen brain outside the normal confines of the skull. **C.** Patient with a right middle cerebral artery ischemic stroke with areas of hemorrhagic conversion, seen as hyperdense (*bright*) areas within the infarcted tissue. This patient also required hemicraniectomy for severe mass effect. Note the lack of midline shift postoperatively.

dedicated fine-slice coronal-section CT scan to document and delineate the extent of the fracture and involved structures. If asymptomatic, they require no treatment. Skull base fractures requiring intervention include those with an associated cranial nerve deficit or CSF leak. A fracture of the temporal bone, for instance, can damage the facial or vestibulocochlear nerve, resulting in vertigo, ipsilateral deafness, or facial paralysis. A communication may be formed between the subarachnoid space and the middle ear, allowing CSF drainage into the pharynx via the eustachian tube or from the ear (otorrhea). Extravasation of blood results in ecchymosis behind the ear, known as *Battle's sign*. A fracture of the anterior skull base can result in anosmia (loss of smell from damage to the olfactory nerve), CSF drainage from the nose (rhinorrhea), or periorbital ecchymoses, known as *raccoon eyes*.

Copious clear drainage from the nose or ear makes the diagnosis of CSF leakage obvious. Often, however, the drainage may be discolored with blood or small in volume if some drains into the throat. The halo test can help differentiate. Allow a drop of the fluid to fall on an absorbent surface such as



A B

Figure 42-7. **A.** Bone-window axial head computed tomography (CT) of a patient who presented aphasic after being struck with the bottom of a beer bottle. CT demonstrates a depressed skull fracture in the left posterior temporoparietal area. **B.** Brain-window axial head CT demonstrating intraparenchymal hematoma caused by laceration of cortical vessels by the edge of the fractured bone. *Arrowhead* indicates traumatic subarachnoid hemorrhage in the sylvanian fissure.

a facial tissue. If blood is mixed with CSF, the drop will form a double ring, with a darker center spot containing blood components surrounded by a light halo of CSF. If this test is indeterminate, the fluid can be sent for beta-2 transferrin testing, a carbohydrate-free isoform of transferrin exclusively found in the CSF.

Many CSF leaks will heal with elevation of the head of the bed for several days. A lumbar drain can augment this method. A lumbar drain is a catheter placed in the lumbar CSF cistern to decompress the cranial vault and allow the defect to heal by eliminating normal hydrostatic pressure. There is no proven efficacy of antibiotic coverage for preventing meningitis in patients with CSF leaks.

Traumatic cranial neuropathies generally can be managed conservatively, with documentation of the extent of impairment and signs of recovery. Patients with traumatic facial nerve palsies may benefit from a course of steroids, although their benefit is unproven. Patients with facial nerve palsy of abrupt onset, who do not respond to steroids within 48 to 72 hours, may be considered for surgical decompression of the petrous portion of the facial nerve. Patients also may present with delayed-onset facial nerve palsy. Again, steroids are used and surgery can be considered, with mixed results.

Closed Head Injury. Closed head injury (CHI) is the most common type of TBI and a significant cause of morbidity and mortality in the United States. There are two important factors that affect the outcome of CHI in general. The initial impact causes the *primary injury*, defined as the immediate injury to neurons from transmission of the force of impact. The long, delicate axons of the neurons can shear as they undergo differential acceleration or deceleration along their projecting pathways. Prevention strategies, such as wearing helmets, remain the best means to decrease disability from primary injury. Subsequent neuronal damage due to the sequelae of trauma is referred to as *secondary injury*. Hypoxia, hypotension, hydrocephalus, intracranial hypertension, thrombosis, and intracranial hemorrhage may all be mechanisms of secondary injury. One focus of basic research in TBI, critical care medicine, and neurosurgical intervention is to decrease the effects of secondary injury .

3▶

The Brain Trauma Foundation's most recent summary of management recommendations for TBI patients was published in 2007 and is endorsed by the American Association of Neurological Surgeons, Congress of Neurological Surgeons, and the World Health Organization. The guidelines standardize the care of these patients with the hope of improving outcomes. Some of the common patterns of CHI, including concussion, contusion, and diffuse axonal injury, are discussed in Types of Closed Head Injury.[5]

Initial Assessment The initial evaluation of a trauma patient remains the same whether or not the primary surveyor suspects head injury. The first three elements of the ABCDs of resuscitation—*a*irway, *b*reathing, and *c*irculation—must be assessed and stabilized. Hypoxia and hypotension are known to worsen outcome in TBI (due to secondary injury), making cardiopulmonary stabilization critical. Patients who cannot follow commands require intubation for airway protection and ventilatory control. The fourth element, assessment of "D," for *d*isability, is undertaken next. Motor activity, speech, and eye opening can be assessed in a few seconds and a GCS score assigned.

The following is an example of how a primary surveyor may efficiently assess disability and GCS: Approach the patient

and enter his or her field of view. Observe whether the patient is visually attentive. Clearly command: "Tell me your name." Then ask the patient to lift up two fingers on each side sequentially, and wiggle the toes. A visually or verbally unresponsive patient should be assessed for response to peripheral stimuli such as nail-bed pressure, or deep central painful stimulation, such as a firm, twisting pinch of the sensitive supraclavicular skin. Watch for eye opening and movement of the extremities, whether purposeful or reflexive. Assess the verbal response. The motor, verbal, and eye-opening scores may be correctly assigned using this rapid examination. An initial assessment of the probability of significant head injury can be made, assuming that pharmacologic and toxic elements have not obscured the examination. The surveyor must also take note of any external signs of head injury, including bleeding from the scalp, nose, or ear, or deformation of the skull or face.

Medical Management Several medical steps may be taken to minimize secondary injury and the systemic consequences of head injury. Patients with a documented CHI and evidence of intracranial hemorrhage or a depressed skull fracture should receive a 17-mg/kg phenytoin loading dose, followed by 1 week of therapeutic maintenance phenytoin, typically 300 to 400 mg/d. Phenytoin prophylaxis has been shown to decrease the incidence of early posttraumatic seizures.[6] There is no evidence to support long-term use of prophylactic antiepileptic agents. Blood glucose levels should be closely monitored by free blood sugar checks and controlled with sliding scale insulin. Fevers also should be evaluated and controlled with antipyretics, as well as source-directed therapy when possible. Hyperglycemia and hyperthermia are toxic to injured neurons and contribute to secondary injury. Head-injured patients have an increased prevalence of peptic ulceration and GI bleeding. Peptic ulcers occurring in patients with head injury or high ICP are referred to as Cushing's ulcers. Ulcer prophylaxis should be used. Compression stockings or athrombic pumps should be used when the patient cannot be mobilized rapidly for prophylaxis of deep venous thrombosis.

Classification TBI can be classified as mild, moderate, or severe. For patients with a history of head trauma, classification is as follows: severe head injury if the GCS score is 3 to 8, moderate head injury if the GCS score is 9 to 12, and mild head injury if the GCS score is 13 to 15. Many patients present to emergency rooms and trauma bays with a history of TBI. A triage system must be used to maximize resource utilization while minimizing the chance of missing occult or progressing injuries.

TBI patients who are asymptomatic, who have only headache, dizziness, or scalp lacerations, and who did not lose consciousness, have a low risk for intracranial injury and may be discharged home without a head CT scan.[7,8] Head-injured patients who are discharged should be sent home with reliable family or friends who can observe the patient for the first postinjury day. Printed discharge instructions, which describe monitoring for confusion, persistent nausea, weakness, or speech difficulty, should be provided to the caretaker. The patient should return to the emergency department for evaluation of such symptoms.

Patients with a history of altered consciousness, amnesia, progressive headache, skull or facial fracture, vomiting, or seizure have a moderate risk for intracranial injury and should undergo a prompt head CT. If the CT is normal, and the neurologic examination has returned to baseline (excluding amnesia of the event), then the patient can be discharged to the care of a responsible adult, again with printed criteria for returning to the emergency room. Otherwise the patient must be admitted for a 24-hour observation period.

Patients with depressed consciousness, focal neurologic deficits, penetrating injury, depressed skull fracture, or changing neurologic examination have a high risk for intracranial injury. These patients should undergo immediate head CT and admission for observation or intervention as needed.

Types of Closed Head Injury

Concussion A concussion is defined as temporary neuronal dysfunction following nonpenetrating head trauma. The head CT is normal, and deficits resolve over minutes to hours. Definitions vary; some require transient loss of consciousness, while others include patients with any alteration of mental status. Memory difficulties, especially amnesia of the event, are very common. Concussions may be graded. One method is the Colorado grading system.[9] Head trauma patients with confusion only are grade 1, patients with amnesia are grade 2, and patients who lose consciousness are grade 3. Studies have shown that the brain remains in a hypermetabolic state for up to a week after injury. The brain is also much more susceptible to injury from even minor head trauma in the first 1 to 2 weeks after concussion. This is known as second-impact syndrome, and patients should be informed that, even after mild head injury, they might experience memory difficulties or persistent headaches.

Contusion A *contusion* is a bruise of the brain, and occurs when the force from trauma is sufficient to cause breakdown of small vessels and extravasation of blood into the brain. The contused areas appear bright on CT scan, as seen in Fig. 42-8. The frontal,

Figure 42-8. Severe bilateral contusions in the basal aspect of the frontal lobes, caused by the brain moving over the rough, irregular skull base during sudden cranial acceleration.

occipital, and temporal poles are most often involved. The brain sustains injury as it collides with rough, bony surfaces. Contusions themselves rarely cause significant mass effect as they represent small amounts of blood in injured parenchyma rather than coherent blood clots. Edema may develop around a contusion, causing mass effect. Contusions may enlarge or progress to frank hematoma, particularly during the first 24 hours. Contusions also may occur in brain tissue opposite the site of impact. This is known as a *contre-coup injury*. These contusions result from deceleration of the brain against the skull.

Diffuse Axonal Injury Diffuse axonal injury is caused by damage to axons throughout the brain, due to rotational acceleration and then deceleration. Axons may be completely disrupted and then retract, forming axon balls. Small hemorrhages can be seen in more severe cases, especially on MRI. Hemorrhage is classically seen in the corpus callosum and the dorsolateral midbrain.

Penetrating Injury These injuries are complex and must be evaluated individually. The two main subtypes are missile (e.g., due to bullets or fragmentation devices) and nonmissile (e.g., due to knives or ice picks). Some general principles apply. If available, skull X-rays and CT scans are useful in assessing the nature of the injury. Cerebral angiography must be considered if the object passes near a major artery or dural venous sinus. Operative exploration is necessary to remove any object extending out of the cranium, as well as for debridement, irrigation, hemostasis, and definitive closure. Small objects contained within brain parenchyma are often left in place to avoid iatrogenic secondary brain injury. Antibiotics are given to decrease the chances of meningitis or abscess formation. High-velocity missile injuries (from high-powered hunting rifles or military weapons) are especially deadly, because the associated shock wave causes cavitary tissue destruction of an area that is much larger than the projectile itself. Projectiles that penetrate both hemispheres or traverse the ventricles are almost universally fatal.

Traumatic Intracranial Hematomas. The various traumatic intracranial hematomas contribute to death and disability secondary to head injury. Hematomas can expand rapidly and cause brain shift and subsequent herniation. Emergent neurosurgical evaluation and intervention often are necessary.

Epidural Hematoma EDH is the accumulation of blood between the skull and the dura. EDH usually results from arterial disruption, especially of the middle meningeal artery. The dura is adherent to bone, and some pressure is required to dissect between the two. EDH has a classic, three-stage clinical presentation that is probably seen in only 20% of cases. The patient is initially unconscious from the concussive aspect of the head trauma. The patient then awakens and has a "lucid interval," while the hematoma subclinically expands. As the volume of the hematoma grows, the decompensated region of the pressure-volume curve is reached, ICP increases, and the patient rapidly becomes lethargic and herniates. Uncal herniation from an EDH classically causes ipsilateral third nerve palsy and contralateral hemiparesis.

On head CT the blood clot is bright, biconvex in shape (lentiform), and has a well-defined border that usually respects cranial suture lines. An EDH is typically found over the convexities but may rarely occur in the posterior fossa as well.

Open craniectomy for evacuation of the congealed clot and hemostasis generally is indicated for EDH. Patients who meet all of the following criteria may be managed conservatively: clot volume <30 cm^3, maximum thickness <1.5 cm, and GCS score >8.[10] Prognosis after successful evacuation is better for EDH than subdural hematoma (SDH). EDHs are associated with lower-energy trauma with less resultant primary brain injury. Good outcomes may be seen in 85% to 90% of patients, with rapid CT scan and intervention.[11]

Acute Subdural Hematoma An acute SDH is the result of an accumulation of blood between the arachnoid membrane and the dura. Acute SDH usually results from venous bleeding, typically from tearing of a bridging vein running from the cerebral cortex to the dural sinuses. The bridging veins are subject to stretching and tearing during acceleration/deceleration of the head, because the brain shifts in relation to the dura, which firmly adheres to the skull. Elderly and alcoholic patients are at higher risk for acute SDH formation after head trauma due to brain atrophy.

On head CT scan, the clot is bright or mixed-density, crescent-shaped (lunate), may have a less distinct border, and does not cross the midline due to the presence of the falx. Most SDHs occur over the cerebral hemispheres, but they may also occur between the hemispheres or layer over the tentorium.

Open craniotomy for evacuation of acute SDH is indicated for any of the following: thickness >1 cm, midline shift >5 mm, or GCS drop by two or more points from the time of injury to hospitalization. Nonoperatively managed hematomas may stabilize and eventually reabsorb, or evolve into chronic SDHs.[12] This management requires frequent neurologic examinations until the clot stabilizes based on serial head CT scans.

The prognosis for functional recovery is significantly worse for acute SDH than EDH because it is associated with greater primary injury to brain parenchyma from high-energy impacts. Prompt recognition and intervention minimizes secondary injury. The elderly patients with low admission GCS, or high postoperative ICP do poorly, with as few as 5% attaining functional recovery.[13]

Chronic Subdural Hematoma Chronic SDH is a collection of blood breakdown products that is at least 2 to 3 weeks old. Acute hematomas are bright white (hyperdense) on CT scan for approximately 3 days, after which they fade to isodensity with brain, and then to hypodensity after 2 to 3 weeks. A true chronic SDH will be nearly as dark as CSF on CT. Traces of white are often seen due to small, recurrent hemorrhages into the collection. These small bleeds may expand the collection enough to make it symptomatic. This phenomenon is referred to as an *acute-on-chronic SDH*. Figure 42-9 demonstrates the CT appearance of an acute-on-chronic SDH. Vascularized membranes form within the hematoma as it matures. These membranes may be the source of acute hemorrhage.

Chronic SDHs often occur in patients without a clear history of head trauma, as they may arise from minor head injury. Alcoholics, the elderly, and patients on anticoagulation are at higher risk for developing chronic SDH. Patients may present with headache, seizure, confusion, contralateral hemiparesis, or coma.

A chronic SDH >1 cm or any symptomatic SDH should be surgically drained. Unlike acute SDH, which consists of a thick, congealed clot, chronic SDH typically consists of a viscous fluid with the texture and dark brown color reminiscent of motor oil. A simple burr hole can effectively drain most chronic SDHs. However, the optimal treatment of chronic SDH remains controversial.[14] Most authorities agree that burr hole drainage should be attempted first to obviate the risks of formal craniotomy. A single burr hole placed over the dependent edge of the

Figure 42-9. Head computed tomography scan of an elderly patient with progressing left hemiplegia and lethargy, demonstrating an acute-on-chronic subdural hematoma. History revealed that the patient sustained a fall 4 weeks before presentation. *Arrowheads* outline the hematoma. The acute component is slightly denser and is seen as the hyperdense area in the dependent portion.

collection can be made, and the space copiously irrigated until the fluid is clear. A second, more anterior burr hole can then be placed if the collection does not drain satisfactorily due to containment by membranes. The procedure is converted to open craniotomy if the SDH is too congealed for irrigation drainage, the complex of membranes prevents effective drainage, or persistent hemorrhage occurs that cannot be reached with bipolar cautery through the burr hole. The required surgical prepping and draping are always performed to allow simple conversion to craniotomy, and the scalp incision and burr holes are placed to allow easy incorporation into larger skin flaps.

There are various strategies to prevent reaccumulation of blood. Subdural or subgaleal drains may be left in place for 1 to 2 days. Mild hydration and bedrest with the head of the bed flat may encourage brain expansion. High levels of inspired oxygen may help draw nitrogen out of the cavity. Regardless of the strategy used, follow-up head CT scans are required postoperatively and approximately 1 month later to document resolution.

Intraparenchymal Hemorrhage Isolated hematomas within the brain parenchyma are most often associated with hypertensive hemorrhage or arteriovenous malformations (AVMs). Bleeding may occur in a contused area of brain. Mass effect from developing hematomas may present as a delayed neurologic deficit. Delayed traumatic intracerebral hemorrhage is most likely to occur within the first 24 hours. Patients with contusion on the initial head CT scan should be reimaged 24 hours after the trauma to document stable pathology. Indications for craniotomy include: any clot volume >50 cm^3 or a clot volume >20 cm^3 with referable neurologic deterioration (GCS 6–8) and associated midline shift >5 mm or basal cistern compression.[15]

Vascular Injury. Trauma to the head or neck may cause damage to the carotid or vertebrobasilar systems. Generally, *dissection* refers to violation of the vessel wall intima. Blood at arterial pressures can then open a plane between the intima and media, within the media, or between the media and adventitia. The newly created space within the vessel wall is referred to as the *false lumen*. Tissue or organs supplied by dissected vessels may subsequently be injured in several ways. Expansion of the hematoma within the vessel wall can lead to narrowing of the true vessel lumen and reduction or cessation of distal blood flow. Slow-flowing or stagnant blood within the false lumen exposed to thrombogenic vessel wall elements may thrombose. Pieces of thrombus may then detach and cause distal embolic arterial occlusion. Also, the remaining partial-thickness vessel wall may rupture, damaging adjacent structures.

Traumatic dissection may occur in the carotid artery (anterior circulation) or the vertebral or basilar arteries (posterior circulation). Dissections may be extradural or intradural. Intradural dissection can present with subarachnoid hemorrhage (SAH). Traditional angiography remains the basis of diagnosis and characterization of arterial dissection. Angiographic abnormalities include stenosis of the true lumen, or "string-sign," visible intimal flaps, and the appearance of contrast in the false lumen. Four-vessel cerebral angiography should be performed when suspicion of dissection exists.

Historically, patients with documented arterial dissection have been anticoagulated with heparin and then warfarin to prevent thromboembolic stroke. Trauma patients often have concomitant absolute or relative contraindications to anticoagulation, complicating management. Antiplatelet therapy is often implemented in lieu of full anticoagulation, however, there is no randomized clinical trial comparing the two therapies.[16] Consider surgical or interventional techniques for persisting embolic disease and for vertebral dissections presenting with SAH. Surgical options include vessel ligation and bypass grafting. Interventional radiology techniques include stenting and vessel occlusion. Occlusion techniques require sufficient collateral circulation to perfuse the vascular territory previously supplied by the occluded vessel.

Carotid Dissection Carotid dissection may result from neck extension combined with lateral bending to the opposite side, or trauma from an incorrectly placed shoulder belt tightening across the neck in a motor vehicle accident. Extension or bending stretches the carotid over the bony transverse processes of the cervical vertebrae, while seat belt injuries cause direct trauma. Symptoms of cervical carotid dissection include contralateral neurologic deficit from brain ischemia, headache, and ipsilateral Horner's syndrome from disruption of the sympathetic tracts ascending from the stellate ganglion on the surface of the carotid artery. The patient may complain of a bruit.

Traumatic vessel wall injury to the portion of the carotid artery running through the cavernous sinus may result in a carotid-cavernous fistula (CCF). This creates a high-pressure, high-flow pathophysiologic blood flow pattern. CCFs classically present with pulsatile proptosis (the globe pulses outward with arterial pulsation), retro-orbital pain, and decreased visual acuity or loss of normal eye movement (due to damage to cranial nerves

III, IV, and VI as they pass through the cavernous sinus). Symptomatic CCFs should be treated to preserve eye function. Fistulae may be closed by balloon occlusion using interventional neuroradiology techniques. Fistulae with wide necks are difficult to treat and may require total occlusion of the parent carotid artery.

Vertebrobasilar Dissection Vertebrobasilar dissection may result from sudden rotation or flexion/extension of the neck, chiropractic manipulation, or a direct blow to the neck. Common symptoms are neck pain, headache, and brain stem stroke or SAH. The risks and benefits of aspirin therapy are unclear when a vertebral dissection extends intracranially. The theoretically increased friability of the vessel wall may increase the risk of SAH when coupled with an antiplatelet agent. Consultation of a stroke neurologist is recommended in this situation.

Brain Death. Brain death occurs when there is an absence of signs of brain stem function or motor response to deep central pain in the absence of pharmacologic or systemic medical conditions that could impair brain function.

Clinical Examination A neurologist, neurosurgeon, or intensivist generally performs the clinical brain death examination. Two examinations consistent with brain death 12 hours apart, or one examination consistent with brain death followed by a consistent confirmatory study generally is sufficient to declare brain death (see below). Hospital regulations and local laws regarding documentation should be followed closely.

Establish the absence of complicating conditions before beginning the examination. The patient must be normotensive, euthermic, and oxygenating well. The patient may not be under the effects of any sedating or paralytic drugs.

Documentation of no brain stem function requires the following: nonreactive pupils; lack of corneal blink, oculocephalic (doll's eyes), oculovestibular (cold calorics) reflexes; and loss of drive to breathe (apnea test). The apnea test demonstrates no spontaneous breathing even when $Paco_2$ is allowed to rise above 60 mmHg.

Deep central painful stimuli are provided by bilateral forceful twisting pinch of the supraclavicular skin and pressure to the medial canthal notch. Pathologic responses such as flexor or extensor posturing are *not* compatible with brain death. Spinal reflexes to peripheral pain, such as triple flexion of the lower extremities, are compatible with brain death.

Confirmatory Studies Confirmatory studies are performed after a documented clinical examination consistent with brain death. A study consistent with brain death may obviate the need to wait 12 hours for a second examination. This is especially important when the patient is a potential organ donor, as brain-dead patients often have progressive hemodynamic instability. Lack of cerebral blood flow consistent with brain death may be documented by cerebral angiography or technetium radionuclide study. A "to-and-fro" pattern on transcranial Doppler ultrasonography indicates no net forward flow through the cerebral vasculature, consistent with brain death. An electroencephalogram (EEG) documenting electrical silence has been used, but generally is not favored because there is often significant artifact which impairs interpretation.

Spine Trauma

The spine is a complex biomechanical structure. The spine provides structural support for the body as the principal component of the axial skeleton, while protecting the spinal cord and nerve roots. Trauma may fracture bones or cause ligamentous disruption. Often, bone and ligament damage occur together. Damage to these elements reduces the strength of the spine and may cause instability, which compromises both supportive and protective functions. Spine trauma may occur with or without neurologic injury.

Neurologic injury from spine trauma is classified as either incomplete or complete. If there is some residual motor or sensory neurologic function below the level of the lesion, as assessed by clinical examination, the injury is defined as incomplete.[17] A patient with complete neurologic dysfunction persisting 24 hours after injury has a very low probability of return of function in the involved area.

Neurologic injury from spine trauma may occur immediately or in delayed fashion. Immediate neurologic injury may be due to direct damage to the spinal cord or nerve roots from penetrating injuries, especially from stab wounds or gunshots. Blunt trauma may transfer sufficient force to the spine to cause acute disruption of bone and ligament, leading to subluxation, which is a shift of one vertebral element in relation to the adjacent level. Subluxation decreases the size of the spinal canal and neural foramina and causes compression of the cord or roots. Such neural impingement can also result from retropulsion of bone fragments into the canal during a fracture. Transection, crush injury, and cord compression impairing perfusion are mechanisms leading to SCI. Delayed neurologic injury may occur during transportation, examination of an improperly immobilized patient, or during a hypotensive episode.

The Mechanics of Spine Trauma. Trauma causes a wide variety of injury patterns in the spine due to its biomechanical complexity. A mechanistic approach facilitates an understanding of the patterns of injury, as there are only a few types of forces that can be applied to the spine. Although these forces are discussed individually, they often occur in combination. Several of the most common injury patterns are then presented to illustrate the clinical results of these forces applied at pathologically high levels.

Flexion/Extension Bending the head and body forward into a fetal position flexes the spine. Flexion loads the spine anteriorly (the vertebral bodies) and distracts the spine posteriorly (the spinous process and interspinous ligaments). High flexion forces occur during front-end motor vehicle collisions, and backward falls when the head strikes first. Arching the neck and back extends the spine. Extension loads the spine posteriorly and distracts the spine anteriorly. High extension forces occur during rear-end motor vehicle collisions (especially if there is no headrest), frontward falls when the head strikes first, or diving into shallow water.

Compression/Distraction Force applied along the spinal axis (axial loading) compresses the spine. Compression loads the spine anteriorly and posteriorly. High compression forces occur when a falling object strikes the head or shoulders, or when landing on the feet, buttocks, or head after a fall from height. A pulling force in line with the spinal axis distracts the spine. Distraction unloads the spine anteriorly and posteriorly. Distraction forces occur during a hanging, when the chin or occiput strikes an object first during a fall, or when a passenger submarines under a loose seat belt during a front-end motor vehicle collision.

Rotation Force applied tangential to the spinal axis rotates the spine. Rotation depends on the range of motion of intervertebral facet joints. High rotational forces occur during off-center impacts to the body or head or during glancing automobile accidents.

Patterns of Injury. Certain patterns of injury resulting from combinations of the previously mentioned forces occur commonly and should be recognized during plain film imaging of the spine. Always completely evaluate the spine. A patient with a spine injury at one level has a significant risk for additional injuries at other levels.

Cervical The cervical spine is more mobile than the thoracolumbar spine. Stability comes primarily from the multiple ligamentous connections of adjacent vertebral levels. Disruption of the cervical ligaments can lead to instability in the absence of fracture. The mass of the head transmits significant forces to the cervical spine during abrupt acceleration or deceleration, increasing risk for injury.

Jefferson Fracture A Jefferson fracture is a bursting fracture of the ring of C1 (the atlas) due to compression forces. There are usually two or more fractures through the ring of C1. The open-mouth odontoid view may show lateral dislocation of the lateral masses of C1. The rule of Spence states that 7 mm or greater combined dislocation indicates disruption of the transverse ligament. The transverse ligament stabilizes C1 with respect to C2. Jefferson fractures dislocated <7 mm usually are treated with a rigid collar, while those dislocated 7 mm or greater usually are treated with a halo vest. Surgical intervention is not indicated.

Odontoid Fractures The odontoid process, or dens, is the large ellipse of bone arising anteriorly from C2 (the axis) and projecting up through the ring of C1 (the atlas). Several strong ligaments connect the dens to C1 and to the base of the skull. Odontoid fractures usually result from flexion forces. Odontoid fractures are classified as type I, II, or III. A type I fracture involves the tip only. A type II fracture passes through the base of the odontoid process. A type III fracture passes through the body of C2. Types II and III are considered unstable and should be externally immobilized or fused surgically. Surgery often is undertaken for widely displaced fractures (poor chance of fusing) and for those that fail external immobilization. Type I fractures usually fuse with external immobilization only.

Hangman's Fracture Traditionally considered a hyperextension/distraction injury from placement of the noose under the angle of the jaw, hangman's fractures also may occur with hyperextension/compression, as with diving accidents, or hyperflexion. The injury is defined by bilateral C2 pars interarticularis fractures. The pars interarticularis is the bone between superior and inferior facet joints. Thus, the posterior bony connection between C1 and C3 is lost. Hangman's fractures heal well with external immobilization. Surgery is indicated if there is spinal cord compression or after failure of external immobilization.

Jumped Facets—Hyperflexion Injury The facet joints of the cervical spine slope forward. In a hyperflexion injury, the superior facet can "jump" over the inferior facet of the level above if the joint capsule is torn. Hyperflexion/rotation can cause a unilateral jumped facet, whereas hyperflexion/distraction leads to bilateral jumped facets. Patients with unilateral injury usually are neurologically intact. Those with bilateral injury, however, typically suffer from spinal cord damage, since the anteroposterior diameter of the spinal canal is compromised by bilateral injury, leading to spinal cord compression (Fig. 42-10).

Thoracolumbar The thoracic spine is stabilized significantly by the rib cage. The lumbar spine has comparatively large vertebrae. Thus, the thoracolumbar spine has a higher threshold for injury than the cervical spine. A three-column model is useful for categorizing thoracolumbar injuries.[18] The anterior longitudinal ligament and the anterior half of the vertebral body constitute the anterior column. The posterior half of the vertebral body and the posterior longitudinal ligament constitute the middle column. The pedicles, facet joints, laminae, spinous processes, and interspinous ligaments constitute the posterior column.

Compression Fracture Compression fracture is a compression/flexion injury causing failure of the anterior column only. It is stable and not associated with neurologic deficit, although the patient may still have significant pain (Fig. 42-11).

Burst Fracture Burst fracture is a pure axial compression injury causing failure of the anterior and middle columns. It is unstable, and perhaps half of patients have neurologic deficit due to compression of the cord or cauda equina from bone fragments retropulsed into the spinal canal.

Chance Fracture Chance fracture is a flexion-distraction injury causing failure of the middle and posterior columns, sometimes with anterior wedging. Typical injury is from a lap seat-belt hyperflexion with associated abdominal injury. It often is unstable and associated with neurologic deficit.

Fracture-Dislocation Fracture-dislocation is failure of the anterior, middle, and posterior columns caused by flexion/distraction, shear, or compression forces. Neurologic deficit can result from retropulsion of middle column bone fragments into the spinal canal, or from subluxation causing decreased canal diameter (Fig. 42-12).

Initial Assessment and Management. The possibility of a spine injury must be considered in all trauma patients. A patient with no symptoms referable to neurologic injury, a normal neurologic examination, no neck or back pain, and a known mechanism of injury unlikely to cause spine injury is at minimal risk for significant injury to the spine. Victims of moderate or severe trauma, especially those with injuries to other organ systems, usually fail to meet these criteria or cannot be assessed adequately. The latter often is due to impaired sensorium or significant pain. Because of the potentially catastrophic consequences of missing occult spine instability in a neurologically intact patient, a high level of clinical suspicion should govern patient care until completion of clinical and radiographic evaluation.

The trauma patient should be kept on a hard flat board with straps and pads used for immobilization. A hard cervical collar is kept in place. These steps minimize forces transferred through the spine, and therefore decrease the chance of causing dislocation, subluxation, or neural compression during transport to the trauma bay. The patient is then moved from the board to a flat stretcher. The primary survey and resuscitation are completed. Physical examination and initial X-rays follow.

For the examination, approach the patient as described in the section on Neurologic Examination earlier in this chapter. Evaluation for spine or SCI is easier and more informative in awake patients. If the patient is awake, ask if he or she recalls details of the nature of the trauma, and if there

was loss of consciousness, numbness, or inability to move any or all limbs. Assess motor function by response to commands or pain, as appropriate. Assess pinprick, light touch, and joint position, if possible. Determining the anatomically lowest level of intact sensation can pinpoint the level of the lesion along the spine. Testing sensation in an ascending fashion will allow the patient to better discern the true stimulus as opposed to determine when it is extinguished. Document muscle stretch reflexes, lower sacral reflexes (i.e., anal wink and bulbocavernosus), and rectal tone.

American Spinal Injury Association Classification The American Spinal Injury Association provides a method of classifying patients with spine injuries. The classification indicates completeness and level of the injury and the associated deficit. A form similar to that shown in Fig. 42-13 should be available in the trauma bay and completed for any spine injury patient. The

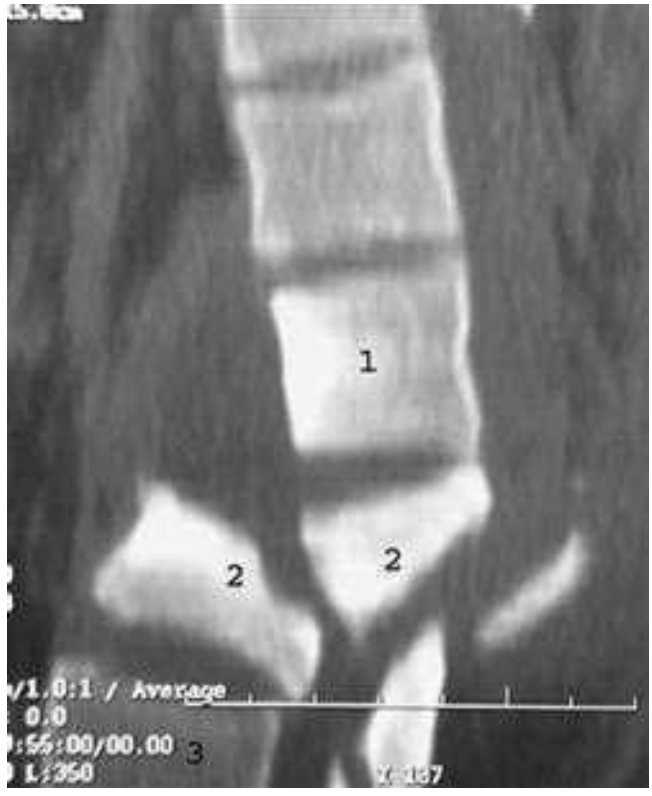

Figure 42-12. Sagittal reconstruction of an axial fine-slice computed tomography scan through the lumbar spine demonstrating a severe fracture-dislocation through the body of L2.

association also has worked to develop recommendations and guidelines to standardize the care of SCI patients in an effort to improve the quality of care.

Neurologic Syndromes. Penetrating, compressive, or ischemic cord injury can lead to several characteristic presentations based on the anatomy of injury. The neurologic deficits may be deduced from the anatomy of the long sensory and motor tracts and understanding of their decussations (Fig. 42-14). Four patterns are discussed. First, injury to the entire cord at a given level results in anatomic or functional cord transection with total loss of motor and sensory function below the level of the lesion. The typical mechanism is severe traumatic vertebral subluxation reducing spinal canal diameter and crushing the cord. Second, injury to half the cord at a given level results in Brown-Séquard syndrome, with loss of motor control and proprioception ipsilaterally and loss of nociception and thermoception contralaterally. The typical mechanism is a stab or gunshot wound. Third, injury to the interior gray matter of the cord in the cervical spine results in a central cord syndrome, with upper extremity worse than lower extremity weakness and various degrees of numbness. The typical mechanism is transient compression of the cervical cord by the ligamentum flavum buckling during traumatic neck hyperextension. This syndrome occurs in patients with preexisting cervical stenosis. Fourth, injury to the ventral half of the cord results in the anterior cord syndrome, with paralysis and loss of nociception and thermoception bilaterally. The typical mechanism is an acute disc herniation or ischemia from anterior spinal artery occlusion.

Studies. Anteroposterior and lateral plain films provide a rapid survey of the bony spine. Plain films detect fractures

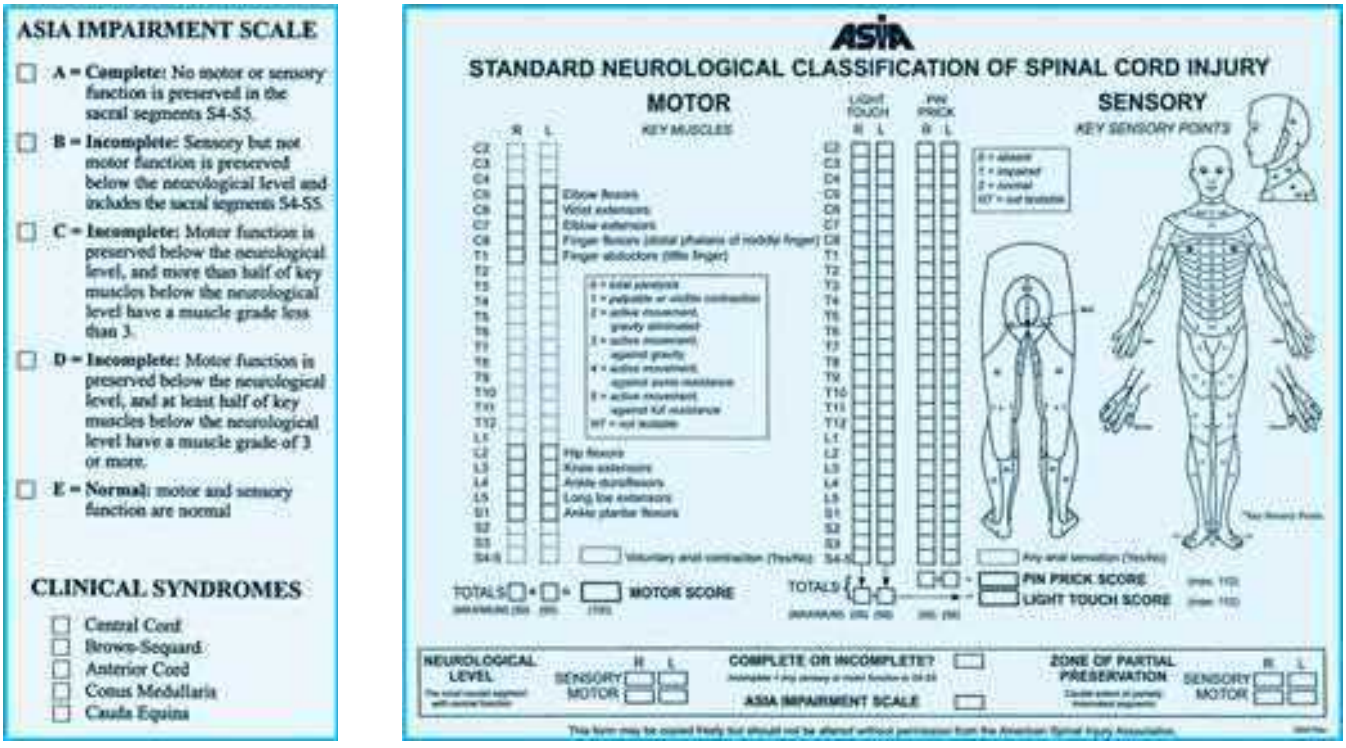

Figure 42-13. The American Spinal Injury Association system for categorizing spinal cord injury patients according to level and degree of neurologic deficit.

and dislocations well. Adequate visualization of the lower cervical and upper thoracic spine often is impossible because of the shoulder girdle. Complete plain film imaging of the cervical spine includes an open-mouth view to assess the odontoid process and the lateral masses of C1. Fine-slice CT scan with sagittal and coronal reconstructions provides good detail of bony anatomy and is good for characterizing fractures seen on plain films, as well as visualizing C7–T1 when not well seen on plain films. MRI provides the best soft tissue imaging. Canal compromise from subluxation, acute disc herniations, or ligamentous disruption is clearly seen. MRI also may detect EDHs or damage to the spinal cord itself, including contusions or areas of ischemia.

Definitive Management

Spinal-Dose Steroids The National Acute Spinal Cord Injury studies (NASCIS I and II) provide the basis for the common practice of administering high-dose steroids to patients with acute SCI. A 30-mg/kg IV bolus of methylprednisolone is given over 15 minutes, followed by a 5.4-mg/kg per hour infusion begun 45 minutes later. The infusion is continued for 23 hours if the bolus is given within 3 hours of injury, or for 47 hours if

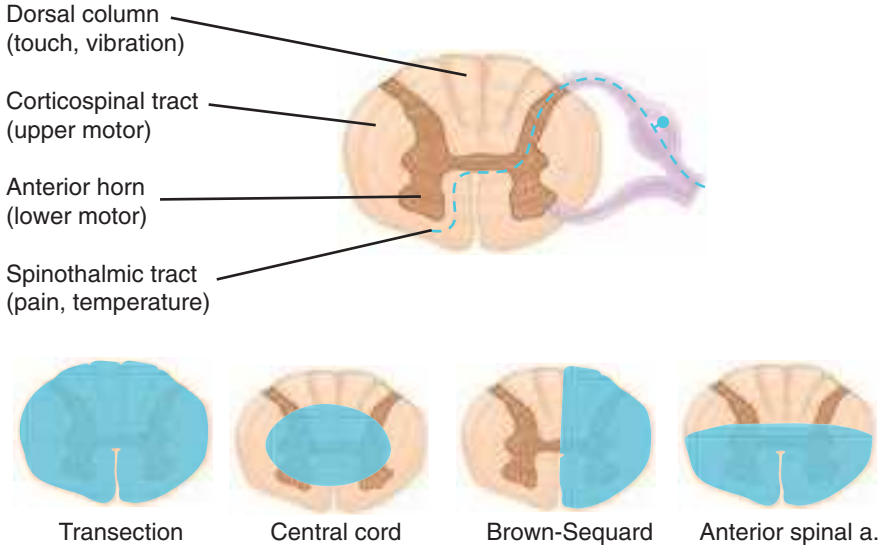

Figure 42-14. Spinal cord injury patterns. a. = artery. (*Adapted with permission from Hoff J, Boland M: Neurosurgery, in Schwartz SI, et al (eds):* Principles of Surgery, *7th ed., New York: McGraw-Hill, 1999, p 1837. Copyright © The McGraw-Hill Companies, Inc.*)

the bolus is given within 8 hours of injury. The papers indicate greater motor and sensory recovery at 6 weeks, 6 months, and 1 year after acute SCI in patients who received methylprednisolone.[19,20] However, the NASCIS trial data have been extensively criticized, as many argue that the selection criteria and study design were flawed, making the results ambiguous. Patients who receive such a large corticosteroid dose have increased rates of medical and ICU complications, such as pneumonias, which have a deleterious effect on outcome. Thus, clear consensus on the use of spinal-dose steroids does not exist.[21] A decision to use or not use spinal-dose steroids may be dictated by local or regional practice patterns, especially given the legal liability issues surrounding SCI. Patients with gunshot or nerve root (cauda equina) injuries, or those who are pregnant, <14 years old, or on chronic steroids were excluded from the NASCIS studies and should not receive spinal-dose steroids. In addition to steroids, hypothermia for SCI has also received attention. There is even less evidence supporting the use of this treatment, and thus, it is not currently recommended.[22]

Orthotic Devices Rigid external orthotic devices can stabilize the spine by decreasing range of motion and minimizing stress transmitted through the spine. Commonly used rigid cervical orthoses include Philadelphia and Miami-J collars. Cervical collars are inadequate for C1, C2, or cervicothoracic instability. Cervicothoracic orthoses brace the upper thorax and the neck, improving stabilization over the cervicothoracic region. Minerva braces improve high cervical stabilization by bracing from the upper thorax to the chin and occiput. Halo-vest assemblies provide the most external cervical stabilization. Four pins are driven into the skull to lock the halo ring in position. Four posts arising from a tight-fitting rigid plastic vest immobilize the halo ring. Lumbar stabilization may be provided by thoracolumbosacral orthoses. A variety of companies manufacture lines of spinal orthotics. A physician familiar with the technique should fit a halo-vest. Assistance from a trained orthotics technician improves fitting and adjustment of the other devices.

Surgery Neurosurgical intervention has two goals. First is the decompression of the spinal cord or nerve roots in patients with incomplete neurologic deficits. These patients should be decompressed expeditiously, especially if there is evidence of neurologic deterioration over time. Second is the stabilization of injuries judged too unstable to heal with external immobilization only. Spine trauma patients with complete neurologic deficit, without any signs of recovery, or those without any neurologic deficits who have bony or ligamentous injury requiring open fixation, may be medically stabilized before undergoing surgery. Surgical stabilization may be indicated for some injuries that would eventually heal with conservative treatment. It also can allow early mobilization, aggressive nursing care, and physical therapy. Solid surgical stabilization may also allow a patient to be managed with a rigid cervical collar who would otherwise require halo-vest immobilization.

Continued Care. Regional SCI centers with nurses, respiratory therapists, pulmonologists, physical therapists, physiatrists, and neurosurgeons specifically trained in caring for these patients may improve outcomes. Frequently encountered ICU issues include hypotension and aspiration pneumonia. Chronically, prevention and treatment of deep venous thrombosis, autonomic hyperreflexia, and decubitus ulcer formation are important. Many patients with cervical or high thoracic cord injuries require prolonged ventilatory support until the chest wall becomes stiff enough to provide resistance for diaphragmatic breathing. Patients with high cervical cord injuries (C4 or above) will often require permanent ventilatory support. Patients should be transferred to SCI rehabilitation centers after stabilization of medical and surgical issues.

Peripheral Nerve Trauma

The peripheral nervous system extends throughout the body and is subject to injury from a wide variety of trauma. Peripheral nerves transmit motor and sensory information from the CNS to the body. An individual nerve may have pure motor, pure sensory, or mixed motor and sensory functions. The key information-carrying structure of the nerve is the axon. The axon transmits information from the neuronal cell body and may measure from <1 mm to >1 m in length. Axons that travel a significant distance are often covered with myelin, which is a lipid-rich, electrically insulating sheath formed by Schwann cells. Myelinated axons transmit signals much more rapidly than unmyelinated axons because the voltage shifts and currents that define action potentials effectively jump from gap to gap over the insulated lengths of the axon.

Axons, whether myelinated or unmyelinated, travel through a collagenous connective tissue known as *endoneurium*. Groups of axons and their endoneurium form bundles known as *fascicles*. Fascicles run through a tubular collagenous tissue known as *perineurium*. Groups of fascicles are suspended in mesoneurium. Fascicles and their mesoneurium run through another tubular collagenous tissue known as *epineurium*. The epineurium and its contents form the nerve.

There are four major mechanisms of injury to peripheral nerves. Nerves may be lacerated, stretched, compressed, or contused. Knives, passing bullets, or jagged bone fractures may lacerate nerves. Adjacent expanding hematomas or dislocated fractures may stretch nerves. Expanding hematomas, external orthoses such as casts or braces, or blunt trauma over a superficial nerve may compress or crush nerves. Shock waves from high-velocity bullets may contuse nerves. These mechanisms of injury cause damage to the various anatomic components of the nerve. The patterns of damage are categorized in Types of Injury section.

Certain nerve segments are particularly vulnerable to injury. The following four characteristics make a nerve segment more vulnerable: proximity to a joint, superficial course, passage through a confined space, and being fixed in position.

Types of Injury. The traditional classification system for peripheral nerve injury is the Seddon classification. Seddon described three injury patterns as defined in the Neurapraxia, Axonotmesis, and Neurotmesis sections. The Seddon classification provides a simple, anatomically based approach to peripheral nerve injury.[23]

Neurapraxia Neurapraxia is defined as the temporary failure of nerve function without physical axonal disruption. Axon degeneration does not occur. Return of normal axonal function occurs over hours to months, often in the 2- to 4-week range.

Axonotmesis Axonotmesis is the disruption of axons and myelin. The surrounding connective tissues, including endoneurium, are intact. The axons degenerate proximally and distally from the area of injury. Distal degeneration is known as *Wallerian degeneration*. Axon regeneration within the connective tissue pathways can occur, leading to restoration of function. Axons regenerate at a rate of 1 mm per day. Significant functional recovery may occur for up to 18 months. Scarring at the site of injury from connective tissue reaction can form a neuroma and interfere with regeneration.

Neurotmesis Neurotmesis is the disruption of axons and endoneurial tubes. Peripheral collagenous components, such as the epineurium, may or may not be intact. Proximal and distal axonal degeneration occurs. The likelihood of effective axonal regeneration across the site of injury depends on the extent of neuroma formation and on the degree of persisting anatomic alignment of the connective tissue structures. For instance, an injury may damage axons, myelin, and endoneurium, but leave perineurium intact. In this case, the fascicle sheath is intact, and appropriate axonal regeneration is more likely to occur than if the sheath is interrupted.

Management of Peripheral Nerve Injury. The sensory and motor deficits should be accurately documented. Deficits are usually immediate. Progressive deficit suggests a process such as an expanding hematoma and may warrant early surgical exploration. Clean, sharp injuries may also benefit from early exploration and reanastomosis. Most other peripheral nerve injuries should be observed. EMG/NCS studies should be done 3- to weeks postinjury if deficits persist. Axon segments distal to the site of injury will conduct action potentials normally until Wallerian degeneration occurs, rendering EMG/NCS before 3 weeks uninformative. Continued observation is indicated if function improves. Surgical exploration of the nerve may be undertaken if no functional improvement occurs over 3 months. If intraoperative electrical testing reveals conduction across the injury, continue observation. In the absence of conduction, the injured segment should be resected and end-to-end primary anastomosis attempted. However, anastomoses under tension will not heal. A nerve graft may be needed to bridge the gap between the proximal and distal nerve ends. The sural nerve often is harvested, as it carries only sensory fibers and leaves a minor deficit when resected. The connective tissue structures of the nerve graft may provide a pathway for effective axonal regrowth across the injury.

Patterns of Injury

Brachial Plexus The brachial plexus may be injured in a variety of ways. Parturition or a motorcycle accident can lead to plexus injury due to dislocation of the glenohumeral joint. Attempting to arrest a fall with one's hands can lead to a stretch injury of the plexus due to abrupt movement of the shoulder girdle. An apical lung (Pancoast) tumor can cause compression injury to the plexus. There are many patterns of neurologic deficits possible with injury to the various components of the brachial plexus, and understanding them all would require extensive neuroanatomic discussion. Two well-known eponymous syndromes are Erb's palsy and Klumpke's palsy. Injury high in the plexus to the C5 and C6 roots resulting from glenohumeral dislocation causes Erb's palsy with the characteristic "bellhop's tip" position. The arm hangs at the side, internally rotated. Hand movements are not affected. Injury low in the plexus, to the C8 and T1 roots, resulting from stretch or compression injury, causes Klumpke's palsy with the characteristic "claw hand" deformity. There is weakness of the intrinsic hand muscles, similar to that seen with ulnar nerve injury.

Radial Nerve The radial nerve courses through the axilla, then laterally and posteriorly in the spiral groove of the humerus. Improper crutch use can cause damage to the axillary portion. The section of the nerve traversing the spiral groove can be damaged by humerus fractures or pressure from improper positioning during sleep. This classically occurs when the patient is intoxicated and is called "Saturday night palsy." The key finding is wrist drop (i.e., weakness of hand and finger extensors). Axillary (proximal) injury causes triceps weakness in addition to wrist drop.

Common Peroneal Neuropathy The common peroneal nerve forms the lateral half of the sciatic nerve (the medial half being the tibial nerve). It receives contributions from L4, L5, S1, and S2. It emerges as a separate nerve in the popliteal fossa and laterally wraps around the fibular neck, after which it splits to form the deep and superficial peroneal nerves. The superficial, fixed location at the fibular neck makes the common peroneal nerve susceptible to compression. The classic cause of traumatic peroneal neuropathy is crush injury from a car bumper striking the lateral aspect of the leg at the knee. Symptoms of common peroneal neuropathy include foot drop (weakness of the tibialis anterior), eversion weakness, and numbness over the anterolateral surface of the lower leg and dorsum of the foot. In contrast, a foot drop due to L5 radiculopathy spares eversion because the S1 fibers are intact. Surgical exploration of a common peroneal crush lesion is typically a low yield endeavor. Rare cases may be due to compressive fibers or adhesions that may be lysed, with the possibility of return of function.

CEREBROVASCULAR DISEASE

Cerebrovascular disease is the most frequent cause of new, rapid-onset, nontraumatic neurologic deficit. It is far more common than seizures or tumors. Vascular structures are subject to a variety of chronic pathologic processes that compromise vessel wall integrity. Diabetes, high cholesterol, high blood pressure, and smoking are risk factors for vascular disease. These conditions can lead to vascular damage by such mechanisms as atheroma deposition causing luminal stenosis, endothelial damage promoting thrombogenesis, and weakening of the vessel wall resulting in aneurysm formation or dissection. These processes may coexist. For instance, a vessel containing an atheromatous plaque will have a decreased luminal diameter. The plaque also may have compromised endothelium, providing the opportunity for thrombus formation, which can lead to acute total occlusion of the remaining lumen. Aneurysms and dissection often occur in atheromatous vessels. Specific patterns of disease relevant to the cerebrovascular system include atheromatous and thrombotic carotid occlusion, brain ischemia from proximal embolic disease, vessel wall rupture leading to hemorrhage, and rupture of abnormal, thin-walled structures, specifically aneurysms and AVMs.

Ischemic Diseases

Ischemic stroke accounts for approximately 85% of acute cerebrovascular events. Symptoms of acute ischemic stroke vary based on the functions of the neural tissues supplied by the occluded vessel, and the presence or absence of collateral circulation. The circle of Willis provides extensive collateral circulation, as it connects the right and left carotid arteries to each other and each to the vertebrobasilar system. Patients with complete occlusion of the carotid artery proximal to the circle of Willis may be asymptomatic if the blood flow patterns can shift and provide sufficient circulation to the ipsilateral cerebral hemisphere from the contralateral carotid and the basilar artery. However, the anatomy of the circle of Willis is highly variable. Patients may have a hypoplastic or missing communicating artery with resultant bilateral ACA supply by one carotid; or the PCA may be supplied by the carotid artery rather than the basilar. Similarly, one vertebral artery is often dominant and the other is hypoplastic. These variations may make disease in a particular vessel more neurologically devastating than in a

patient with full collateral circulation. Occlusion distal to the circle of Willis generally results in a stroke in the territory supplied by that particular artery.

Neurologic deficit from occlusive disease may be temporary or permanent. A patient with sudden-onset focal neurologic deficit that resolves within 24 hours has had a transient ischemic attack. A patient with permanent deficit has had a completed stroke.

Thrombotic Disease

The most common area of neurologically significant vessel thrombosis is the carotid artery in the neck. Disease occurs at the carotid bifurcation. Thrombosis of a carotid artery chronically narrowed by atheroma can lead to acute carotid occlusion. As discussed previously, this can be asymptomatic. The more common concern is thromboembolus. Intracranial arterial occlusion by local thrombus formation may occur, but it is rare compared to embolic occlusion.

Management. Complete occlusion of the carotid artery without referable neurologic deficit requires no treatment. A patient with new neurologic deficit and an angiographically confirmed complete carotid occlusion contralateral to the symptoms should be considered for emergent carotid endarterectomy.[24] Surgery should be performed within 2 hours of symptom onset. This time restriction significantly reduces the number of candidates. Surgery should not be performed on obtunded or comatose patients. This time restriction significantly reduces the number of candidates.

Embolic Disease

Emboli causing strokes may originate from a number of sources, including: the left atrium, during atrial fibrillation, a hypokinetic left ventricular wall segment, valvular vegetations, an atheromatous aortic arch, stenotic/atheromatous carotid bifurcations, or from the systemic venous system in the presence of a right-to-left shunt, such as a patent foramen ovale. The majority of emboli enter the anterior (carotid) circulation rather than the posterior (vertebrobasilar) circulation. Characteristic clinical syndromes result from embolic occlusion of the various vessels.

Common Types of Strokes

Anterior Cerebral Artery Stroke The ACA supplies the medial frontal and parietal lobes, including the motor strip, as it courses into the interhemispheric fissure. ACA stroke results in contralateral leg weakness.

Middle Cerebral Artery Stroke The MCA supplies the lateral frontal and parietal lobes and the temporal lobe. MCA stroke results in contralateral face and arm weakness. Dominant-hemisphere MCA stroke causes language deficits. Proximal MCA occlusion with ischemia and swelling in the entire MCA territory can lead to significant intracranial mass effect and midline shift (see Fig. 42-6).

Posterior Cerebral Artery Stroke The PCA supplies the occipital lobe. PCA stroke results in a contralateral homonymous hemianopsia (see Fig. 42-6).

Posterior Inferior Cerebellar Artery Stroke The PICA supplies the lateral medulla and the inferior half of the cerebellar hemispheres. PICA stroke results in nausea, vomiting, nystagmus, dysphagia, ipsilateral Horner's syndrome, and ipsilateral limb ataxia. The constellation of symptoms resulting from PICA occlusion is referred to as the *lateral medullary* or *Wallenberg's syndrome*.

Management. Ischemic stroke management has two goals: reopen the occluded vessel and maintain blood flow to ischemic "penumbra" tissues bordering the vascular territory. Reopening the vessel may be attempted with recombinant tPA.[25] tPA administration within 3 hours of the onset of neurologic deficit improves outcome at 3 months. In the setting of suspected ischemic stroke, a head CT must be performed immediately to differentiate ischemic from hemorrhagic stroke. Intracranial hemorrhage, major surgery within the previous 2 weeks, GI or genitourinary hemorrhage in the previous 3 weeks, platelet count less than 100,000/μL, and systolic blood pressure >185 mmHg are among the contraindications to tPA therapy.

Patients not eligible for tPA require hemodynamic optimization and neurologic monitoring. Admit such patients to the ICU stroke service for blood pressure management and frequent neurologic checks. Permissive hypertension allows for maximal cerebral perfusion. Systolic blood pressure >180 mmHg may require treatment, but the optimal mean arterial pressure goal is between 100 to 140 mmHg. Give normal saline solution without glucose (which could injure neurons in the penumbra), and aim for normovolemia. A stroke patient who worsens clinically should undergo repeat head CT to evaluate for hemorrhage or increasing mass effect from swelling, which typically peaks 3 to 5 days after the stroke. Significant swelling from an MCA or cerebellar strokes may cause herniation and brain stem injury. A decompressive hemicraniectomy or suboccipital craniectomy can be a life-saving intervention for these select stroke patients.

Hemorrhagic Diseases

Intracranial hemorrhage from abnormal or diseased vascular structures accounts for approximately 15% of acute cerebrovascular events. Hypertension and amyloid angiopathy account for most intraparenchymal hemorrhages, although AVMs, aneurysms, venous thrombosis, tumors, hemorrhagic conversion of ischemic infarct, and fungal infections also may be the cause. The term *intracranial hemorrhage* frequently is used to mean intraparenchymal hemorrhage and will be used here. Intracranial hemorrhage causes local neuronal injury and dysfunction and also may cause global dysfunction due to mass effect if sufficiently large. AVM or aneurysm rupture results in SAH because the major cerebral and cortical blood vessels travel in the subarachnoid space, between the pia and the arachnoid membrane. SAH can cause immediate concussive-like neuronal dysfunction by exposure of the brain to intra-arterial pressure pulsations during the hemorrhage; it can cause delayed ischemia from cerebral arterial vasospasm. Patients presenting with intracranial hemorrhages that do not follow typical patterns should undergo angiography or MRI to evaluate for possible underlying lesions, such as AVM or tumor.

Hemorrhagic stroke typically occurs within the basal ganglia or cerebellum. The patient is usually hypertensive on admission and has a history of poorly controlled hypertension. Such patients are more likely to present with lethargy or obtundation, compared to those who suffer an ischemic stroke. Depressed mental status results from brain shift and herniation secondary to mass effect from the hematoma in deep structures. Ischemic stroke does not cause mass effect acutely; and therefore, patients are more likely to present with normal consciousness and a focal neurologic deficit. Hemorrhagic strokes tend to present with a relatively gradual decline in neurologic function as the hematoma expands, rather than the immediately maximal symptoms caused by ischemic stroke. Table 42-3 provides a

Table 42-3

Anatomic distribution of intracranial hemorrhages and correlated symptoms

% OF INTRACRANIAL HEMORRHAGES	LOCATION	CLASSIC SYMPTOMS
50	Basal ganglia (putamen, globus pallidus), internal capsule	Contralateral hemiparesis
15	Thalamus	Contralateral hemisensory loss
10–20	Cerebral white matter (lobar)	Depends on location (weakness, numbness, partial loss of visual field)
10–15	Pons	Hemiparesis; may be devastating
10	Cerebellum	Lethargy or coma due to brain stem compression and/or hydrocephalus
1–6	Brain stem (excluding pons)	Often devastating

listing of relative incidences of intracranial hemorrhage by anatomic distribution

Hypertension. Hypertension increases the relative risk of intracranial hemorrhage by approximately fourfold, likely due to chronic degenerative vasculopathy. Hypertensive hemorrhages often present in the basal ganglia, thalamus, or pons, and result from breakage of small perforating arteries that branch off of much larger parent vessels (Fig. 42-15).

Most hypertensive hemorrhages should be medically managed. The hematoma often contains intact, salvageable axons because the blood dissects through and along neural tracts, and surgical clot evacuation destroys these axons. Factors potentially favoring surgery include: superficial clot location, young age, nondominant hemisphere, rapid deterioration, and significant mass effect. However, the most comprehensive randomized clinical trials to date did not show an overall improved outcome in surgically evacuated intracranial hemorrhage, except for the subgroup of patients with clot <1 cm from the cortical surface.[26] Medical management includes moderate blood pressure control, normalizing platelet and clotting function, phenytoin, and electrolyte management. Intubate patients who cannot clearly follow commands to prevent aspiration and hypercarbia. Follow and

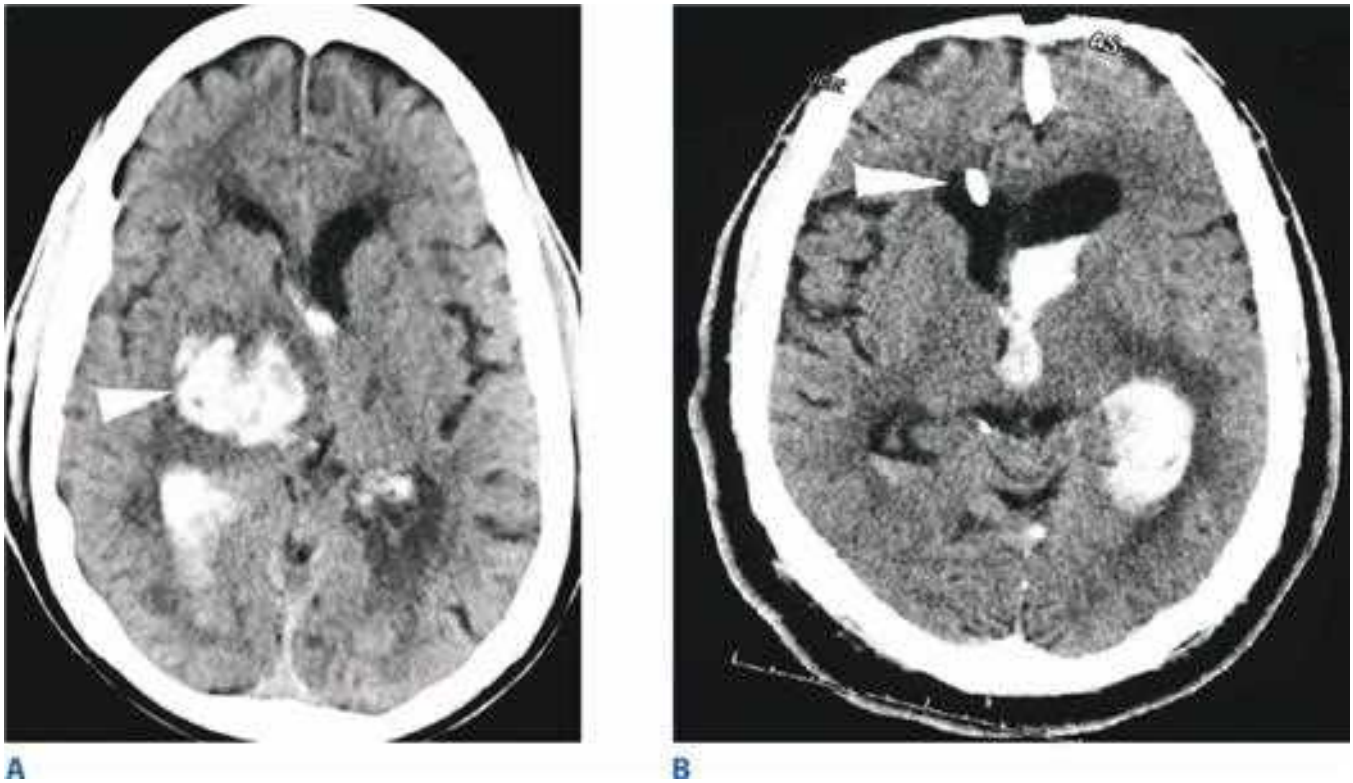

Figure 42-15. **A.** Head computed tomography scan of a patient with left-sided weakness and progressive lethargy reveals a right basal ganglia hemorrhage (*arrowhead*). The blood clot is bright white. Hypodensity around the clot represents cerebral edema. There is blood within the ventricular system. **B**. Another patient with intraventricular extension of a basal ganglia hemorrhage. The patient developed right-sided weakness and then lethargy. Head computed tomography indicated hydrocephalus. A ventriculostomy was placed for cerebrospinal fluid drainage (*arrowhead* indicates cross-sectional view of the catheter entering the anterior horn of the right lateral ventricle).

document the neurologic examination and communicate with the family regarding appropriateness for rehabilitation vs withdrawal of care.

Amyloid Angiopathy. The presence of pathologic amyloid deposition in the media of small cortical vessels compromises vessel integrity and tends to cause more superficial (lobar) hemorrhages than hypertensive intracranial hemorrhage. Amyloid laden vessels may hemorrhage multiple times. The superficial location of amyloid hemorrhages may make surgical evacuation less morbid compared to typical deep hypertensive hemorrhages. Nonetheless, medical management and family counseling should be approached similarly to patients with hypertensive hemorrhages.

Cerebral Aneurysm. An aneurysm is a focal dilatation of the vessel wall and is most often a balloon-like outpouching, but may also be fusiform. Aneurysms usually occur at branch points of major vessels (e.g., internal carotid artery bifurcation), or at the origin of smaller vessels (e.g., posterior communicating artery or ophthalmic artery). Approximately 85% of aneurysms arise from the anterior circulation (carotid) and 15% from the posterior circulation (vertebrobasilar). Table 42-4 shows the percentage distribution of cerebral aneurysms by location. Aneurysms are thin walled and at risk for rupture. The major cerebral vessels, and therefore aneurysms, lie in the subarachnoid space. Rupture results in SAH. The aneurysmal tear may be small and seal quickly, or it may not. SAH may consist of a thin layer of blood in the CSF spaces, or thick layers of blood around the brain and extending into brain parenchyma, resulting in a clot with mass effect. Because the meningeal linings of the brain are sensitive, SAH usually results in a sudden, severe "thunderclap" headache. A patient will classically describe "the worst headache of my life." Presenting neurologic symptoms may range from mild headache to coma to sudden death. The Hunt-Hess grading system categorizes patients clinically (Table 42-5).

Patients with symptoms suspicious for SAH should have a head CT immediately. Acute SAH appears as a bright signal in the fissures and CSF cisterns around the base of the brain, as shown in Fig. 42-16. CT is rapid, noninvasive, and approximately 95% sensitive. In patients with suspicious symptoms but negative head CT, a lumbar puncture (LP) should be performed. An LP with xanthochromia and high red blood cell counts (usually 100,000/mL), which do not decrease between tubes 1 and 4, is consistent with SAH. Negative CT and LP essentially rules out SAH. Patients diagnosed with SAH

Table 42-4

Prevalence of cerebral aneurysm by location

PREVALENCE	ANEURYSM LOCATION (VERNACULAR NAME)
Anterior circulation 85%	30% Anterior communicating artery (A-Comm)
	25% Posterior communicating artery (P-Comm)
	20% Middle cerebral artery bifurcation
	10% Other
Posterior circulation 15%	10% Basilar artery, most frequently at the basilar tip
	5% Vertebral artery, usually at the posterior inferior cerebellar artery

Table 42-5

The Hunt-Hess clinical grading system for subarachnoid hemorrhage

HUNT-HESS GRADE	CLINICAL PRESENTATION
0	Asymptomatic; unruptured aneurysm
1	Awake; asymptomatic or mild headache; mild nuchal rigidity
2	Awake; moderate to severe headache, cranial nerve palsy (e.g., cranial nerve III or IV), nuchal rigidity
3	Lethargic; mild focal neurologic deficit (e.g., pronator drift)
4	Stuporous; significant neurologic deficit (e.g., hemiplegia)
5	Comatose; posturing

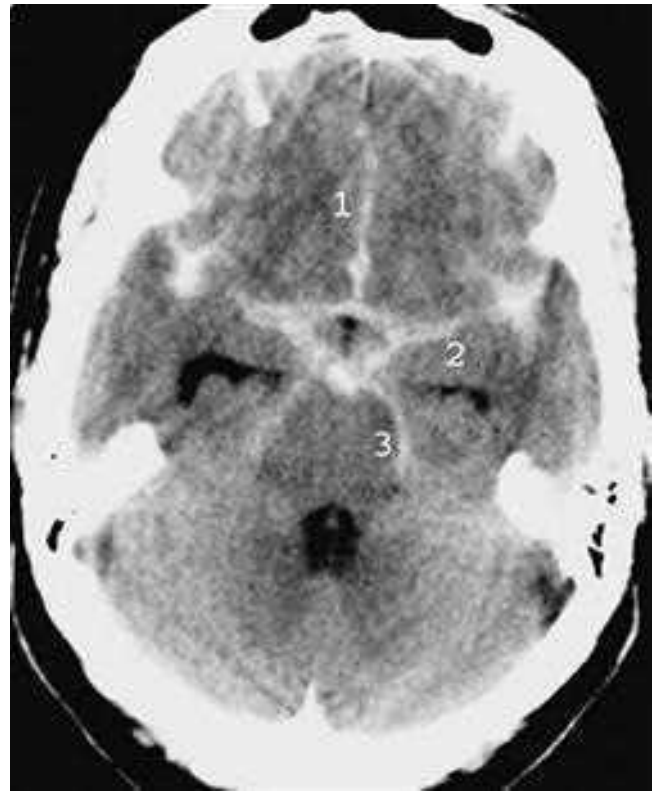

Figure 42-16. Head computed tomography scan of a patient who experienced a sudden, severe headache. Subarachnoid hemorrhage is visible as hyperdense signal in the interhemispheric fissure (*1*), bilateral sylvian fissures (*2* shows the left fissure), and in the ambient cisterns around the midbrain (*3*). This gives the classic five-pointed-star appearance of a subarachnoid hemorrhage. Visible temporal tips of the lateral ventricles indicate hydrocephalus.

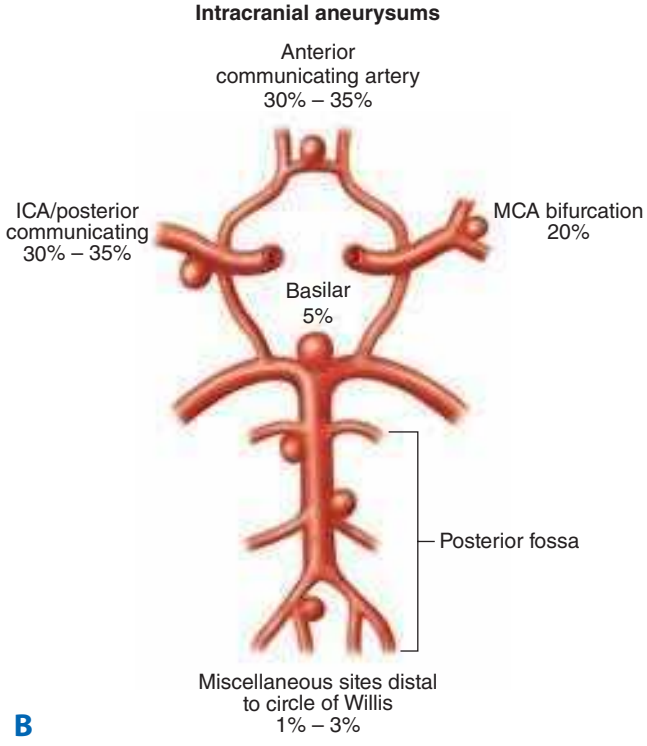
require four-vessel cerebral angiography within 24 hours to assess for aneurysm or other vascular malformation. Catheter angiography remains the gold standard for assessing the patient's cerebral vasculature, relevant anomalies, and presence, location, and morphology of the cerebral aneurysms. Figure 42-17A demonstrates the typical anteroposterior digital subtraction angiographic view of a cerebral aneurysm. Figure 42-17B shows the anatomy of the circle of Willis in a simplified graphic representation to assist in visualizing the locations of various cerebral aneurysms.

A



B

Figure 42-17. **A.** Anteroposterior view after injection of contrast dye in the right internal carotid artery demonstrates an aneurysm of the middle cerebral artery bifurcation. **B.** Figure depicting the anatomy of the circle of Willis and the common sites for aneurysms. St. Louis: Mosby-Year Book, Inc., 1991, p 81. Copyright Elsevier.*)

SAH patients should be admitted to the neurologic ICU. Hunt-Hess grade 4 and 5 patients require intubation and hemodynamic monitoring and stabilization. The current standard of care for ruptured aneurysms requires early aneurysmal occlusion. There are two options for occlusion. The patient may undergo craniotomy with microsurgical dissection and placement of a titanium clip across the aneurysm neck to exclude the aneurysm from the circulation and reconstitute the lumen of the parent vessel. The second option is to "coil" the aneurysm via an endovascular approach. The patient is taken to the interventional neuroradiology suite for placement of looped titanium coils inside the aneurysm dome. The coils support thrombosis and prevent blood flow into the aneurysm. Factors favoring craniotomy and clipping include young age, good medical condition, and broad aneurysm necks. Factors favoring coiling include age, medical comorbidities, and narrow aneurysm necks. Due to coil migration or compaction over time, surgical clipping is believed to result in a more definitive cure. The decision to clip or coil is complex and should be fully explored. The International Subarachnoid Aneurysm Trial researchers suggested that endovascular occlusion resulted in better outcomes for certain types of cerebral aneurysms, although this trial was marred by poor selection and randomization techniques, and the validity of its conclusions have been questioned.[27] Long-term outcomes may be better in younger patients with clipped aneurysms.[28] Debate also continues regarding optimal care for unruptured intracranial aneurysms.[29]

SAH patients often require 1 to 3 weeks of ICU care after aneurysm occlusion for medical complications that accompany neurologic injury. In addition to routine ICU concerns, SAH patients are also at risk for cerebral vasospasm. In vasospasm, cerebral arteries constrict pathologically and can cause ischemia or stroke from 4 to 21 days after SAH. Current vasospasm prophylaxis includes maintenance of optimal perfusion with hypertension and mild hypervolemia, as well as administration of nimodipine, a calcium channel blocker that may decrease the incidence and degree of spasm. Neurointerventional options for treating symptomatic vasospasm include intra-arterial papaverine or nicardipine, and balloon angioplasty for larger caliber vessels.

Aneurysmal SAH has an approximate mortality rate of 50% in the first month. Approximately one-third of survivors return to pre-SAH function, and the remaining two thirds have mild to severe disability. Most require rehabilitation after hospitalization.

4▶

Arteriovenous Malformations. AVMs are abnormal, dilated arteries and veins without an intervening capillary bed. The nidus of the AVM contains a tangled mass of vessels but no neural tissue. AVMs may be asymptomatic or present with SAH, intraparenchymal hemorrhage, or seizures. Small AVMs present with hemorrhage more often than large AVMs, which tend to present with seizures. Headache, bruit, or focal neurologic deficits are less common symptoms. AVMs hemorrhage at an average rate of 2% to 4% a year. Figure 42-18 demonstrates the angiographic appearance of an AVM in arterial and venous phases.

There are several management differences for intracranial hemorrhage due to AVM vs. aneurysm. Definitive therapy for the AVM usually is delayed 3 to 4 weeks to allow the brain to recover from acute injury. There is less risk of devastating early rebleeding from AVMs, and vasospasm is much less common. Three therapeutic modalities for AVMs are currently in common use: microsurgical excision, interventional radiology or endovascular embolization, and stereotactic radiosurgery

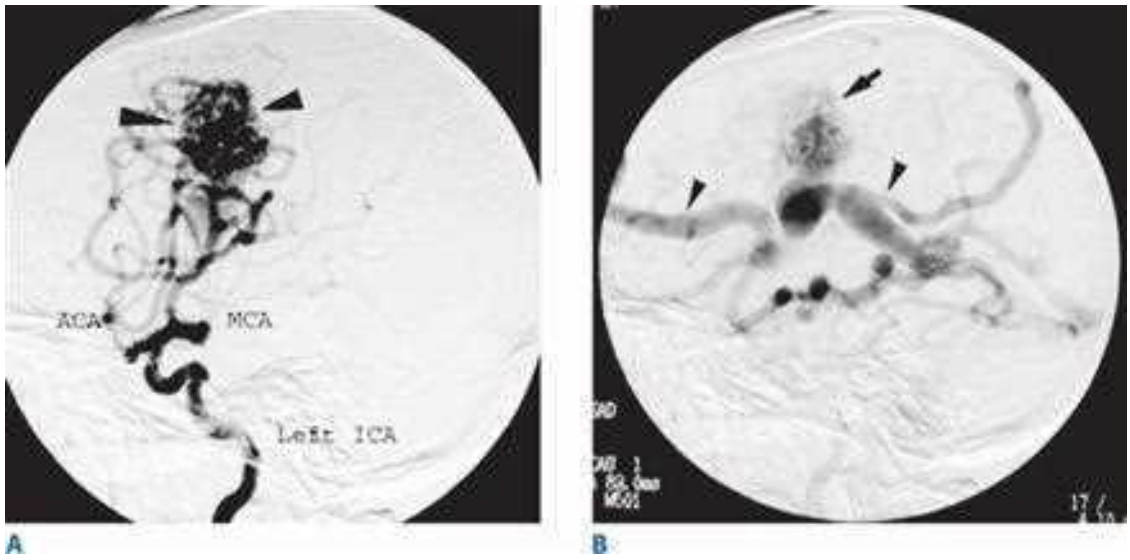


Figure 42-18. **A.** Lateral view after injection of contrast dye in the left internal carotid artery demonstrates a 3 × 4 cm left frontal arteriovenous malformation indicated by *arrowheads*. This image was taken 1.06 seconds after dye injection, and is referred to as an *arterial phase image*. **B.** Same view taken 4.10 seconds after dye injection, providing a *venous phase image*. The *arrow* points to the arteriovenous malformation nidus. The *arrowheads* indicate two pathologically enlarged draining veins. ACA = anterior cerebral artery; ICA = internal carotid artery; MCA = middle cerebral artery.

(SRS). AVMs that are large, near eloquent cortex, or that drain to deep venous structures are considered high grade and more difficult to surgically resect without causing a significant neurologic deficit. Radiosurgery can treat these lesions, although it is limited to lesions <3 cm in diameter and has a 2-year lag time (i.e., the AVM may bleed in the interval). Embolization reduces flow through the AVM. It is usually considered adjunctive therapy, but it may serve as the sole treatment for deep, inaccessible lesions.

TUMORS OF THE CENTRAL NERVOUS SYSTEM

A wide variety of tumors affect the brain and spine. Primary benign and malignant tumors arise from the various elements of the CNS, including neurons, glia, and meninges . Tumors metastasize to the CNS from many primary sources. Presentation 5▶ varies widely depending on relevant neuroanatomy. Prognosis depends on histology and anatomy. Modern brain tumor centers use team approaches to CNS tumors, as patients may require a combination of surgery, radiation therapy, chemotherapy, SRS, and research protocol enrollment. Tumors affecting the peripheral nervous system are discussed in the Peripheral Nerve section.

Intracranial Tumors

Intracranial tumors can cause brain injury from mass effect, dysfunction or destruction of adjacent neural structures, swelling, or abnormal electrical activity (seizures). Supratentorial tumors commonly present with focal neurologic deficit, such as contralateral limb weakness, visual field deficit, headache, or seizure. Infratentorial tumors often cause increased ICP due to hydrocephalus from compression of the fourth ventricle, leading to headache, nausea, vomiting, or diplopia. Cerebellar hemisphere or brain stem dysfunction can result in ataxia, nystagmus, or cranial nerve palsies. Infratentorial tumors rarely cause seizures.

All patients with symptoms concerning for brain tumor should undergo MRI with and without gadolinium. Initial management of a patient with a symptomatic brain tumor generally includes dexamethasone for reduction of vasogenic edema and phenytoin if the patient has seized. Patients with significant weakness, lethargy, or hydrocephalus should be admitted for observation until definitive care is administered.

Metastatic Tumors

Prolonged cancer patient survival and improved CNS imaging have increased the likelihood of diagnosing cerebral metastases. The sources of most cerebral metastases are (in decreasing frequency): lung, breast, kidney, GI tract, and melanoma. Lung and breast cancers account for more than half of cerebral metastases. Metastatic cells usually travel to the brain hematogenously and frequently seed the gray-white junction. Other common locations are the cerebellum and the meninges. Meningeal involvement may result in carcinomatous meningitis, also known as *leptomeningeal carcinomatosis*. MRI pre- and postcontrast administration is the study of choice for evaluation. Figure 42-19 demonstrates bilateral cerebellar metastases. These lesions are typically well circumscribed, round, and multiple. Such findings should prompt a metastatic work-up, including CT scan of the chest, abdomen, and pelvis, and a bone scan.

Management largely depends upon the primary tumor, overall tumor burden, patient's medical condition, and location and number of metastases. The beliefs of the patient and family regarding aggressive care must be considered. Craniotomy plus whole-brain radiation therapy (WBRT) or stereotactic radiosurgery (SRS) to the tumor bed has been shown to benefit patients with a single surgically accessible metastatic lesion, compared to radiation therapy alone. Median survival increased from 15 to 40 weeks in one randomized trial.[30] Postoperative radiotherapy may not increase overall survival but it does significantly reduce original lesion recurrence.[31] Studies do not support craniotomy unless all detectable metastases can be resected. Recent data suggest that SRS (e.g., gamma knife) may be applied to multiple metastases in one session with improved outcome.[32]

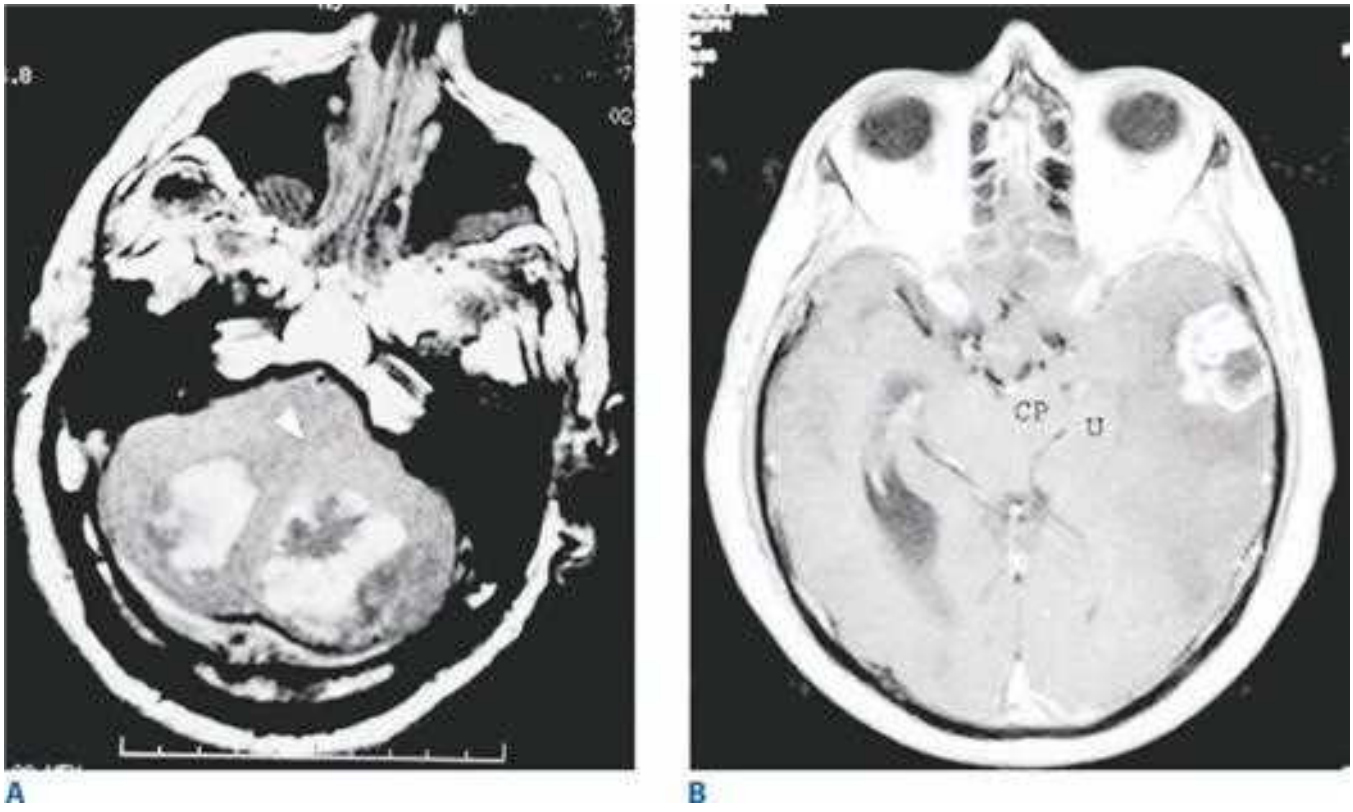

Figure 42-19. **A**. Precontrast T1-weighted axial magnetic resonance imaging demonstrating bilateral hemorrhagic cerebellar metastases. Patient presented with ataxia and then lethargy progressing to deep coma. This patient has total effacement of the fourth ventricle and severe brain stem compression. The fourth ventricle cerebrospinal fluid space should be at the tip of the *arrowhead*. Patient recovered to normal mental status after emergent posterior fossa craniotomy. **B**. Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a ring-enhancing lesion in the lateral left temporal lobe with moderate edema. The uncus (*U*) is compressing the left cerebral peduncle (*CP*) and displacing the brain stem to the right.

Glial Tumors

Glial cells provide the anatomic and physiologic support for neurons and their processes in the brain. The several types of glial cells give rise to distinct primary CNS neoplasms.

Astrocytoma. Astrocytoma is the most common primary CNS neoplasm. The term *glioma* often is used to refer to astrocytomas specifically, excluding other glial tumors. Astrocytomas are graded from I to IV. Grades I and II are referred to as low-grade astrocytoma, grade III as anaplastic astrocytoma, and grade IV as glioblastoma multiforme (GBM). Prognosis varies significantly between grades I/II, III, and IV, but not between I and II. Median survival is 8 years after diagnosis with a low-grade tumor, 2 to 3 years with an anaplastic astrocytoma, and roughly 1 year with a GBM. GBMs account for almost two-thirds of all astrocytomas, anaplastic astrocytomas account for two-thirds of the rest, and low-grade astrocytomas the remainder. Figure 42-20 demonstrates the typical appearance of a GBM.

The great majority of astrocytomas infiltrate adjacent brain. Juvenile pilocytic astrocytomas and pleomorphic xanthoastrocytomas are exceptions. These tumors are circumscribed, low grade, and associated with a good prognosis. Histologic features associated with higher grade include hypercellularity, nuclear atypia, and endovascular hyperplasia. Necrosis is present only with GBMs; it is required for the diagnosis.

Gross total resection should be attempted for suspected astrocytomas. Motor cortex, language centers, deep or midline structures, or brain stem location may make this impossible without unacceptable, devastating neurologic deficit. Such lesions may be limited to stereotactic needle biopsy specimen. Gross total resection followed by radiation therapy improves survival for all grades, although radiation therapy may be delayed until recurrence in low-grade tumors. Chemotherapy such as temozolomide is of limited efficacy and typically is reserved for GBM. There are various ongoing research studies for GBM adjuvant therapy; these should be discussed with the patient and family. Other options include Iotrex-containing balloons for conformal radiation brachytherapy (Glia-Site), placed in the resection cavity at the time of surgery for recurrence. Adjuvant therapy remains marginally effective; survival has changed little over the last several decades.

Oligodendroglioma. Oligodendroglioma accounts for approximately 10% of gliomas. They often present with seizures. Calcifications and hemorrhage on CT or MRI suggest the diagnosis. Oligodendrogliomas are also graded from I to IV; grade portends prognosis. Prognosis is better overall than for astrocytomas. Median survival ranges from 2 to 7 years for highest and lowest grade tumors, respectively. Aggressive resection improves survival. Many oligodendrogliomas will respond to procarbazine, lomustine (CCNU), vincristine (PCV) chemotherapy. A particular chromosomal deletion, 1p19q, has been associated with robust response to the chemotherapeutic agent temozolomide. Radiation has not been clearly shown to prolong survival.

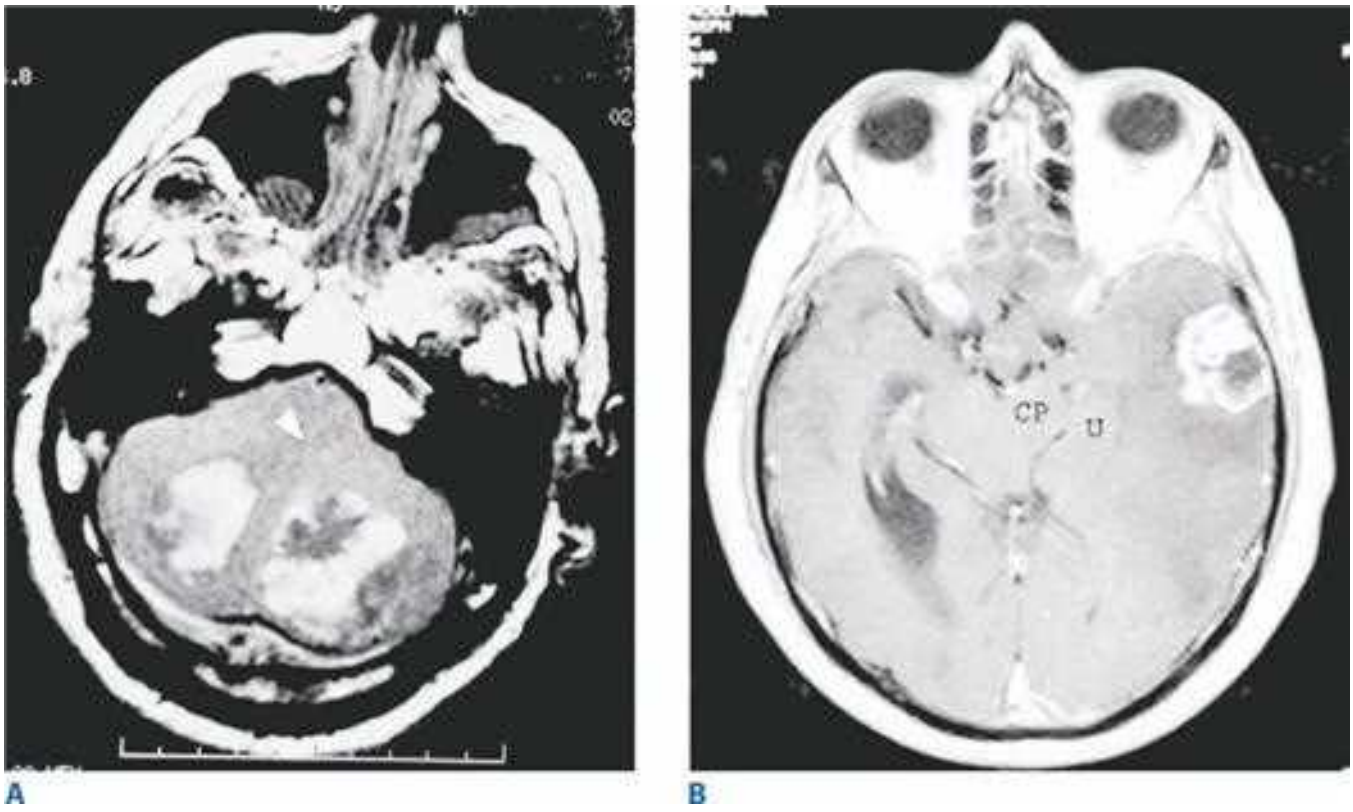

Figure 42-20. **A**. Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a ring-enhancing lesion in the anteromedial right temporal lobe with central necrosis (*dark area*) consistent with glioblastoma multiforme. **B**. T2-weighted axial magnetic resonance imaging with extensive bright signal signifying peritumoral edema seen with glioblastoma multiformes.

Ependymoma. The lining of the ventricular system consists of cuboidal/columnar ependymal cells from which ependymomas may arise. Although most pediatric ependymomas are supratentorial, two- thirds of adult ependymomas are infratentorial. Supratentorial ependymomas arise from the lateral or third ventricles. The infratentorial tumors arise from the floor of the fourth ventricle (i.e., off the posterior brain stem). The most common symptoms are headache, nausea, vomiting, or vertigo, secondary to increased ICP from obstruction of CSF flow through the fourth ventricle. The tumors may grow out the foramina of Luschka to form a cerebellopontine angle mass. They may also spread through the CSF to form "drop mets" in the spinal canal. The two main histologic subtypes are papillary and anaplastic, the latter characterized by increased mitotic activity and areas of necrosis. Gross total resection often is impossible because the tumor arises from the brain stem. The goal of surgery is to achieve maximal resection without injuring the very delicate brain stem. Suboccipital craniotomy and midline separation of the cerebellar hemispheres allows access to tumors in the fourth ventricle. Postoperative radiation therapy significantly improves survival. Patients with CSF spread documented by LP or contrast MRI should also have whole-spine radiation plus focused doses to visualized metastases.

Choroid Plexus Papilloma. The choroid plexus is composed of many small vascular tufts covered with cuboidal epithelium. It represents part of the interface between blood and brain. The choroid cells create CSF from blood and release it into the ventricular system. Choroid plexus papillomas and choroid plexus carcinomas (rare, mostly pediatric) may arise from these cells. Papillomas usually occur in infants (typically supratentorial in the lateral ventricle) but also occur in adults (usually infratentorial in the fourth ventricle). Papillomas are well circumscribed and vividly enhance due to extensive vasculature. Like ependymomas, adult choroid plexus papillomas usually present with symptoms of increased ICP. Treatment is surgical excision. Total surgical excision is curative; recurrent papillomas should be re-resected. Radiation or chemotherapy are not indicated for papillomas. Radiation is adjunctive to aggressive surgery for carcinomas, but the results are generally poor.

Neural Tumors and Mixed Tumors

Neural and mixed tumors are a diverse group that includes tumors variously containing normal or abnormal neurons and/or normal or abnormal glial cells. Primitive neuroectodermal tumors arise from bipotential cells, capable of differentiating into neurons or glial cells.

Medulloblastoma. Primitive neuroectodermal tumor is the most common type of medulloblastoma. Most occur in the first decade of life, but there is a second peak around age 30. Medulloblastoma is the most common malignant pediatric brain tumor. They are usually midline. Most occur in the cerebellum and present with symptoms of increased ICP. Histologic characteristics include densely packed small round cells with large nuclei and scant cytoplasm. They are generally not encapsulated, frequently disseminate within the CNS, and should undergo surgical resection followed by radiation therapy and chemotherapy.

Ganglioglioma. Ganglioglioma is a mixed tumor in which both neurons and glial cells are neoplastic. They occur in the first three decades of life, often in the medial temporal lobe, as circumscribed masses that may contain cysts or calcium and may enhance. The presenting symptom is usually a seizure, due to the medial temporal location. Patients have a good prognosis after complete surgical resection.

Neural Crest Tumors

Multipotent neural crest cells develop into a variety of disparate cell types, including smooth muscle cells, sympathetic and parasympathetic neurons, melanocytes, Schwann cells, and arachnoid cap cells. They migrate in early development from the primitive neural tube throughout the body.

Miscellaneous Tumors

Meningioma. Meningiomas are derived from arachnoid cap cells of the arachnoidea mater. They appear to arise from the dura mater grossly and on MRI and are commonly referred to as *dural-based tumors*. The most common intracranial locations are along the falx (Fig. 42-21), the convexities (i.e., over the cerebral hemispheres), and the sphenoid wing. Less common locations include the foramen magnum, olfactory groove, and inside the lateral ventricle. Most are slow growing, encapsulated, benign tumors. Aggressive atypical or malignant meningiomas may invade adjacent bone or cerebral cortex. Previous cranial irradiation increases the incidence of meningiomas. Approximately 10% of patients with a meningioma have multiple meningiomas. Total resection is curative, although involvement with small perforating arteries or cranial nerves may make total resection of skull base tumors impossible without significant neurologic deficit. Small, asymptomatic meningiomas can be followed until symptomatic or until significant growth is documented on serial imaging studies. Atypical and malignant meningiomas may require postoperative radiation. Patients may develop recurrences from the surgical bed or distant de novo tumors.

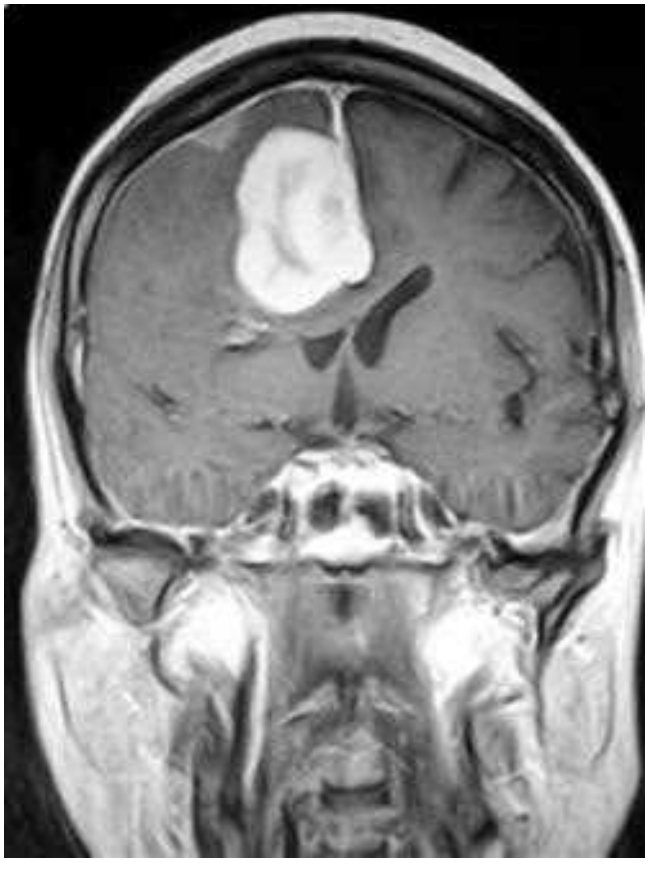

Figure 42-21. Postcontrast T1-weighted coronal magnetic resonance imaging demonstrating a brightly enhancing lesion arising from the falx cerebri with moderate edema and mass effect on the right lateral ventricle. This is a falcine meningioma. Note also the small separate meningioma arising from the dura over the cerebral convexity.

Vestibular Schwannoma (Acoustic Neuroma). Vestibular schwannomas predominantly arise from the superior half of the vestibular portion of the vestibulocochlear nerve (cranial nerve VIII) (Fig. 42-22). Commonly, patients present with progressive hearing loss, tinnitus, or balance difficulty. Large tumors may cause brain stem compression and obstructive hydrocephalus. Bilateral acoustic neuromas are pathognomonic for neurofibromatosis type 2 (NF2), a syndrome resulting from mutation of chromosome 22. NF2 patients have an increased incidence of spinal and cranial meningiomas and gliomas.

Vestibular schwannomas may be treated with microsurgical resection or SRS (gamma knife or linear accelerator technology). The main complication with treatment is damage to the facial nerve (cranial nerve VII), which runs through the internal auditory canal with the vestibulocochlear nerve. Risk of facial nerve dysfunction increases with increasing tumor diameter.

Pituitary Adenoma. Pituitary adenomas arise from the anterior pituitary gland (adenohypophysis). Tumors <1 cm diameter are considered microadenomas; larger tumors are macroadenomas. Pituitary tumors may be functional (i.e., secrete endocrinologically active compounds at pathologic levels) or nonfunctional (i.e., secrete nothing or inactive compounds). Functional tumors are often diagnosed when quite small, due to endocrine dysfunction. The most common endocrine syndromes are Cushing's disease, due to adrenocorticotropic hormone secretion, Forbes-Albright syndrome, due to prolactin secretion, and acromegaly, due to growth hormone secretion. Nonfunctional tumors are typically diagnosed as larger lesions causing mass effects such as visual field deficits due to compression of the optic chiasm or panhypopituitarism due to compression of the gland. Figure 42-23 demonstrates a large pituitary adenoma. Hemorrhage into a pituitary tumor causes abrupt symptoms of headache, visual disturbance, decreased mental status, and endocrine dysfunction. This is known as *pituitary apoplexy*.

Symptomatic pituitary tumors should be decompressed surgically to eliminate mass effect and/or to attempt an endocrine cure. However, prolactin-secreting tumors (prolactinomas) usually shrink with dopaminergic therapy alone, namely bromocriptine, which inhibits production and secretion of prolactin. Consider surgery for prolactinomas with persistent mass effect or endocrinologic dysfunction in spite of adequate dopamine agonist therapy. Most pituitary tumors are approached through the nose via the transsphenoidal approach, and minimally invasive, endoscopic surgical techniques are being used increasingly.

Hemangioblastoma. Hemangioblastomas occur almost exclusively in the posterior fossa,with about 20% occuring in patients with von Hippel-Lindau (VHL) disease, a multisystem neoplastic disorder. Other tumors associated with VHL are renal cell

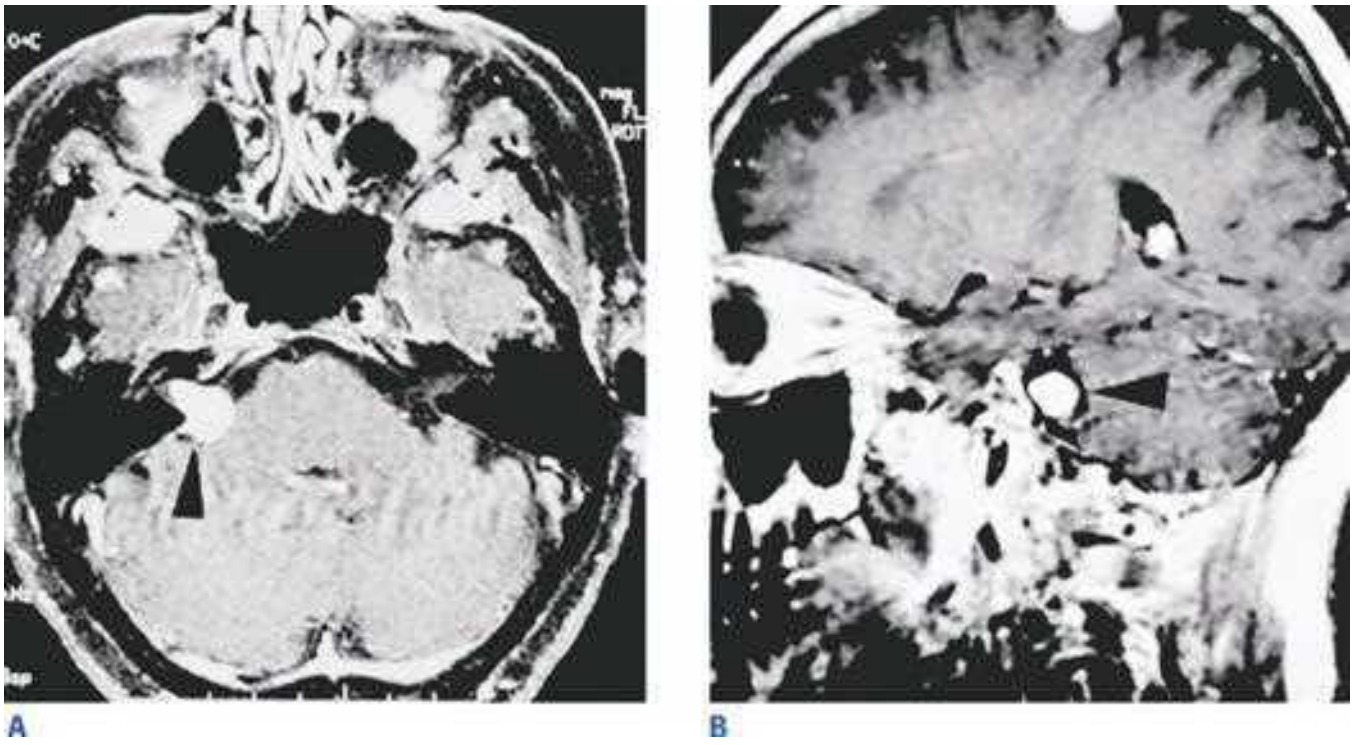

Figure 42-22. **A**. Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a brightly enhancing mass on the right vestibular nerve with an enhancing tail going into the internal auditory canal (*arrowhead*). Pathology demonstrated vestibular schwannoma. **B**. Postcontrast T1-weighted sagittal magnetic resonance imaging of the same lesion, indicated by the *arrowhead*. Note small incidental meningioma at the top of the scan.

Figure 42-23. Postcontrast T1-weighted sagittal magnetic resonance imaging demonstrating a large sellar/suprasellar lesion (*arrowheads*) involving the third ventricle superiorly and abutting the midbrain and pons posteriorly. The patient presented with progressive visual field and acuity loss. Pathology and lab work revealed a nonfunctioning pituitary adenoma.

carcinoma, pheochromocytoma, and retinal angiomas. Many appear as cystic tumors with an enhancing tumor on the cyst wall known as the *mural nodule*. Surgical resection is curative for sporadic (non-VHL associated) tumors. Pathology reveals abundant thin-walled vascular channels; internal debulking may be bloody. En bloc resection of the mural nodule alone, leaving the cyst wall, is sufficient.

Lymphoma. CNS lymphoma may arise either primarily in the CNS or secondarily from systemic disease. Recent rising incidence may be due to growing transplant and AIDS populations. Presenting symptoms include mental status changes, headache due to increased ICP, and cranial nerve palsy due to lymphomatous meningitis (analogous to carcinomatous meningitis). Often, lymphoma appears hyperdense on CT due to dense cellularity, and most lesions typically enhance with contrast. Surgical excision is not indicated. A stereotactic needle biopsy specimen usually confirms the diagnosis. Subsequent treatment includes steroids, whole-brain radiation, and chemotherapy. Intrathecal methotrexate is an option.

Embryologic Tumors

Embryologic tumors result from embryonal remnants that fail to involute completely or differentiate properly during development.

Craniopharyngioma. Craniopharyngiomas are benign cystic lesions that occur most frequently in children. There is a second peak of incidence around 50 years of age. Calcification occurs in all pediatric and roughly half of adult craniopharyngiomas. Symptoms result from compression of adjacent structures, especially the optic chiasm. Pituitary or hypothalamic dysfunction or hydrocephalus may develop. Treatment is primarily surgical. Excision is somewhat easier in children, as the tumor is often soft and easily suctioned. Adult tumors are often firm and adherent to adjacent vital structures. Visual loss, pituitary endocrine

hypofunction, diabetes insipidus, and cognitive impairment from basal frontal injury are common complications.

Epidermoid. Epidermoid tumors are cystic lesions with stratified squamous epithelial walls from trapped ectodermal cell rests that grow slowly and linearly by desquamation into the cyst cavity. The cysts contain keratin, cholesterol, and cellular debris (Fig. 42-24). They occur most frequently in the cerebellopontine angle and may cause symptoms due to brain stem compression. Recurrent bouts of aseptic meningitis may occur due to release of irritative cyst contents into the subarachnoid space (Mollaret's meningitis). Treatment is surgical drainage and removal of the cyst wall. Intraoperative spillage of cyst contents may lead to severe chemical meningitis and must be avoided by containment and aspiration.

Dermoid. Dermoids are less common than epidermoid tumors. They contain hair follicles and sebaceous glands in addition to a squamous epithelium. Dermoids may be found anywhere along the craniospinal axis. They are more commonly midline structures and are associated with more anomalies than epidermoids. They may be associated with trauma, as from a lumbar puncture that drags skin structures into the spine. Bacterial meningitis may occur when dermoids are associated with a dermal sinus tract. Treatment of symptomatic lesions is surgical resection, again with care to control cyst contents.

Teratoma. Teratomas are germ cell tumors that arise in the midline, often in the pineal region (the area behind the third ventricle, above the midbrain and cerebellum). They contain elements from all three embryonal layers: ectoderm, mesoderm, and endoderm. Teratomas may contain skin, cartilage, GI glands, and teeth. Teratomas with more primitive features are more malignant, while those with more differentiated tissues are more benign. Surgical excision may be attempted. However, the prognosis for malignant teratomas is very poor.

Figure 42-24. Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a nonenhancing mass in the left cerebellopontine angle with brain stem compression. *White arrowhead* indicates interface of tumor and brain stem. *Black arrowhead* indicates deformed fourth ventricle. Pathology revealed epidermoid tumor.

Spinal Tumors

A wide variety of tumors affect the spine. Approximately 20% of CNS tumors occur in the spine. Unlike cranial tumors, the majority of spinal tumors are histologically benign. Understanding two major spinal concepts—stability and neural compression—facilitates an understanding of the effects of spinal tumors. Destruction of bones or ligaments can cause spinal instability, leading to deformities such as kyphosis, subluxation, or possible subsequent neural compression. Tumor growth in the spinal canal or neural foramina can cause direct compression of the spinal cord or nerve roots and cause pain and loss of function. Classically, the pain is worse at night. Anatomic categorization provides the most logical approach to these tumors. Certain tumors present in characteristic locations. An understanding of the anatomy leads to an understanding of the clinical presentation and possible therapeutic options.

Extradural Tumors. Extradural tumors account for approximately 55% of spinal tumors. This category includes tumors arising within the bony vertebral structures and from within the epidural space. Destruction of the bone can lead to instability and fractures, causing pain and/or deformity. Epidural expansion can lead to spinal cord or nerve root compression with myelopathy, radiculopathy, or a combination thereof.

Metastatic Tumors Metastatic tumors are the most common extradural tumors. Spinal metastases most commonly occur in the thoracic and lumbar vertebral bodies because the greatest volume of red bone marrow is found in these regions. The most common primary sources of spine metastasis are lymphoma, lung, breast, and prostate. Other sources include renal, colon, thyroid, sarcoma, and melanoma. Most spinal metastases create osteolytic lesions. Osteoblastic, sclerotic lesions suggest prostate cancer in men and breast cancer in women.

Patients with progressive neurologic dysfunction due to a metastatic lesion should undergo urgent surgery followed by radiation therapy.[33] Patients with debilitating pain may undergo radiation therapy with close observation for neurologic deterioration. Preoperative neurologic function correlates with postoperative function. Patients may lose function over hours. These patients should be given high-dose IV dexamethasone, taken immediately to MRI, and then to the OR or radiation therapy suite. Indications for surgery include failure of radiation therapy, spinal instability, recurrence after radiation therapy, and the need for diagnosis in cases of unknown primary tumors. Most cases with significant bone involvement require both decompression and fusion. Bony fusion usually takes 2 to 3 months. Prognosis governs operative decisions. Surgery is unlikely to improve quality of life for patients with a life expectancy of 3 months or less, but it is likely to improve quality of life for patients with life expectancy of 6 months or more. Benefit for patients with 3- to 6-months life expectancy is unclear and requires frank discussion with the patient and family. Patients who are unlikely to tolerate general anesthesia, are already completely paralyzed, or who have very radiosensitive tumors such as multiple myeloma and lymphoma, should not generally undergo surgery.

Primary Tumors Hemangiomas are benign tumors found in 10% of people at autopsy. They occur in the vertebral bodies of the thoracolumbar spine and are frequently asymptomatic. They are often vascular and may hemorrhage, causing pain or neurologic deficit. Large hemangiomas can destabilize the spine and predispose to fracture. Osteoblastic lesions include osteoid osteoma and osteoblastoma. The latter tends to be larger and more destructive. Aneurysmal bone cysts are nonneoplastic, expansile, lytic lesions containing thin-walled blood cavities that usually occur in the lamina or spinous processes of the cervicothoracic spine. They may cause pain or sufficiently weaken the bone to cause a fracture. Cancers arising primarily in the bony spine include Ewing's sarcoma, osteosarcoma, chondrosarcoma, and plasmacytoma.

Intradural Extramedullary Tumors

Intradural extramedullary tumors constitute approximately 40% of spinal tumors and arise from the meninges or nerve root elements. They may compress the spinal cord, causing myelopathy, or the nerve roots, causing radiculopathy. The most common intradural extramedullary tumors are typically benign, slow growing, and well circumscribed. Rare benign epidural masses include arachnoid cysts, dermoids, and epidermoids. Rare malignant epidural tumors include metastases and high-grade gliomas, or "drop" metastases from posterior fossa gliomas.

Meningioma Meningiomas arise from the arachnoidea mater. They appear to be dural based and enhance on MRI. An enhancing "dural tail" may be seen. They occur most commonly in the thoracic spine (Fig. 42-25) but also arise in the cervical and lumbar regions. Some spinal meningiomas grow into the epidural space. Growth causes cord compression and progressive myelopathy with hyperreflexia, spasticity, and gait difficulties. Surgical excision is the treatment of choice. The surgeon often finds a clean margin between the tumor, dura, and spinal cord, allowing en bloc resection without damage to the cord.

Schwannoma Schwannomas are derived from peripheral nerve sheath Schwann cells. They are benign, encapsulated tumors that rarely undergo malignant degeneration. While two- thirds are entirely intradural, one-sixth are entirely extradural, and one-sixth have a classic "dumbbell" shape from intradural and extradural components. Symptoms result from radiculopathy, often presenting as pain or myelopathy. Symptomatic lesions should be surgically resected. The parent nerve root usually can be preserved. Patients with multiple schwannomas likely have NF2. In these patients, a careful neurologic examination is needed to determine which lesions are symptomatic and require resection.

Neurofibroma In contrast to schwannomas, neurofibromas tend to appear more fusiform and to grow within the parent nerve, rather than forming an encapsulated mass branching off the nerve. Neurofibromas are benign but not encapsulated. They present similarly to schwannomas, and the two may be difficult to differentiate on imaging. Salvage of the parent nerve is more challenging with neurofibromas. To improve the likelihood of total resection, thoracic and high cervical nerve roots may be sacrificed with minimal deficit. Patients with multiple neurofibromas likely have NF1, also known as *von Recklinghausen's neurofibromatosis*. Resection for symptomatic lesions should be offered.

Intramedullary Tumors. Intramedullary tumors constitute approximately 5% of spinal tumors. They arise from within the parenchyma of the spinal cord. Common presenting symptoms are local dysesthesia, burning pain, radicular pain, sensory loss, weakness, or sphincter dysfunction. Patients with such symptoms should undergo MRI of the entire spine with and without enhancement.

Figure 42-25. T2-weighted sagittal magnetic resonance imaging of the midthoracic spine demonstrating a well-encapsulated tumor arising from the dura posteriorly and compressing the spinal cord. *Arrowhead* points to dorsal location of the mass. The patient presented with worsening gait and lower extremity spasticity. Pathology demonstrated meningioma.

Ependymoma Ependymomas are the most common intramedullary tumors in adults. There are several histologic variants. The myxopapillary type occurs in the conus medullaris or the filum terminale in the lumbar region and has the best prognosis after resection. The cellular type occurs more frequently in the cervical cord. Many spinal ependymomas have cystic areas and may contain hemorrhage. Surgical removal can improve function. A distinct tumor margin often exists, allowing safer excision. Postoperative radiation therapy after subtotal resection may prolong disease control.

Astrocytoma Astrocytomas are the most common intramedullary tumors in children, although they also occur in adults. They may occur at all levels, although more often in the cervical cord. The tumor may interfere with the CSF-containing central canal of the spinal cord, leading to a dilated central canal, referred to as *syringomyelia* (*syrinx*). Spinal astrocytomas are usually

low grade, but complete excision is rarely possible due to the nonencapsulated, infiltrative nature of the tumor. As a result, patients with astrocytomas fare worse overall than patients with ependymomas.

Other Tumors. Other types of rare tumors include high-grade astrocytomas, dermoids, epidermoids, teratomas, hemangiomas, hemangioblastomas, and metastases. Patients usually present with pain. Prognosis generally depends on preoperative function and the histologic characteristics of the lesion.

SPINE: BASIC CONCEPTS

The spine is a complex structure and is subject to an extensive array of pathologic processes, including degeneration, inflammation, infection, neoplasia, and trauma. Discussions of spine trauma, tumor, and infection are addressed separately in this chapter in the Infection—Spine, Spinal Tumors, and Spine Trauma sections. General concepts, common patterns of disease, and basic operative interventions are presented here.

The spine consists of a series of stacked vertebrae, intervening discs, and longitudinal ligaments. The vertebrae consist of the vertebral body anteriorly and the pedicles, articular facets, laminae, and spinous processes posteriorly. The intervertebral discs have two components. The tough, fibrous ring that runs around the outer diameter of the two adjacent vertebral bodies is known as the *annulus fibrosus*. The spongy material inside the ring of the annulus is known as the *nucleus pulposus*. The annulus and the nucleus provide a cushion between adjacent vertebral bodies, absorb forces transmitted to the spine, and allow some movement between the vertebral bodies. The ligaments stabilize the spine by limiting the motion of adjacent vertebrae.

Stability and neural compression are the two concepts critical to understanding the mechanics and pathologic processes affecting the spine.

Stability

The spinal column is the principal structural component of the axial spine, and it must bear significant loads. The vertebrae increase in size from the top to the bottom of the spine, correlating with the increased total loads that the more caudal elements must bear. The cervical spine is the most mobile. Cervical stability depends greatly on the integrity of the ligaments that run from level to level. The thoracic spine is the least mobile, due to the stabilizing effect of the rib cage. The lumbar spine has relatively massive vertebrae, supports heavy loads, and has intermediate mobility. The sacral spine is fused together and has no intrinsic mobility. The load borne by the lumbar spine is transmitted to the sacrum, and then the pelvis through the sacroiliac joints. The coccyx is the most inferior segment of the spine and has no significant contribution to load bearing or mobility.

A stable spine is one that can bear normally experienced forces resulting from body mass, movement, and muscle contraction, while maintaining normal structure and alignment. An unstable spine will shift or sublux under these forces. The determinants of spinal stability vary throughout the cervical, thoracic, and lumbar portions. In elementary form, stability depends on the structural integrity of the hard, bony elements of the vertebral column, as well as the tensile integrity and security of the supporting ligamentous attachments. Plain X-rays and CT scans are sensitive for detecting bony defects such as fractures or subluxation, while MRI better detects disruptions of the soft tissues, including ligaments and intervertebral discs. Specific patterns of abnormalities seen on imaging studies may suggest or diagnose spinal instability.

A common form of nontraumatic spinal instability is lumbar spondylolisthesis, which is typically a forward slippage of a lumbar vertebra relative to the lower vertebra on which it rests. This results from congenital or degenerative disruption of the pars interarticularis, the critical bridge of bone that spans adjacent facet joints. In the setting of a pars defect, there is no solid bony connection between the adjacent vertebrae. The spine is unstable and anterior listhesis (slippage) may result. Patients typically present with severe low back pain that is exacerbated with movement and load bearing (mechanical low back pain). Radiculopathy in this setting indicates neuroforaminal compression. Figure 42-26 demonstrates an L4 and L5 spondylolisthesis.

Neural Compression

Besides providing a stable, central element of the body's support structure, the spine also protects the spinal cord and nerve roots as they pass through the neural foramina to form the peripheral nervous system. In a healthy spine, the spinal cord and nerve roots are suspended in CSF, free of mechanical compression. Pathologic processes that can lead to CSF space impingement and neural compression include: hypertrophic degenerative changes in the intervertebral discs and facet joints, expansion of epidural masses such as tumors or abscesses, and subluxation (i.e., slippage) of adjacent vertebral bodies. Subluxation may be due to trauma that exceeds the spine's load-bearing capabilities and leads to structural failure, or chronic structural degradation by degenerative disease, infection, or tumor. Subluxation

Figure 42-26. Lateral lumbar spine X-ray demonstrates a 25% anterior slippage of L4 on L5 due to a defect in the L4 pars interarticularis. This is called *spondylolisthesis*.

reduces the cross-sectional area of the central canal and the neural foramina (see Fig. 42-10B). Reduced central canal area can lead to myelopathy. Reduced neural foraminal area can lead to radiculopathy.

Myelopathy. Compression of the spinal cord can cause disturbance of function known as *myelopathy*. This dysfunction may be secondary to the direct effects of compression, cord ischemia due to reduced perfusion, or pathologic changes due to repeated cord trauma. These mechanisms lead to demyelination of the corticospinal tracts, which are long descending motor tracts. Corticospinal tract damage leads to upper motor neuron signs and symptoms, including hyperreflexia, spasticity, and weakness. These mechanisms also cause damage to the dorsal columns, which carry ascending proprioception, vibration, and two-point discrimination information. Loss of proprioception makes fine motor tasks and ambulation difficult.

Radiculopathy. Compression of the nerve roots causes disturbance of root function, known as *radiculopathy*. Characteristic features of radiculopathy include lower motor neuron signs and symptoms (hyporeflexia, atrophy, and weakness) and sensory disturbances such as numbness or tingling sensations (paresthesias), burning sensations (dysesthesias), and shooting (radicular) pain. Myelopathy and radiculopathy often present together in diseases that involve the central canal and the neural foramina. This combination can lead to lower motor neuron dysfunction at the level of disease, and upper motor neuron dysfunction below that level.

Patterns of Disease

Cervical Radiculopathy. The cervical nerve roots exit the central canal above the pedicle of the same-numbered vertebra and at the level of the higher adjacent intervertebral disc. For example, the C6 nerve root passes above the C6 pedicle at the level of the C5–C6 discs. The cervical nerve roots may be compressed acutely by disc herniation, or chronically by hypertrophic degenerative changes of the discs, facets, and ligaments. Table 42-6 summarizes the effects of various disc herniations. Most patients with acute disc herniations will improve without surgery. NSAIDs or cervical traction may help alleviate symptoms. Patients whose symptoms do not resolve or who have significant weakness should undergo decompressive surgery. The two main options for nerve root decompression are anterior cervical discectomy and fusion (ACDF) and posterior cervical foraminotomy (keyhole foraminotomy). ACDF allows more direct access to and removal of the pathology (anterior to the nerve root). However, the procedure requires fusion because discectomy causes a collapse of the interbody space and instability will likely occur. Figure 42-27 demonstrates a C6–C7 ACDF with the typical interposed graft and plating system. Keyhole foraminotomy allows for decompression without requiring fusion, but it is less effective for removing centrally located canal pathology.

Cervical Spondylotic Myelopathy. The term *spondylosis* refers to diffuse degenerative and hypertrophic changes of the discs, intervertebral joints, and ligaments, which collectively result in spinal stenosis. Spinal cord dysfunction (myelopathy) due to cord compression from cervical spinal degenerative disease is therefore referred to as *cervical spondylotic myelopathy* (CSM). Classically CSM presents with spasticity and hyperreflexia due to corticospinal tract dysfunction, upper extremity weakness and atrophy from degeneration of the motor neurons in the anterior horns of the spinal gray matter, and loss of lower extremity proprioception due to dorsal column injury. Figure 42-28 demonstrates typical findings. Some patients complain of difficulty buttoning shirts, using utensils, and ambulating. Spondylosis is usually diffuse, so the usual treatment for CSM is multilevel (usually C3–C7) cervical laminectomy, although patients with disease localized over one to three levels may be candidates for anterior decompression and fusion. Figure 42-29 demonstrates the postoperative appearance of a vertebral corpectomy and fusion for CSM. Thorough cervical laminectomy decompresses the cord posteriorly. Patients often have slow recovery due to the extensive chronic changes in the cervical cord and may benefit from rehabilitation programs. The other disease that classically presents with combined upper and lower motor neuron symptoms is amyotrophic lateral sclerosis (ALS). Care must be taken to avoid offering cervical laminectomy to a patient with undiagnosed ALS. Two findings help differentiate CSM from ALS: cranial nerve dysfunction such as dysphagia (not typically caused by cervical spine disease) and sensory disturbance (not found in ALS).

Thoracic Disc Herniation. Thoracic disc herniation accounts for <1% of herniated discs. A patient may present with radicular pain or sensorimotor changes in the lower extremities due to cord compression. A posterior approach via midline incision and laminectomy should be avoided because of the high incidence of cord injury from manipulation and retraction. Anterior approaches via thoracotomy minimize risk to the cord and allow excellent access to the disc. The radicular arteries running from the aorta to the thoracic cord should be spared, when possible, to avoid ischemia. Alternatively, a posterolateral approach is possible via resection of the rib head and facet joint. Finally, a transpedicular approach may be attempted for lateral disc herniations.[34]

Lumbar Radiculopathy. Lumbar nerve roots exit the thecal sac, pass over the higher adjacent disc space, and exit the canal under the pedicle of the same-numbered vertebra. Therefore,

Table 42-6

Cervical disc herniations and symptoms by level

LEVEL	FREQUENCY (%)	ROOT INJURED	REFLEX	WEAKNESS	NUMBNESS
C4–C5	2	C5	—	Deltoid	Shoulder
C5–C6	19	C6	Biceps	Biceps brachii	Thumb
C6–C7	69	C7	Triceps	Wrist extensors (wrist drop)	Second and third digits
C7–T1	10	C8	—	Hand intrinsics	Fourth and fifth digits

A B

Figure 42-27. **A.** Anteroposterior cervical spine X-ray showing the position of an anterior cervical plate used for stabilization after C6–C7 discectomy. Patient presented with right triceps weakness and dysesthesias in the right fifth digit. Magnetic resonance imaging revealed a right paracentral C6–C7 herniated disc compressing the exiting C7 nerve root. **B.** Lateral cervical spine X-ray of the same patient clearly demonstrates the position of the plate and screws. The allograft bone spacer placed in the drilled-out disc space is also apparent.

Figure 42-28. T2-weighted sagittal magnetic resonance imaging of the cervical spine showing multilevel degenerative changes causing spinal stenosis that is worst at C5–C6. Note the bright signal within the cord at that level, consistent with myelopathy.

Figure 42-29. Lateral cervical spine X-ray status post C5 corpectomy for cervical spondylotic myelopathy. This involves removal of the C4–C5 disc, C5 vertebral body, and C5–C6 disc, decompressing at two levels. A bone strut is visible bridging C4 to C6. The plate and screws stabilize the segments.

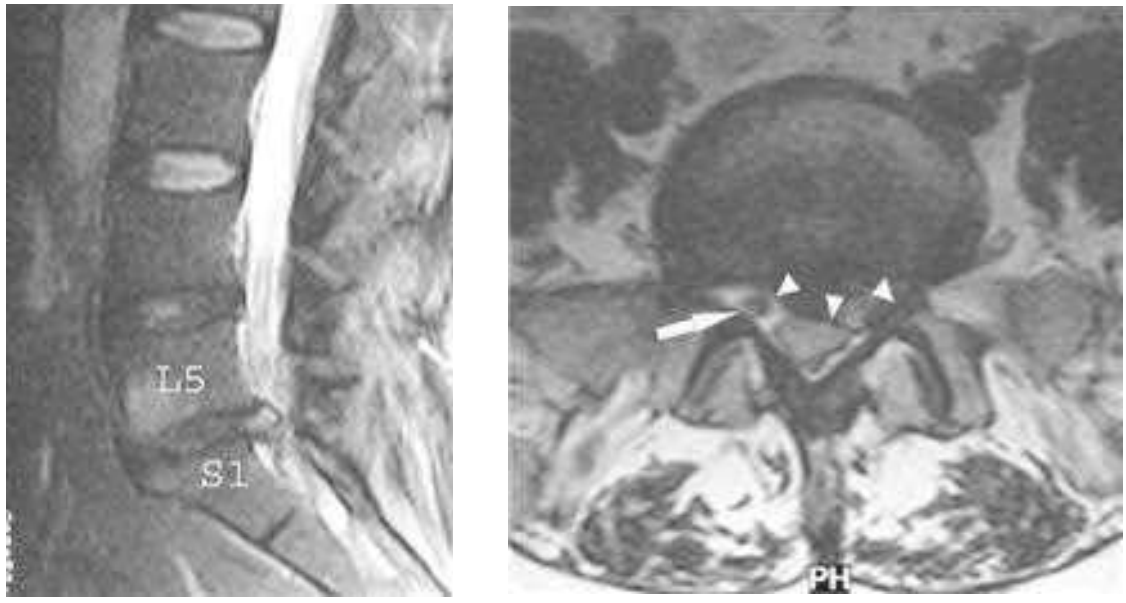

Figure 42-30. **A.** T2-weighted sagittal magnetic resonance imaging shows an L5–S1 disc herniation causing significant canal compromise and displacement of nerve roots. **B.** T2-weighted axial magnetic resonance imaging of the same patient shows the large left paracentral disc herniation at L5–S1. *Arrowheads* delineate the extent of the herniation. The *arrow* indicates the right S1 nerve root passing through free of compression. The left S1 nerve root is under severe compression and is not seen.

the L5 nerve root passes over the L4–L5 disc space and exits under the L5 pedicle (Fig. 42-30). Lumbar discs may herniate with or without a history of trauma or straining. Normally they cause lancinating (radicular) pain down the leg (Table 42-7). Most acute herniated lumbar discs improve symptomatically without surgery. Surgery is indicated for symptoms persisting more than 6 to 8 weeks, progressive motor deficit (e.g., foot drop), or for patients with incapacitating pain not manageable with analgesics.

Discectomy is performed using a midline incision, partial removal of the overlying laminae (hemilaminectomy or laminotomy), identification of the thecal sac and nerve root, and extraction of disc fragments. Free-floating disc fragments may be found. Often, however, the herniated disc material is still contained within the annulus, requiring incision of the posterior longitudinal ligament and curettage of the disc space. After lumbar discectomy, approximately two-thirds of patients will have complete relief of pain, and up to 85% will have significant improvement.

Neurogenic Claudication. Neurogenic claudication is characterized by low back and leg pain that occurs while walking and is relieved by stopping, leaning forward, or sitting. It is normally caused by degenerative lumbar stenosis causing compression of the cauda equina. Neurogenic claudication must be distinguished from vascular claudication, which tends to resolve quickly with cessation of walking. There is typically no need to change position, and the pain follows a stocking distribution rather than a dermatomal distribution. Pallor and coldness of the feet, and normal neurologic examination are also typical, though diabetic patients may present a challenge with microvascular neuropathy. Patients with neurogenic claudication have a slowly progressive course and may be surgical candidates when their pain interferes with their lifestyle. The usual surgery is an L3 to L5 lumbar laminectomy to decompress the nerve roots.

Cauda Equina Syndrome. Cauda equina syndrome is due to compression of the cauda equina and may result from massive disc herniation, EDH, epidural abscess, tumor, or subluxation from trauma. Patients with cauda equina compression often present with urinary retention, saddle anesthesia, or progressing leg weakness. Saddle anesthesia is numbness in the perineum, genitals, buttocks, and upper inner thighs. Patients with suspected cauda equina syndrome should undergo immediate MRI of the lumbar spine to evaluate for a surgical lesion. Mass lesions should be removed urgently via laminectomy to preserve sphincter function and ambulation.

Table 42-7

Lumbar disc herniations and symptoms by level

LEVEL	FREQUENCY (%)	ROOT INJURED	REFLEX	WEAKNESS	NUMBNESS
L3–L4	5	L4	Patellar	Quadriceps	Anterior thigh
L4–L5	45	L5	—	Tibialis anterior (foot drop)	Great toe
L5–S1	50	S1	Achilles	Gastrocnemius	Lateral foot

Spine Fusion Surgery

Fusion surgery is often required for patients with spinal instability resulting from disease, surgical intervention, or both. Fusion procedures lock adjacent vertebrae together. Fusion occurs when the body forms a solid mass of bone incorporating the adjacent vertebrae, eliminating normal intervertebral movement. Stabilization and immobilization promote bony fusion. Internal instrumentation and external orthoses are often used to stabilize and immobilize the fused spinal segments.

Spinal Instrumentation

Internal fixation devices for spinal segmental immobilization have been developed for all levels of the spine. Most spinal instrumentation constructs have two elements. 6▶ The first element is a device that solidly attaches to the vertebral bodies. Options include wires wrapped around laminae or spinous processes, hooks placed under the lamina or around the pedicles, or screws placed in the pedicles or the vertebral bodies. The second element is a device that traverses vertebral segments. Options include rods and plates that lock directly to the wires, hooks, or screws at each vertebral level. Spinal instrumentation devices are available for anterior and posterior fusion in the cervical, thoracic, and lumbar regions. Most modern spinal instrumentation devices are made of titanium to minimize problems with future MRI scanning (Fig. 42-31). All spinal instrumentation constructs will eventually fail by loosening or breaking if bony fusion does not occur.

Arthrodesis

Arthrodesis refers to the obliteration of motion or instability by incorporating the relevant components into a solid mass of bone. Arthrodesis must occur in any fused segment to have long-term stability. Failure of arthrodesis results in failed fusion, often in the form of a fibrous nonunion. The rates of successful fusion are higher in the cervical spine than the lumbar spine. Arthrodesis requires ingrowth of new bone formed by the patient's osteoblasts across the unstable defect. Inserting graft material, such as autograft or allograft, into the defect provides a bridge for osteoblasts and promotes fusion. The term *autograft* refers to the patient's own bone, often harvested from the iliac crest. Iliac crest bone graft is a source of both cortical and cancellous bone. Cortical bone provides structural support, while cancellous bone provides a matrix for bony ingrowth. The term *allograft* refers to sterilized bone from human tissue banks. Allografts also may be cortical, cancellous, or both. Allograft lacks the array of osteoinductive endogenous compounds intrinsic to autograft, although supplemental products such as demineralized bone matrix paste can be added to encourage new bone formation. Other techniques for increasing the rates of successful fusion are being developed, including the integration of osteoinductive bone morphogenetic proteins, known as *BMPs*, into the fusion constructs.

Dynamic stabilization refers to the creation of spinal stability without achieving a bony fusion. The concept applies to both cervical and lumbar motion segments. Artificial lumbar and cervical disc replacement therapies are recent developments in degenerative spine disease that address this concept. However, their use is limited to very select cases. Another motion preservation technique that may hold promise is segmental "soft" stabilization.[35] In

B

Figure 42-31. **A.** Lateral lumbar spine X-ray showing pedicle screws and connecting rods used to stabilize L4 with respect to L5. This instrumentation was placed as part of a fusion operation to stabilize progressive L4–L5 spondylolisthesis with intractable low back pain. **B.** Anteroposterior lumbar spine X-ray showing L3 to L5 instrumentation with pedicle screws and connecting rods. The patient had previously sustained an L4 burst fracture. Note the significant loss of height of the L4 body compared to adjacent levels. The small row of staples to the right delineates the incision over the iliac crest used to harvest cancellous bone as a nonstructural osteoinductive autograft fusion designed to induce formation of a solid bone bridge from L3 to L5 (arthrodesis).

cases of degenerative spondylolisthesis, such systems in the lumbar spine allow for decompressive laminectomy without increasing slippage. In theory, adjacent level facets and discs are spared the stresses of a neighboring bony fusion moment arm.

PERIPHERAL NERVE

Common pathologic processes that compromise function of the peripheral nervous system include mechanical compression, ischemia, inflammation, and neoplasia.

Peripheral Nerve Tumors

Most peripheral nerve tumors are benign and grow slowly. Significant pain increases the likelihood that the patient has a malignant tumor. Treatment for peripheral nerve tumors is surgical resection to establish diagnosis and evaluate for signs of malignancy. These tumors have various degrees of involvement with the parent nerve. Some can be resected with minimal or no damage to the nerve. Tumors that grow within the nerve often contain functioning fascicles. Total excision of these tumors requires sacrifice of the parent nerve. The choice of subtotal resection, nerve preservation, and observation, vs. total resection with nerve sacrifice depends on tumor histology and the function of the parent nerve.

Schwannoma. Schwannomas are the most common peripheral nerve tumors, also referred to as *neurilemomas* or *neurinomas*. Most occur in the third decade of life. These benign tumors arise from Schwann cells, which form myelin in peripheral nerves. The most characteristic presentation is a mass lesion with point tenderness and shooting pains on direct palpation. Spontaneous or continuous pain suggests malignancy. Schwannomas tend to grow slowly and eccentrically on parent nerves. The eccentric location and discrete encapsulated nature of these tumors often allow total resection without significant damage to the parent nerve. Subtotal resection and observation is reasonable for schwannomas entwined in important nerves, as the incidence of malignant transformation is extremely low.

Neurofibroma. Neurofibromas arise within the nerve and tend to be fusiform masses, unlike schwannomas, which tend to grow out of the nerve. Neurofibromas often present as a mass that is tender to palpation. They usually lack the shooting pains characteristic of schwannomas. Neurofibromas are often difficult to resect completely without sacrifice of the parent nerve. Neurofibromas have a higher incidence of malignant transformation; therefore, patients with known residual tumors require close observation. Patients with NF1 often have multiple neurofibromas. These patients should be offered resection for symptomatic tumors. Risk of malignant degeneration is up to 10%. Malignant neurofibromas have the histologic characteristics of sarcoma.

Malignant Nerve Sheath Tumors. Malignant nerve sheath tumors include solitary sarcomas, degenerated neurofibromas, and neuroepitheliomas. Patients with malignant peripheral nerve tumors typically complain of constant pain, rather than pain only on palpation, and are more likely to have motor and sensory deficits in the distribution of the parent nerve. Treatment for these tumors is radical excision. This often requires sacrifice of the parent nerve. Invasion of nearby soft tissues may occur and necessitate wide resection or amputation in an attempt to prevent systemic metastasis.

Entrapment Neuropathies

Entrapment neuropathy presents as neurologic dysfunction in nerves passing through a pathologically small, fixed space. Nerve dysfunction may result directly from chronic, repetitive pressure on the nerve, or from ischemic damage due to impaired perfusion.[36] Entrapment causing dysfunction of nerve signaling may be associated with numbness, paresthesias, weakness, or muscle atrophy. The two most common sites of entrapment neuropathy are the ulnar nerve at the medial aspect of the elbow and the median nerve at the wrist. Usually EMG/NCS demonstrate slowing across the entrapped segment of nerve. Mechanical peripheral nerve disorders resulting from trauma (brachial plexus disruption, radial nerve damage from humerus fractures, and common peroneal nerve crush injuries) are discussed in the section on Trauma.

Ulnar Neuropathy. The ulnar nerve has contributions from the C7, C8, and T1 nerve roots, arises from the medial cord of the brachial plexus, and supplies most of the intrinsic hand muscles (interossei and third and fourth lumbricals), and sensation to the fourth and fifth digits. It passes posteriorly to the medial epicondyle at the elbow in the condylar groove. This segment is superficial and subject to external compression and repetitive minor impacts. Patients with ulnar entrapment at the elbow present with numbness and tingling in the medial palm, as well as the fourth and fifth digits. Motor deficits include weakness and wasting of the intrinsic hand muscles. Treatment for symptomatic ulnar entrapment neuropathy is surgical exploration and incision of the fibrous aponeurotic arch that overlies the nerve. A 6-cm curvilinear incision centered between the medial epicondyle and the olecranon allows exploration of up to 10 cm of nerve and lysis of compressive tissues.

Carpal Tunnel Syndrome. The median nerve has contributions from the C5 to T1 nerve roots, arises from the medial and lateral cords of the brachial plexus, and supplies the muscles of wrist and finger flexion and sensation to the palmar aspect of the first, second, and third digits. The median nerve passes through the carpal tunnel in the wrist, lying superficial to the four deep and four superficial flexor tendons. The transverse carpal ligament is a tough, fibrous band that forms the roof of the carpal tunnel. The ligament attaches to the pisiform and hamate medially and the trapezium and scaphoid laterally. Patients complain of numbness and tingling in the supplied digits, clumsiness, and worsening with sleep or repetitive wrist movement. Patients may notice wasting of the thenar eminence. Treatment for symptomatic carpal tunnel syndrome unresponsive to splinting, analgesics, and rest is surgical division of the flexor retinaculum. This often provides prompt relief of pain symptoms and slow recovery of numbness and strength.

Autoimmune and Inflammatory Disorders

These are not surgical diseases, but they merit brief mention as they are included in the differential diagnosis for new-onset weakness. Their characteristic presentations help distinguish them from weakness due to structural lesions.

Guillain-Barré Syndrome. Guillain-Barré syndrome is an acute inflammatory demyelinating polyradiculopathy often occurring after viral infection, surgery, inoculations, or

mycoplasma infections. Patients classically present with weakness ascending from the legs to the body, arms, and even cranial nerves. Symptoms usually progress over 2 to 4 weeks and then resolve. Care is supportive. Respiratory weakness may require ventilatory support.

Myasthenia Gravis. Myasthenia gravis is an autoimmune process in which antibodies form to the acetylcholine receptors of muscles, leading to fluctuating weakness. Most patients have either thymic hyperplasia or thymoma. The most common symptoms are diplopia, ptosis, dysarthria, and dysphagia. More severe cases have limb or respiratory involvement. Weakness worsens with repetitive movement. Treatment is with acetylcholinesterase inhibitors and possible thymectomy.

Eaton-Lambert Syndrome. Eaton-Lambert syndrome is an autoimmune process with antibodies to the presynaptic calcium channels. This is a paraneoplastic syndrome most commonly associated with oat cell carcinoma. Patients have weakness of proximal limb muscles that improves with repetitive movement. This diagnosis must prompt oncologic evaluation.

INFECTION

CNS infections of interest to neurosurgeons include those that cause focal neurologic deficit due to mass effect, require surgical aspiration or drainage because antibiotic therapy alone is insufficient, cause mechanical instability of the spine, or occur after neurosurgical procedures. 7▶

Cranial

Osteomyelitis. The skull is highly vascular and resistant to infections. Osteomyelitis of the skull may develop by contiguous spread from pyogenic sinus disease or from contamination by penetrating trauma. *Staphylococcus aureus* and *S. epidermidis* are the most frequent causative organisms. Patients usually present with redness, swelling, and pain. Contrast head CT aids diagnosis and shows the extent of involved bone, along with associated abscesses or empyema. Osteomyelitis treatment entails surgical debridement of involved bone followed by 2 to 4 months of antibiotics. Craniotomy wound infections are a special concern because performing a craniotomy creates a devascularized free bone flap susceptible to infection and not penetrated by antibiotics. These wounds must be débrided and the bone flaps removed and discarded. Subsequent care involves appropriate antibiotic therapy, observation for signs of recurrent infection off antibiotics, and return to the OR for titanium or methylmethacrylate cranioplasty 6 to 12 months later.

Subdural Empyema. Subdural empyema is a rapidly progressive pyogenic infection. The subdural space lacks significant barriers to the spread of the infection, such as compartmentalization or septations. Subdural empyemas usually occur over the cerebral convexities. Potential infectious sources include sinus disease, penetrating trauma, and otitis. Streptococci and staphylococci are the most frequent sources. Presenting symptoms include fever, headache, neck stiffness, seizures, or focal neurologic deficit. Neurologic deficit results from inflammation of cortical blood vessels, leading to thrombosis and stroke. The most common deficit is contralateral hemiparesis. Patients with suggestive symptoms should undergo rapid contrast CT scan. LP frequently fails to yield the offending organism and risks herniation due to mass effect. Typical treatment is wide hemicraniectomy, dural opening, and lavage. The pus may be thick or septated, making burr hole drainage or small craniotomy insufficient. Patients then require 1 to 2 months of antibiotics. Subdural empyema has 10% to 20% mortality risk and common chronic sequelae, including development of a seizure disorder and residual hemiparesis. However, many patients do make a good recovery.

Brain Abscess. Brain abscess is encapsulated infection within the brain parenchyma. It may spread hematogenously in patients with endocarditis or intracardiac or intrapulmonary right-to-left shunts, by migration from the sinuses or ear, or via direct seeding by penetrating trauma. Disorganized cerebritis often precedes formation of the organized, walled-off abscess. Patients may present with nonspecific symptoms such as headache, nausea, or lethargy, or with focal neurologic deficit such as hemiparesis. Alternatively, patients may present in extremis if the abscess ruptures into the ventricular system. Abscesses appear as well-demarcated, ring-enhancing, thin-walled lesions on CT scan and MRI, and often have associated edema and mass effect. Patients require antibiotic therapy after needle aspiration or surgical evacuation. Antibiotic therapy without surgical evacuation may be considered for patients with small, multiple, or critically located abscesses. Abscesses that are large, cause mass effect, decreased mental status, or that fail to decrease in size after 1 week of antibiotics, should be evacuated. Nonsurgical management still requires aspiration or biopsy specimen for organism culture and sensitivities. Blood and CSF cultures rarely give definitive diagnosis. Removal of an encapsulated abscess significantly shortens the length of antibiotic therapy required to eliminate all organisms. Common chronic sequelae after successful treatment include seizures or focal neurologic deficit.

Spine

Pyogenic Vertebral Osteomyelitis. Pyogenic vertebral osteomyelitis is a destructive bacterial infection of the vertebrae, usually of the vertebral body. Vertebral osteomyelitis frequently results from hematogenous spread of distant disease, but may occur as an extension of adjacent disease, such as psoas abscess or perinephric abscess. *S. aureus* and *Enterobacter* spp. are the most frequent etiologic organisms. Patients usually present with fever and back pain. Diabetics, IV drug abusers, and dialysis patients have increased incidence of vertebral osteomyelitis. Epidural extension may lead to compression of the spinal cord or nerve roots with resultant neurologic deficit. Osteomyelitis presents a lytic picture on imaging and must be distinguished from neoplastic disease. Adjacent intervertebral disc involvement occurs frequently with pyogenic osteomyelitis, but rarely with neoplasia. Plain films and CT help assess the extent of bony destruction or deformity such as kyphosis. MRI shows adjacent soft tissue or epidural disease. Most cases can be treated successfully with antibiotics alone, although the organism must be isolated to steer antibiotic choice. Blood cultures may be positive. Surgical intervention may be required for debridement when antibiotics alone fail, or for stabilization and fusion in the setting of instability and deformity.

Tuberculous Vertebral Osteomyelitis. Tuberculous vertebral osteomyelitis, also known as *Pott's disease*, occurs most commonly in underdeveloped countries and in the immunocompromised.

Several features differentiate tuberculous osteomyelitis from bacterial osteomyelitis. The infection is indolent and symptoms often progress slowly over months. Tuberculosis rarely involves the intervertebral disc. The involved bodies may have sclerotic rather than lytic changes. Multiple nonadjacent vertebrae may be involved. The upper lumbar and lower thoracic vertebrae are most commonly affected. Diagnosis requires documentation of acid-fast bacilli. Treatment involves long-term antimycobacterial drugs. Patients with spinal instability or neural compression from epidural inflammatory tissue should undergo debridement and fusion as needed.

Discitis. Primary infection of the intervertebral disc space, or discitis, is most commonly secondary to postoperative infections. Spontaneous discitis occurs more commonly in children. *S. aureus* and *S. epidermidis* account for most cases. The primary symptom is back pain. Other signs and symptoms include radicular pain, fevers, paraspinal muscle spasm, and localized tenderness to palpation. Many cases will resolve without antibiotics, which generally are given for positive blood or biopsy specimen cultures or persistent constitutional symptoms. Most patients will have spontaneous fusion across the involved disc and do not need debridement or fusion.

Epidural Abscess. Epidural abscesses may arise from or spread to the adjacent bone or disc, so distinguishing between vertebral osteomyelitis or discitis and a spinal epidural abscess may be difficult. The most common presenting signs and symptoms are back pain, fever, and tenderness to palpation of the spine. The most significant risk of epidural abscess is weakness progressing to paralysis due to spinal cord or nerve root damage. Cord and root damage may be due to direct compression or to inflammatory thrombosis resulting in venous infarction. *S. aureus* and *Streptococcus* spp. are the most common organisms. Methicillin-resistant *S. aureus* now constitutes a significant proportion of these infections, as high as 40%.[37] The source may be hematogenous spread, local extension, or operative contamination. MRI best demonstrates the epidural space and degree of neural compromise. Patients with spinal epidural abscess and neurologic compromise should undergo surgical debridement for decompression and diagnosis, followed by culture-directed antibiotic therapy. Relative contraindications to surgery include prohibitive comorbidities or total lack of neurologic function below the involved level. Patients with no neurologic deficits and an identified organism may be treated with antibiotics alone and very close observation. However, this management strategy remains somewhat controversial because these patients can undergo rapid and irreversible neurologic decline. Most epidural abscesses can be accessed via laminectomy without fusion. Collections predominantly anterior to the cervical or thoracic cord may require anterior approach and fusion.

FUNCTIONAL NEUROSURGERY

Epilepsy Surgery

Seizures result from uncontrolled neuronal electrical activity. Seizures may result from irritative lesions in the brain, such as tumors or hematomas, or from physiologic or structural abnormalities. Seizures may involve a part of the brain (focal) or the entire brain (generalized). Focal seizures may be associated with normal consciousness (simple) or decreased consciousness (complex). All generalized seizures cause loss of consciousness. Focal seizures may secondarily generalize. Patients with multiple unprovoked seizures over time are considered to have epilepsy. The type of epilepsy depends on such factors as type of seizures, electroencephalographic (EEG) findings, associated syndromes, and identifiable etiologies. All patients with unexplained seizures (i.e., no obvious cause such as head trauma or alcohol withdrawal) require thorough neurologic evaluation, including imaging to evaluate for a mass lesion. Antiepileptic drugs (AEDs) form the first line of therapy for epilepsy, initially as monotherapy, then as combination therapy. Epilepsy patients who have failed satisfactory trials of several AED combination regimens may be candidates for surgical intervention. Lack of seizure control or patient intolerance of the medications may constitute failure. Epilepsy surgery can decrease the frequency of seizures by resection of the electrical source of the seizures, or decrease the severity of seizures by disconnecting white matter tracts through which the abnormal electrical activity spreads. Four types of epilepsy surgery are discussed in sections that follow. Epilepsy surgery appears to be extremely underused, given the relatively low risk of the procedures, and the crippling social and economic effects of uncontrolled or partially controlled epilepsy.[38] Patients with symptoms, imaging abnormalities, and EEG analysis compatible with a specific seizure focus are most likely to have good results from epilepsy surgery.

Anterior Temporal Lobectomy. Medial temporal lobe structural abnormalities can lead to complex partial seizures (CPS). Many patients with CPS have poor seizure control on medications. Patients with CPS may have significant reduction in seizure frequency or cessation of seizures after resection of the anterior temporal lobe. The amygdala and the head of the hippocampus are removed as part of the lobectomy. Resection may be taken back approximately 4.5 cm from the temporal tip in the language-dominant hemisphere, and 6 cm from the temporal tip in the language nondominant hemisphere, with low risk of significant neurologic deficits.[39] The two main risks of anterior temporal lobectomy are memory impairment and visual loss. Removal of the hippocampus in a patient with an atrophied or nonfunctional contralateral hippocampus causes a global memory deficit. Interruption of the optic radiations, which carry visual signals from the contralateral superior visual quadrants of both eyes, causes a contralateral superior quadrantanopia, known as a *pie in the sky* field cut.

Corpus Callosotomy. Patients with generalized seizures, atonic seizures associated with drop attacks, or absence seizures, who are found to have bilaterally coordinated pathologic cortical discharges on EEG and who fail AED therapy, may be candidates for corpus callosotomy. The corpus callosum is a large white matter tract that connects the cerebral hemispheres. Loss of consciousness requires simultaneous seizure activity in both hemispheres. Focal or partial seizures may spread via the corpus callosum to the contralateral hemisphere, causing generalization and loss of consciousness. Division of the corpus callosum can interrupt this spread. Patients may have decreased numbers of seizures and/or fewer episodes of lost consciousness. Usually only the anterior half or two-thirds of the corpus callosum is divided, as more extensive division increases the risk of disconnection syndrome. Patients with disconnection syndrome are unable to match objects in the opposite visual hemifields, to identify objects held in one hand with the other hemifield, and to write with the left hand or name objects held in the left hand (in left hemisphere–dominant patients).

Hemispherectomy. Children with intractable epilepsy, structural anomalies in one hemisphere, and contralateral hemiplegia, may have improved seizure control after resection of the hemisphere (anatomic hemispherectomy) or disruption of all connections to the hemisphere (functional hemispherectomy). Functional hemispherectomy often is preferred over anatomic hemispherectomy because of the high incidence of complications such as hematoma formation and ventriculoperitoneal shunt dependence associated with the latter.

Vagus Nerve Stimulation. Neuromodulatory treatments like vagus nerve stimulation (VNS), approved by the FDA in 1997, are less invasive and offer some titratability in addition to reversibility unlike the resective surgical options previously described. Since first reported in 1985, VNS has proven to be efficacious in certain patient populations for several disorders such as treatment-resistant major depressive disorder, bipolar disorder, and epilepsy. In VNS, a pulse generator is placed under the skin in the chest and is connected to the vagus nerve by an electrical lead. Chronic, intermittent VNS has been proven to be an effective option for patients suffering from medically refractory seizures who are not candidates for surgical resection. Although only a small minority of patients will be entirely seizure-free, three blinded, randomized-controlled trials have examined VNS, and demonstrated significant clinical improvement compared to sham.[40-42] Generally VNS is well-tolerated and safe, as device implantation is associated with a low rate of perioperative complications. Additionally, the majority of side effects are stimulation-dependent and thus, reversible. For the most part, VNS is limited in its application because it can only exert its effects by altering neural activity via the vagus nerve. Procedures with brain region-specificity are being investigated.

Deep Brain Stimulation

The following summary of deep brain stimulation (DBS) will include a review of the current U.S. Food and Drug Administration (FDA)-approved indications, as well the expanding applications of this therapy, currently being investigated preclinically and in clinical trials. While the mechanism of action of DBS continues to elude our understanding, it is well-established that administering electrical stimulation to a nucleus in the brain known to be involved in a given disease can disrupt the pathologic signals emanating to or from this brain region. A fine electrical lead is placed in a deep brain nucleus and connected to pulse generators placed in the chest in a manner similar to cardiac pacemakers. Connector wires travel from the generators in the subcutaneous space up the neck and in the subgaleal space in the head, to connect the pulse generators to the electrical leads. Proper lead placement is accomplished with stereotactic guidance. A frame is rigidly fixed to the patient's head, and an MRI is obtained with the frame in place. Calculation of the coordinates of the millimeter-sized deep brain nuclei is performed in relation to the three-dimensional space defined by the fixed frame, allowing for accurate targeting of the nucleus (Fig. 42-32). Postoperatively, the pulse generators can be interrogated and adjusted with hand-held, transcutaneous, noninvasive devices as needed for symptom control.

Essential Tremor. Essential tremor is the most common movement disorder in the western world and is characterized by action tremor (4–8 Hz rhythmic oscillations) of the hands, forearms, head, and voice. Essential tremor often starts in the third or fourth decade of life, and increases in frequency and amplitude with age. Beta blockers can decrease symptoms, but patients with poor medical control and significant functional impairment significantly benefit from placement of a deep brain stimulator in the contralateral ventralis intermediate nucleus of the thalamus. In properly selected patients, DBS of this region of the thalamus appears to provide robust and durable symptom control. [43,44]

Figure 42-32. Fast spin echo coronal magnetic resonance imaging demonstrating position of deep brain stimulator leads in the subthalamic nuclei bilaterally. The electrodes appear thick and wavy due to magnetic susceptibility artifact.

Parkinson's Disease. Parkinson's disease is a progressive disorder characterized by rigidity, bradykinesia, and resting tremor, due to loss of dopamine-secreting neurons in the substantia nigra. Dopaminergic agents such as levodopa/carbidopa and anticholinergic agents such as amantadine and selegiline form the basis of medical therapy. Patients with poor medical control or significant drug side effects may benefit significantly from placement of bilateral deep brain stimulators in the subthalamic nuclei. Although the globus pallidus interna has also been a widely targeted area, the subthalamic nuclei is now the most accepted target in deep brain stimulation for Parkinson's disease.[45] Deep brain stimulation provides durable symptom relief with good postoperative neuropsychologic function in properly selected patients .[46]

Recently, a large randomized controlled trial compared bilateral DBS (n=121) to best medical therapy in advanced Parkinson's disease (n=134).[47] The DBS group did significantly better in both motor function and quality of life. While adverse events were 3.8 times more likely in the DBS group, 99% of these events had resolved by 6 months. There was a 0.8% risk of death due to the procedure, and there was no difference in risk of adverse events when comparing older (≥70 years) to younger patients (<70 years). Thus, the benefits of DBS over medical therapy are clear, especially when considering quality of life measures.

Another recent randomized controlled trial focused on defining the optimal targets for DBS in Parkinson's disease.[48] While the subthalamic nucleus (STN) and the globus pallidus interna (GPi) have been successfully targeted in the past, a direct comparison of the two was lacking. In this study, 299 subjects

were randomized to receive either bilateral STN or GPi stimulators and were evaluated for 2 years. The primary outcome was motor function, as assessed by part III of the Unified Parkinson's Disease Rating Scale (UPDRS). The study found no significant difference in motor improvement between target sites. However, a significant difference was found in a secondary outcome measuring depression. On the Beck Depression Inventory, the pallidal stimulation group improved slightly compared with the STN group, which actually worsened slightly. Nevertheless, the actual incidence of depressive episodes requiring prolonged or new hospitalization was 2.6% and 0.7% in GPi and STN, respectively, which was not significantly different. On the other hand, the STN group was found to require less adjunctive dopaminergic pharmacotherapy than the GPi group. In terms of overall severe adverse events, there was no difference between groups. The investigators concluded that both target sites are effective and that nonmotor factors such as psychiatric symptoms may be a consideration in DBS target selection.

Dystonia. The FDA humanitarian device exemption has been made for DBS for dystonia, but is limited to patients ≥7 years of age with primary dystonia, including generalized and/or segmental dystonia, hemidystonia, or cervical dystonia (torticollis). Dystonia is characterized by sustained muscle contractions that cause repetitive movements and involuntary postures. Cognitive function is typically spared, and pharmacological therapy is frequently inadequate. The positive impact of DBS on Parkinson's and essential tremor has led neurologists and neurosurgeons to direct their attention to DBS for treatment of idiopathic focal and generalized dystonia.

Although the pathophysiology of idiopathic dystonia is unclear, positron-emission tomography studies have shown disturbed glucose metabolism in the GPi, suggesting secondary pathologic activation of the motor cortex. Indeed, the GPi is currently considered the most efficacious target for dystonia, and controlled trials indicate approximately a 50% improvement in motor function and disability.[49] Since many patients undergoing surgery for dystonia are children and young adults, DBS is an attractive surgical option because it can be titrated, revised and reversed according to individual needs and growth patterns.

Obsessive-Compulsive Disorder. The safety and efficacy of DBS, as well as its titratability and reversibility, that have been demonstrated for the treatment of movement disorders in the 1990s and 2000s has spawned an increasing interest and awareness of the capabilities of nonlesional surgical treatments for diseases of the brain. An obvious outgrowth of DBS for movement disorders has been the treatment of medically refractory psychiatric disorders. Despite the dark history of frontal leucotomy procedures that dominated the early 20th century, nonlesional DBS for psychiatric disorders are now considered potential treatment strategies.

Functional neuroimaging has implicated certain brain regions in the pathogenesis of a variety of psychiatric disorders. The FDA has approved a humanitarian device exemption for DBS targeting the ventral capsule/ventral striatum for severe obsessive-compulsive disorder (OCD). Recent case reports and pilot studies have reported remission in patients suffering from refractory OCD following DBS. A pilot study using a blinded, staggered-onset design found that four (66.7%) of six patients met a stringent criterion as "responders" (≥35% improvement), according to the Yale-Brown Obsessive Compulsive Scale after 12 months of stimulation.[50] In this study, patients did not improve during the sham phase. Adverse events were generally mild and modifiable with setting changes, and stimulation interruption led to rapid yet reversible development of depressive symptoms in two cases. Thus, DBS has promise as a therapy of last resort for carefully selected cases of severe OCD.

Expanding Indications of Deep Brain Stimulation. There are multiple disorders, both psychiatric and neurologic, that have exhibited significant promise as potential indications for DBS in large-scale trials. Recently, there have been reports of significant improvements in refractory depression with DBS. Lozano and colleagues performed an open label study with extended follow-up on 20 patients targeting an area within the subcallosal cingulate gyrus (SCG) with bilateral DBS.[51] At the last follow-up visit in this study (range: 3–6 years), the average response rate was 64%, according to the Hamilton Rating Scale for Depression. Of note, impairment in social functioning was improved, and no significant adverse events were reported. Because two patients died by suicide during depressive relapses, it remains unclear if DBS can only improve quality of life or significantly suppress relapses and extend life-span in this extremely delicate patient population. Of note, as seen in OCD, the ventral capsule/ventral striatum has also been targeted for depression, as well as the nucleus accumbens directly, which lies within the ventral striatum. Studies of DBS in this region report an approximate 40% to 60% response rate, and results from a recent, multicenter randomized controlled trial are pending.[52]

DBS as a potential therapy for epilepsy targeting the anterior nucleus of the thalamus has been investigated in a multicenter, double-blind, randomized trial (SANTE).[53] In this trial, the group receiving DBS showed a 29% greater reduction in seizure frequency in relation to the sham group in the last month of the blinded phase. Complex partial and the "most severe" seizures were significantly reduced in the DBS-on group. After the blinded phase of the trial was complete, 54% of patients had a seizure reduction of at least 50%. Fourteen patients were seizure-free for at least 6 months; eight were seizure-free for at least one year, four for at least two years, and one patient for more than four years. Because of the modest benefit during the blinded phase of this trial, FDA-approval has yet to be granted to DBS for epilepsy targeting the thalamus in the United States, though approval has been given in Europe and Canada.

The region-specific, neuromodulatory capabilities of DBS have inspired the open label use of this technique in many other neurologic and psychiatric disorders, including but not limited to Tourette syndrome, Huntington's disease, and Alzheimer disease. Preclinical studies of both substance abuse and obesity have also shown promise.[54,55] The opportunity to model reward-seeking behaviors associated with these disorders in animals provides the ability to not only test safety, but also study mechanisms and inform the design of future clinical trials.

Trigeminal Neuralgia

Trigeminal neuralgia, also known as *tic douloureux*, is characterized by repetitive, unilateral, sharp, and lancinating pains in the distribution of, typically, the second, but sometimes third, branch of cranial nerve V, the trigeminal nerve. The patient may describe a "trigger point," an area on the face that elicits the pain when touched. A current leading etiologic hypothesis for trigeminal neuralgia is irritation and pulsatile compression of the root entry zone of the nerve by an artery in the posterior fossa, usually a loop of the superior cerebellar artery. The pain is excruciating and can be debilitating. Medical therapy, including carbamazepine and amitriptyline, may

reduce the frequency of events. Options for medically refractory cases include percutaneous injection of glycerol into the path of the nerve, peripheral transection of the nerve branches, SRS, and microvascular decompression (MVD).

MVD involves performing a small posterior fossa craniotomy on the side of the symptoms, retraction of the cerebellar hemisphere, and exploration of cranial nerve V. If an artery is found near the nerve, the vessel is freed of any adhesions and nonabsorbable material is placed between the nerve root and the artery. MVD remains the first definitive management option because SRS is associated with a substantial incidence of facial numbness.[56,57]

STEREOTACTIC RADIOSURGERY

The term *stereotactic radiosurgery* (SRS) refers to techniques that allow delivery of high-dose radiation that conforms to the shape of the target and has rapid isodose fall-off, minimizing damage to adjacent neural structures . The two most common devices used for conformal SRS for intracranial lesions are the LINAC (linear accelerator) and the gamma knife. LINAC delivers a focused beam of X-ray radiation from a port that arcs part way around the patient's head. Linear accelerators are commonly used to provide fractionated radiation for lesions outside the CNS. They are found in most radiation oncology departments. After upgrades to the software and collimators, SRS can be performed with these existing units, . The gamma knife delivers 201 focused beams of gamma radiation from cobalt sources through a specially designed colander-like helmet. Gamma knife units are used only for intracranial disease and cost up to $5 million; thus, they are most appropriate in high patient–volume centers. There is ongoing debate in the literature regarding the two technologies.[58–60] Both continue to evolve, allowing more precise and complex isodose conformation to complex lesions. Most lesions can be treated equally well with either technology. Lesions abutting the medulla or the spinal cord should not be treated with SRS, because these structures do not tolerate the radiation dose delivered to structures within millimeters of the target. Also, medullary or spinal cord compression can result from swelling of the lesion after the radiosurgery dose, resulting in devastating neurologic deficit.

Proton beam is an evolving SRS technology that may play a specialized role in treatment of lesions where posttarget exiting radiation limits photon-based therapies.[61] For example, the physical properties of photons cause destruction upon entry and exit from tissue, which can be particularly harmful to skull-base or clival lesions such as chordoma, in which the exiting pathway travels through the brain stem. Proton beam therapy uses accelerated protons, which dissipate energy upon impact and do not cause additional exiting damage. Currently, there are very few centers using this technology.

CyberKnife is another radiosurgery system that has neurosurgical application. It is a frameless, robotic, LINAC-based system that allows for targeting of spinal neoplasms with higher resolution than conventional external beam radiotherapy.[62] Using imaging tracking in real time, the CyberKnife is able to adjust to breathing artifact and patient movement. The application of this technology is rapidly growing.

Arteriovenous Malformations

SRS has been found to be an effective stand-alone therapy for AVMs up to 3 cm in diameter. SRS is best for lesions that are difficult to access surgically due to high likelihood of postoperative neurologic deficit. However, SRS is not effective for lesions >3 cm. Effective obliteration and elimination of the risk of hemorrhage takes 2 to 3 years. Overall, there is an approximately 2% annual incidence of AVM hemorrhage,[63] although one study found a 50% decrease in hemorrhage rate during the latency period before angiographic obliteration.[64] Nonetheless, surgical excision remains the preferred therapeutic modality, while SRS is reserved for cases deemed very high-risk for surgery due to location or patient factors.[65] Some patients with large AVMs who undergo surgery will have unresectable residual lesions. In these patients, SRS may be used as an effective adjunctive therapy in these patients.

Vestibular Schwannomas

SRS has been introduced as a therapeutic alternative to microsurgical resection for vestibular schwannomas up to 2.5 cm in maximum diameter. SRS provides high rates of tumor growth arrest and possible reduction in size with low rates of facial nerve palsy. Patients with functional ipsilateral preprocedure hearing may be more likely to retain functional hearing postprocedure than with microsurgery. The limitations of SRS include inability to treat tumors >2.5 cm, the possibility of radiation-induced malignant transformation of these benign tumors, and lack of long-term follow-up. SRS centers are accumulating experience with these tumors and accumulating data on long-term results.[66,67] The indications for microsurgery and SRS will continue to evolve. Either approach should be undertaken at a high-volume center, as studies show the patient outcomes improve with increased surgeon experience.[68]

Intracranial Metastases

Patients with solitary or multiple intracranial metastases may be treated primarily with SRS.[69] Patients have improved survival after SRS compared to no treatment or WBRT, and similar survival to patients undergoing total surgical resection. Patients with lesions >3 cm in diameter or evidence of ICH should undergo surgical decompression rather than SRS. Some studies show improved survival with up to seven intracranial masses. Patients with multiple intracranial masses have almost zero long-term survival, and most will die of their intracranial disease. Patients with intracranial metastases live 3 to 6 months on average with medical care and WBRT. This can be extended to 9 to 16 months with SRS or surgery, depending on tumor type, age, and patient condition.[70]

CONGENITAL AND DEVELOPMENTAL ANOMALIES

Dysraphism

Dysraphism describes defects of fusion of the neural tube involving the neural tube itself, or overlying bone or skin. Dysraphism may occur in the spine or head. Neural tube defects are among the most common congenital abnormalities. Prenatal vitamins, especially folic acid, reduce the incidence of neural tube defects.

Spina Bifida Occulta

Spina bifida occulta is congenital absence of posterior vertebral elements. The spinous process is always missing, the laminae may be missing to various degrees, but the underlying neural tissues are not involved. Spina bifida occulta is found in 25% of the general population, and is asymptomatic unless associated with other developmental abnormalities.

Spina Bifida with Myelomeningocele

Spina bifida with myelomeningocele describes the congenital absence of posterior vertebral elements with protrusion of the meninges through the defect, with underlying neural structural abnormalities. Common findings include weakness and atrophy of the lower extremities, gait disturbance, urinary incontinence, constipation, and deformities of the foot. Myelomeningoceles arising from the high lumbar cord usually cause total paralysis and incontinence, while those arising from the sacral cord may have only clawing of the foot and partial urinary function loss. Myelomeningocele patients often have hydrocephalus and a Chiari II malformation, an abnormal downward herniation of the cerebellum and brain stem through the foramen magnum. Patients with abnormal protrusion of meninges through the bony defect without abnormalities of the underlying neural tissue have a meningocele. Most of these patients are neurologically normal.

Encephalocele

Herniation of brain encased in meninges through the skull that forms an intracranial mass is referred to as *encephalocele*. Herniation of meninges without brain tissue is referred to as a *meningocele*. Most occur over the convexity of the skull. More rarely, the tissue protrudes through the skull base into the sinuses. Treatment involves excision of the herniated tissue and closure of the defect. Most patients with encephaloceles and meningoceles have impaired cognitive development. Patients with greater amounts of herniated neural tissue tend to have more severe cognitive deficits.

Craniosynostosis

Craniosynostosis is the abnormal early fusion of a cranial suture line with resultant restriction of skull growth in the affected area and compensatory bulging at the other sutures. Skull growth occurs at the cranial sutures for the first 2 years of life, at the end of which the skull has achieved >90% of its eventual adult size. Fusion of the sagittal suture, or sagittal synostosis, results in a boat-shaped head, known as *scaphocephaly*. Unilateral coronal synostosis results in ipsilateral forehead flattening and outward deviation of the orbit, known as *plagiocephaly*. The contralateral normal forehead appears to bulge by comparison. Bilateral coronal synostosis results in a broad, flattened forehead, known as *brachycephaly*, and is often associated with maxillary hypoplasia and proptosis. Unilateral or bilateral lambdoid synostosis results in flattening of the occiput. Occipital flattening can result from abnormal suture fusion (synostosis), or from physical remolding of the skull caused by always placing the baby in the supine position for sleep (known as *positional plagiocephaly*). Placing the baby in the prone position or tilted onto the contralateral side may restore near-normal skull shape in most cases of lambdoid synostosis, avoiding surgery. Treatment for synostoses in general is surgical, involving resection of the fused suture, or more complex reconstructive techniques for severe or refractory cases.

Hydrocephalus

Excess CSF in the brain that results in enlarged ventricles is known as *hydrocephalus*. CSF flows from the ventricles to the subarachnoid space and is then absorbed into the venous blood through the arachnoid granulations. Hydrocephalus may be classified as communicating or obstructive (outlined in the next two sections), and congenital or acquired. Congenital lesions associated with or causing hydrocephalus include stenosis of the cerebral aqueduct, Chiari malformation, myelomeningocele, and intrauterine infection. Acquired hydrocephalus may result from occlusion of arachnoid granulations by meningitis, germinal matrix hemorrhage, or SAH. CSF pathways may be occluded by adjacent tumors (Fig. 42-33).

A

B

Figurve 42-33. **A.** Axial head computed tomography scan revealing dilated ventricular system. Note dilated atria of the lateral ventricles (*arrowheads*) and rounded third ventricle (*arrow*). The large size of the ventricles and lack of transependymal flow indicate a chronic process (contrast to Fig. 42-2). The patient had normal-pressure hydrocephalus and had improved ambulation after placement of a ventriculoperitoneal shunt. **B**. Higher cut from same scan showing ventricular catheter in place in the frontal horn of the right lateral ventricle.

Communicating Hydrocephalus. Obstruction at the level of the arachnoid granulations constitutes communicating hydrocephalus. This usually causes dilation of the lateral, third, and fourth ventricles equally. The most common causes in adults are meningitis and SAH. Hydrocephalus may be transient after SAH, with re-establishment of normal CSF absorption after the protein content of the CSF returns to normal and the granulations reopen.

Obstructive Hydrocephalus. Obstruction of CSF pathways is known as *obstructive hydrocephalus*. Ventricles proximal to the obstruction dilate, while those distal to the obstruction remain normal in size. Typical patterns include dilation of the lateral ventricles due to a colloid cyst occluding the foramen of Monro, dilation of the lateral and third ventricles due to a tectal (midbrain) glioma or pineal region tumor occluding the cerebral aqueduct, or dilation of the lateral and third ventricles with obliteration of the fourth ventricle by an intraventricular tumor of the fourth ventricle. Obstructive hydrocephalus may present precipitously and require urgent shunting to prevent herniation.

Chiari I Malformation

Chiari I malformation is the caudal displacement of the cerebellar tonsils below the foramen magnum. It may be seen as an incidental finding on MRI scans in asymptomatic patients. Symptomatic patients usually present with headache, neck pain, or symptoms of myelopathy, including numbness or weakness in the extremities. A syrinx may be associated, but the brain stem and lower cranial nerves are normal in Chiari I malformations. Chiari II malformations are more severe and involve caudal displacement of the lower brain stem and stretching of the lower cranial nerves. Symptomatic patients may be treated with suboccipital craniectomy to remove the posterior arch of the foramen magnum, along with removal of the posterior ring of C1. Removal of these bony structures relieves the compression of the cerebellar tonsils and cervicomedullary junction, and may allow re-establishment of normal CSF flow patterns. Figure 42-34 demonstrates typical MRI appearance of a Chiari I malformation.

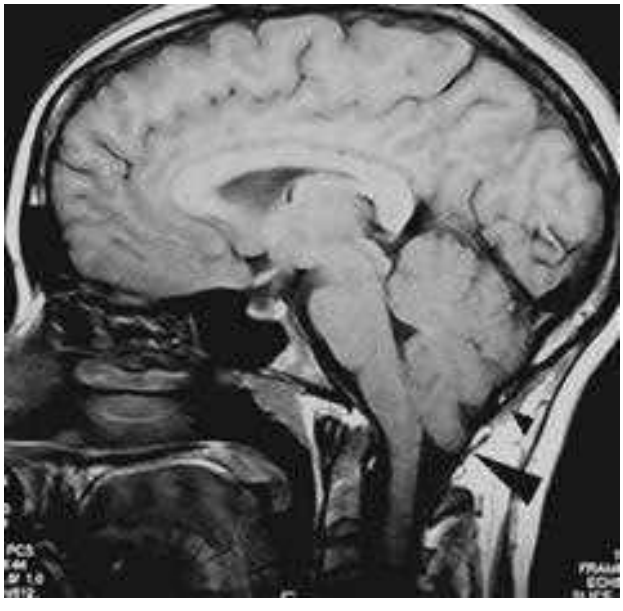

Figure 42-34. T1-weighted sagittal magnetic resonance imaging of a patient with a Chiari I malformation. The *large arrowhead* points to the cerebellar tonsils. The *small arrowhead* points to the posterior arch of the foramen magnum.

chapter 43

Orthopedic Surgery

Bert J. Thomas, Freddie H. Fu, Bart Muller, Dharmesh Vyas, Matt Niesen, Jonathan Pribaz, and Klaus Draenert

Key Point

1. The main principle of internal fixation for fracture care (most commonly intramedullary nails or plate and screw fixation) is to create a stable construct that will allow the fracture to heal in proper alignment.
2. Often, in open fractures, definitive treatment of the fracture is delayed until the wound is sufficiently cleaned and healthy soft tissue is available to cover the fracture.
3. When compartment syndrome is suspected, emergent fasciotomy must be performed in which the overlying tight fascia is released through long incisions. These must be done as soon as possible because the damage to muscles and nerves will result in irreversible necrosis and contractures causing severe loss of function.
4. Fractures of the scapula often result from significant trauma and can be associated with injuries to the head, lungs, ribs, and spine.
5. The shoulder is one of the most commonly dislocated joints and most dislocations are anterior. Posterior dislocations are associated with seizures or electric shock.
6. Humeral shaft fractures occur from direct trauma to the arm or from a fall on an outstretched arm, especially in elderly patients. The radial nerve spirals around the humeral shaft and is at risk for injury, therefore a careful neurovascular exam is important.
7. Hemorrhage from pelvic trauma can be life threatening. An important first line treatment in the emergency room is the application of a pelvic binder or sheet that is wrapped tightly around the pelvis to control bleeding.
8. In spinal injury spinal stability must be assessed, and the patient immobilized until his spine is cleared. CT scan is more reliable in assessing spine injury than plain radiographs.
9. Spinal cord injuries should be triaged to trauma centers since trauma center care is associated with reduced paralysis.
10. According to the CDC and the National Health Interview Survey approximately 50 million adults (22% of the US population) have been diagnosed with some form of arthritis. This number is projected to grow to an astounding 67 million adults by 2030 (or 25% of the U.S. population).
11. Weight loss of as little as 11 pounds has been shown to decrease the risk of developing knee osteoarthritis in women by 50%. Similarly, patients who engage in regular physical activity have been found to have lower incidence of arthritis.
12. Smaller incisions come with the disadvantage of decreased visualization intra-operatively and associated risks of component malposition, intraoperative fracture and nerve or vascular injury. The only documented benefit of minimally invasive techniques appears to be improved cosmesis.

INTRODUCTION

Orthopedic surgery is a specialty with which every physician should be familiar. Anyone who cares for patients in an outpatient or emergency room setting will find that the majority of presenting complaints involve the musculoskeletal system. A basic understanding of musculoskeletal anatomy is assumed, and understanding the principles of care for musculoskeletal trauma is essential.

For physicians, the field of orthopedics offers an array of subspecialties with such diversity that it seems that "there is something for everyone." Trauma specialists have the satisfaction of physically putting complex fractures back together. Sports medicine offers remarkably rapid recovery in athletes who have suffered fibrocartilage tears with ever improving arthroscopic techniques and instrumentation. Spine surgeons see remarkable results from their minimally invasive microscopic techniques, while also managing massive deformities with new instrumentation and open surgery. Joint reconstruction is one of our most exciting subspecialties, working with orthopedic bioengineers to develop improved designs, biomaterials, and minimally invasive surgical approaches to return function faster for patients crippled by arthritis and injury. Musculoskeletal oncology offers the intellectual challenge of arriving at appropriate differential diagnoses as well as the technical challenge of limb salvage and major reconstructive surgery. Pediatric orthopedics is an especially challenging and rewarding subspecialty because of the remarkable ability of children to heal even severe injuries rapidly and completely. The incredible array of congenital and developmental disorders makes pediatrics a uniquely intellectually challenging field as well. The authors hope that our readers will share our enthusiasm for orthopedic surgery and all of its subspecialties: trauma, sports, spine, joint replacement, musculoskeletal oncology, and pediatric orthopedics.

ORTHOPEDIC TRAUMA

Introduction

Musculoskeletal injuries resulting from trauma include fractures of bones, damage to joints, and injuries to soft tissues. Long bone fractures can be described as transverse, oblique, spiral, segmental, or comminuted (Fig. 43-1). The goals of treating musculoskeletal injuries are to restore the normal anatomy, immobilize injured extremities for both pain relief and to allow for healing, and to repair or reconstruct these injuries to restore function.

Fractures frequently result from high energy trauma as well as from falls onto an extremity (Fig. 43-2).The majority of fractures can heal well with immobilization, which stabilizes the fracture while new bone forms at the fracture site. Methods of immobilization can vary and depend on the fracture being treated. The most common tool used in orthopedics to

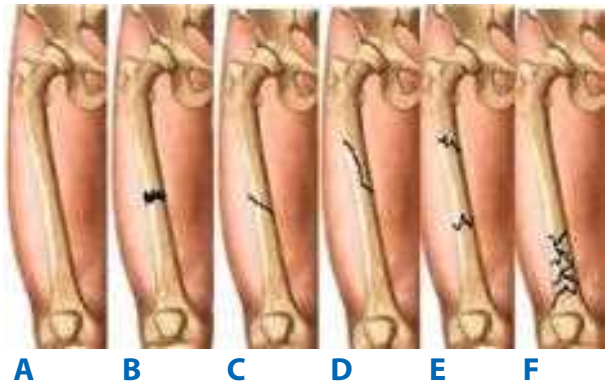

Figure 43-1. Types of fractures **A.** normal femur, **B.** transverse, **C.** oblique, **D.** spiral, **E.** segmental, **F.** comminuted.

treat fractures is immobilization with a splint or cast, and their proper application is important to successfully treat the injury without causing additional problems. A successful splint contains adequate padding on the underlying skin, and particularly over bony prominences, to prevent pressure or burns that can be caused by plaster. Splints, which are not circumferential, are preferred for acute injuries because they allow room for swelling which inevitably occurs after a fracture.

Fractures that are displaced or angulated require closed reduction to properly realign the bone. This is done using analgesia, local or general anesthesia, and often muscle relaxation. Reduction is performed with axial traction and reversal of the mechanism of injury in order to restore length, rotation, and angulation. A splint is then applied and can be gently molded to help hold the reduction in place. It is important to obtain X-rays after a close reduction to verify acceptable alignment of the fracture, and to perform a neurovascular exam to ensure the splint is not too tight.

For certain fractures, splint or cast immobilization alone is not enough and in these instances internal fixation is used.

Figure 43-2. Transverse tibia fracture and segmental fibula fracture.

The main principle of orthopedic implants for fracture care is to create a stable construct that will allow the fracture to heal in proper alignment. Screws can be placed across a fracture to create compression at the fracture site, which promotes healing. Plates can be placed on the cortex of bones and held with screws, which creates a long area of fixation to stabilize the fracture. Intramedullary rods are commonly used for long bone fractures, such as the femur and tibia (Fig. 43-3A). Prior to their placement, the marrow in the canal is usually removed with a reamer. The rod is then inserted into the canal. Screws can then be placed across the cortices of the bone through holes in the rod proximal and distal to the fracture to create a locked construct that further stabilizes the rod (Fig. 43-3B). In situations where patients are severely injured and cannot safely undergo surgery, or when the soft tissues are too swollen or injured to allow for surgical incisions to be safely made, an external fixation device can be used to temporarily immobilize the fracture. External fixators involve pins placed in bone proximal and distal to the fracture through healthy tissues that are connected by strong rods on the outside extremity, creating a stable construct.

Open Fractures

An open fracture occurs when the bone breaks through the skin. These typically result from high energy injuries and are often associated with significant damage to the surrounding soft tissues and contamination of the wound (Fig. 43-4A). These injuries require immediate irrigation and debridement in the operating room and treatment with antibiotics to prevent wound infections and osteomyelitis (Fig. 43-4B). They can also cause injuries to surrounding vessels and nerves, which must be addressed as well. Often, definitive treatment of the fracture is delayed until the wound is sufficiently cleaned and healthy soft tissue is available to cover the fracture.

Compartment Syndrome

Compartment syndrome is an orthopedic emergency caused by significant swelling within a compartment of an injured extremity that jeopardizes blood flow to the limb. Increased pressure within the compartment compromises perfusion to muscles and can cause ischemia or necrosis. Patients complain of pain and numbness, and passive stretch of muscles within the compartment causes severe pain. While the diagnosis is based on clinical exam, pressures can be measured with needles placed into the compartment, which is necessary in unconscious patients who will not show these exam findings. When compartment syndrome is suspected, emergent fasciotomy must be performed in which the overlying tight fascia is released through long incisions. These must be done as soon as possible because the damage to muscles and nerves will result in irreversible necrosis and contractures causing severe loss of function.

TREATMENT OF FRACTURES AND DISLOCATIONS

Clavicle Fractures

Fractures of the clavicle are one of the most common fractures in orthopedics. They typically occur following a fall onto the shoulder and the majority of clavicle fractures occur in the middle third of the clavicle. Since the bone is subcutaneous, the fracture is often evident on inspection. Most clavicle fractures can be treated nonoperatively with a sling, range of motion

A B

Figure 43-3. **A.** Transverse femur fracture. **B.** Intramedullary rod stabilizes femur fracture.

exercises, and gradual return to normal activities. Fractures that are significantly displaced and shortened, or that penetrate the skin, are treated with open reduction internal fixation, typically with plate and screw fixation.

Distal clavicle fractures are less common and may occur along with coracoclavicular ligament ruptures. These injuries can be more troublesome and are at risk for nonunion if the bone ends are not in contact. If there is displacement of the fracture, surgical management is often recommended.

Acromioclavicular (AC) joint injuries occur from either a fall directly onto the shoulder or onto an outstretched hand and can result in tears of the acromioclavicular and coracoclavicular ligaments. A step-off, or separation, of the AC joint may be apparent on radiographs. The majority of

A B

Figure 43-4. **A.** Open grade 3 comminuted tibia-fibula fracture (motorcycle injury). **B.** External fixator temporarily stabilizes grade 3 open tibia fracture.

these injuries can be treated with a sling and gentle range of motion. Injuries resulting in severe displacement of the clavicle may require open reduction and surgical repair.

The sternoclavicular (SC) joint is the only articulation between the upper extremity and the axial skeleton, and injuries to this joint are rare. Anterior dislocations occur more frequently and closed reduction can be attempted, followed by sling immobilization. Posterior SC joint dislocations can be dangerous, resulting in pulmonary or neurovascular compromise, and closed reduction under general anesthesia is recommended with a vascular surgeon present in case of vascular injury.

Scapula Fractures

Fractures of the scapula often result from significant trauma and can be associated with injuries to the head, lungs, ribs, and spine.

4▶ Most scapula fractures are treated nonoperatively with the exception of fractures to the glenoid. As with most intra-articular fractures, displacement of the articular surface of the glenoid is an indication for open reduction and internal fixation.

Shoulder Dislocations

The shoulder is one of the most commonly dislocated joints and most dislocations are anterior. They are often associated with injuries to the labrum (Bankart lesion), impression fractures of the humeral head (Hill-Sachs lesion), and rotator cuff tears. Pos-

5▶ terior dislocations are associated with seizures or electric shock. Adequate radiographs are required to diagnose a shoulder dislocation, with the axillary view being the most critical. If proper X-rays are not performed then dislocations can be missed and can result in significant debilitation of the shoulder. Dislocation of the shoulders can be managed with closed reduction followed by a short period of sling immobilization.

Proximal Humerus Fractures

Proximal humerus fractures occur most frequently in elderly patients following a fall onto the shoulder, though they can also occur following high-energy trauma. They have historically been classified by the number of fracture fragments using the Neer classification, which divides the proximal humerus into 4 parts: the humeral head, greater and lesser tuberosities, and the humeral shaft. Treatment is determined by the displacement of the fracture fragments, the amount of angulation of the fracture, and the amount of comminution (which means multiple fracture fragments). If there is suspicion of an intra-articular fracture, a computerized tomography (CT) scan is often indicated. The majority of proximal humerus fractures is minimally displaced and can be treated with sling immobilization, followed by early shoulder motion and pendulum exercises. Displaced fractures and fractures involving the humeral head are at increased risk for osteonecrosis and therefore surgery is often recommended. If there is adequate bone stock and the fracture can be successfully reduced, open reduction internal fixation with plate and screw fixation is the treatment of choice. Older patients with osteoporotic bone and comminuted fractures are typically treated with a prosthetic replacement of the humeral head, or a hemiarthroplasty.

Humeral Shaft Fractures

Humeral shaft fractures occur from direct trauma to the arm or from a fall on an outstretched arm, especially in elderly patients. The radial nerve spirals around the humeral shaft and

6▶ is at risk for injury, therefore a careful neurovascular exam is important. Most radial nerve injuries are neuropraxias, or stretching of the nerve, and function typically returns in 3 to 4 months. The majority of humeral shaft fractures can heal with nonsurgical management if they are within an acceptable degree of angulation. They are treated with a coaptation splint or functional bracing, which consists of a plastic clamshell brace with Velcro straps. Close follow-up with serial radiographs is important to verify healing of the fracture, and gentle motion exercises are begun within 1 to 2 weeks. Fractures with significant angulation are most commonly treated with open reduction and plate fixation, with care to protect the radial nerve as it often lies close to the fracture site. Intramedullary nailing can also be performed, though it carries the risk of shoulder pain from the nail insertion.

Distal Humerus Fractures

Fractures of the distal humerus result from falls onto the elbow or onto an outstretched arm. Supracondylar fractures are most common, occurring above the elbow joint and do not involve the articular surface. Those minimally displaced can be treated with a posterior long arm splint, with the elbow typically flexed to 90 degrees. Fractures involving the articular surface are treated with plate fixation, and depending on the fracture pattern may require 2 plates, one placed medially and one posterolaterally. As with other intra-articular fractures, the goals of treatment are anatomic reduction of the joint surface with stable fixation, restoration of the anatomic alignment of the joint, and early range of motion. Severely comminuted fractures, especially in the elderly, may be treated with a total elbow replacement, which involves replacing the joint surfaces of the distal humerus, proximal ulna, and radial head with prosthetic components. Fractures about the elbow are notorious for developing stiffness and therefore early motion of the elbow is paramount to a successful outcome. Range of motion should be started as soon as the patient can tolerate therapy.

Elbow Dislocations

Dislocations of the elbow are common and typically occur posteriorly after a fall on an outstretched hand. A dislocation results in injury to the joint capsule and rupture of the lateral collateral ligament, though the medial collateral ligament can also be involved. They may even be associated with a fracture of the radial head, coronoid, or the epicondyles of the humerus. Simple elbow dislocations should be urgently reduced with the patient under sedation and treated briefly in a posterior long arm splint. Stiffness of the elbow is a common complication following elbow dislocations and therefore short-term immobilization (about 7–10 days) and early range of motion is recommended.

Dislocations associated with fractures may be treated surgically if there is any instability of the elbow joint. A severe injury, known as the "*Terrible Triad*," includes an elbow dislocation, a radial head fracture, and a coronoid fracture. These are unstable injuries and require repair of the torn lateral collateral ligament (LCL), fixation or replacement of the radial head, and possible fixation of the coronoid depending on the size of the fracture fragment.

Radial Head Fractures

Most fractures of the radial head can be treated nonoperatively, simply with a sling for 1 to 2 days followed by motion exercises. However, if there is a displaced fracture or if the fracture blocks pronation or supination of the forearm, then surgery is recommended. If the fracture can be well reduced, it is fixed with 1 or 2 screws. If the radial head is fractured into multiple pieces, the treatment of choice is a radial head replacement with a

metallic implant. Excision of the radial head can also be performed, but this is reserved for elderly patients with limited demands and may contribute to elbow instability or wrist symptoms over time.

Olecranon Fractures

Olecranon fractures occur following a fall directly onto a flexed elbow. Nondisplaced fractures are treated with a splint in 45 to 90 degrees of flexion for a short time followed by range of motion exercises to prevent stiffness. Because the triceps inserts on the olecranon, the pull of the muscle often displaces the fracture, causing a loss of the ability to actively extend the elbow, and therefore should be fixed surgically. Simple transverse fractures can be fixed with a tension band construct, which consists of cerclage wiring passed through the ulna and wrapped in a figure-of-8 fashion around 2 pins placed proximally into the olecranon, creating a compressive force across the fracture to promote healing. Comminuted fractures are treated with plate and screw fixation. Because of the subcutaneous location of the olecranon, this hardware can be irritating to the patient and may need to be removed after the fracture has healed.

Forearm Fractures

Forearm fractures are common injuries that result from high energy trauma or from falls onto an outstretched arm. Both bone forearm fractures often require surgery with plate and screw fixation. The radius has a bow and rotates around the straight ulna for proper pronation and supination of the forearm, and therefore this anatomic relationship needs to be restored to maintain function. An isolated fracture of the ulna shaft, or a "nightstick fracture," occurs from a direct blow to the side of the forearm. These can usually be treated in a cast, though fractures that are angulated or displaced can be treated with open reduction and plate fixation. A Monteggia fracture is an ulna shaft fracture along with a radial head dislocation. The radial head dislocation may be missed without radiographs of the elbow and therefore a fracture of the ulna should raise suspicion of this injury. These injuries require surgery to fix the ulna fracture with plate and screw fixation and to reduce radial head. A Galeazzi fracture is a radial shaft fracture with disruption of the distal radioulnar joint (DRUJ) at the wrist. After the radius is fixed with plate and screw fixation, the DRUJ is assessed for stability and may need wires placed across the joint temporarily.

Pelvic Fractures

Pelvic fractures are indicative of high energy trauma and are associated with head, chest, abdominal, and urogenital injuries. Hemorrhage from pelvic trauma can be life threatening and patients can present with hemodynamic instability, requiring significant fluid resuscitation and blood transfusions. The bleeding that occurs is often due to injury to the venous plexus in the posterior pelvis, though it can also be due to a large vessel injury such as a gluteal artery. Immediate resuscitation is critical and these patients may require surgical exploration or interventional radiology embolization to stop the bleeding. An important first-line treatment in the emergency room is the application of a pelvic binder or sheet that is wrapped tightly around the pelvis to help control bleeding. An external fixator may also be placed in the operating room. Other associated injuries are bladder and urethral injuries that manifest with bleeding from the urethral meatus or blood in the catheter and need to be assessed with a retrograde urethrogram.

7▶

The pelvis is a ring structure made up of the sacrum and the two innominate bones that are held together by strong ligaments. Because it is a ring, displacement can only occur if the ring is disrupted in two places. This may occur either from fractures of the bones or tears of the ligaments. There are three main fracture patterns that occur from trauma to the pelvis. An anteroposterior force to the pelvis causes an "open book" injury pattern in which the pelvis springs open, hinged on the intact posterior ligaments with widening of the pubic symphysis. A lateral compression pattern results from a crush injury that causes fractures to the ileum, sacrum, and pubic rami. Vertical shear injuries are very unstable since they result from disruption of the strong posterior pelvic ligaments and are associated with significant blood loss and visceral injuries. Fractures of the sacrum may be difficult to see on x-ray and therefore CT scans are often needed to visualize the fracture pattern. The sacral nerves pass through foramen in the sacrum and therefore fractures that are close to this foramen can result in nerve injuries.

Treatment of pelvic fractures depends on the fracture pattern. Stable, minimally displaced fractures can be treated nonoperatively with protected weight bearing. Open book injuries in which the pubic symphysis is widened and the posterior pelvic ligaments are also injured need to be fixed surgically, which is typically performed with screws placed percutaneously through the ileum into sacrum to stabilize the pelvis posteriorly and a plate and screws over the pubic symphysis to stabilize it anteriorly. Displaced sacral fractures and iliac wing fractures are treated with screws or plates, while pubic rami fractures can usually be managed nonoperatively. While most pelvic fractures are caused by high energy trauma, elderly patients with osteoporotic bone can also suffer pelvic fractures after a fall, usually fracturing the pubic rami. Since these are stable injuries, they can be managed nonoperatively with protected weight bearing.

Acetabular Fractures

The acetabulum forms the socket of the hip joint, and fractures occur when the femoral head is driven into it in the setting of high energy trauma. CT scans are important to visualize the fracture pattern. These fractures often require surgery in order to restore a congruent, stable acetabulum, because incongruity of the hip can lead to early degenerative changes and osteoarthritis. These are best treated in the hands of experienced orthopedic trauma surgeons.

Hip Dislocations

Hip dislocations almost always result from high energy trauma and most commonly occur posteriorly. They can cause injury to the sciatic nerve, which runs directly posterior to the hip joint, and may be associated with a fracture of the acetabulum or femoral head. Hip dislocations need to be emergently reduced because of the risk of osteonecrosis of the femoral head when reduction is delayed. They can usually be reduced in the emergency room with adequate sedation and muscle relaxation, but sometimes patients need general anesthesia to aid in the reduction. If this is unsuccessful, or if a fracture fragment gets trapped inside the joint, then an open reduction is performed. Hip dislocations that are associated with a femoral head fracture are at increased risk for osteonecrosis of the femoral head and posttraumatic osteoarthritis.

Hip Fractures

Hip fractures are an extremely common injury seen in orthopedics and are associated with significant morbidity and mortality. They most often occur in elderly patients after grounds level falls, are much more common in women than men, and

occur more commonly in patients with osteoporosis. Patients who suffer hip fractures are at increased risk for many complications, including deep vein thrombosis, pulmonary embolism, pneumonia, deconditioning, pressure sores, and even death, as the mortality rate in the first year following a hip fracture is around 25%. One of the most important reasons for performing surgery is to prevent these complications, and getting patients out of bed and walking as soon as possible diminishes their risk. Therefore, surgery is almost always the treatment of choice for hip fractures, and the type of surgery performed is determined by the anatomic location of the fracture and the fracture pattern. Surgery should be performed as soon as possible, typically within 24 to 48 hours; however, since many of these patients suffer other comorbidities, they must be properly medically optimized before surgery. The goals of surgery are to minimize pain, restore hip function, and allow early mobilization, the importance of which cannot be overemphasized. The functional outcome for patients following a hip fracture is largely based on their level of mobility and independence before their injury. Many patients become less independent, may require assistive devices to help them walk, and some may require a long-term nursing or rehabilitation facility.

Femoral Neck Fractures Femoral neck fractures occur with the capsule of the hip joint. The blood supply to the femoral neck and head comes from branches of the medial and lateral femoral circumflex arteries, which run along the femoral neck, and therefore fractures in this area put the vascular supply at risk and can lead to osteonecrosis. Femoral neck fractures that are nondisplaced have a low risk of disruption of blood flow and therefore can be treated with in situ internal fixation. Three cancellous screws are placed through a small incision over the lateral proximal femur, directed up through the femoral neck and into the femoral head. Patients can usually begin protected weight bearing immediately after surgery. Displaced femoral neck fractures will likely disrupt the blood supply and therefore need to be treated with a prosthetic replacement. Most commonly a hemiarthroplasty is performed in which the femoral neck and head are replaced with a metal stem into the femoral canal and a metal head (Fig. 43-5A). Patients who have severe osteoarthritis of the hip joint and had significant arthritic hip pain before their fracture may receive a total hip replacement, in which the acetabulum is also replaced with a prosthesis, typically a plastic cup inside a metal shell (Fig. 43-5B). Patients can begin weight bearing immediately after surgery.

Intertrochanteric Hip Fractures. Intertrochanteric hip fractures occur between the greater and lesser trochanters of the proximal femur. Because the blood supply to this area is abundant, osteonecrosis is uncommon and therefore these fractures can be fixed with internal fixation. Displaced fractures need to be realigned, and this involves placing the patient on a fracture table where traction and rotation can be applied to the affected leg to reduce the fracture. There are two devices that can be used. A sliding hip screw includes a large screw placed from the lateral cortex of the proximal femur across the fracture and into the femoral neck and head, followed by a side plate along with lateral cortex of the femur, which is then fixed to the shaft with screws. A cephalomedullary nail includes a nail placed down the medullary canal from the piriformis fossa and a large screw that engages the nail as it is passed from the lateral cortex up into the neck and head. Both devices form stable constructs (though the

A B

Figure 43-5. A. Failed hip hemiarthroplasty (periprosthetic fracture). **B.** Periprosthetic fracture repaired with modular femoral component.

cephalomedullary nail is preferred for certain fracture patterns) and allow protected weight bearing postoperatively.

Subtrochanteric Hip Fractures. Subtrochanteric hip fractures occur in the proximal femoral shaft just distal to the lesser trochanter in an area of high biomechanical stresses. While they can occur in elderly patients after a fall, they are also seen in high energy trauma. Because of the forces of muscles attached to the fractured segments, they tend to be significantly displaced and it can be difficult to reduce these fractures. They are most often treated with a long cephalomedullary nail that includes a screw distally to lock the nail in place and prevent rotation of the femur. Fractures that cannot be reduced closed on a fracture table or that are severely comminuted require open reduction followed by a cephalomedullary nail or by a plate and screws that is placed over the lateral cortex of the femoral shaft. In most cases, protected weight bearing can begin soon after surgery.

Femoral Shaft Fractures

Fractures of the femoral shaft are caused by high energy trauma and may be associated with other severe injuries. Long bone fractures, such as femoral shaft fractures, put these patients are risk for complications such as thromboembolic events and acute respiratory distress syndrome (ARDS), and therefore it is important to fix these quickly, typically within 24 hours. They are most commonly fixed with an intramedullary nail that can be placed antegrade (from the piriformis fossa or greater trochanter down the canal) or retrograde (through an incision into the knee joint and up the canal), with screws placed through proximal and distal holes to lock the nail in place, creating a stable fixation to allow weight bearing. Trauma patients who are hemodynamically unstable or who have other life-threatening injuries are treated temporarily with an external fixator until they can safely undergo surgery.

Distal Femur Fractures

Distal femur fractures are the result of a fall from a height or from high-energy trauma. They can also occur in elderly patients with osteoporotic bone after a fall onto the knee. While nondisplaced fractures in the elderly may be treated nonoperatively with a hinged knee brace and motion exercises, most require surgery. These fractures can involve the articular surface of the knee joint, so anatomic reduction of the joint surface is crucial. They are fixed with plates and screws placed over the medial or lateral cortex, depending on the fracture pattern, and early knee range of motion is encouraged to prevent stiffness. These intra-articular fractures require the patient to be nonweight bearing until the fracture shows signs of healing.

Knee Dislocations

Dislocation of the knee is a rare but devastating injury that can be limb-threatening. When the knee dislocates, the anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) are torn, and various degrees of injury occur to the LCL, medial collateral ligament (MCL), posterolateral corner, joint capsule, and menisci. The danger however is due to the close proximity of the popliteal artery that runs directly behind the knee, which may kink or suffer a tear of the intimal wall when the knee dislocates. A neurovascular exam is extremely important, followed by immediate reduction of the knee and repeat exam of the pulses. If there is evidence of diminished or absent pulses, an angiogram must be performed, and vascular surgery may need to perform emergent vascular repair. With regard to the ligamentous injuries, an MRI will identify what structures have been torn. Because a dislocation causes so much damage to the knee, multiligamentous reconstruction is recommended in order to stabilize the knee joint. Stiffness and instability of the knee are common complications after this injury.

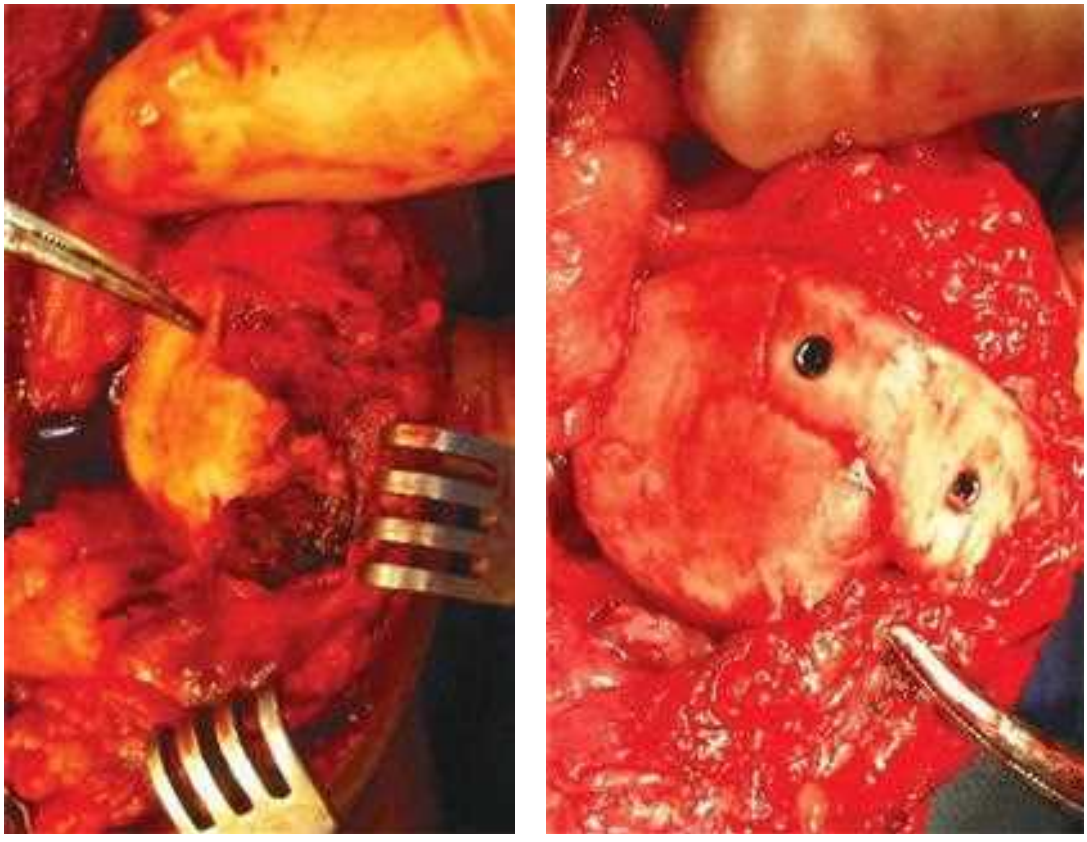
Patella/Extensor Mechanism Injuries

The extensor mechanism is comprised of the quadriceps tendon, the patella, and the patella ligament and functions to extend the knee. Injuries can result after a fall directly onto the knee or from forcible contraction of the quadriceps. It is important to examine the knee for the ability to actively extend the knee, since quadriceps tendon ruptures, patella fractures, or patella ligament ruptures can result in a loss of active knee extension, requiring surgery. Nondisplaced patella fractures can be treated nonoperatively with a cast or knee immobilizer, holding the knee in full extension, and weight bearing is permitted. Displaced or comminuted fractures require surgery with either tension band wiring or screws. Acute osteochondral fractures can be managed with internal fixation (Fig. 43-6A and B). Quadriceps tendon and patella ligament ruptures with loss of active knee extension are treated with suture repair. After surgery, the knee is held in extension and knee flexion is slowly increased over several weeks using a hinged knee brace.

Patella dislocations are common injuries that occur when the femur is forcibly internally rotated on an externally rotated tibia while the foot is planted on the ground. They typically dislocate laterally and often relocate spontaneously. Patients present with a significant knee effusion and on physical exam may elicit a positive apprehension test, in which a lateral force to the patella elicits pain and the sensation of an impending dislocation. Dislocated patellas can be reduced by extending the knee and manual reduction, and are treated with temporary knee immobilization. There is a high risk for recurrent dislocations, which may require surgical intervention. Osteochondral injuries to the trochlear groove and patella may be managed with the Draenert technique of autologous osteochondral transplant (Fig. 43-7A and B).

Tibial Plateau Fractures

The tibial plateau is comprised of the articular surfaces and underlying cancellous bone of the medial and lateral plateaus of the proximal tibia. Fractures of the plateau result from axial loads sustained in falls from a height or high energy trauma, and are often associated with injuries to the menisci and cartilage of the knee. Fractures can involve the medial, lateral, or both plateaus with significant comminution, angulation, and depression, creating a challenging injury to fix. A CT scan is important to visualize the intra-articular involvement of the fracture. Minimally displaced fractures may be treated nonoperatively with strict nonweight bearing until the fracture heals. Fractures associated with displaced articular fragments require surgery in order to restore the smooth contour of the articular surface. They are treated with plates and screws placed medially, laterally, or both. Since there is often a depression of the cancellous bone, bone graft or bone substitutes may be needed to buttress the articular surface and restore the anatomic alignment of the tibia. Patients are kept strictly nonweight bearing for several weeks until the fracture begins to heal, though early range of motion is encouraged. Repair of ligament or meniscus injuries may also be indicated at the time of surgery. Knee stiffness and osteoarthritis are common complications of these injuries.



A B

Figure 43-7. **A.** Knee traumatic articular lesion (trochlear groove). **B.** Lesion repaired with Draenert technique (autologous osteochondral transplant).

Tibial Shaft Fractures

Tibial shaft fractures are the most common long bone fractures and they occur following high energy trauma, direct blows, and severe twisting injuries. Trauma and direct blows to the tibia result in transverse or comminuted fracture patterns, while torsional injuries cause spiral fractures. Fractures with minimal angulation can be treated with reduction and casting, followed by transition to a functional brace and slow return to weight bearing, and may need to be immobilized for several months since these fractures can be slow to heal. Most tibial shaft fractures, especially comminuted and angulated fractures, are treated with an intramedullary nail placed down the tibial canal, with interlocking screws placed proximally and distally, and weight bearing can begin soon after surgery. Plate and screw fixation can also be used, however since the tibia is subcutaneous, hardware placed along the shaft can increase the risk of wound breakdown, and therefore intramedullary nailing is the preferred treatment. Fibula shaft fractures often occur along with tibial shaft fractures, though they usually heal well without surgery.

Tibial Plafond (Pilon) Fractures

The tibial plafond is the distal tibial articular surface of the ankle joint. Pilon fractures are typically high energy injuries from axial compression or a shear force. These injuries can cause significant soft tissue injury, severely comminuted intra-articular fragments, and wound healing problems, making these fractures very difficult to treat. Due to the soft tissue injury, these fractures are initially treated with external fixation until the swelling subsides, which may take several days to weeks. The goals of surgery are to restore the articular surface, fix the fibula in order to maintain and establish anatomic length, bone graft any cancellous bone defects, and stabilize the distal tibia with plate and screw fixation. Patients are kept nonweight bearing for many weeks until the fracture heals. Despite best efforts, patients may suffer from ankle pain and stiffness, arthritis, wound healing problems, infection, nonunion, and some patients eventually need ankle fusion in the future.

Ankle Dislocations

The ankle joint is a complex hinge joint comprised of the distal tibial plafond, medial malleolus, and lateral malleolus and their articulation with the talus. Several ligaments also contribute to the stability of the ankle joint, including the deltoid ligament medially, the syndesmotic ligaments between the tibia and fibula, and the anterior talofibular, posterior talofibular, and calcaneofibular ligaments laterally. Dislocations of the ankle joint result from a severe twisting injury and often occur with fractures. At times, dislocations can place significant pressure on the overlying skin and can cause neurovascular compromise, therefore prompt reduction is extremely important followed by splinting.

Ankle Fractures

Ankle fractures are very common and result from a twisting injury to the ankle. The patterns of ankle fractures depend on the direction of force and the position of the foot and ankle at the time of injury. The goals of treating ankle fractures are to restore the anatomy of the ankle joint and to restore the length and rotation of the fibula. Initial treatment includes closed reduction and placement of a well-padded splint in order to protect the skin. Swelling can be a significant problem so elevation of the foot is encouraged. If surgery is to be performed, it is usually delayed 1 to 2 weeks until the swelling decreases to limit the risk of wound healing problems.

Lateral Malleolus Fractures Isolated fractures of the lateral malleolus require anatomic reduction of the fracture in order to restore normal ankle joint congruity. The talus can sublux laterally following lateral malleolus fractures, and even 1 millimeter of talar shift decreases the surface contact between the talus and the tibia by 40%, increasing the risk of developing arthritis. Closed reduction and casting can be successful, however if the fracture cannot be adequately reduced, then open reduction internal fixation of the fibula is done with plate and screw fixation.

Medial Malleolar Fractures An isolated fracture of the medial malleolus is usually an avulsion-type injury. Minimally displaced fractures can be treated with a cast or walking boot, while displaced fractures are fixed with screws placed up through the tip of the malleolus.

Bimalleolar Fractures Fractures to both the medial and lateral malleoli often require surgery. These injuries are more unstable and the talus will often sublux or completely dislocate laterally. They are treated by reducing and fixing both malleoli during surgery. Occasionally, the posterior articular surface of the distal tibia, or posterior malleolus, can be fractured as well, resulting in a trimalleolar ankle fracture. Often it is a small fragment and does not need to be fixed, however if it involves >25% of the articular surface it should be fixed with screws placed either anteriorly or posteriorly.

Syndesmosis injuries The syndesmosis is comprised of several ligaments between the distal tibia and fibula that provide stability to the ankle joint by resisting axial, rotational, and translational forces. The syndesmosis can be disrupted at the time of ankle fractures and requires special attention. Widening of the space between the distal tibia and fibula after fixing the fractures is indicative of a syndesmosis injury and it is treated with 1 or 2 screws placed laterally from the fibula into the tibia, parallel to the ankle joint. Patients are kept non-weight bearing for several weeks. The screws are often removed after 12 weeks, though they can be left in place and are typically asymptomatic.

Calcaneal Fractures

Calcaneal fractures occur following a fall from a height and are often associated with other injuries, including lumbar spine fractures. These injuries are often intra-articular and can result in collapse of weight-bearing posterior facet of the calcaneous. CT scans are useful to better visualize the fracture pattern. Most fractures can be treated nonoperatively in a well-padded splint and patients are kept nonweight bearing for up to 12 weeks. Displaced intraarticular fractures can be treated surgically once the swelling subsides with lag screws or with a thin plate and screw fixation. Despite adequate treatment, calcaneal fractures can be debilitating injuries, leading to significant heel pain and arthritis.

Talus Fractures

Fractures of the talus commonly result from forced dorsiflexion of the ankle, causing the talar neck to impact on the anterior distal tibia. The blood supply to the talus can be jeopardized after a fracture and may lead to osteonecrosis, which is an unfortunately common complication following talus fractures. Nondisplaced fractures are treated with a cast and have a 15% risk of osteonecrosis, while displaced fractures are often treated surgically with screw fixation. There is a high risk of osteonecrosis, ranging from 30% to 100%, and a high risk of arthritis.

Foot Fractures

The tarsal bones, including the navicular, the cuboid, and the three cuneiform bones, link the hind foot to the metatarsals and provide mechanical stability to the arch of the foot. Isolated fractures to these bones are rare and are often treated nonoperatively with a cast or boot. The Lisfranc ligament, which connects the 2nd metatarsal head to the medial cuneiform, is an important stabilizer of the midfoot. Lisfranc injuries can be seen following torsional forces to the foot or from crush injuries. These injuries often require surgery since anatomic reduction is extremely important for a successful outcome. Metatarsal fractures similarly result from twisting or crush injuries and most can be treated nonoperatively with a hard-soled shoe and weight bearing as tolerated. The base of the 5th metatarsal, however, warrants close attention. Fractures at the metaphyseal-diaphyseal junction of the proximal 5th metatarsal (Jones fractures) can jeopardize blood flow and are at risk for nonunion. Therefore, Jones fractures need close follow-up to assess for healing and may need screw fixation. Injuries to the metatarsal-phalangeal joints and phalangeal fractures can be treated symptomatically or with buddy taping with weight bearing as tolerated in a hard-soled shoe.

INTRODUCTION

Sports Medicine

Sports medicine deals with the prevention and treatment of injuries related to sports and exercise. These injuries encompass various areas in the musculoskeletal system. In recent years, sports-related injuries have increased and the sports medicine field has been expanding. The growth in sports and sports-related injuries has likely to do with: a) that athletes participate in sport-specific training year round (and in multiple sports) rather than just seasonal training, b) that there has been an increase in "weekend warriors," c) that patients have become more aware of physical fitness, are better educated, and have higher performance expectations, and d) that more people undertake recreational activities.

The orthopedic subspecialty of sports medicine treats a broad spectrum of patients, ranging from children who have just started participating in their first sports to the specialized care of professional athletes. Medical treatment of athletes, recreational or professional, can be complex as short- and long-term outcomes are influenced by the higher demand that athletes put on their bodies. Additionally, the orthopedic sports medicine specialist does not only treat the patient's injuries, but also has to consider the return to activity in a later stadium. "Getting back in the game" is sometimes subject to pressure from third parties (e.g., team members, coaches, parents, fans), which makes treatment and the rehabilitation a challenging process.

Surgical intervention for ligament and cartilage injuries in sports medicine patients is usually done using arthroscopic techniques. The most frequently injured joints are the shoulder, hip and knee. Therefore, treatment of common injuries in these joints will be the scope of this paragraph.

SHOULDER

Rotator Cuff

Rotator cuff injuries are among the most common reasons to visit an orthopedic sports specialist. Often, these injuries are associated with either forceful or repeated overhead or pulling movements. The rotator cuff provides shoulder movement and glenohumeral joint stability and injuries typically lead to pain, weakness and restricted movement of the arm. Over recent years, the treatment of the rotator cuff injuries has considerably improved with regard to indication for surgery, surgical techniques and rehabilitation protocols. With the introduction of arthroscopy, shoulder surgery has become less invasive with all advantages associated. Currently, it has been established that arthroscopic techniques are equal or superior to open techniques for most indications. Controversies surrounding rotator cuff repair remain and include, but are not limited to, use of acromioplasty, enhancement of healing with orthobiologics (Fig. 43-8), single- vs. double-row fixation and the treatment of massive or large tears. Rehabilitation after surgery plays an important role to restore strength, motion and function and to enable the patient to return to sports. Typically, rehabilitation is made up of three consecutive stages: immobilization, passive exercise, and active exercise. Immobilization and passive exercise usually start in the first 4 to 6 weeks after surgery. Immobilization can be established by using a sling and passive exercise should be initiated by the therapist. The therapist moves the arm in different positions to improve range of motion (ROM) while providing support. After 4 to 6 weeks, active exercises can be gradually introduced. At 8 to 12 weeks, muscle strength and improvement of arm control are increased by starting a strengthening exercise program.

Shoulder Instability

The most common etiology for shoulder instability is related to trauma, especially shoulder dislocation. After a shoulder has dislocated, it becomes vulnerable to repeat episodes of instability and may develop to being a chronic problem. Most of the shoulder's stability is provided by the rotator cuff and shoulder capsule. The most common dislocation is in the anterior-inferior direction, although posterior dislocations do occur. Typically, patients with an anterior dislocation present with pain and an internally rotated shoulder. Younger patients are more susceptible to suffer from repeat dislocations than older patients.[6–8] The position of the humeral head with respect to the glenoid and other bony pathology can be identified with radiographs. Views from different angles should be obtained to thoroughly evaluate; an anterior-posterior (AP) view, along with glenoid (axillary) view, and a " Y" view of the shoulder are recommended in assessing this injury. Since most of the shoulder's stability is provided by soft tissue, usually this is also injured. Following successful reduction magnetic resonance imaging (MRI) should be obtained to identify underlying causes and concomitant injuries.

Relocation of the shoulder is generally accomplished with the patient in supine position and the arm under gentle traction and slight abduction. Some sedation is helpful as it relaxes the patient's musculature and relieves the pain. Whether or not to immobilize a first-time-dislocated shoulder or not, remains controversial, as well as the position of immobilization or the early surgical repair of capsulolabral structures. Prolonged immobilization is not recommended since this will often lead to substantial stiffness in the shoulder and does not appreciably decrease the redislocation rate. A small minority of patients with atraumatic multidirectional instability can generally be treated with shoulder rehabilitation. Unfortunately, many patients experience recurrent dislocations, in which case surgical stabilization of the shoulder should be considered. Many open stabilizing procedures have been described and, depending on etiology,

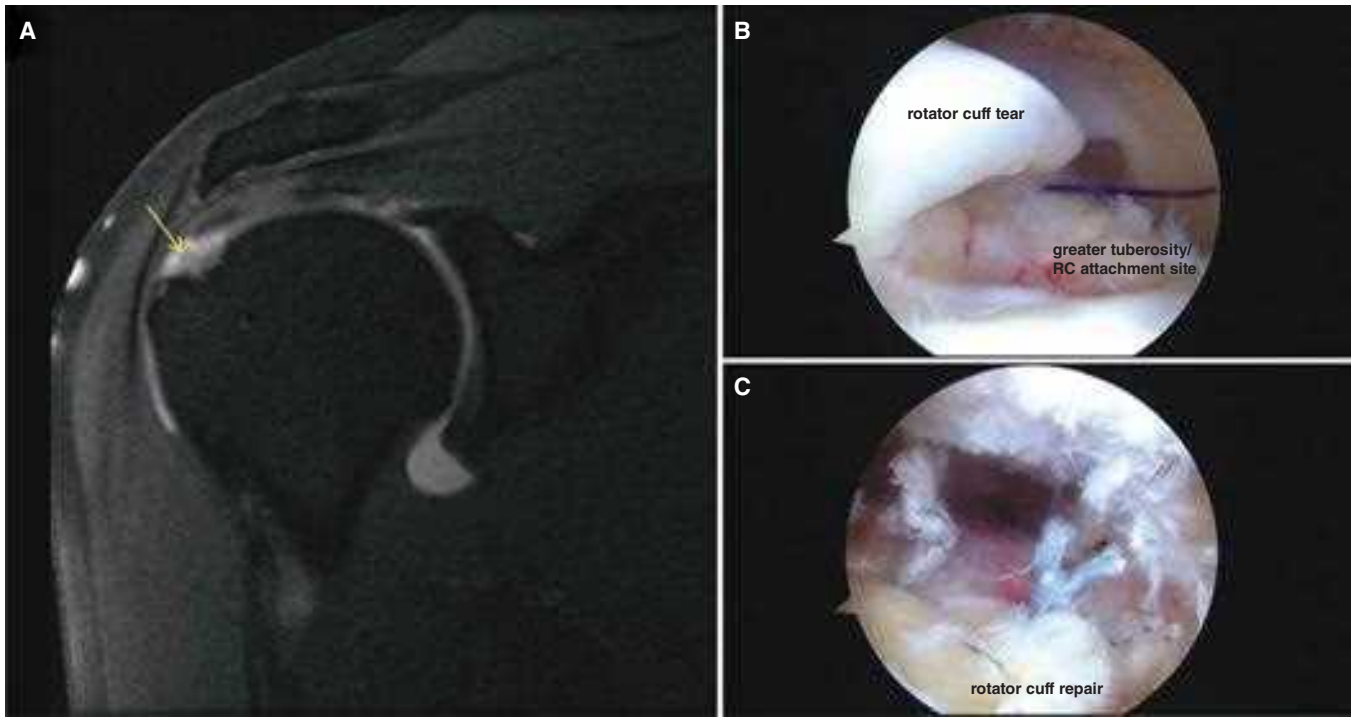

Figure 43-8. Imaging and treatment of rotator cuff tears. **A.** MRI coronal T2 image showing a full-thickness and moderately retracted tear (arrow) of the supraspinatus tendon. **B.** Arthroscopic image showing the supraspinatus tendon tear as viewed from a posterior portal during the surgery. **C.** Arthroscopic image showing completion of repair of the supraspinatus tendon tear using suture anchors imbedded in the greater tuberosity of the humerus and attached sutures that capture and reduce the torn tendon to its native insertion site.

many are still being applied such as the open Bankart repair, Latarjet procedure, remplissage and humeral head restoration. However, arthroscopic soft-tissue restoration has been the front-line treatment for recurrent instability. After surgery, the shoulder is temporarily immobilized with a sling. When the sling is removed, exercises to rehabilitate the ligaments, improve ROM and prevent from scarring, will be started. Strengthening exercises will gradually be added to the rehabilitation plan.

Superior Labrum and Biceps Tendon

The labrum helps to deepen the socket and stabilizes the glenohumeral joint. Additionally, it serves as an attachment point for many of the shoulder ligaments, as well one of the biceps tendons. A superior labrum anterior and posterior lesion may occur in the superior part of the labrum, usually anterior and posterior to the attachment of the biceps tendon, with occasional involvement of the biceps tendon in certain cases. Injuries to the superior labrum can be caused by trauma or by repetitive shoulder motion. Radiographs are generally obtained to evaluate for concomitant injuries or osteoarthritic changes. The labrum itself, and other soft tissue, is better visualized with MRI with addition of a gadolinium arthrogram adding sensitivity for labral injury detection (Fig. 43-9).

Conservative and operative treatments have had mixed results depending on the patient's age, activity level, type of tear and presence of concomitant injuries. If symptoms do not improve with adequate physical therapy and/or nonsteroidal anti-inflammatory drugs (NSAIDs), surgical intervention is usually indicated. Some SLAP injuries involve the biceps tendon, which may require either tenotomy or tenodesis.[10,11]

After surgical labrum repair, the shoulder needs to be immobilized to protect the repair and allow for healing. Usually a sling is used for 4 weeks after surgery. Then a physical therapy program will gradually start improving ROM and prevent from scar formation and stiffness to develop. As healing progresses, exercises to strengthen the shoulder muscles and the rotator cuff will gradually be added to the program around 4 to 6 weeks after surgery. Return to early interval throwing can generally be allowed around 3 to 4 months after surgery.

Impingement Syndromes

After minor trauma or repetitive injury, patients may experience pain and discomfort which can be due to irritation of the tissues in the subacromial space. In many cases these shoulder impingement syndromes are caused by simple bursitis or tendonitis of the long head of the biceps or supraspinatus tendon.[5] Occasionally, impingement syndromes can progress to tears of the supraspinatus tendon, which can be confirmed by MRI or ultrasound.

The goal of treatment is to reduce pain and restore function. Initial treatment is generally nonsurgical and based on rest, NSAIDs, and physical therapy. If pain is not relieved, an injection of a local anesthetic and a cortisone preparation may be helpful.

If conservative treatment does not relieve pain, surgery is recommended, with the goal to excise the bursa and create more subacromial space. Generally, surgery is performed arthroscopically and encompasses bursectomy and subacromial decompression via acromioplasty. If the rotator cuff (supraspinatus tendon) is also injured, arthroscopic repair is usually indicated to restore function, sometimes is accompanied by a bony resection of the inferior portion of the acromion.

The Acromioclavicular Joint

The acromioclavicular joint is a gliding synovial joint and not very mobile. The joint is stabilized by three ligaments: the superior acromioclavicular ligament, the inferior acromioclavicular

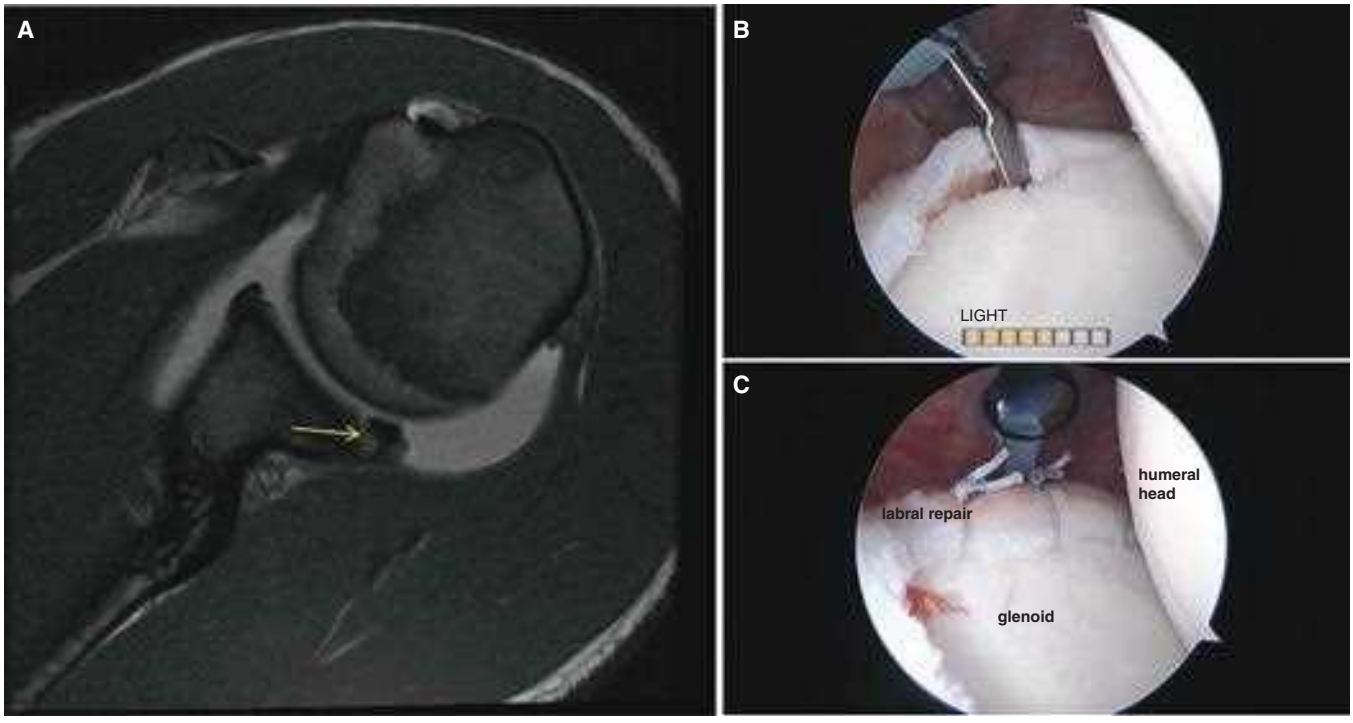

Figure 43-9. Imaging and treatment of a shoulder glenoid labrum tear. **A.** MRI axial T1 image showing a tear of the posterior superior labrum (arrow). **B.** Arthroscopic image with the patient in the lateral decubitus position showing detachment of the torn labrum away from the glenoid. **C.** Arthroscopic image demonstrating repair of the labrum to its attachment site using anchors in the glenoid and sutures that fixes the labrum to the glenoid.

ligament, and the coracoclavicular ligament. Injuries to these ligaments are commonly sustained playing contact sports such as football and ice hockey and may cause displacement of the joint. An acromioclavicular sprain is referred to as a shoulder separation and type I and II are usually treated symptomatic. Controversy exists however regarding early or delayed surgical reconstruction for type III tears. Frank tearing of the coracoclavicular ligaments, associated with significant displacement, is oftentimes reconstructed surgically.

KNEE

The knee is the largest joint in the human body and is a pivotal hinge joint, which allows flexion and extension as well as a medial and lateral rotation. The knee bears tremendous axial loads as well as torsional and sheer forces, making it vulnerable to both acute injury and the development of osteoarthritis. In sports, the major stabilizing structures such as the ACL and the medial collateral ligament (MCL) are frequently injured. Other frequent knee injuries are to the menisci, posterolateral corner, the posterior cruciate ligament (PCL) or patellofemoral.

Menisci

The menisci are crescent-shaped pieces of fibrocartilage shaped that provide joint stability, shock absorption, load distribution, and proprioception. Sudden meniscal tears often happen during sports, usually during contact or while squatting and twisting the knee. Typical symptoms associated with meniscus injury are pain, stiffness and swelling, catching or locking of the knee, buckling or " giving way" and impaired ROM. Radiographs are typically obtained to assess possible concomitant injuries, the presence of (early) osteoarthritis, and leg alignment. However, since menisci do not show on radiographs, an MRI is obtained to assess the status of the menisci and the soft tissue surrounding the knee joint (Fig. 43-10). Small tears on the outer edge of the meniscus may not cause symptoms and—provided the knee is stable—nonsurgical treatment may be sufficient.

The most commonly performed surgical procedure for meniscus tears is partial (subtotal) meniscectomy. However, it has become increasingly clear over recent years that preservation of the load-distributing function of the meniscus is important in preventing from development of early osteoarthritis. Research into the use of orthobiologics (e.g. microfracture of the notch, fibrin clot) for meniscal repairs has expanded the indications for repair over (subtotal) meniscectomy.[15–19] Tears have been reported in virtually all portions of the meniscus, with radial and longitudinal tears being the most common. Tears of the root of the meniscus are less common, but are increasingly being recognized as devastating injuries that cause serious alterations of knee contact forces. Surgical techniques are developing to repair the root to restore its function.[20,21] Meniscus transplantation may be an option for young patients with a largely deficient meniscus.[22]

The paradigm of treatment of torn menisci is shifting thanks to the development of superior surgical techniques, use of orthobiologics and promising first results with root repair and meniscus transplantations. Physicians must be further educated on the significance of meniscal preservation when there is potential for healing.

Directly after surgery, the knee is immobilized with a brace and weight bearing is protected to allow the meniscus to heal. When healing is complete, ROM and strength will need

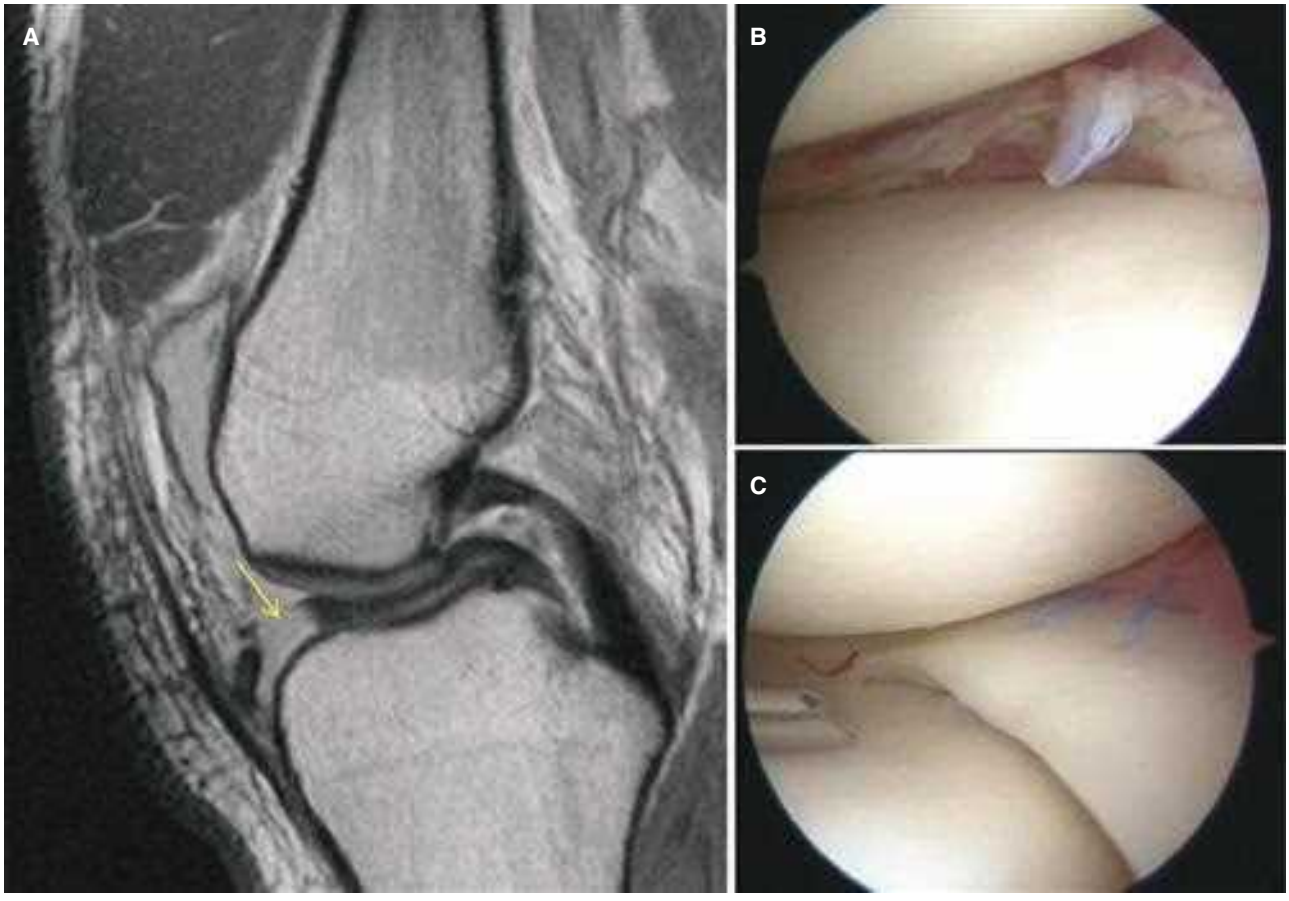

Figure 43-10. Imaging and treatment of a knee lateral and meniscus tear. **A.** MRI sagittal T2 image of the knee showing a displaced bucket-handle lateral meniscus tear (arrow). **B.** Arthroscopic image showing the remnant rim of the lateral meniscus prior to reduction and fixation of the torn bucket-handle fragment. **C.** Arthroscopic image after the torn segment is reduced and fixed to the remaining meniscus and the lateral capsule using suture.

to be regained. Physical therapy is an integral component of healing and return to play, which usually is allowed between 4 to 6 months after surgery.

Collateral Ligaments

The MCL is the most frequently injured knee ligament, which usually occurs after excessive valgus stress of the knee. Oftentimes, this is associated with (medial) meniscus injury and sometimes with an ACL. The combination of MCL, medial meniscus, and ACL injury is also known as the "unhappy triad" and occurs most commonly in contact sports.

The MCL has good healing potential and grade I and II injuries usually improve with bracing and activity modification. Grade III injuries may also improve with conservative treatment and often these injuries are treated non-operatively initially. The majority of MCL injuries occur in the mid-substance or at the femoral insertion side. There is a small subset of tibial sided grade III tears though, that is associated with worse clinical outcome and surgical repair is more often advocated. Reconstruction is rare, since surgical repair is usually effective in restoring the MCL. Lateral collateral ligament (LCL) injuries are much less common than MCL ligament injuries, but similarly most often managed conservatively.

With return of ROM and normal gait pattern, patients are functionally progressed towards return to sports. A functional brace during sports is advised.

Cruciate Ligaments

The cruciate ligaments are situated centrally within the intercondylar notch of the knee. The biomechanical function of both the ACL and the PCL is complex and three-dimensional, but to simplify: both play an important role in providing antero-posterior and rotational stability of the knee.

ACL tears are a common sports injury, especially in sudden cutting and stopping sports (e.g. soccer, basketball) or contact sports (e.g. football). A torn ACL will result in altered knee biomechanics and kinematics and thus potentially lead to the early development of degenerative changes in the knee joint. Since a torn ACL will not heal without surgery, surgical ACL reconstruction is generally treatment of choice in patients who are young and active. Patients with a more sedentary lifestyle and who experience no persisting or disabling instability in daily life, may be effectively treated with conservative management (i.e., bracing and physical therapy).

A patient with an ACL tear typically presents with pain and swelling, instability, loss of ROM, joint line tenderness (with associated meniscus injury), and discomfort while walking. Radiographs are obtained to evaluate joint condition and possible associated osseous injuries. To visualize the ACL and other soft tissue in the knee however, an MRI should be obtained. Although an MRI is not required to make the diagnosis, the information it provides is invaluable with regard to objectifying anatomic characteristics by taking measurements,

Figure 43 -11. MR imaging of a torn ACL. **(A-C)** Proton density sagittal cuts; showing anteroposterior tibial insertion site length measurement "x", intra-articular ligament length measurement "y" and ACL inclination angle measurement "z". Oblique (in the same plane as the ACL runs) coronal cuts showing a complete ACL tear with separate images of a PL bundle tear (D) and an AM bundle tear (E).

assessing concomitant injuries and presurgical planning in general (Fig. 43-11).

Reconstruction is performed with use of a tendon-graft that will replace the native ACL. Commonly used graft sources are the patellar tendon, the hamstrings and the quadriceps tendon. These tendons can be harvested from the same knee (i.e., autografts), during the same procedure. Alternatively a donor graft (i.e., allograft) can be used. Both have their own subset of pros and cons, with the most important pro being absence of donor-site morbidity for allograft and better healing potential for autograft.

Injuries of the PCL are less common than other knee ligament injuries. Frequently seen causes are a bent knee hitting a dashboard in a car accident or falling on a knee that is bent during running. A rupture of the PCL is usually better tolerated than ACL rupture, since many tears (i.e., grade I and II) have the potential to heal on their own and do not result in much knee stability problems. Most Grade I and II injuries are treated nonoperatively. Combined PCL/PLC and PCL/MCL and Grade III PCL injuries however, do present a challenge with regard to management decision-making. Chronic PCL-deficient (Grade III) knees have an increased incidence of osteoarthrosis, particularly in the patellofemoral and medial knee compartments. Indication for surgery is influence by age, activity level, and presence of concomitant injuries. Different surgical techniques have been proposed; the most common are the " inlay" technique and the transtibial technique.

The goal of cruciate ligament (both ACL and PCL) reconstruction is to restore native knee kinematics, to provide the patient with the best potential for a successful outcome and to prevent from the development of long-term complications, such as osteoarthrosis.

Posterolateral Corner

Critical structures of the posterolateral corner (PLC) are the LCL, popliteus tendon and popliteofibular ligament. These structures each contribute to the static and dynamic stability of the knee and are commonly injured concomitant with other ligamentous injury, mostly together with the torn ACL.[38] The importance of closely evaluating the PLC after knee injury is demonstrated by the fact that a deficient PLC causes altered knee biomechanics and subsequently increases stress on surrounding stabilizing structures. As such, it has been shown that a deficient PLC is a primary cause of cruciate ligament reconstruction failure.

Acute high-grade injuries of the PLC with obvious deficient structures require surgical intervention. Since primary repair becomes increasingly difficult as time between injury and surgery increases, a cut-off of 2 to 3 weeks is usual to either repair or reconstruct the deficient structures. With more chronic PLC injuries, reconstruction is recommended to restore knee stability.

HIP

Femoroacetabular Impingement

Femoroacetabular impingement (FAI) is a pathologic condition that refers to impingement of the anterior femoral head-neck junction against the anterosuperior labrum. This is frequently caused by abnormal bony offset at the femoral head-neck junction, abnormal acetabular anteversion or excessive anterolateral acetabular bony rim coverage (Pincer lesion), and combined CAM-Pincer lesions. Recognition of FAI can be clinically and radiologically difficult. However, familiarity with this disorder is essential, as FAI can lead to labral tears, cartilage delamination, and if untreated, osteoarthritis.

Commonly, patients present with anterior groin pain exacerbated by activities involving hip flexion or pain over the greater trochanter as well as grinding or popping. Patients report pain with flexion and internal rotation and after prolonged sitting. On examination, there is a decrease in internal rotation that appears out of proportion to the loss of the other ranges of motion and there is limited flexion. The impingement test, elicited by 90 degrees of flexion, adduction and internal rotation of the hip, is almost always positive.

The imaging findings of FAI can be seen on plain radiographs, CT scan, MRI, and MRA. Some of the abnormalities seen include abnormal lateral femoral head/neck offset seen as a lateral femoral neck bump, os acetabulae, synovial herniation pits, acetabular over-coverage, hyaline cartilage abnormalities, and labral tears.

Treatment of FAI has traditionally been surgical and has come from open surgical treatment with open acetabuloplasty, and later open procedures through a transtrochanteric approach and combined open-arthroscopy assisted techniques to full arthroscopic approaches. Hip arthroscopy is becoming increasingly popular and being more frequently applied for this indication. This popularity is largely the result of studies reporting on improvement of functional outcome measures with follow-up up to 10 years, with low complication rates in several large study populations.

SPINE

Spinal Trauma

In spinal injury spinal stability must be assessed, and the patient
8▶ immobilized until his spine is cleared. CT scan is more reliable in assessing spine injury than plain radiographs. When neurologic deficits are present a decompressive procedure may be indicated. In spinal cord compression, prompt decompression should be performed. Animal models of spinal cord injury suggest that prompt decompression can lead to objective improvement of recovery. Spinal cord injuries should be triaged
9▶ to trauma centers since trauma center care is associated with reduced paralysis.

Occipital Cervical Dislocation

Motor vehicle accidents can cause dislocation of the occiput on the condyles of the atlas (C1). Most patients with this injury suffer cervical cord injury, and do not survive. Traction on the spine is contraindicated. Treatment consists of stabilization and fusion in situ using a screw plate from the mid cervical spine to the occiput.

Fractures of C1 (Jefferson Fracture)

Fracture of the C1 ring was described by Jefferson in 1920. The thin anterior and posterior rings of the C1 vertebra fracture with axial loads. C1 fracture causes the e lateral masses of C1 to spread, which is visible on a through- the- mouth AP X-Ray image of the cervical spine. This injury is rarely associated with neurologic injury. Bracing with a cervicothoracic orthosis or a halo ring and vest is the recommended treatment for a Jefferson fracture.

Fractures of C2 (Odontoid Fracture)

Half of normal cervical rotation occurs at the atlanto-axial joint. The odontoid (Dens) is a small bony process which arises from the body of C2, and articulates with the body of C1 (the Atlas). Odontoid fractures are most often type I fractures (an avulsion fracture off the tip of the dens). Type I fractures occur when there is tension applied to the alar ligaments (which span from the tip of the odontoid to the skull bypassing the C1 vertebra). Type I fractures are stable and managed nonoperatively.

A type II fracture, at the base of the odontoid, results from lateral loading forces. Operative stabilization is the preferred treatment since immobilization in a halo vest results in nonunion rates ranging from 20% to 80%. Transfixing the odontoid fracture with a screw maintains rotational movement. Posterior fusion of C1 on C2 with sublaminar wiring resulting in decreased range of motion is another option.

Type III fractures extend into the body of C2, below the origin of the odontoid process. Type III fractures are generally treated with halo brace. (Anderson and D'Alonzo)

Hangman's Fractures of C2

Hangman's fractures result from sudden extension forces on the neck and occur between the superior and inferior facets (pars interarticularis) of C2. Treatment is simple immobilization in a halo vest. Higher energy injuries causing severe extension forces can dislocate the C2-3 facet complex and damage the C2-3 disc. Such fractures can compromise the spinal canal, and death can occur from compromise of respiration. Significantly displaced Hangman's fractures are managed by internal fixation and bone grafting between C2 and C3.

Compression Fracture of the Cervical Spine

In C3 to C7 an axial load can cause fracture of the endplate while preserving the posterior cortex of the vertebral body. These fractures generally heal well, and are treated nonoperatively with analgesics and a cervical brace.

Burst Fractures of the Cervical Spine

Diving accidents are the classic cause of *Burst fractures* of the cervical spine. The axial load when an unrestrained passenger in an automobile accident strikes the windshield the posterior cortex of the vertebral body fractures leading to displacement of bony fragments into the canal injuring the spinal cord. Burst fractures are treated surgically by anterior debridement of the fracture and reconstruction using a bone graft strut stabilized with a plate and screws.

Unilateral and Bilateral Facet Dislocation

Another injury associated with motor vehicle accidents is facet dislocation. A restrained passenger can suffer forced flexion with distraction resulting in dislocation of the facets. The diagnosis can be made on lateral radiographs. Treatment consists of axial traction with cranial tongs, graduated application of weight, and periodic X-Rays. The patient is kept awake for safety concerns. When reduction is attained, patients are taken to surgery for posterior fusion with interspinous process wiring or a screw plate.

Clay-Shoveler's Injury

Clay-Shoveler's injury can result from a motor vehicle accident or from shoveling soil or clay. The injury (of C6, C7, T1, and T2) is the result of avulsion fracture of the spinous process by the paraspinal muscle forces. The fracture is treated nonoperatively with analgesics and a soft collar.

FRACTURES OF THE THORACIC AND LUMBAR SPINE

Thoracic Lumbar Spine Injury

The ribs stabilize fractures of the thoracic spine, making these fractures more stable than similar fractures of the lumbar spine. Neurologic injuries are more common in the thoracic and proximal lumbar spine because of the presence of the spinal cord, which ends at the L2 level.

Compression Fracture

Compression fractures result from osteoporosis and abnormal bone density as well as trauma. Compression fractures involve a fracture of the superior or inferior endplate without associated posterior cortex fracture. Thoracolumbar compression fractures are treated nonoperatively with braces and analgesics.

Burst Fracture

Burst fractures are caused by falls and high energy automobile accidents. One or both endplates and the anterior cortex of the vertebrae with an associated fracture of the posterior cortex. The posterior cortex fracture differentiates the burst fracture from a compression fracture and results in retropulsion of bone into the canal, which can cause nerve injury. A vertical lamina fracture may contain an invaginated segment of the dura mater with accompanying nerve roots, and posterior surgery can result in dural tear or nerve injury.

If nerve injury is noted, treatment is an anterior exposure and removal of the fractured anterior elements (corpectomy) and a strut graft is placed. A laterally placed plate and screws add stability to the construct.

Seatbelt Injuries (Flexion Distraction Injuries)

A seatbelt injury occurs when there is acute forward flexion of the trunk and anterior (i.e. seatbelt) restraint. The pelvis and upper torso move forward, and failure of the spine under tension begins with the posterior elements. Tearing of the dorsal fascia, the interspinous ligament, dislocation of the facets, and tearing of the discs occurs. The bone of the spinous process, the lamina, the pedicles, and the vertebral body fail in tension ("Chance Fracture").

In flexion distraction injuries through soft tissue, posterior internal fixation and bone graft is recommended. "Chance fractures" are treated with bracing.

Fracture Dislocations of the Spine

Fracture dislocations of the spine displace the bony elements by translation or rotation resulting in canal narrowing and nerve injury.

Reduction of the displaced bones is the best way to improve the canal dimensions.

Patients with fracture dislocations of the spine and partial nerve function can recover. Fracture dislocations are treated operatively with surgical stabilization.

Disc Herniation

Disc herniation, most common between ages of 20 and 50, can occur in the cervical, thoracic, or the lumbar spine, and consists of a tear of the annulus allowing the nucleus pulposus material to extrude through the annulus and enter the canal, pressing on the exiting nerve or the 'traversing' nerve roots. In the cervical spine, spinal cord compression can occur.

Symptoms of most disc herniations resolve within eight weeks as the nerve root accommodates and inflammation recedes. The bulk of the extruded nucleus pulposus resorbs over time. When symptoms persist beyond six to eight weeks, excision of the involved disc and decompression of the nerve roots may be indicated.

In cervical disc herniation an anterior approach to the spine is performed with dissection through a transverse incision on the neck. Dissection is carried between the trachea and the carotid sheath. The disc is then removed. The disc space may be bone grafted to fuse the vertebrae. A locking screw low profile titanium plate is then attached to the vertebrae.

Posterior decompression and laminectomy exposes the posterior elements of the spine. A portion of the lamina is removed to allow access to the canal to correct foraminal impingement or to remove lateral disc herniations. While the posterior approach does not require fusion with plates and screws, central disc herniation cannot be managed through a posterior approach since the spinal cord cannot be safely retracted.

For lumbar disc herniation a midline incision is used and laminectomy allows visualization of the lateral recess. Retraction of the dura allows visualization of the traversing nerve roots as well as of the disc fragment.

Spinal Stenosis

A loss of hydration of the discs causes loss of disc height and bulging of annular tissue and the ligamentum flavum which effectively narrows the canal (spinal stenosis). Osteophyte formation on the facet joints can also cause nerve impingement. Cervical stenosis can cause myelopathic symptoms (hyperreflexia, ataxia, balance problems, weakness, and pain).

Lumbar stenosis causes neurogenic claudication (progressive pain, weakness, and numbness in the legs). The claudication symptoms result from standing and walking which increases lumbar lordosis. The symptoms resolve with sitting and bending forward (decreasing lumbar lordosis).

Spinal stenosis is treated with epidural steroid injections and physical therapy. Resistant cases may require surgical decompression and stabilization with plates and screws.

Spinal stenosis usually occurs in patients over 50 years of age. With degenerative spondylolisthesis or scoliosis fusion procedures with instrumentation may be required to prevent progression of the deformity.

Back Pain and Degenerative Disc Disease

Back pain occurs in the majority of adults but is usually self-limited resolving in one to two weeks. Chronic unremitting back pain suggests the possibility of infection, malignancy, or metastatic disease.

While radiographs are one option in the management of disabling low back pain, they are ineffective at ruling out malignancy, and radiographic findings correlate poorly with symptoms. Patients with severe degenerative symptoms may have no pain, while others with mild degenerative findings complain of severe pain. The potential for secondary gain and psychiatric problems and the unpredictable results of spine fusion add to the difficulty of diagnosis and choosing a treatment plan.

Intervertebral disc replacement prostheses are now used to treat degenerative disc disease. The potential for loosening, creation of wear debris, and bone loss complicating revision surgery are concerns, as are the proximity of the device to the spinal canal and the great vessels.

Scoliosis

Scoliosis is a lateral curvature of the spine. Lateral bending of the spine is always accompanied by rotational deformity (coupling).

In order to measure the severity of scoliosis lines are drawn along the endplates of the vertebral bodies at either end of the curve and the angle formed when these lines intersect is magnitude of the curve.

Scoliotic curves are classified as congenital, degenerative, metabolic (mucopolysaccharidoses), neurogenic (cerebral palsy), and myogenic curves (muscular dystrophy). Idiopathic scoliosis is the most common form, and represents a spectrum of genetic disease.

Adults with scoliosis may present with axial pain and imbalance in posture. Treatment for scoliosis may include medications, therapy, and activity modification. In severe cases with objective deformity surgical correction of the deformity may be indicated.

Idiopathic Scoliosis

The majority of idiopathic scoliosis curves become apparent during adolescence and progress during skeletal growth. Initial management consists of observation. Rapidly progressing curves are treated with braces. Brace treatment is recommended for curves between 20 and 40 degrees. For patients with large curves, surgical intervention may be needed using rods with grafting and fusion.

Neuromuscular Scoliosis

Neurologic conditions such as polio and cerebral palsy can lead to 'uncompensated' scoliosis curves where the patient is unable to lean with his upper body to restore balance. Scoliosis correction surgery may be needed to facilitate sitting balance, and to avoid skin breakdown caused by pelvic obliquity.

JOINT RECONSTRUCTION

Introduction to Arthritis

Arthritis refers to a large number of medical conditions, including osteoarthritis, rheumatoid arthritis, septic arthritis, and post-traumatic arthritis. Each has the potential to lead to loss of articular cartilage lining the joints. According to the CDC and the National Health Interview Survey approximately 50 million adults (22% of the U.S. population) have been diagnosed with some form of arthritis. This number is projected to grow to an astounding 67 million adults by 2030 (or 25% of the U.S. population).

10▶

The number of individuals suffering from arthritic conditions will continue to rise as the 'baby boomer' generation enters old age and with the rise in obesity in the U.S. population, as age and obesity are two major factors in the onset of arthritis.

Conservative Management and Prevention of Arthritis

Conservative measures to treat arthritis include weight loss, activity modification, rest, bracing, physical therapy, pain management, and assistive devices such as canes or walkers. Conservative measures have the potential to decrease symptoms and improve function and quality of life. These measures can successfully manage a patient's condition and avoid a surgical procedure. Osteoarthritis symptoms tend to be intermittent in nature or associated with high impact activities. Initially treat all patients with conservative measures and avoid surgery if possible

Conservative measures can also play a role in the prevention of arthritis. Weight loss of as little as 11 pounds has been shown to decrease the risk of developing knee osteoarthritis in women by 50%. Similarly, patients who engage in regular physical activity have been found to have lower incidence of arthritis.

11▶

Arthritis causes pain, loss of range of motion, decreased ability to perform work duties or participate in social functions, and decreased quality of life. Despite conservative therapy, frequently more invasive treatments are needed to effectively manage the patient's symptoms.

Examination of the Patient

A thorough history and physical examination (H&P) is indicated for all orthopedic patients. Patient history should include location, quality, severity, timing, and radiation of pain along with any referred pain, associated signs and symptoms, modifying factors, prior treatments, including both conservative and surgical treatments. Other details within the H&P are equally important for diagnostic purposes and to successfully develop a treatment plan. If you listen carefully to your patient, they will often tell you their diagnosis. Location of "hip pain" can narrow a differential diagnosis. Patients with activity related groin pain often are found to have hip arthritis, whereas patients with peri-trochanteric pain (lateral hip pain) may be suffering from trochanteric bursitis. The importance of listening and focusing on the patient's description of location and type of pain cannot be overemphasized.

Physical examination should begin by observing the patient's gait, both with and without assistive devices if possible. This demonstrates how significantly the patient is affected functionally and the effect of the patient's pain. Typical gait patterns include a "Trendelenburg gait" where abductor weakness may lead to a poor outcome following total hip arthroplasty. Other aspects of the exam include assessment for leg length discrepancy, joint contractures, skin changes, assessment for prior surgical incisions to evaluate for prior treatments or to plan future surgical approaches, neurovascular examination, strength and range of motion. These details document functional status and help to formulate a differential diagnosis. Patients with 'hip pain' may have lumbar spinal stenosis, radiculopathy, or vascular disease that may be playing a large role in their presentation. Once an appropriate physical examination is complete, weight-bearing radiographs are needed. Advanced imaging, including CT and MRI are rarely indicated in initial work up of patients. Once a diagnosis is made, specific treatment directed towards the patient's condition can be initiated. The goals of treatment are to improve pain, preserve motion and to maximize patient function, independence, and quality of life.

Injections

Joint injections are commonly performed into the knee and shoulder. Common injections into the knee include corticosteroids and Hyaluronic-acid gels. Corticosteroid injections can decrease inflammation within the joint. These injections are usually administered in combination with a local anesthetic, such as Lidocaine, in order to provide more immediate relief for both diagnostic and therapeutic purposes. If the patient has immediate relief of their pain symptoms with injection of the joint, this localizes the source of the patient's pain to the joint and may assists with diagnosis. At the same time any benefit received is therapeutic for the patient. Hyaluronic acid injections have become popular and are commonly referred to as "*viscosupplemenation*." The exact mechanism of these injections is not known, however patients may benefit from these injections by increasing the viscosity of the synovial fluid. The injections do not lead to articular cartilage repair. There is a risk of joint infection, cartilage injury from the needle, hemarthrosis, and failure to receive benefit. A theoretical risk of altered glucose metabolism in diabetics also exists with corticosteroid injections.

Surgical Management of Arthritis

The most commonly performed procedure for arthritis of a major joint is arthroplasty, or joint replacement. Joint replacements, including hip and knee arthroplasty are considered two of the most successful procedures performed in all of surgery. However, other nonarthroplasty options exist. These are typically performed for specific diagnoses under specific indications.

Osteotomy. Osteotomy is cutting the bone to change the position of the fragments in order to improve length, rotation, alignment, or angulation. Osteotomy can be performed for both congenital and acquired deformities that are thought to be contributing to the patient's pain or development or progression of disease. Pelvic and femoral osteotomy can be utilized in treatment of developmental dysplasia of the hip. With this procedure the position of the acetabulum can be altered in order to provide more appropriate coverage of the femoral head, which is usually deficient anteriorly and laterally. Femoral osteotomies can also be performed to correct anteversion and varus/valgus deformity of the femoral neck. Osteotomies are performed to obtain more normal alignment and coverage of the femoral head within the acetabulum to prevent or delay future disease.

An osteotomy commonly used in the knee is a proximal tibia osteotomy. An adult patient who presents with isolated medial compartment knee arthritis and associated varus deformity would be an ideal candidate for valgus (high tibial) osteotomy. An osteotomy that realigns the knee into slight valgus has the potential to off-load the medial compartment, slow disease progression and prevent or delay the need for more invasive procedures (unicompartmental or total knee arthroplasties).

Arthrodesis. Arthrodesis is a treatment option for severe arthritis where the overlying articular cartilage is removed and the two opposing bones are allowed to heal together. After successful arthrodesis no motion is possible through the joint and the source of pain is removed. Arthrodesis of large joints, such as the knee, shoulder or hip, are typically explored as an option in the face of infection, in elderly, low demand patients or in young and active patients who are considered too young for a joint replacement (concern for component wear and need for early revision). Arthrodesis can also serve as a "last resort" procedure in orthopedics, when joint preserving treatments fail, fracture, infection, etc. Arthrodesis requires removal of overlying articular cartilage from bone and frequently the use of autograft or allograft bone and the use of hardware for internal fixation or temporary external fixation.

Joint Arthroplasty/Joint Replacement. Joint arthroplasty is considered the final option for patients suffering from pain associated with arthritis in the joint. The surfaces of the bones are replaced after removing the damaged articular cartilage. The amount of bone and the determination of how to make the bone cuts is made based on pre-operative radiographs and templating, cutting guides, computer navigation, and anatomic measurements. The cut bony surfaces are covered with new components, usually made of metal, ceramic, or polyethylene. These new components are sized to appropriately match the patient, based on templating pre-operative radiographs, intra-operative measurements, and examination for stability, leg length, alignment, and range of motion.

If all compartments or surfaces of the joint are replaced, the arthroplasty is referred to as a total joint arthroplasty. In comparison, if only one surface or compartment of the joint is replaced, it is referred to as hemiarthroplasty (hip, shoulder) or unicompartmental arthroplasty (knee). Total hip and knee arthroplasties are considered the most successful of all surgical procedures performed in terms of patient outcome and improvement in pain.

Hip Arthroplasty

Background Hip arthroplasty is utilized for end stage arthritis in the hip that has failed a reasonable trial of non-operative measures (Fig. 43-12). Conventional hip arthroplasty commonly refers to *total hip arthroplasty* where both the femoral head and neck are replaced. Hip resurfacing is a form of hip arthroplasty, used in younger patients with end stage arthritis. Resurfacing of the femoral head is performed with a metal cap (without performing a femoral neck cut and placing a stemmed femoral component) and the acetabular surface is replaced with a metal cup. Resurfacing functionally achieves the same result as a total hip arthroplasty, however it preserves femoral bone for later conversion to total hip arthroplasty if necessary. Finally, hemiarthroplasty describes the replacement of the femoral head and neck with a stemmed femoral component in isolation. The acetabulum is not addressed surgically.

Figure 43-12. Osteoarthritis femoral head. Note erosion of weight-bearing cartilage and peripheral osteophytes.

History of Hip Arthroplasty The history of hip arthroplasty (hip replacement) may be broken down into a "Pre-Charnley" era and a "Post-Charnley" era, referring to the significant contributions of Sir John Charnley to the evolution of hip arthroplasty. Prior to Charnley's contributions, hip arthroplasty consisted of a variety of procedures with highly variable results. Early attempts at relieving hip pain were made with interpositional arthroplasty, where tissue layers, plastic, or metal were placed between the worn articular surfaces. Fracture of the interposed material or loosening of components often led to failure.

Later attempts introduced stemmed components to improve fixation. One of the earliest femoral components was designed by Austin-Moorem. This prosthesis replaced the femoral head and neck with a metal component secured into the femoral shaft with a stem extending down the diaphysis. This prosthesis was utilized in hemiarthroplasty for many years and served as a step in the development of total hip arthroplasty with the later addition of the acetabular component.

Surgical Approaches to the Hip A variety of approaches to the hip joint have been utilized in joint arthroplasty, including anterior approach (Smith Petersen), anterolateral approach

(Watson-Jones), lateral approach (Hardinge), and posterior approach (Kocher Langenbach). Each approach contains a unique set of advantages and disadvantages. Below, a comparison of the anterior and posterior approaches is made.

Anterior approach (Smith Petersen)—This approach utilizes the internervous plane between the femoral nerve and superior gluteal nerve. Superficially, the plane between the sartorius (femoral nerve) and tensor fasciae lata (superior gluteal nerve) is dissected, while deep, the plane between the rectus femoris (femoral nerve) and gluteus minimus (superior gluteal nerve) is dissected. The anterior approach to the hip is a "muscle sparing approach" and theoretically leads to less muscle damage and functional loss. Measuring serum CK values, the level of CK found with a posterior approach is nearly 2 times the value found in comparison to that seen with an anterior approach to the hip. Other advantages to this approach include low dislocation rates, decreased postoperative restrictions, and excellent acetabular exposure. Downsides include difficult preparation and placement of the femoral component and lack of a true extensile approach.

Posterior approach (Kocher Langenbach)—In comparison to the anterior approach, the posterior approach is a muscle splitting approach. In addition, there is no true internervous plane. After incising the skin and subcutaneous fat, the fascia lata is incised along with the gluteus maximus in line with the skin incision. The short external rotators are exposed and dissected, including the piriformis, superior and inferior gemelli, obturatorinternus and externus, and quadratus femoris. This allows internal rotation of the hip along with flexion and adduction to dislocate the femoral head for exposure. The posterior approach has an increased risk of post-operative dislocation, however this is minimized if soft tissue repair is performis. Postoperatively patients are required to follow strict hip precautions to minimize risk of dislocations; avoiding placing the hip in excessive flexion, adduction, and internal rotation ("The Heisman pose"). The posterior approach is extensile and provides excellent exposure of both the femur and acetabulum for complex and revision cases.

Minimally invasive total hip arthroplasty has been advocated in recent years. Theoretical benefits include improved cosmesis, decreased soft tissue damage, and decreased blood loss, quicker postoperative recovery and a shorter hospital stay. However, smaller incisions come with the disadvantage of decreased visualization intra-operatively and associated risks of component malposition, intraoperative fracture, and nerve or vascular injury. In fact, the only documented benefit of minimally invasive techniques appears to be improved cosmesis.

12▶

A greater trochanteric osteotomy can be performed in order to mobilize the abductors. This can improve exposure to the acetabulum and femur and can be useful particularly in revision cases.

Bearing Surfaces in Hip Arthroplasty The most common combination of bearing surfaces used in total hip arthroplasty is a metal femoral head (generally cobalt chrome), articulating with a polyethylene liner. Ceramic and metal are alternative bearing surfaces commonly utilized in total hip arthroplasty, either used in combination with a polyethylene acetabular liner (ceramic on poly or metal on poly) or in metal on metal and ceramic on ceramic articulations. Metal on metal and ceramic on ceramic articulations have the advantage of lower friction and decreased wear rates in comparison to metal on polyethylene articulations. Metal on metal articulation is utilized commonly in hip resurfacing, however its use in total hip arthroplasty is controversial. Metal on metal articulation has many advantages, including lower wear rates and decreased associated osteolysis. The surgeon also has the ability to use a larger femoral head, thus achieving a greater femoral head to neck ratio and providing the patient a greater arc of motion prior to impingement and subsequent dislocation. Metal on metal (MOM) articulations have been associated with production of metal ions, pseudotumors, hypersensitivity reactions, and early failure when used in total hip arthroplasty (Fig. 43-13). Metal ions pose a theoretic risk of causing problems with pregnancy or a theoretic risk of cancer. Studies have failed to demonstrate a statistical increase in cancer in patients who have MOM articulations in comparison to metal on poly articulations. Ceramic on ceramic articulations have the lowest wear rate and friction of all current bearing combinations. However, ceramic has poor mechanical properties and can lead to component fracture due to its comparatively brittle nature.

Figure 43-13. Failed ceramic on metal hip arthroplasty components. Note the metallic staining on the ceramic femoral head.

Alignment of Hip Arthroplasty Components Proper alignment of hip arthroplasty components is vital to a successful procedure and patient outcome. Surgeons aim for appropriate alignment of components to restore a functional and stable range of motion. This is accomplished with combined anteversion of the femoral and acetabular components, appropriate abduction of the acetabulum and focus on staying true to Sir John Charnley's principles: establishing a low friction articulation, medializing the acetabular component and center of rotation and restoring abductor length and tension with restoration of appropriate length and femoral offset. Inappropriate placement of components can lead to early failure, accelerated component wear, dislocation, need for revision surgery and poor patient outcome and satisfaction.

Knee Arthroplasty

Background Knee Arthroplasty is indicated for end stage arthritis within the knee that has failed to respond to a reasonable trial of non-operative and conservative measures. (Figs. 43-14 and 43-15) Knee arthroplasty commonly refers to total knee arthroplasty where the distal femur, tibia, and patella are resurfaced after any remaining articular cartilage and a layer of subchondral bone are resected. A unicompartmental knee arthroplasty

Figure 43-14. Valgus deformity. Osteoarthritis of lateral compartment right knee.

Figure 43-15. Osteoarthritis of both knees. Note varus alignment of right knee, and valgus alignment of left knee ("windswept deformity").

consists of replacing one compartment of the knee, most commonly the medial compartment, for unicompartmental disease. Similarly, isolated replacement of the patellofemoral joint can be performed for end stage patellofemoral arthritis

Surgical Approach to the Knee Total knee arthroplasty is generally accomplished through a medial parapatellar approach. This approach utilizes a longitudinal skin incision, usually midline over the patella, extending on average from 5 cm proximal to the patella to the tibial tubercle distally. Dissection is carried down to the capsule where a medial parapatellar arthrotomy is performed to gain access to the joint. This approach provides excellent exposure to all three compartments of the knee after patellar dislocation. On occasion, a lateral parapatellar arthrotomy is warranted and this can be performed safely. In the event that the patella does not dislocate, the arthrotomy can be extended proximally through the quadriceps. This has no effect on patient outcome.

Once the joint surfaces are adequately exposed, remaining articular cartilage and a thin layer of underlying bone are removed prior to placement of prosthetic components. Bone cuts are made based on pre-operative templating, cutting guides, computer navigation, and anatomic measurements (Figs. 43-16 and 43-17).

Bearing Surfaces in Knee Arthroplasty The femoral component consists of a metal prosthetic cap designed and sized to fit the normal shape of the femoral condyles. The tibia is cut perpendicular to the anatomic and mechanical axis and a flat, stemmed, metal tray is placed, which most often articulates with a polyethylene liner. The patella is resurfaced with a polyethylene component. Options exist for a mobile bearing

Figure 43-16. Standard total knee instruments.

A B

Figure 43-17. **A.** Varus knee with osteoarthritis. **B.** Right total knee replacement.

knee arthroplasty. With this design the polyethylene component is not fixed rigidly to the metal tibial tray and has the ability to more highly conform to the femoral component through the range of motion arc with designed ability for motion in its articulation with the tibial tray. Although excellent results have been published, this design has not been proven to lead to improved outcome or decreased component wear.

Two types of primary total knee arthroplasty systems exist, including cruciate retaining and posterior stabilized systems. As the name implies, with cruciate retaining systems, the posterior cruciate ligament (PCL) is retained in hopes of preserving more normal knee kinematics and femoral rollback with flexion, while in posterior stabilized systems the ligament is sacrificed and the components are designed to accommodate for the loss. These two systems have equivalent results in knee arthroplasty.

Alignment and Balancing in Knee Arthroplasty Appropriate alignment of the components and balancing of the flexion and extension gaps are essential for a successful result in knee arthroplasty. Inappropriate component position can lead to early wear and failure, knee instability, pain, and post-operative stiffness with poor range of motion. The surgeon must perform appropriate soft tissue balancing and bone cuts to accomplish this and subsequently must place the appropriate sized components, usually replacing the exact amount of bone and cartilage that was removed to create the articulation, and restore stability. The knee must be stable to varus and valgus stress at all points through the range of motion arc and still be able to attain a full range of motion arc from full extension to deep flexion.

Computer Navigation and Joint Arthroplasty

Computer navigated joint arthroplasty has the theoretical benefit of more accurate and consistent placement of arthroplasty components through intraoperative feedback to the surgeon regarding component position, planned bone cuts and alignment (Fig. 43-18). In theory this would lead to improved patient outcomes (Fig. 43-19A and B). Negatives include increased costs of the technology and prolonged operative times. Use of computer navigation in total joint arthroplasty has been shown to provide statistically significant improvement in accuracy of component placement. Use of computer navigation will likely increase in the future as technology continues to improve.

Fixation Options in Joint Arthroplasty

Components in hip and knee arthroplasty can be secured into position with cement or biologic fixation. The cement most commonly used is polymethylmethacrylate (PMMA). PMMA serves as a grout between the component and the bone surface. Components secured without cement are grit blasted or porous coated to allow bony ongrowth or ingrowth, respectively. Hydroxyapatite can also be utilized on the implant surfaces to promote bone ingrowth or ongrowth through osteoconductive properties. A majority of hip joint arthroplasty components are now secured without cement where initial fixation of components is accomplished through press fit techniques. In knee arthroplasty, cement utilization is generally preferred. In hip replacement patients where biologic fixation would be unreliable such as an elderly, osteoporotic patient, or patients with prior radiation, cement may be a better option. With revision total hip arthroplasty, cement fixation

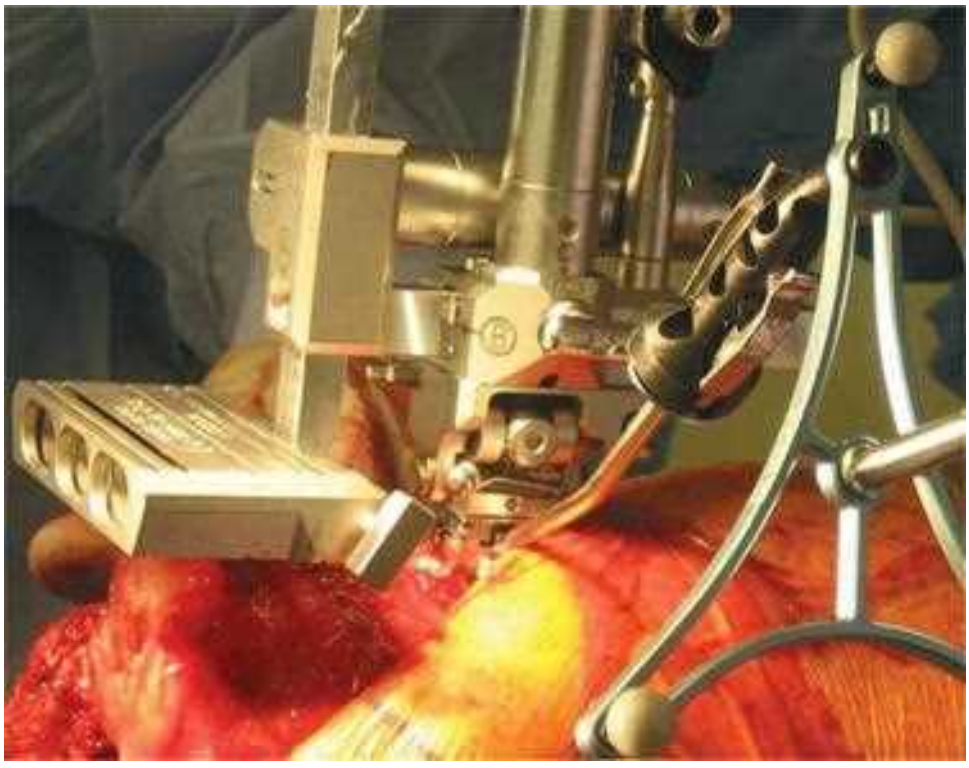

Figure 43-18 Computer assisted robotic targeting arm for total knee replacement.

of components has been shown to lead to earlier mechanical failure.

Osteolysis and Aseptic loosening. Osteolysis is a term used to describe abnormal resorption of bone. Osteolysis can be caused by underlying infection, metastatic disease, or in the case of joint replacement, the production of wear debris. Even with appropriately positioned components, some wear of the bearing surfaces is expected. However, the wear rates and the size and amount of wear debris with the different bearing surfaces can be quite different. The wear rate of ceramic

A **B**

Figure 43-19. **A.** Valgus knee with osteoarthritis. **B.** Robotic assisted total knee.

Figure 43-20 Failed total knee replacement. Note subsided, loose, tibial component.

on ceramic articulations is the lowest of all bearing surfaces, however there is increased risk of component fracture and postoperative "squeaking." In metal on polyethylene articulations, wear debris is produced and polyethylene particles are phagocytized by local macrophages. "Activated" macrophages lead to an osteolytic process and bone resorption. Particulate methylmethacrylate cement debris can also play a role in osteolysis. Improperly positioned components or patient related factors such as high impact activities can lead to a high wear rate. A substantial osteolytic response may occur and lead to component micromotion and aseptic loosening. Patients who present to clinic with pain following joint arthroplasty and an increasing zone of osteolysis in the periprosthetic region frequently need revision surgery (Fig. 43-20) Alternative bearing surfaces continue to be explored in hopes of decreasing or completely preventing wear of components and associated osteolysis and aseptic loosening.

Complications in Joint Arthroplasty. The risk of any complication following joint arthroplasty procedures falls in the range of 5% to 10%. Risks shared by hip and knee arthroplasties include infection, intra-operative or post-operative fracture, vascular injury with need of intra-operative or post-operative blood transfusion, nerve injury or nerve palsy (most commonly involving the deep peroneal nerve and loss of ankle dorsiflexion), periprosthetic fracture, stress shielding, component fracture or wear, and medical complications, including venous thromboembolic disease (DVT and PE), myocardial infarction, or cerebrovascular accident. Complications unique to total hip arthroplasty include dislocation, leg length discrepancy, iliopsoas impingement, or tendonitis.

Dislocation Following Hip Arthroplasty. Dislocation can result from malpositioned components (inadequate combined anteversion of the femoral neck and acetabulum, excessive ab- or adduction of the acetabular component), non-compliant patients, those with cognitive or neuromuscular disorders, inadequate soft tissue repair or excessive soft tissue loss from surgeries or revision surgery, fracture, improper restoration of length, and/or offset. Historically, there has been significant debate as to the role of the surgical approach and incidence of hip dislocation following hip arthroplasty. However, comparable dislocation rates have been found with anterolateral (0.70%), lateral (0.43%), and posterior with soft tissue repair (1.01%) approaches. Dislocation is often the result of poor patient compliance with post-operative restrictions, neuromuscular or cognitive conditions, or excessive soft tissue loss**.** History, physical examination and appropriate radiographs are vital to proper treatment of dislocation. Closed reduction can usually be performed with conscious sedation and gentle traction or manipulation. Rarely, open reduction may be necessary. Patients with multiple dislocations should be assessed for improperly positioned components. Patients with recurrent dislocations and improperly positioned components may need revision of the component. Patients with recurrent dislocations and properly positioned components should be considered for conversion to hemiarthroplasty or to a constrained total hip arthroplasty which provides improved stability.

ORTHOPEDIC PATHOLOGY AND ONCOLOGY

Diagnosis of Malignant Bone Tumors

History. Diagnosis of musculoskeletal tumors begins with a thorough patient history. A history of unremitting pain, unrelated to activity, or pain that interferes with sleep, suggests malignancy. Patient age can help in establishing a differential. Round blue cell lesions are most likely neuroblastoma in a five-year old, Ewing's sarcoma in a 10-year old, lymphoma in a 20-year old, and myeloma in a 60-year old. Gender also adds information, for instance, giant cell tumor is more common in females, osteosarcoma in males. Multiple bone involvement may suggest fibrous dysplasia, enchondromas (Ollier disease, Maffucci's syndrome), or osteochondromas (multiple hereditary exostoses).

Laboratory Test. Laboratory tests determine the level of cellular turnover (lactate dehydrogenase [LDH]) or of bone destruction (calcium, alkaline phosphatase). Elevated Prostate-specific antigen (PSA) suggests prostate cancer.

Imaging. Radiographic studies are critical to the diagnosis of bony tumors. Radiographs can help assess the aggressiveness of the tumor. Four questions should be addressed when assessing radiographs: (a) Where is the tumor—in which bone (Table 43-1) and in which part of the bone (Table 43-2)? (b) What is the tumor doing to the bone (clinical behavior)? (c) What is the bone doing to the tumor (biologic response)? (d) What is the matrix pattern? Matrix is the acellular interstitial substance produced by tumor cells. Particular attention should be paid to the junction between the tumor and the host bone since this margin can also indicate the aggressiveness of the tumor. Ewing's sarcoma has a characteristic 'onion skin' periosteal reaction pattern. This reaction pattern also occurs in other tumors and infections.

Table 43-1

Common locations of bone tumors

FEMUR	
Distal posterior	Parosteal osteosarcoma
Distal anterior	Periosteal osteosarcoma, periosteal chondroma or chondrosarcoma, myositis ossificans
TIBIA	
Adamantinoma, chondromyxoid, Fibroma	
HANDS AND FEET	
Enchondroma, exostosis	
Calcaneus	Unicameral bone cyst, lipoma, chondroblastoma, osteosarcoma
SPINE	
Anterior	Metastatic, myeloma, Paget disease, vascular malformation, Giant Cell Tumor
Posterior	Osteoid osteoma, osteoblastoma; Aneurysmal Bone Cyst
PELVIS	
Metastatic, myeloma, chondrosarcoma, giant cell tumor, aneurysmal bone cyst, Paget disease, Ewing's Sarcoma	
SACRUM	
Chordoma (midline), chondrosarcoma, giant cell tumor, aneurysmal bone cyst, lymphoma	
RIBS	
Metastatic, myeloma, fibrous dysplasia, chondrosarcoma	

OSTEOSARCOMA

The most common primary malignant bone tumor is osteosarcoma (Fig. 43-21). Osteosarcomas are classified as osteoblastic, chondroblastic, fibroblastic, telangiectatic, round cell, and MFH-like, according to the predominant cell type. Most osteosarcomas present in patients between 10 and 20 years of age. Secondary osteosarcomas occur in older patients in abnormal bone affected by Paget's disease or radiation.

Table 43-2

Tumor location in bone

Chondroblastoma, clear cell chondrosarcoma, GCT, infection, dysplasia epiphysealis hemimelica (DEH)

Metaphysis
Most common site of involvement

Diaphysis
FEGNOMASHIC: F-Fibrous dysplasia, EG-Eosinophilic Granuloma, N- NonOssifying Fibroma, O-Osteoid osteoma, M- Myeloma, A-Adamantinoma, S-Simple Bone Cyst, H-Histiocytosis, I-Infection

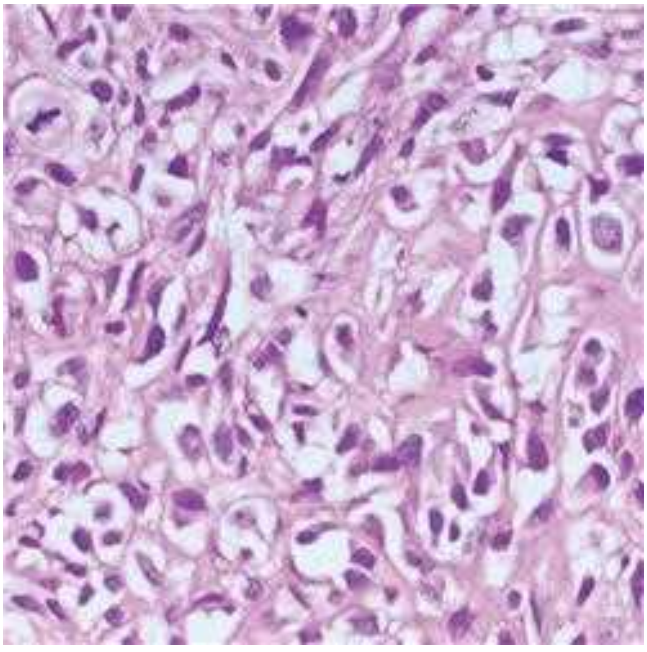

Figure 43-21. Osteosarcoma.

Parosteal Osteosarcoma

Parosteal osteosarcomas occur in women ages 20 to 50, "pasted on" the surface of the posterior distal femoral metaphysis. The preferred treatment is wide surgical excision.

Periosteal Osteosarcoma

Periosteal osteosarcoma occurs on the anterior surface of the distal femur or proximal tibia. The lesion appears chondroblastic on histology. Radiographs show scalloping of the underlying cortex with a 'sunburst' periosteal reaction. Treatment is wide surgical excision.

Paget's Sarcoma

Paget's sarcoma is a rare complication of Paget's disease. In Paget's disease with multiple bone involvement, osteogenic sarcoma, fibrosarcoma, chondrosarcoma, and MFH have occurred, most often in the pelvis, but also in the humerus, femur, spine, and skull. Imaging may demonstrate osteolytic areas, and loss of normal fatty marrow and multifocal lesions. Treatment of Paget's sarcoma is surgical excision, but the prognosis is poor.

Radiation-Induced Sarcoma

The three criteria for diagnosis sarcoma of radiation induced sarcoma are: (a) histology different from the original lesion, (b) sarcoma develops in the irradiated field, and (c) 3 to 5 year latent period between radiation and sarcoma development. Radiation for carcinoma of the breast and cervix can result in osteosarcoma, chondrosarcoma, fibrosarcoma, or MFH. Treatment is a combination of chemotherapy and surgery.

EWING'S SARCOMA

Ewing's sarcoma is the second most common primary bone tumor in patients under 30. The typical presentation is a tumor in the diaphysis of the femur in a young white male.

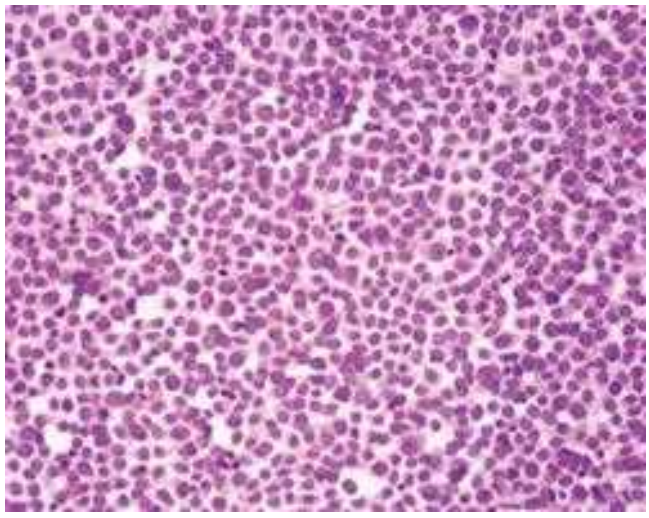

Figure 43-22. Ewing's sarcoma.

An "onion skin" periosteal reaction may be seen on radiographs. A large soft-tissue extension from the primary bone tumor may be seen and histology reveals a small round blue cell tumor (Fig. 43-22). Diagnosis is confirmed with bone marrow biopsy specimen. Bone scan can identify multiple lesions. Treatment is chemotherapy and surgery or radiation therapy for spine or pelvic lesions.

CARTILAGE FORMING TUMORS

Chondrosarcomas

Chondrosarcomas typically occur in male patients over 40 years of age, and are the third most common primary bone malignancies. Primary chondrosarcomas can form clear cell, mesenchymal, or dedifferentiated neoplastic cartilage. Secondary chondrosarcomas may also develop in pre-existing lesions such as exostoses or enchondromas. Pelvis, shoulder, and ribs are frequent locations. Chondroid or "popcorn" calcifications are typical on radiographs. Clear cell chondrosarcoma and mesenchymal chondrosarcoma occur in younger patients (second to fifth decades of life). Clear cell chondrosarcomas are low-grade lesions that often affect the epiphyses.

The treatment of chondrosarcoma is surgical excision, since cells are not chemosensitive or radiosensitive. For high-grade lesions, wide or radical resection is recommended. Pelvic and scapular chondrosarcomas have a high recurrence rate and adjuvant chemotherapy does not improve survival rates.

FIBROUS LESIONS OF BONE

Desmoplastic Fibroma

Desmoplastic fibroma is a rare tumor occurring in the mandible, femur, pelvis, radius, or tibiain young adults. Radiographs show a metadiaphyseal "soap bubble" appearance and endosteal scalloping. Histology resembles desmoid tumors or fibromatosis. Recommended treatment is wide excision.

Malignant Fibrous Histiocytoma of Bone

MFH occurs in the metadiaphysis of long bones after conditions like nonossifying fibromas and bone infarcts. Radiographs typically show destructive lesions with soft-tissue extension. Histology resembles osteosarcoma with fibroblasts, histiocytes and giant cells, but no neoplastic osteoid formation. Treatment is wide surgical excision.

Malignant Vascular Tumors

Hemangioendothelioma. Hemangioendothelioma is a malignant neoplasm arising from vascular endothelium in long bones. Radiographs show a metadiaphyseal lytic lesion with a "soap bubble" appearance. Histology reveals eosinophilic cells in a basophilic stroma. Lesions may be multifocal. Treatment consists of curettage for low-grade lesions and wide excision for high-grade lesions.

Hemangiopericytoma

Hemangiopericytoma is usually a solitary lesion occurring in the soft tissues or the axial skeleton and proximal long bones in middle-aged or elderly males. Histology reveals branching "staghorn" vascular spaces. The tumor cells resemble cells normally seen adjacent to capillaries. Treatment is wide excision.

Angiosarcoma of Bone

Angiosarcoma is a soft tissue malignancy usually seen in elderly males. Histology reveals vascular channels with anaplasia. Treatment is wide excision, or if inaccessible surgically, radiation.

MISCELLANEOUS TUMORS

Giant Cell Tumor of Bone

Giant cell tumor occurs in the knee, distal radius, proximal humerus, and pelvis in women 20 to 40 years of age. Presenting complaints include pain and pathologic fracture. Imaging reveals eccentric, epimetaphyseal lytic lesions eroding the subchondral bone. Histology reveals multinucleate giant cells and mononuclear stromal cells (Fig. 43-23). These tumors can occasionally metastasize to the chest. Primary malignant giant cell tumor has a poor prognosis. Treatment of giant cell tumors is with curettage and high-speed burr. Recurrence rates are high with simple curettage, and the use of cryosurgery, phenol, or polymethylmethacrylate bone cement may help decrease recurrence rates. After pathologic fractures, wide excision may

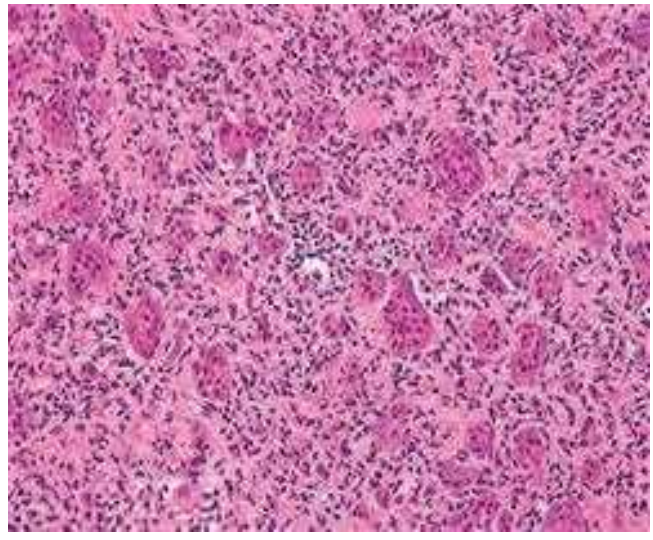

Figure 43-23. Giant cell tumor.

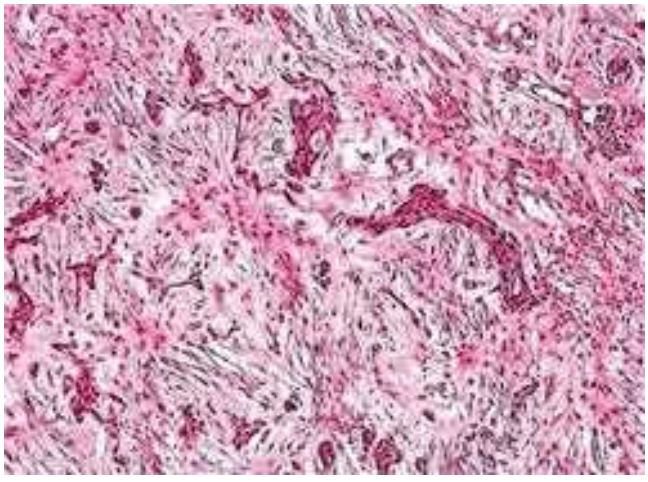

Figure 43-24. Adamantinoma.

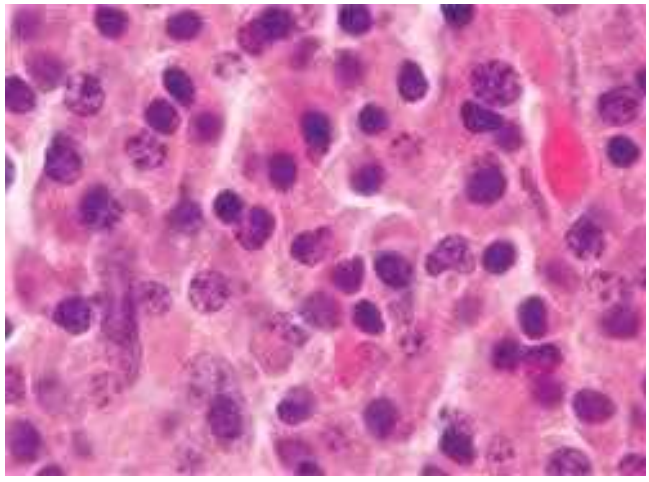

Figure 43-25. Plasmacytoma.

be required. In tumors that are inaccessible surgically, radiation may be indicated.

Ossifying Fibroma and Adamantinoma

Ossifying fibroma occurs in the anterior cortex of the tibial diaphysis of young males. Radiographs have a soap bubble appearance. Patients may present with pain but often the diagnosis is incidental on radiographs. Histology resembles fibrous dysplasia, but with osteoblastic rimming. Ossifying fibroma may be a precursor to adamantinoma.

Adamantinomas are low grade malignancies capable of metastasis seen in the tibia. Histology reveals a tubular, basaloid, squamoid, or spindled pattern (Fig. 43-24). While ossifying fibroma is benign, careful monitoring is needed because they may be a precursor of adamantinoma. The treatment of adamantinoma is with wide surgical excision.

Primary Lymphoma of Bone

Primary lymphoma accounts for about 5% of all neoplasms of bone. Long bone involvement is more frequent than spine. Lymphoma of bone typically occurs in males in their forties. Histology reveals large B cell lymphomas. Treatment is a combination of chemotherapy and radiation. Surgery may be required for stabilization of pathologic fractures.

Chordoma

Chordoma arises from notochordal rests in the sacrum. These tumors are found in middle-aged to older men and presents with bladder and bowel symptoms. An MRI shows a destructive lesion with a large soft-tissue mass. Histology shows epithelioid cells arranged in cords with vacuolated physaliferous cells. Treatment is surgical excision and muscle flaps and a mesh for reconstruction. Urinary diversion and colostomy may be needed for loss of bladder and bowel control.

Multiple Myeloma

Myeloma, the most common primary bone malignancy, is a proliferative disorder of B cells, with plasma cells, evidence of monoclonal M protein in the serum and/or urine, and hypercalcemia, renal insufficiency, anemia, or bone disease. A solitary myeloma lesion in bone is known as a *plasmacytoma* (Fig. 43-25). Presenting symptoms in myeloma range from bone pain and osteopenia, to focal lytic lesions with pathologic fractures and hypercalcemia. Myeloma protein 1-alpha stimulates osteoclast formation. Osteoclast activating factors increase receptor activator of nuclear factor κB ligand (RANKL) in the bone marrow. RANKL induces osteoclast differentiation and activation. Myeloma cells inhibit osteoblast differentiation and activity. Serum and urine electrophoresis detect the M protein. Work up also includes complete blood cell count, erythrocyte sedimentation rate, calcium levels, renal function assessment, and β-2-microglobulin levels, and a skeletal survey. Bone scans may show a false-negative result in more than two-thirds of patients and a dual energy X-ray absorptiometry scan. Plasmacytoma is usually treated with radiation to the lesion. Myeloma is treated with chemotherapy, stem cell transplantation, and radiation therapy. Many patients with myeloma develop a vertebral compression fracture. Kyphoplasty can be useful in providing pain relief. The risks of cement extravasation and related complications are lower with kyphoplasty than with vertebroplasty. If there is instability or if there is neural compression, surgical stabilization may be required.

METASTATIC BONE TUMORS

Metastatic bone tumors are more common than primary bone tumors. Metastatic tumors affect the lung, liver, and bone. Cancers that commonly metastasize to bone are breast, prostate, lung, thyroid, and kidney. In patients older than 40 years of age, metastases and myeloma are the most common lesions in bone. The most common site of involvement is the axial skeleton and proximal ends of long bones. Bronchogenic and renal cell carcinomas can metastasize distal to the knee and elbow. Malignant cells are able to detach from one location and set up a focus at a distant site. Work up of a patient with suspected metastatic disease to bone should include CT of chest, abdomen, and pelvis, mammography, tumor markers, serum, and urine electrophoresis, and bone scans.

PEDIATRIC ORTHOPEDICS

BIRTH INJURIES

Brachial Plexus Palsy

Injury of the brachial plexus during delivery occurs in two births in every 1000. Large birth weight, forceps delivery, breech presentation, and prolonged labor are risk factors. Brachial plexus

injury usually represents a stretch injury on the nerve roots. Management is therapy and passive exercise to preserve motion in the shoulder while awaiting return of neurologic and motor function. Surgical repair of injured nerve roots and trunks may be required in severe cases.

Cerebral Palsy

Cerebral palsy results from an injury to the brain which may be associated with mental impairment. Cerebral palsy is classified as spastic, athetotic, ataxic, and may present with spasticity, hemiplegia, diplegia, or scoliosis. The typical cerebral palsy patient is hyperreflexic with increased muscle tone and spasm. Treatment includes tendon lengthening procedures, release of contractures, and tendon transfers to maintain motion and function.

Hip dislocation or subluxation results from unbalanced muscle forces in many cerebral palsy patients. Treatment consists of abductor tendon releases. When soft tissue releases are unsuccessful, tendon balancing procedures may be combined with open reduction of a hip joint and acetabular reconstruction and osteotomy of the proximal femur. Knee contractures are treated with hamstring lengthening.

Foot and ankle deformities are treated even in nonambulatory patients to facilitate shoe wear. The most common foot deformity in cerebral palsy is an equinovalgus foot caused by heel cord contracture and peroneal spasm. Tendon balancing is usually necessary and bony reconstruction may also be needed in severe cases.

Skeletal Growth

Injury, inflammatory disease, and developmental disorders in actively growing bones requires special attention to preserving the growth plates. The pediatric skeleton is incompletely ossified making diagnosis of an injury difficult, since significant portions of the skeleton are invisible on radiographs. The epiphysis, generally containing an articular surface, is found at the ends of the long bone. The physis or growth plate is found beneath the epiphysis. The physis has six specific zones: the *reserve zone*, the *zone of differentiation*, the *zone of proliferation*, the *zone of maturation*, the *hypertrophic zone,* and finally, the *zone of calcification*.

Injury or insult to the growth plate can lead to premature growth arrest or angular deformity of the limb. Surrounding the metaphyseal and diaphyseal bone, is the periosteum. This metabolically active layer of tissue synthesizes new bone onto the diaphyseal and metaphyseal bone and provides circumferential growth of the bones.

Ossification centers in the epiphysis and appear in a predictable order, and can help determine "bone age."

Pediatric Fractures

In a pediatric patient, the epiphyseal growth plate is unossified and at risk of fracture. Reduction and stabilization of epiphyseal fractures is critical to minimize permanent growth disturbances and deformity.

Classification of Growth Plate Injuries

Salter and Harris described a useful classification for epiphyseal fractures. A Salter-Harris Type I injury is a simple transverse fracture through the physis. A Salter-Harris Type II fracture contains a component of fracture through the growth plate in continuity with a fracture of the metaphysis. Salter-Harris Type III fracture occurs through the physis and exits through the growth plate. While a Salter-HarrisType IV fracture line extends through the physis from the metaphysis into the epiphysis. A Salter-Harris Type V fracture crushes the physis itself.

Treatment of growth plate fracture requires anatomic reduction of the fragments. Internal fixation avoids placing hardware across the growth plate to minimize the chance of premature growth plate closure.

Diaphyseal Injuries in a Pediatric Patient

Long bones diaphyseal fractures are generally treated closed. Pediatric patients are capable of extensive remodeling so that an angular deformity within the plane of an adjacent joint is often completely remodeled by the growth of the child. When internal fixation of a diaphyseal fracture is required, the physis is avoided.

Fractures of the Pediatric Hip

Pediatric patients with hip fractures may be treated with a spica cast. The spica cast includes the abdomen, lower back, pelvis, and lower limb, and derives its name from the resemblance of the plaster wrap over the hip to wheat ("spica").

Fractures of the Femoral Shaft

Femoral shaft fractures in a child younger than six years old may be managed with a spica cast. Femur fractures in patients older than six years of age can be managed by internal fixation with a flexible intramedullary nail. Children 14 years of age are treated with an adult style intramedullary reamed nail. Extra-articular fractures of the distal femur or proximal tibia are managed in a long leg cast.

Pediatric Ankle Fractures

Salter-Harris I and II fractures are managed with casting. Salter-Harris III or IV fractures are managed by closed reduction and internal fixation with percutaneous pins or screws. Smooth pins are used, and the physis is avoided unless necessary for stability.

The Tillaux (Salter-Harris Type II) fracture involves a fracture through the lateral epiphysis and the lateral physis. In these patients the growth plate is in the process of closing and open reduction and internal fixation is needed. The "triplane" fracture (Salter-Harris Type IV) is managed by closed reduction with percutaneous pinning.

Pediatric Elbow Fractures

Management of pediatric elbow fractures is complex. A fracture of the distal humeral epiphysis can be misdiagnosed as a dislocation of the elbow. Familiarity with the timing of the ossification centers' appearance aids in diagnosis. Treatment is closed reduction and percutaneous pinning.

Injury to the brachial artery, the radial, ulnar, and medial nerves are possible. Neurovascular exam is required before, during, and after treatment. Close follow-up for maintenance of reduction and neurovascular status is needed.

DEVELOPMENTAL DISEASE

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) is seen in firstborn females with a positive family history, and breech birth.

Untreated hip dislocations can lead to a dysplastic acetabulum. Newborns are examined for hip instability within the first 72 hours. Ortolani's test consists of gentle elevation and abduction of the femur causing a palpable click in the relocation of a dislocated hip. Barlow's test is gentle adduction and depression of the femur which causes a palpable click as a hip slips into a dislocated position. Infants with a dislocated or dislocatable hip

will have apparent length discrepancies of the femur when hip is positioned in 90 degrees. Since the bones are not yet ossified, X-ray images of the acetabulum and femoral head are not reliable for diagnosis. Ultrasound can often demonstrate a dislocated or dislocatable hip. Early treatment with abduction and flexion in a Pavlik harness can result in a normal hip joint.

Treatment of DDH

In a child with a dislocatable hip, a Pavlik harness can maintain the hips in flexion and abduction. Avoid severe abduction to avoid avascular necrosis of the head. For mild to moderate dysplasia, 6 to 12 weeks in a Pavlik harness is sufficient. In severe disease, adductor tenotomy may be needed.

If treatment is delayed, open reduction may be necessary. Through an anterior approach the pulvinar can be removed and the femoral head located. Adductor tenotomy and femoral shortening may be indicated. Osteonecrosis of the femoral head can result from open reduction resulting in pain and decreased motion. Some patients with severe DDH may require pelvic osteotomy creating an acetabular shelf, or a varus osteotomy of the proximal femur, or a combination of the two.

Legg-Calvé-Perthes Disease

Osteonecrosis of the proximal femoral epiphysis can cause flattening of the femoral head called Legg-Calvé Perthes disease. The typical patient is a 7-year-old male who presents with groin or knee pain, decreased hip motion, and a limp. Treatment includes traction, physical therapy, abduction exercises, and crutches. Femoral and pelvic osteotomies may be needed in extreme cases.

Slipped Capital Femoral Epiphysis

Children ages 10 to 16 years old can develop displacement of the epiphysis on the femoral neck with no history of injury. Slipped capital femoral epiphysis(SCFE) is associated with African American heritage, obesity, and is more common in boys than in girls. One-quarter of cases are bilateral. Patients generally present with groin and anterior thigh or even knee pain and decreased motion. In pediatric patients with knee pain, assess the ipsilateral hip as well.

Treatment for slipped capital femoral epiphysis patients is percutaneous screw fixation through the femoral neck to engage the epiphysis. Reduction of the slipped epiphysis is not recommended because of an increased risk of avascular necrosis. One screw is adequate to prevent further slip.

Lower Extremity Rotational Abnormalities

Intoeing can result from femoral anteversion, tibial torsion, and metatarsus adductus. Remember that a mild degree of intoeing is normal in young children 3 to 5 years of age.

Excessive internal rotation of the femur will usually correct by age 8. Severe rotation with functional impairment that does not correct by age 10 or 11 may require rotational femoral osteotomy.

Bilateral intoeing gait in one- and two-year-old children can result from tibial torsion which generally will completely resolve without treatment.

Metatarsus adductus in infants will also resolve spontaneously in most cases.

Congenital Talipes Equinovarus

Club foot is a common problem associated with contractures of the medial tendons of the foot, a tight Achilles tendon, and contractures of the ankle, hindfoot, and midfoot. Talipes equinovarus can be corrected by sequential corrective casting of the foot. A successful program of casting may be complete in one to five months. In patients with severe disease or who initiate treatment after nine months of age, surgical release of contracted soft tissues may be necessary.

Osgood-Schlatter Disease

Osgood-Schlatter disease is a common problem most often seen in athletically active adolescents. This disorder is characterized by ossification in the distal patellar tendon at the point of its tibial insertion. This disorder is thought to result from mechanical stress on the tendinous insertion. Radiographs show calcified ossicles within the tendon at its insertion. The disease presents with severe local pain and tenderness in the area of the tibial tubercle.

Treatment for the disease is activity restriction. If the symptoms are improved, athletic participation can be resumed. Symptoms regress after skeletal maturity or the discontinuance of active athletic participation.

chapter 44

Surgery of the Hand and Wrist

Scott D. Lifchez and J. Alex Kelamis

INTRODUCTION

The highly mobile, functional, and strong hand is a major distinguishing point between humans and the nonhuman primates. The hand is an essential participant for activities of daily living, vocation, and recreational activities. The hand is even adaptable enough to read for the blind and speak for the mute. The underlying goal of all aspects of hand surgery is to maximize mobility, sensibility, stability, and strength while minimizing pain. These goals are then maximized to the extent possible given the patient's particular pathology. Hand surgery is a regional specialty. Hand surgeons integrate components of neurologic, orthopedic, plastic, and vascular surgery in the care of patients with disorders of the upper extremities. 1▶

ANATOMY OF THE HAND AND WRIST

In order to understand any disorder of the hand, one must understand the anatomy of the underlying structures. Examination of the hand is based on demonstrating the function or lack thereof of each of these structures. 2▶

Bones

The hand is highly mobile in space to allow maximum flexibility in function. As such, a number of directions particular to the hand are necessary in order to properly describe position, motion, and so on.[1] Palmar (or volar) refers to the anterior surface of the hand in the anatomic position; dorsal refers to the posterior surface in the anatomic position. The hand can

Key Points

1. Surgery of the hand is a regional specialty, integrating components of neurologic, orthopedic, plastic, and vascular surgery.
2. Understanding hand anatomy is the key to proper diagnosis of injury, infection, and degenerative disease of the hand.
3. After evaluation and/or treatment, patients should be splinted to protect the injured digits and keep the collateral ligaments of the injured joints on tension (metacarpophalangeal joints flexed, interphalangeal joints extended).
4. Healing of an injured or diseased structure in the hand is not the endpoint of treatment; the goal of any intervention must be to obtain structure healing, relief of pain, and maximization of function.
5. If a patient managed conservatively for cellulitis does not improve within 24 to 48 hours of appropriate intravenous antibiotics, abscess must be suspected.
6. Clinical examination, particularly noting the area of greatest tenderness and/or inflammation, is the most useful diagnostic tool for hand infections.

rotate at the wrist level; rotation to bring the palm down is called pronation, rotation to bring the palm up is called supination. Because the hand can rotate in space, the terms medial and lateral are avoided. Radial and ulnar are used instead as these terms do not vary with respect to the rotational position of the hand. Abduction and adduction, when used on the hand, refer to movement of the digits away from and toward the middle finger, respectively (Fig. 44-1).

The hand is comprised of 19 bones arranged in five rays.[2] A *ray* is defined as a digit (finger or thumb) from the metacarpal base to the tip of the digit (Fig. 44-2A). The rays are numbered 1 to 5, beginning with the thumb. By convention, however, they are referred to by name: thumb, index, middle, ring, and small. There are five metacarpals, comprising the visible palm of the hand. Each digit has a proximal and a distal phalanx, but only the fingers have a middle phalanx as well. The metacarpophalangeal (MP) joint typically allows 90° of flexion with a small amount of hyperextension. In addition, the fingers can actively abduct (move away from the middle finger) and adduct (move toward the middle finger). The thumb, in contrast, moves principally in the flexion-extension arc at the MP joint. Although there can be laxity in the radial and ulnar direction, the thumb cannot actively move in these directions at the MP level. The proximal interphalangeal joint (PIP) is the critical joint for finger mobility. Normal motion is 0 to 95° (full extension to flexion). The distal interphalangeal joint (DIP) also moves only in a flexion-extension plane from 0 to 90° on average. The thumb interphalangeal joint (IP) also moves only in a flexion-extension plane. Its normal motion is highly variable between individuals, but averages 0 to 80°.

Each of the MP and IP joints has a radial and ulnar collateral ligament to support it. The IP joint collateral ligaments are on tension with the joint fully extended. For the fingers, the MP joint collateral ligaments are on tension with the joint bent 90°. Collateral ligaments have a tendency to contract when not placed on tension; this becomes relevant when splinting the hand (see later Trauma section on splinting).

The wrist consists of eight carpal bones divided into two rows (Fig. 44-2B).[2] The proximal row consists of the scaphoid, lunate, and triquetrum. The lunate is the principle axis of motion of the hand onto the forearm. It bears approximately 35% of the load of the wrist onto the forearm. The scaphoid is shaped like the keel of a boat and bears 55% of the load of the hand onto the forearm, but also serves as the principle link between the proximal and distal rows, allowing for motion while maintaining stability. Both the scaphoid and the lunate articulate with the radius. The triquetrum resides ulnar to the lunate. It does not interact with the ulna proximally; rather, it interacts with a cartilage suspended between the ulnar styloid and the distal radius called with triangular fibrocartilage complex (TFCC) (Fig. 44-2B). The remaining 10% of load of the hand onto the forearm is transmitted through the TFCC.[3]

The distal row consists of four bones. The trapezium resides between the scaphoid and the thumb metacarpal. Distally, it has a saddle-shaped surface, which interacts with a reciprocally saddle-shaped base of the thumb metacarpal to allow for high mobility of the thumb carpometacarpal (CMC) joint in radial-ulnar and palmar-dorsal directions and opposition (Fig. 44-1B). The trapezoid rests between the scaphoid and the index finger metacarpal. The capitate, the largest carpal bone and first to ossify in a child, lies between the lunate and the middle finger metacarpal, but also interacts with the scaphoid on its proximal radial surface. The index and middle finger CMC joints are highly stable and have minimal mobility. The hamate is the ulnar-most bone in the distal row, sitting between the triquetrum proximally and the ring and small finger metacarpals distally. The ring and small finger CMC joints are mobile, principally in the flexion-extension direction.

The pisiform is a carpal bone only by geography. It is a sesamoid bone within the FCU tendon (see below). It does not bear load and can be excised, when necessary, without consequence.

Muscles Affecting the Hand and Wrist

The wrist is moved by multiple tendons that originate from the forearm and elbow. The digits of the hand are moved by both intrinsic (originating within the hand) and extrinsic (originating in the forearm) muscles. All of these muscles are innervated by the median, radial, or ulnar nerves (or their branches) (Fig. 44-3).

Three muscles flex the wrist, all of which originate from the medial epicondyle of the humerus. The flexor carpi radialis (FCR, median nerve) inserts on the volar base of the index finger metacarpal. The flexor carpi ulnaris (FCU, ulnar nerve) also originates from the proximal ulna and inserts on the volar base of the small finger metacarpal. The palmaris longus (PL) tendon does not insert on a bone; it inserts on the palmar fascia, located deep to the skin in the central proximal palm, and is absent in up to 15% of patients. The FCR also deviates the wrist radially, whereas the FCU deviates the wrist ulnarly.

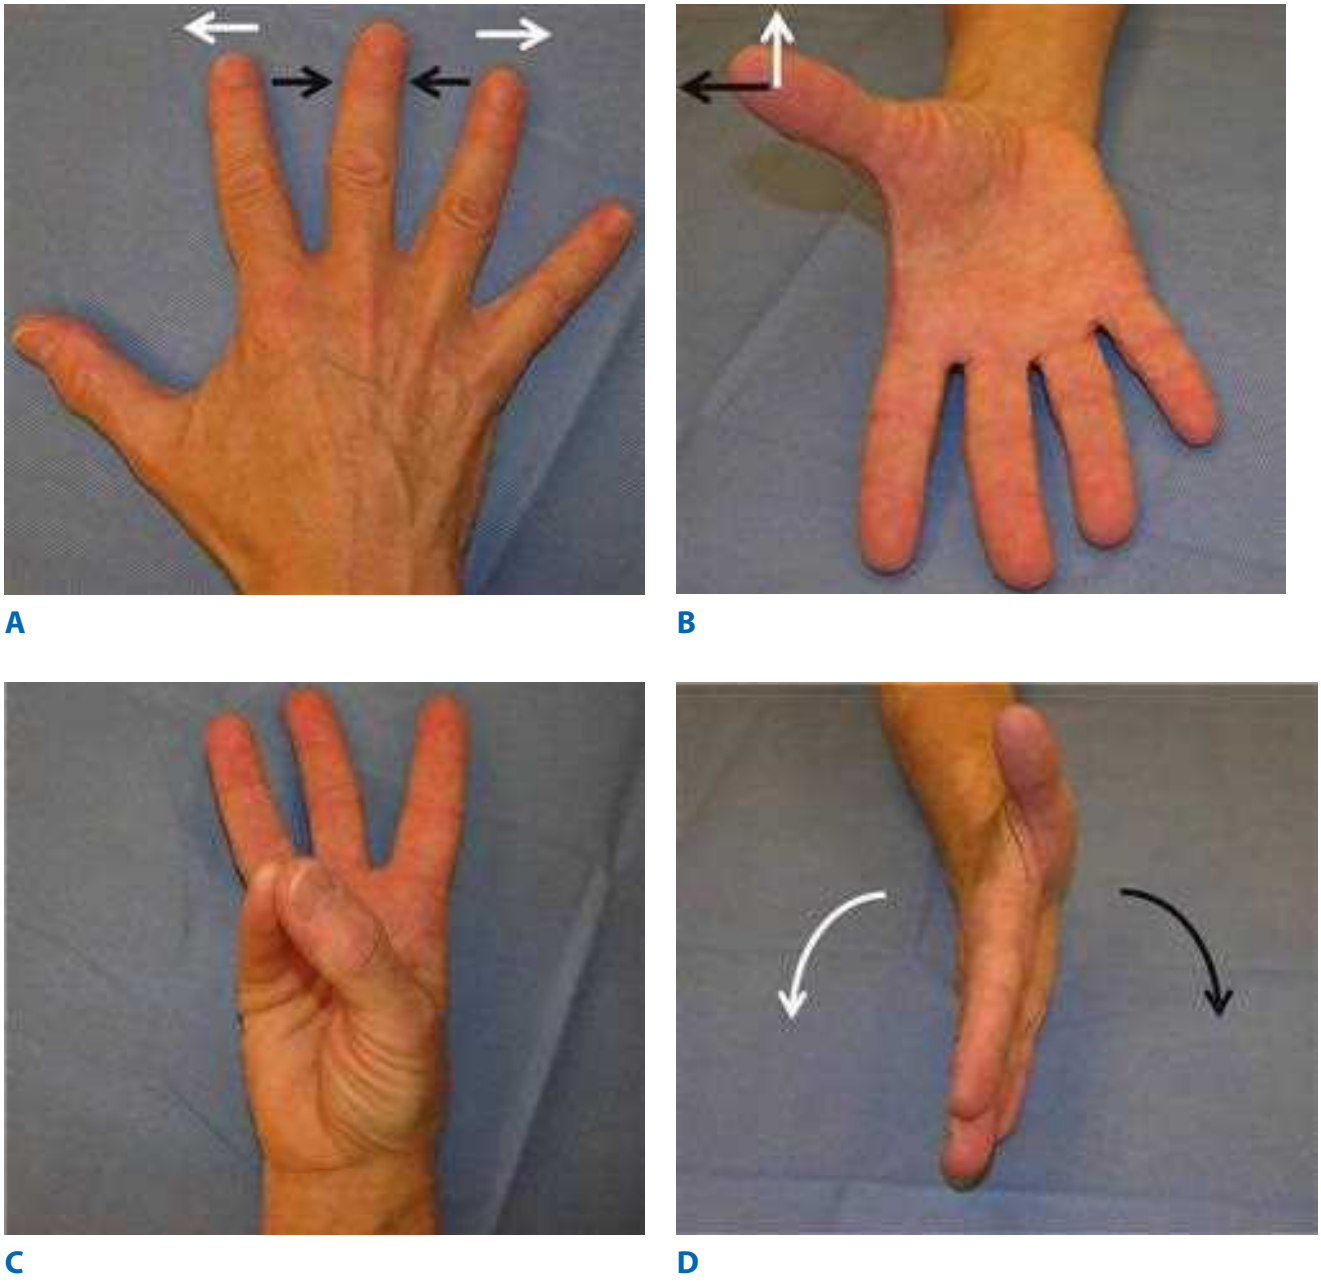

Figure 44-1. Directions of finger, hand, and wrist motion. **A.** Finger abduction (*white arrows*) and adduction (*black arrows*). **B.** Thumb radial (*black arrow*) and palmar (*white arrow*) abduction. **C.** Thumb and small finger opposition. **D.** Hand/wrist pronation (*black arrow*) and supination (*white arrow*).

All three wrist extensors are innervated by the radial nerve or its branches. The extensor carpi radialis longus (ECRL) originates from the distal shaft of the humerus and inserts on the dorsal base of the index finger metacarpal. The extensor carpi radialis brevis (ECRB) originates from the lateral epicondyle of the humerus and inserts on the dorsal base of the middle finger metacarpal. The extensor carpi ulnaris (ECU) also originates from the lateral epicondyle of the humerus and inserts on the dorsal base of the small finger metacarpal. The ECRL deviates the wrist radially, whereas the ECU deviates the wrist ulnarly.

The long flexors of the fingers all originate from the medial epicondyle of the humerus. The flexor digitorum superficialis (FDS) inserts on the base of the middle phalanx of each finger and primarily flexes the PIP joint. The flexor digitorum profundus (FDP) inserts on the base of the distal phalanx and primarily flexes the DIP joint. The flexor pollicis longus (FPL) originates more distally, from the ulna, radius, and interosseous membrane between them in the forearm. It inserts on the base of the distal phalanx of the thumb and primarily flexes the IP joint. All of these tendons can also flex the more proximal joint(s) in their respective rays. All of these muscles are innervated by the median nerve (or its branches) except the FDP to the ring and small fingers, which are innervated by the ulnar nerve.

The extrinsic extensors of the fingers and thumb are all innervated by the posterior interosseous nerve (PIN, branch of the radial nerve). The extensor digitorum communis (EDC) originates from the lateral epicondyle of the humerus and extends the MP joints of the fingers. Unlike most tendons that attach directly into a bone, the EDC tendons do not insert on the dorsal base of the proximal phalanx, but rather into a soft tissue sling called the

Figure 44-2. Bony architecture of the hand and wrist. **A.** Bones of the hand and digits. All rays have metacarpophalangeal (MP) joints. The fingers have proximal and distal interphalangeal joints (PIP and DIP), but the thumb has a single interphalangeal (IP) joint. **B.** Bones of the wrist. The proximal row consists of the scaphoid, lunate, and capitate. The distal row bones articulate with the metacarpals: the trapezium with the thumb, the trapezoid with the index, the capitate with the middle, and the hamate with the ring and small. The pisiform bone is a sesamoid within the flexor carpi ulnaris tendon. It overlaps the triquetrum and hamate but does not contribute to a carpal row. CMC = carpometacarpal; TFCC = triangular fibrocartilage complex.

sagittal hood, which surrounds the proximal phalanx base and pulls up on the volar surface in a hammock-like manner. More distally in the dorsal forearm, the extensor indices proprius (EIP) and extensor digiti quinti (EDQ) originate from the ulna, radius, and posterior interosseous membrane and insert on the sagittal hood of the index and small fingers, respectively.

The thumb has three separate extrinsic extensors. All of these originate from the dorsal ulna in the mid-forearm and are innervated by the PIN. The abductor pollicis longus (APL) inserts on the radial base of the thumb metacarpal to produce some extension, but mostly abduction. The extensor pollicis brevis (EPB) inserts on the base of the thumb proximal phalanx.

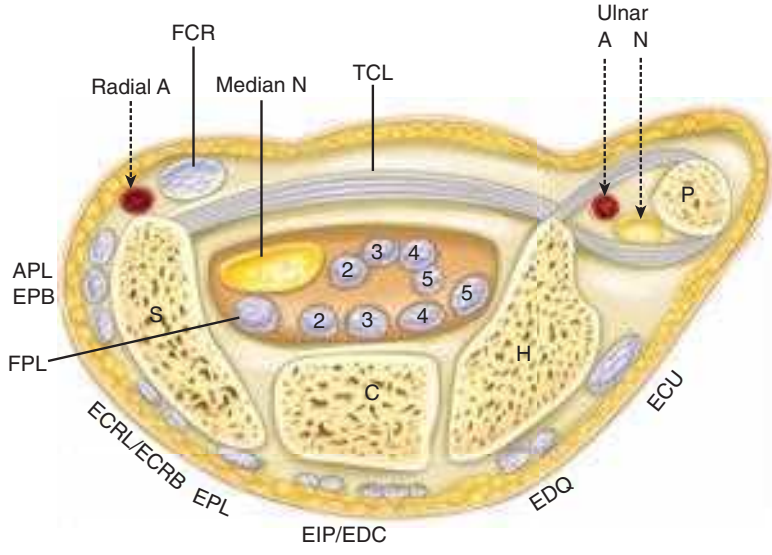

Figure 44-3. Cross-section of the wrist at the midcarpal level. The relative geography of the neurologic and tendinous structures can be seen. The transverse carpal ligament (TCL) is the roof of the carpal tunnel, passing volar to the median nerve and long flexor tendons. The TCL is also the floor of the ulnar tunnel, or Guyon's canal, passing dorsal to the ulnar artery and nerve. The wrist and digital extensor tendons are also seen, distal to their compartments on the distal radius and ulna. Bones: C = capitate; H = hamate; P = pisiform; S = scaphoid. Tendons (flexor digitorum superficialis is volar to flexor digitorum profundus within the carpal tunnel): 2 = index finger; 3 = middle finger; 4 = ring finger; 5 = small finger. A = artery; APL = abductor pollicis longus; ECRB = extensor carpi radialis brevis; ECRL = extensor carpi radialis longus; ECU = extensor carpi ulnaris; EDC = extensor digitorum communis; EDQ = extensor digiti quinti; EIP = extensor indices proprius; EPB = extensor pollicis brevis; EPL = extensor pollicis longus; FCR = flexor carpi radialis; FPL = flexor pollicis longus; N = nerve.

The extensor pollicis longus (EPL) inserts on the base of the thumb distal phalanx.

The intrinsic muscles of the hand are what allow humans fine, subtle movements of the hand. Microsurgery, typing, and even video gaming would be difficult, if not impossible, without them.

The thenar muscles originate from the volar radial surface of the scaphoid and trapezium and the flexor retinaculum. The abductor pollicis brevis (APB) inserts on the radial base of the thumb proximal phalanx and abducts the thumb in a radial and volar direction. The opponens pollicis (OP) inserts on the radial distal aspect of the thumb metacarpal and draws the thumb across the palm toward the small finger. The flexor pollicis brevis (FPB) inserts on the base of the thumb proximal phalanx and flexes the thumb MP joint. The APB, OP, and superficial head of the FPB are all innervated by the thenar motor branch of the median nerve.

The lumbrical muscles are unique in the body in that they originate from a tendon. Each finger's lumbrical originates from the FDP tendon in the palm. The lumbrical tendon passes along the radial aspect of the digit to flex the MP and extend the IP joints. The index and middle lumbricals are median nerve innervated, and the ring and small finger lumbricals are ulnar nerve innervated.

The hypothenar muscles originate from the pisiform, hamate, and flexor retinaculum and insert on the ulnar base of the small finger proximal phalanx. The abductor digiti quinti (ADQ) abducts the small finger. The opponens digiti quinti (ODQ) brings the small finger across the palm in reciprocal motion to the OP. The flexor digiti quinti (FDQ) flexes the small finger metacarpal. All of these muscles are innervated by the ulnar nerve.

The interosseous muscles occupy the space between the metacarpal bones. Their tendons insert on the bases of the proximal phalanges. All act to flex the MP joints and extend the IP joints. The three palmar interosseous muscles adduct the fingers. The four dorsal interosseous muscles abduct the fingers. The adductor pollicis originates from the middle finger metacarpal and inserts on the ulnar base of the thumb proximal phalanx. It acts to adduct the thumb. All of these muscles, as well as the deep head of the FPB, are innervated by the ulnar nerve.

Tendons and Pulleys

Multiple pulleys pass over or surround the extrinsic tendons en route to or within the hand. There purpose is to maintain tendon position near the bone, allowing maximal translation of tendon excursion into joint motion.

The most well known of the wrist-level pulleys is the flexor retinaculum, also known as the transverse carpal ligament. It attaches to the scaphoid tubercle and trapezium radially and the hook of the hamate bone and pisiform ulnarly. Deep to this ligament, between the scaphoid (radially) and the hamate (ulnarly), pass the FDS, FDP, and FPL tendons as well as the median nerve. This area is also known as the carpal tunnel (see Fig. 44-3).

On the dorsum of the wrist, the extensor retinaculum is divided into six compartments. Beginning on the radial aspect of the radius, the first compartment contains the APL and EPB tendons. The second holds the ECRL and ECRB tendons. The EPL passes through the third compartment. The fourth compartment contains the EIP and EDC tendons, the fifth the EDQ, and the sixth the ECU. The sixth compartment is located on the ulnar aspect of the distal ulna. Although the compartments end at the radiocarpal/ulnocarpal joints, the relative geography of the tendons is preserved over the carpal bones (see Fig. 44-3).

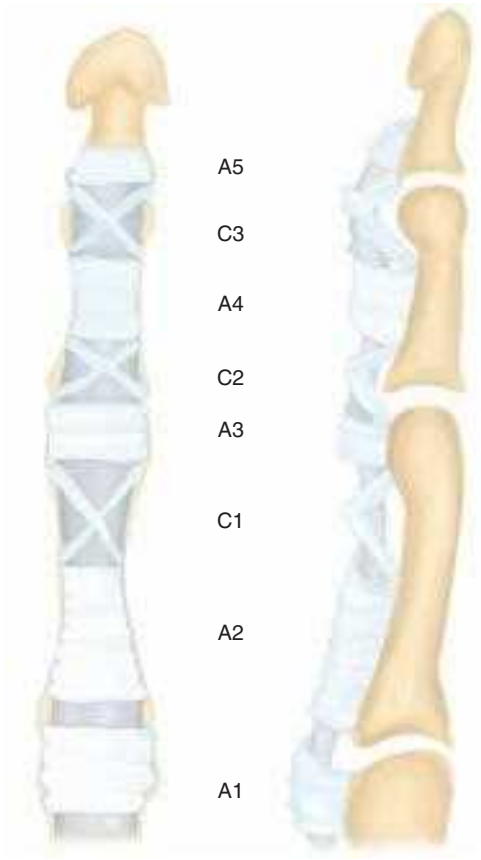

Figure 44-4. Drawing of anteroposterior and lateral view of the pulley system.

In the hand, the pulleys maintain the long flexor tendons in close apposition to the fingers and thumb. There are no extensor pulleys within the hand. Each finger has five annular and three cruciate pulleys (Fig. 44-4). The second and fourth (A2 and A4) pulleys are the critical structures to prevent bowstringing of the finger.[4] The remaining pulleys can be divided as needed for surgical exposure or to relieve a stricture area.

Vascular

Two major arteries serve the hand. The radial artery travels under the brachioradialis muscle in the forearm. At the junction of the middle and distal thirds of the forearm, the artery becomes superficial and palpable, passing just radial to the FCR tendon. At the wrist level, the artery splits into two branches. The smaller, superficial branch passes volarly into the palm to contribute to the superficial palmar arch. The larger branch passes dorsally over the scaphoid bone, under the EPL and EPB tendons (known as the anatomic snuffbox) and back volarly between the proximal thumb and index finger metacarpals to form the superficial palmar arch.

The ulnar artery travels deep to the FCU muscle in the forearm. When the FCU becomes tendinous, the ulnar artery resides deep and slightly radial to it. At the wrist, the artery travels between the hamate and pisiform bones superficial to the transverse carpal ligament (known as Guyon's canal) into the palm. The larger, superficial branch forms the superficial palmar arch. The deeper branch contributes to the deep palmar

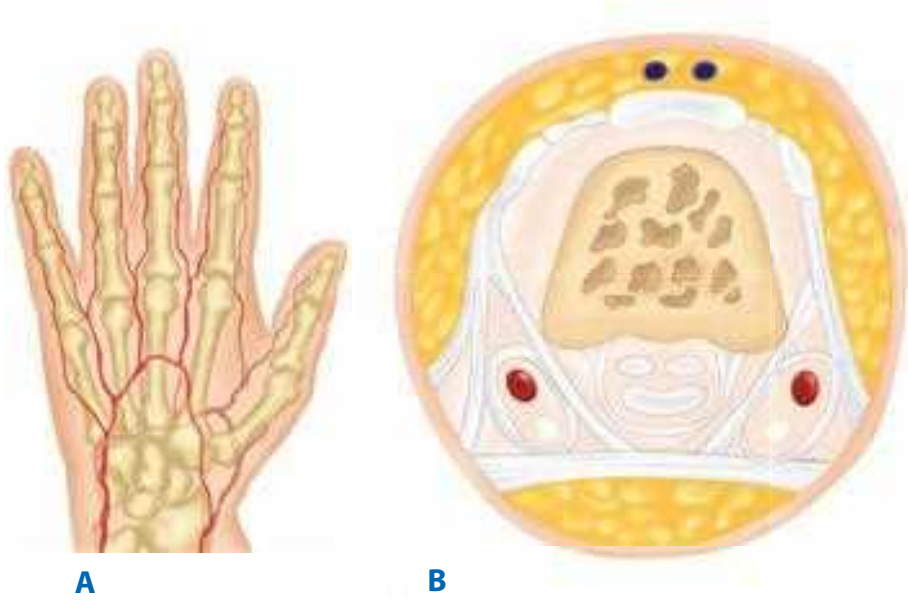

Figure 44-5. Arteries of the hand and finger. **A.** Relative position of the superficial and deep palmar arches to the bony structures and each other; note the radial artery passes dorsal to the thumb metacarpal base, through the first web space, and anterior to the index metacarpal base as it forms the deep arch. **B.** The neurovascular bundles lay volar to the midaxis of the digit with the artery dorsal to the nerve; Grayson's ligament (volar) and Cleland's ligament (dorsal) connect the bone to the skin surrounding the bundle.

arch (Fig. 44-5A). In 97% of patients, at least one of the deep or superficial palmar arches is intact, allowing for the entire hand to survive on the radial or ulnar artery.[5]

Each digit receives a radial and ulnar digital artery. For the thumb, the radial digital artery may come from the deep palmar arch or the main body of the radial artery. The larger ulnar digital artery comes off the deep arch as either a discrete unit, the princeps pollicis artery, or less frequently as the first common digital artery, which then splits into the radial digital artery to the index finger and the ulnar digital artery to the thumb. The second, third, and fourth digital arteries typically branch off the superficial palmar arch and pass over the similarly named interosseous spaces respectively, ultimately dividing into two proper digital arteries each. The ulnar digital artery of the small finger comes off as a separate branch from the superficial arch. Within the finger, the proper digital arteries travel lateral to the bones and tendons, just palmar to the midaxis of the digit, but dorsal to the proper digital nerves (Fig. 44-5B).

Nerve

Three principal nerves serve the forearm, wrist, and hand: the median, radial, and ulnar nerves. The most critical of these from a sensory standpoint is the median nerve. The median nerve begins as a terminal branch of the medial and lateral cords of the brachial plexus. It receives fibers from C5–T1. The palmar cutaneous branch of the median nerve separates from the main body of the nerve 6 cm proximal to the volar wrist crease and serves the proximal, radial-sided palm. The main body of the median nerve splits into several branches after the carpal tunnel: a radial digital branch to the thumb, an ulnar digital nerve to the thumb, and a radial digital nerve to the index finger (sometimes beginning as a single first common digital nerve); the second common digital nerve that branches into the ulnar digital nerve to the index finger and the radial digital nerve to the middle finger; and a third common digital nerve that branches into the ulnar digital nerve to the middle finger and a radial digital nerve to the ring finger. The digital nerves provide volar-sided sensation from the metacarpal head level to the tip of the digit. They also, through their dorsal branches, provide dorsal-sided sensation to the digits from the midportion of the middle phalanx distally via dorsal branches. The thenar motor branch of the median nerve most commonly passes through the carpal tunnel and then travels in a recurrent fashion back to the thenar muscles. Less commonly, the nerve passes through or proximal to the transverse carpal ligament en route to its muscles.

In the forearm, the median nerve gives motor branches to all of the flexor muscles except the FCU, and the ring and small finger portions of the FDP. Distal median motor fibers (with the exception of those to the thenar muscles) are carried through a large branch called the anterior interosseous nerve.

The ulnar nerve is a terminal branch of the medial cord of the brachial plexus. It receives innervation from C8 and T1 roots. The FCU and FDP (ring/small) receive motor fibers from the ulnar nerve. In the distal forearm, 5 cm above the head of the ulna, the nerve gives off a dorsal sensory branch. Once in the hand, the nerve splits into the motor branch and sensory branches. The motor branch curves radially at the hook of the hamate bone to innervate the intrinsic muscles, as described earlier. The sensory branches become the ulnar digital nerve to the small finger and the fourth common digital nerve, which splits into the ulnar digital nerve to the ring finger and the radial digital nerve to the small finger. The sensory nerves provide distal dorsal sensation similar to the median nerve branches.

The radial nerve is the larger of two terminal branches of the posterior cord of the brachial plexus. It receives fibers from C5–T1 nerve roots. It innervates all of the extensor muscles of the forearm and wrist through the PIN branch except for the ECRL, which is innervated by the main body of the radial nerve in the distal upper arm. There is no ulnar nerve contribution to extension of the wrist, thumb, or finger MP joints. As noted earlier, the ulnar innervated intrinsic hand muscles are the principle extensors of the finger IP joints, although the long finger extensors (EDC, EIP, EDQ) make a secondary contribution to this function.

In the proximal dorsal forearm, the superficial radial nerve (SRN) is the other terminal branch of the radial nerve. It travels deep to the brachioradialis muscle until 6 cm proximal to the radial styloid, where it becomes superficial. The SRN provides sensation to the dorsal hand and the radial three and a half digits up to the

level of the mid-middle phalanx (where the dorsal branches of the proper digital nerves take over, as described earlier). The dorsal branch of the ulnar nerve provides sensation to the ulnar one and a half digits and dorsal hand in complement to the SRN.

HAND EXAMINATION

Emergency Room/Inpatient Consultation

A common scenario in which the hand surgeon will be introduced to the patient is in trauma or other acute situations. The patient is evaluated by inspection, palpation, and provocative testing.

On inspection, one should first note the position of the hand. The resting hand has a normal cascade of the fingers, with the small finger flexed most and the index finger least (Fig. 44-6). Disturbance of this suggests a tendon or skeletal problem. Also note any gross deformities or wounds and what deeper structures, if any, are visible in such wounds. Observe for abnormal coloration of a portion or all of the hand (this can be confounded by ambient temperature or other injuries), edema, and/or clubbing of the fingertips.

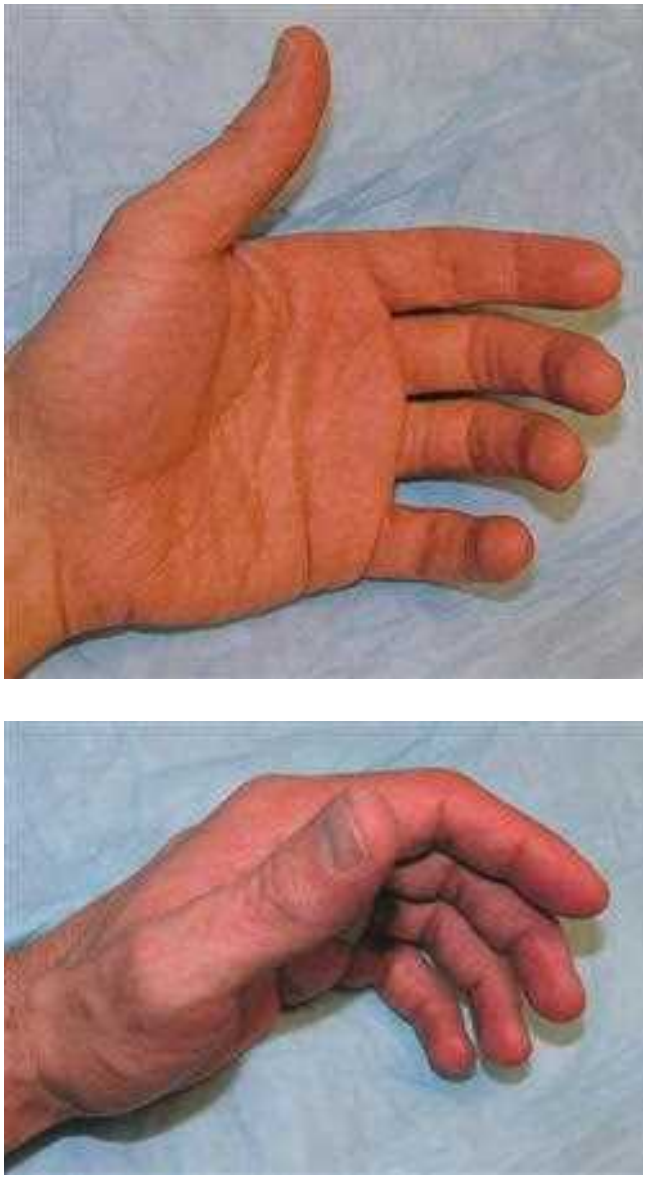

Figure 44-6. In the normal resting hand, the fingers assume a slightly flexed posture from the index finger (least) to the small finger (most).

Palpation typically begins with the radial and ulnar artery pulses at the wrist level. Pencil Doppler examination can supplement this and evaluate distal vessels. A pulsatile signal is normally detectable by pencil Doppler in the pad of the finger at the center of the whorl of creases. Discrepancies between digits should be noted. If all other tests are inconclusive, pricking the involved digit with a 25-gauge needle should produce bright red capillary bleeding. If an attached digit demonstrates inadequate or absent blood flow (warm ischemia), the urgency of completing the evaluation and initiating treatment markedly increases.

Sensation must be evaluated prior to any administration of local anesthetic. At a minimum, light and sharp touch sensation should be documented for the radial and ulnar aspects of the tip of each digit. Beware of writing "sensation intact" at the conclusion of this evaluation. Rather, one should document what was tested (e.g., "light and sharp touch sensation present and symmetric to the tips of all digits of the injured hand"). In the setting of a sharp injury, sensory deficit implies a lacerated structure until proven otherwise. Once sensation has been evaluated and documented, the injured hand can be anesthetized for patient comfort during the remainder of the examination (see below).

Ability to flex and extend the wrist and digital joints is typically examined next. At the wrist level, the FCR and FCU tendons should be palpable during flexion. The wrist extensors are not as readily palpated due to the extensor retinaculum. Ability to flex the DIP joint (FDP) is tested by blocking the finger at the middle phalanx level. To test the FDS to each finger, hold the remaining three fingers in slight hyperextension and ask the patient to flex the involved digit (Fig. 44-7). This maneuver makes use of the fact that the FDP tendons share a common muscle belly. Placing the remaining fingers in extension prevents the FDP from firing, and allows the FDS, which

Figure 44-7. The examiner holds the untested fingers in full extension, preventing contracture of the flexor digitorum profundus. In this position, the patient is asked to flex the finger, and only the flexor digitorum superficialis will be able to fire.

has a separate muscle belly for each tendon, to fire. Strength in grip, finger abduction, and thumb opposition is tested and compared to the uninjured side. Range of motion for the wrist, MP, and IP joints should be noted and compared to the opposite side.

If there is suspicion for closed space infection, the hand should be evaluated for erythema, swelling, fluctuance, and localized tenderness. The dorsum of the hand does not have fascial septae; thus dorsal infections can spread more widely than palmar ones. The epitrochlear and axillary nodes should be palpated for enlargement and tenderness. Findings for specific infectious processes will be discussed in the Infections section.

Additional exam maneuvers and findings, such as those for office consultations, will be discussed with each disease process covered later in this chapter.

HAND IMAGING

Plain X-Rays

Almost every hand evaluation should include plain X-rays of the injured or affected part. A standard, anteroposterior, lateral, and oblique view of the hand or wrist (as appropriate) is rapid, inexpensive, and usually provides sufficient information about the bony structures to achieve a diagnosis in conjunction with the symptoms and findings.[6]

Lucencies within the bone should be noted. Most commonly, these represent fractures, but they can on occasion represent neoplastic or degenerative processes. Great care should be taken to evaluate the entire X-ray, typically beginning away from the area of the patient's complaint. Additional injuries can be missed, which might affect the treatment plan selected and eventual outcome.

Congruency of adjacent joints should also be noted. The MP and IP joints of the fingers should all be in the same plain on any given view. Incongruency of the joint(s) of one finger implies fracture with rotation. At the wrist level, the proximal and distal edge of the proximal row and proximal edge of the distal row should be smooth arcs,[7] known as Gilula's arcs (Fig. 44-8A). Disruption of these implies ligamentous injury or possibly dislocation (Fig. 44-8B).

Computed Tomography

Computed tomography (CT) scanning of the hand and wrist can provide additional bony information when plain X-rays are insufficient. Comminuted fractures of the distal radius can be better visualized for number and orientation of fragments. Scaphoid fractures can be evaluated for displacement and comminution preoperatively as well as for the presence of bony bridging postoperatively (Fig. 44-9). CT scans are also useful for CMC fractures of the hand where overlap on a plain X-ray lateral view may make diagnosis difficult.

Unlike the trunk and more proximal extremities, CT scans with contrast are less useful to demonstrate abscess cavities due to the small area of these spaces.

Ultrasonography

Ultrasonography has the advantages of being able to demonstrate soft tissue structures and being available on nights and weekends. Unfortunately, it is also highly operator dependent. In the middle of the night when magnetic resonance imaging (MRI) is not available, ultrasound may be able to demonstrate a large deep infection in the hand but is rarely more useful than a thorough clinical examination.

Magnetic Resonance Imaging

MRI provides the best noninvasive visualization of the soft tissue structures. With contrast, MRI can demonstrate an occult abscess. Unfortunately, it is often not available on an urgent basis for hand issues when this information is often needed. MRI can also demonstrate soft tissue injuries such as cartilage or ligament tears or tendonitis (usually by demonstrating edema in the area in question). It can demonstrate occult fractures that are not sufficiently displaced to be seen on X-ray or CT (again, by demonstrating edema). MRI can also demonstrate vascular disturbance of a bone, as in a patient with avascular necrosis of the scaphoid (Fig. 44-10).

Angiography

Angiography of the upper extremity is rarely used. In many centers, MRI and CT angiography provide sufficient resolution of the vascular structures to make traditional angiography unnecessary.

A **B**

Figure 44-8. Gilula's arcs are seen shown in this normal patient (**A**) and in a patient with a scaphoid fracture and perilunate dislocation (**B**).

Figure 44-9. **A.** Preoperative images demonstrate a nonunion of a scaphoid fracture sustained 4 years earlier. Postoperatively, cross-sectional imaging with a computed tomography scan in the coronal plan demonstrates bone crossing the previous fracture line. This can be difficult to discern on plain X-rays due to overlap of bone fragments.

Also, primary vascular disease of the upper extremity is relatively uncommon. In the trauma setting, vascular disturbance usually mandates exploration and direct visualization of the structures in question, and angiography is thus obviated.

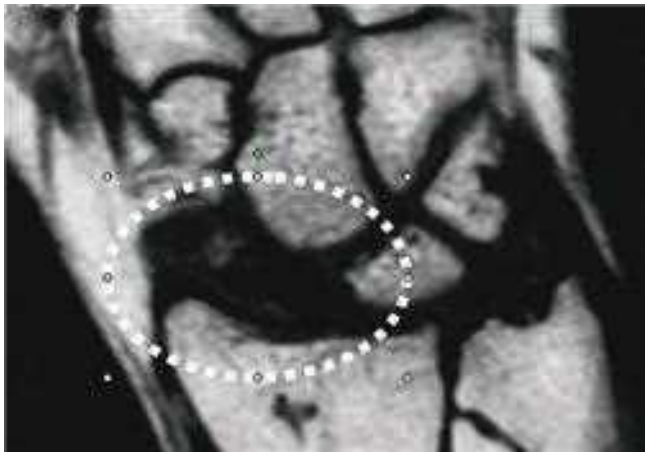

Figure 44-10. T1-weighted magnetic resonance imaging shows perfused bone as *white*. In this patient, there is the absence of whiteness where the scaphoid should be (*dashed circle*), consistent with avascular necrosis.

For a patient with vascular disease of the upper extremity, angiography of the upper extremity is usually performed through a femoral access much like with the leg. An arterial catheter can be used to deliver thrombolytic drugs to treat a thrombotic process.

TRAUMA

The upper extremity–injured patient may have additional injuries to other parts of the body. All injured patients should receive an appropriate trauma survey to look for additional injuries.

The patient with upper extremity trauma is evaluated as described in the Hand Examination section. Sensory examination should be performed early. Once sensory status has been documented, administration of local anesthesia can provide comfort to the patient during the remainder of the evaluation and subsequent treatment. Patients should receive tetanus toxoid for penetrating injuries if more than 5 years have passed since the last vaccination.

Local Anesthesia

Anesthetic blockade can be administered at the wrist level, digital level, or with local infiltration as needed. Keep in mind that all local anesthetics are less effective in areas of inflammation.

The agents most commonly used are lidocaine and bupivacaine. Lidocaine has the advantage of rapid onset, whereas bupivacaine has the advantage of long duration (average 6–8 hours).[8] Although bupivacaine can produce irreversible heart block in high doses, this is rarely an issue with the amounts typically used in the hand. For pediatric patients, the tolerated dose is 2.5 mg/kg. This can be easily remembered by noting that when using 0.25% bupivacaine, 1 mL/kg is acceptable dosing.

A commonly held axiom is that epinephrine is unacceptable to be used in the hand. Several recent large series have dispelled this myth.[9] Epinephrine should not be used in the fingertip and not in concentrations higher than 1:100,000 (i.e., what is present in commercially available local anesthetic with epinephrine). Beyond that, its use is acceptable and may be useful in an emergency room (ER) where tourniquet control may not be available. Also, because most ER procedures are done under pure local anesthesia, many patients will not tolerate the discomfort of the tourniquet beyond 30 minutes.[10] Epinephrine will provide hemostasis and also prolong the effect of the local anesthetic.

Simple lacerations, particularly on the dorsum of the hand, can be anesthetized with local infiltration. This is performed in the standard fashion.

Blocking of the digital nerves at the metacarpal head level is useful for volar injuries distal to this point and for dorsal injuries beyond the midpoint of the middle phalanx (via dorsal branches of the proper digital nerves). Fingertip injuries are particularly well anesthetized by this technique. A digit can be anesthetized via a flexor sheath approach or via the dorsal web space (Fig. 44-11A,B).

Blocking one or more nerves as they cross the wrist can provide several advantages: anesthesia for multiple injured digits, avoiding areas of inflammation where the local anesthetic agent may be less effective, and avoiding injection where the volume of fluid injected may make treatment harder (such as fracture reduction). Four major nerves cross the wrist: the median nerve, SRN, ulnar nerve, and dorsal sensory branch of the ulnar nerve (Fig. 44-11C–E). When blocking the median and ulnar nerves, beware of intraneural injection, which can cause irreversible neural scarring. If the patient complains of severe paresthesias with injection or high resistance is encountered, the needle should be repositioned.

Fractures and Dislocations

For dislocations and displaced fractures, a visible deformity is often present. Nondisplaced fractures may not show a gross deformity but will have edema and tenderness to palpation at the fracture site. A fracture is described by its displacement, rotation, and angulation. A fracture is also described in terms of comminution and the number and complexity of fracture fragments. Displacement is described as a percentage of the diameter of the bone; rotation is described in degrees of supination or pronation with respect to the rest of the hand; angulation is described in degrees. To avoid confusion, it is useful to describe which direction the angle of the fracture points. All injuries should be evaluated for nearby wounds (open) that may introduce bacteria into the fracture site or joint space.

Once the initial force on the fracture ceases, the tendons passing beyond the fracture site provide the principal deforming force. Their force is directed proximally and, to a lesser extent, volarly. Based on this, the stability of a fracture can be determined by the orientation of the fracture with respect to the shaft of the bone. Transverse fractures are typically stable. Oblique fractures typically shorten. Spiral fractures typically rotate as they shorten and thus require surgical treatment.

Fractures of the tuft of the distal phalanx are common. Catching of a finger in a closing door is a common causative mechanism. These fractures are often nondisplaced and do not require treatment beyond protection of the distal phalanx from additional trauma while the fracture heals.

Displaced transverse fractures of the phalanges can usually be reduced with distraction. The distal part is pulled away from the main body of the hand and then pushed in the direction of the proximal shaft of the finger, and then distraction is released. Postreduction X-rays should routinely be performed to document satisfactory reduction. Oblique and spiral fractures usually are unstable after reduction. The involved digit(s) should be splinted until appropriate surgical intervention can be performed.

Articular fractures of the IP and MP joints are worrisome because they may compromise motion. Chip fractures must be evaluated for instability of the collateral ligaments. If the joint is stable, the patient should initially be splinted for comfort. Motion therapy should be instituted early (ideally within the first week) to prevent stiffness. For larger fractures, the patient should be splinted until surgical treatment can be performed. In surgery, the fracture is typically internally fixated to allow for early motion, again with the goal of preventing stiffness.[11]

Dislocations of the PIP joints produce traction on the neurovascular structures but usually do not lacerate them. In general, the patient should not be sent home with a joint that remains dislocated. Most commonly, the distal part is dorsal to the proximal shaft and sits in a hyperextended position. For this patient, the examiner gently applies pressure to the base of the distal part until it passes beyond the head of the proximal phalanx. Once there, the relocated PIP joint is gently flexed, confirming the joint is in fact reduced. The joint is splinted in slight flexion to prevent redislocation. On occasion, the head of the proximal phalanx may pass between the two slips of the FDS tendon. For these patients, the joint may not be reducible in a closed fashion.

Angulated fractures of the small finger metacarpal neck ("boxer's fracture") are another common injury seen in the ER. Typical history is that the patient struck another individual or rigid object with a hook punch. These are often stable after reduction using the Jahss maneuver (Fig. 44-12).

Fractures of the thumb metacarpal base are often unstable. The Bennett fracture displaces the volar-ulnar base of the bone. The remainder of the articular surface and the shaft typically dislocate dorsoradially and shorten. The thumb often appears grossly shortened, and the proximal shaft of the metacarpal may reside at the level of the trapezium or even the scaphoid on X-ray. In a Rolando fracture, a second fracture line occurs between the remaining articular surface and the shaft. These fractures nearly always require open reduction and internal fixation.

Most nondisplaced fractures do not require surgical treatment. The scaphoid bone of the wrist is a notable exception to this rule. Due to peculiarities in its vascular supply, particularly vulnerable at its proximal end, nondisplaced scaphoid fractures

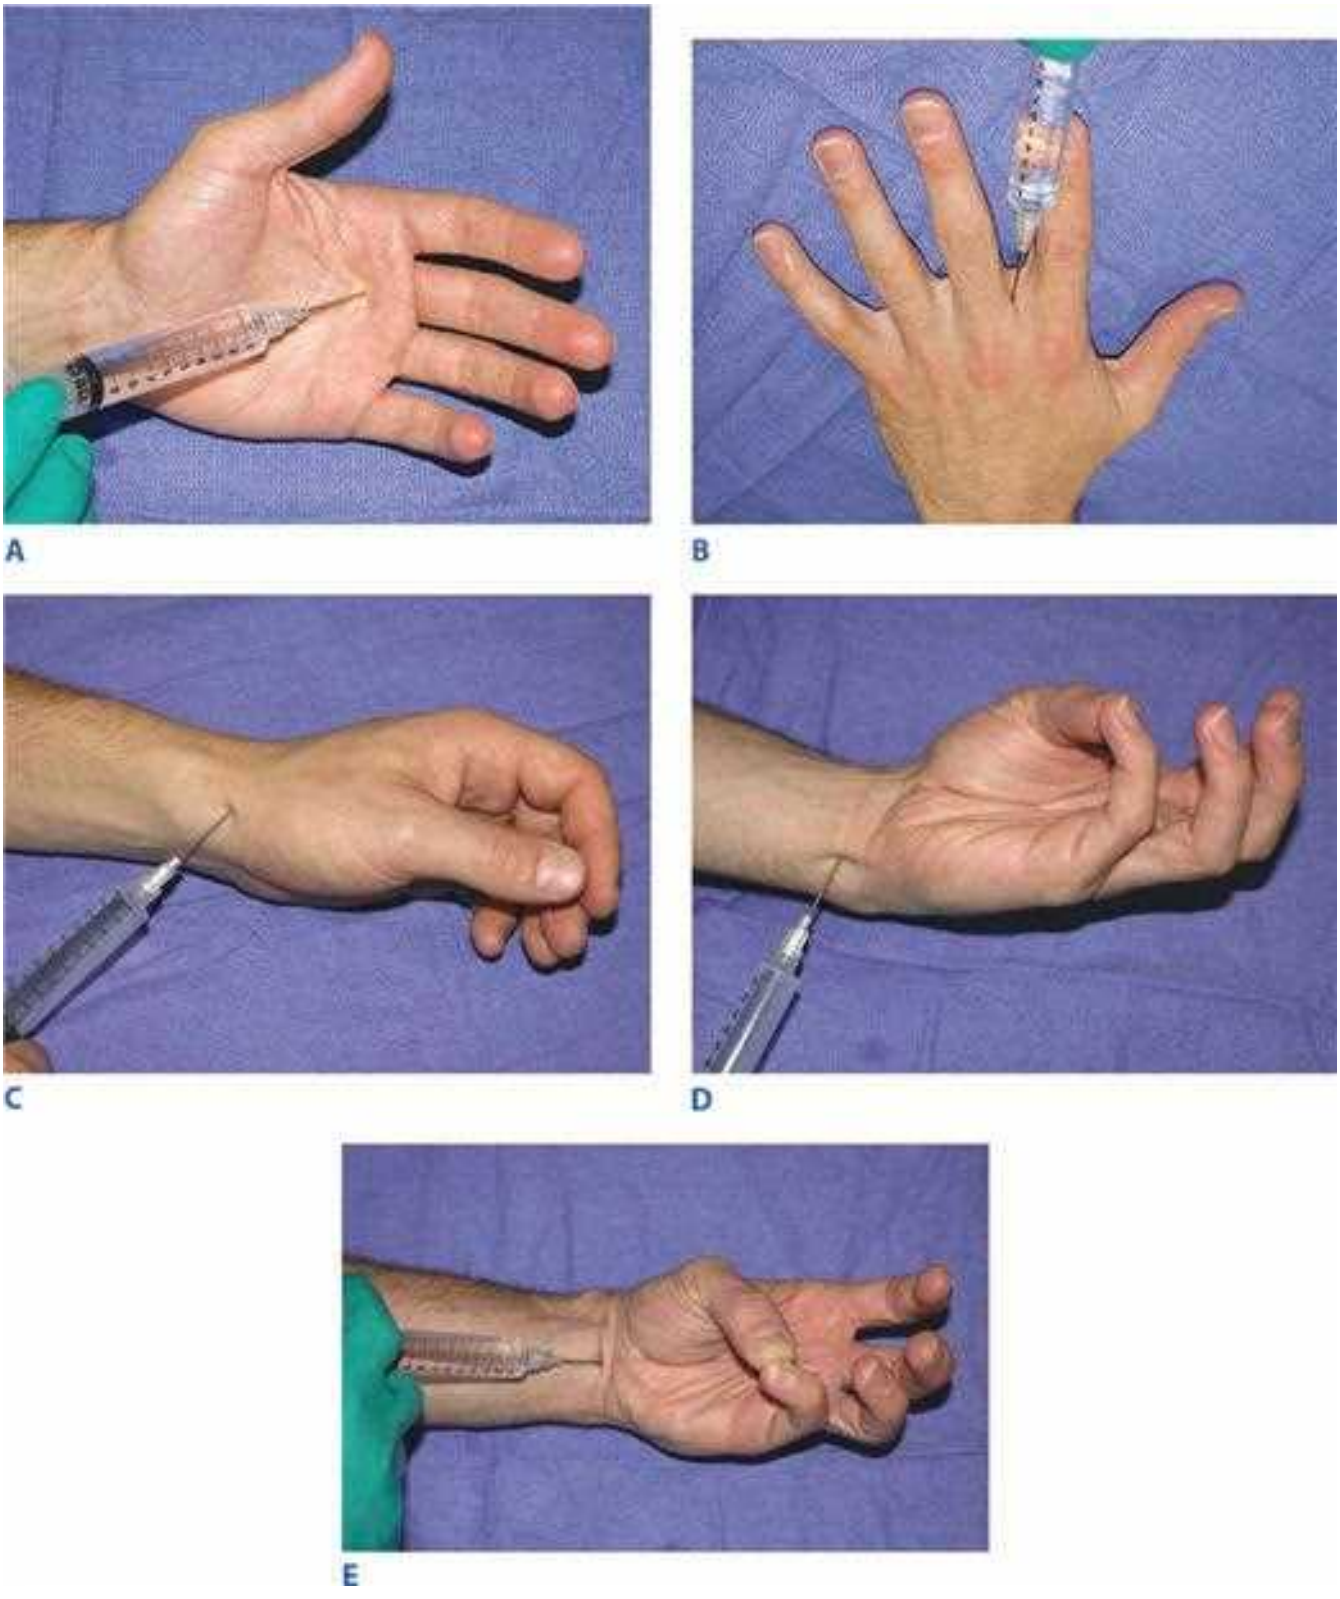

Figure 44-11. Local anesthesia can be administered at the digital or the wrist level. **A.** A single injection into the flexor tendon sheath at the metacarpal head level provides complete anesthesia for the digit. **B.** Alternatively, one can inject from a dorsal approach into the web space on either side. **C.** The superficial radial nerve is blocked by infiltrating subcutaneously over the distal radius from the radial artery pulse to the distal radioulnar joint. The dorsal sensory branch of the ulnar nerve is blocked in similar fashion over the distal ulna. **D.** To block the ulnar nerve, insert the needle parallel to the plane of the palm and deep to the flexor carpi ulnaris tendon; aspirate to confirm the needle is not in the adjacent ulnar artery. **E.** To block the median nerve, insert the needle just ulnar to the palmaris longus tendon into the carpal tunnel. One should feel two points of resistance: one when piercing the skin, the second when piercing the antebrachial fascia.

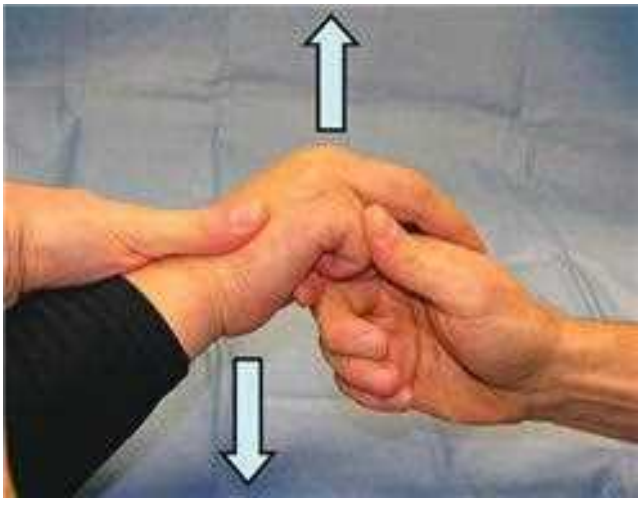

Figure 44-12. The Jahss maneuver. The surgeon fully flexes the patient's small finger into the palm and secures it in his distal hand. The proximal hand controls the wrist and places the thumb on the patient's fracture apex (the most prominent dorsal point). The examiner distracts the fracture, pushes dorsally with the distal hand (*up arrow*), and resists dorsal motion with the proximal hand (*down arrow*).

can fail to unite in up to 20% of patients even with appropriate immobilization. Recent developments in hardware and surgical technique have allowed stabilization of the fracture with minimal surgical exposure. One prospective randomized series of scaphoid wrist fractures demonstrated shortening of time to union by up to 6 weeks in the surgically treated group, but no difference in rate of union.[12] Surgery may be useful in the younger, more active patient who would benefit from an earlier return to full activity.

Ligament injuries of the wrist can be difficult to recognize. Patients often present late and may not be able to localize their pain. In severe cases, the ligaments of the wrist can rupture to the point of dislocation of the capitate off the lunate or even the lunate off the radius. Mayfield and colleagues classified the progression of this injury into four groups.[13] In the most severe group, the lunate dislocates off the radius into the carpal tunnel. In some circumstances, the scaphoid bone may break rather than the scapholunate ligament rupturing. Attention to the congruency or disruption of Gilula's arcs will help the examiner to recognize this injury. For patients with type 4 (most severe) and some with type 3 injury, the examiner should also evaluate for sensory disturbance in the median nerve distribution because this may indicate acute carpal tunnel syndrome and necessitate more urgent intervention. Although the Mayfield pattern of injury is most common, force can also transmit along alternate paths through the carpus.[14]

After reduction of fractures and dislocations (as well as after surgical repair of these and many other injuries), the hand must be splinted in a protected position. For the fingers, MP joints should be splinted 90°, and the IP joints at 0° (called the *intrinsic plus position*). The wrist is generally splinted at 20° extension because this puts the hand in a more functional position. This keeps the collateral ligaments on tension and helps prevent secondary contracture. In general, one of three splints should be used for the ER patient (Fig. 44-13). The ulnar gutter splint uses places plaster around the ulnar border of the hand. It is generally appropriate for small finger injuries only. Dorsal plaster splints can be used for injuries of any of the fingers. Plaster is more readily contoured to the dorsal surface of the hand than the volar surface, particularly in the setting of trauma-associated edema. For thumb injuries, the thumb spica splint is used to keep the thumb radially and palmarly abducted from the hand.

3▶

Tendons

Injuries to the flexor and extensor tendons compromise the mobility and strength of the digits. On inspection, injury is normally suspected by loss of the normal cascade of the fingers. The patient should be examined as described earlier to evaluate for which tendon motion is deficient. If the patient is unable to cooperate, extension of the wrist will produce passive flexion of the fingers and also demonstrate a deficit. This is referred to at the tenodesis maneuver.

Flexor tendon injuries are described based on zones (Fig. 44-14). Up until 40 years ago, zone 2 injuries were always reconstructed and never repaired primarily due to concern that the bulk of repair within the flexor sheath would prevent tendon glide. The work of Dr. Kleinert and colleagues at the University of Louisville changed this "axiom" and established the principle of primary repair and early controlled mobilization postoperatively.[15] Flexor tendon injuries should always be repaired in the operating room. Although they do not need to be repaired on the day of injury, the closer to the day of injury they are repaired, the easier it will be to retrieve the retracted proximal end in surgery. The laceration should be washed out and closed at the skin level only using permanent sutures. The hand should be splinted as described earlier; one notable difference is that the wrist should be splinted at slight flexion (about 20°) to help decrease the retracting force on the proximal cut tendon end.

Extensor tendons do not pass through a sheath in the fingers. As such, bulkiness of repair is less of a concern. With proper supervision/experience and equipment, primary extensor tendon repair can be performed in the ER.

Very distal extensor injuries near the insertion on the dorsal base of the distal phalanx may not have sufficient distal tendon to hold a suture. Closed injuries, called mallet fingers, can be treated with extension splinting of the DIP joint for 6 continuous weeks. For patients with open injuries, a dermatotenodesis suture is performed. A 2-0 or 3-0 suture is passed through the distal skin, tendon remnant, and proximal tendon as a mattress suture. Using a suture of a different color than the skin closing sutures will help prevent removing the dermatotenodesis suture(s) too soon. The DIP joint is splinted in extension.

More proximal injuries are typically repaired with a 3-0 braided permanent suture. Horizontal mattress or figure-of-eight sutures should be used, two per tendon if possible. Great care should be used to ensure matching the appropriate proximal and distal tendon ends. The patient is splinted with IP joints in extension and the wrist in extension per usual. MP joints should be splinted in 45° flexion, sometimes less. Although this position is not ideal for MP collateral ligaments, it is important for taking tension off of the tendon repairs.

Nerve Injuries

In the setting of a sharp injury, a sensory deficit implies a nerve laceration until proven otherwise. For blunt injuries, even displaced fractures and dislocations, nerves are often contused but not lacerated and are managed expectantly. Nerve repairs require

Figure 44-13. Commons splints used for hand injuries/surgeries. **A.** Ulnar gutter splint. The ring and small fingers are included. The surgeon pushes on the dorsum of the fingers with the distal hand to produce interphalangeal (IP) joint extension and metacarpophalangeal (MP) joint flexion to 90°, while the proximal hand controls wrist position. **B.** Dorsal four-finger splint. As with the ulnar gutter splint, finger MP joints are flexed to 90° with IP joints kept fully extended. **C.** Thumb spica splint. One easy method to fabricate is to place one slab of plaster radially over the wrist and thumb with a second square of plaster over the thenar eminence, which joins the first. In this patient, the IP joint was not included. For injuries at, or distal to, the MP joint, the IP should be included in the splint.

appropriate microsurgical equipment and suture; they should not be performed in the ER. As with tendons, nerve injuries do not require immediate exploration. However, earlier exploration will allow for easier identification of structures and less scar tissue to be present. The nerve must be resected back to healthy nerve fascicle prior to repair. Delay between injury and repair can thus make a difference between the ability to repair a nerve primarily or the need to use a graft. The injured hand should be splinted with MPs at 90° and IPs at 0°, as described earlier.

Vascular Injuries

Vascular injuries have the potential to be limb or digit threatening. A partial laceration of an artery at the wrist level can potentially cause exsanguinating hemorrhage. Consultations for these injuries must be evaluated urgently.

Initial treatment for an actively bleeding wound should be direct local pressure for no less than 10 continuous minutes. If this is unsuccessful, an upper extremity tourniquet inflated to 100 mmHg above the systolic pressure should be used. One should keep this tourniquet time to less than 2 hours to avoid tissue necrosis. Once bleeding is controlled well enough to evaluate the wound, it may be cautiously explored to evaluate for bleeding points. One must be very cautious if attempting to ligate these to ensure that adjacent structures such as nerves are not included in the ligature.

The hand must be evaluated for adequacy of perfusion to the hand as a whole as well as the individual digits. Capillary refill, turgor, Doppler signal, and bleeding to pinprick all provide useful information regarding vascular status. The finger or hand with vascular compromise requires urgent operative exploration. Unlike the complete amputation, in which the amputated part can be cold preserved (see below), devascularization without amputation produces warm ischemia, which is tolerated only for a matter of hours.

For the noncritical vascular injury, two treatment options exist. Simple ligation will control hemorrhage. At least one of the palmar arterial arches is intact in 97% of patients,[5] so this will usually not compromise hand perfusion. Each digit also has two arterial inflows and can survive on one (see Amputations and Replantation section below). In the academic hospital setting, however, consideration should be given to repairing all vascular injuries. Instructing a resident in vascular repair in the noncritical setting will produce a more skilled and prepared resident for when a critical vascular injury does arise.

SPECIAL CONSIDERATIONS

Amputations and Replantation

After replantation was first reported,[16] replantation was attempted for nearly all amputations. Over the ensuing decades, more stringent guidelines have been established regarding what should be replanted. Indications for replantation include amputations of the thumb, multiple digit amputations, and amputations in children. Relative contraindications to replantation include crush injuries, injuries to a single digit distal to the PIP joint, and patients who are unable to tolerate a long surgical procedure. As with all guidelines, one should evaluate the particular needs of the injured patient.

In preparation for replantation, the amputated part and proximal stump should be appropriately treated. The amputated part should be wrapped in moistened gauze and placed in a sealed plastic bag. This bag should then be placed in an ice water bath. Do not use dry ice, and do not allow the part to contact ice directly; frostbite can occur in the amputated part, which will decrease its chance of survival after replantation. Bleeding should be controlled in the proximal stump by as minimal a means necessary, and the stump should be dressed with a nonadherent gauze and bulky dressing.

For digital amputations deemed unsalvageable, revision amputation can be performed in the ER if appropriate equipment is available. Bony prominences should be smoothed off with a rongeur and/or rasp. Great care must be taken to identify the digital nerves and resect them back as far proximally in the wound as possible; this helps decrease the chance of painful neuroma in the skin closure. Skin may be closed with permanent or absorbable sutures; absorbable sutures will spare the patient the discomfort of suture removal several weeks later. For more proximal unsalvageable amputations, revision should be performed in the operating room to maximize vascular and neural control.

Prostheses can be made for amputated parts. The more proximal the amputation, the more important to function the prosthesis is likely to be. Although finger-level prostheses are generally considered cosmetic, patients with multiple finger amputations proximal to the DIP have demonstrable functional benefit from their prosthesis as well.[17]

Fingertip Injuries

Fingertip injuries are among the most common pathologies seen in an ER. The usual history is that a door closed on the finger (commonly the middle, due to its increased length) or something heavy fell on the finger.

Initial evaluation should include: wound(s) including the nail bed, perfusion, sensation, and presence and severity of fractures. For the common scenario, complex lacerations with minimally displaced fracture(s) and no loss of perfusion, the wound is cleansed, sutured, and splinted in the ER. To properly assess the nail bed, the nail plate (hard part of the nail) should be removed. A Freer periosteal elevator is well suited for this purpose. Lacerations are repaired with 6-0 fast gut suture. Great care must be taken when suturing because excessive traction with the needle can further lacerate the tissue. After repair, the nail folds are splinted with the patient's own nail plate (if available) or with aluminum foil from the suture pack. This is done to prevent scarring from the nail folds down to the nail bed that would further compromise healing of the nail.

In some situations, tissue may have been avulsed in the injury and be unavailable for repair. Choice of treatment options depends on the amount and location of tissue loss (Fig. 44-15).

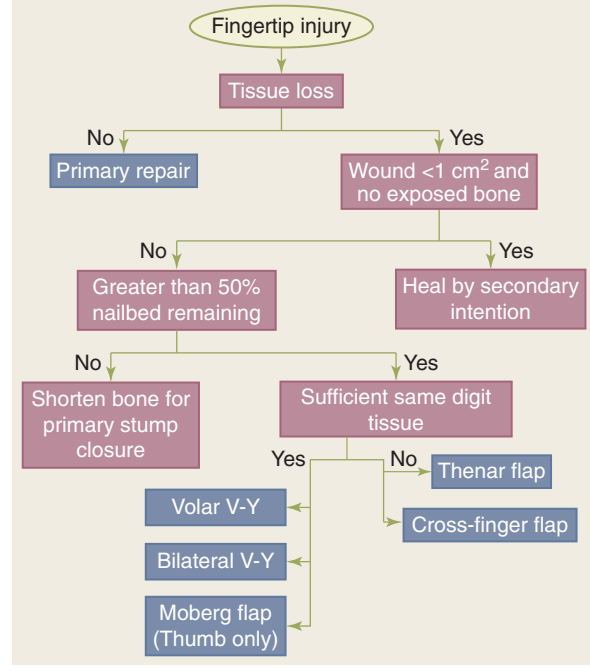

Figure 44-15. Treatment algorithm for management of fingertip injuries. See text for description of flaps.

For wounds less than 1 cm^2 with no exposed bone, secondary intention will produce excellent functional and aesthetic results. For larger wounds or wounds or with bone exposed, one must decide if the finger is worth preserving at the current length or if shortening to allow for primary closure is a better solution. A useful guideline is the amount of fingernail still present; if greater than 50% is present, local or regional flap coverage may be a good solution.

If sufficient local tissue is present, homodigital flaps can be considered. A wide range of antegrade and retrograde homodigital flaps can be mobilized to cover the defect. Some carry sensation or can receive nerve coaptation to recover sensation over time.[18] For the thumb only, the entire volar skin including both neurovascular bundles can be raised and advanced distally up to 1.5 cm.[19] The thumb receives separate vascularity to its dorsal skin from the radial artery. This flap is not appropriate for the fingers. Patients retain full sensibility in the advanced skin and can be mobilized within days of surgery (Fig. 44-16A–C).

For wounds too large to cover with homodigital tissue, regional flaps can be considered. The skin from the distal radial thenar eminence can be raised as a random pattern flap (Fig. 44-16D–F). The finger is maintained in flexion for 14 to 21 days until division of the flap pedicle and inset of the flap. Some authors have reported prolonged stiffness in patients over 30 years old, but careful flap design helps minimize this complication.[20] Alternatively, the skin from the dorsum of the middle phalanx of an adjacent digit can be raised as a flap to cover the volar P3 (Fig. 44-16G–I). The flap is inset at 14 to 21 days. Long-term studies have shown this flap develops sensation over time.[21]

Patients with fingertip injures must be assessed for the possibility of salvage of the injured digit(s) taken within the context of the patient's recovery needs and goals. The surgeon then matches the available options to the particular patient needs.

High-Pressure Injection Injuries

High-pressure devices are commonly used for cleaning and applications of liquids such as lubricants and paint. Most commonly, the inexperienced worker accidentally discharges the device into his nondominant hand at the base of the digit. Severity of injury depends on the amount and type of liquid injected; hydrophobic compounds cause greater damage.

These injuries are typically quite innocuous to inspection. They are, however, digit-threatening emergencies. The patient should be informed of the severity of the injury, and exploration is ideally performed within 6 hours of injury. Up to 50% of such injuries result in loss of the digit, but early recognition and treatment are associated with increased chance of digit survival.[22] Early frank discussion with the patient and initiation of appropriate treatment produce the best results and medicolegal protection.

Compartment Syndromes

Compartment syndromes can occur in the forearm and/or the hand. As in other locations, these are potentially limb-threatening issues. Principle symptoms are pain in the affected compartments, tense swelling, tenderness to palpation over the compartment, and pain with passive stretch of the muscles of the compartment.[23] Pulse changes are a late finding; normal pulses do not rule out compartment syndrome.

There are three compartments in the forearm and four groups of compartments in the hand. The volar forearm is one compartment. On the dorsum of the forearm, there is the dorsal compartment as well as the mobile wad compartment, beginning proximally over the lateral epicondyle. In the hand, the thenar and hypothenar eminences each represent a compartment. The seven interosseous muscles each behave as a separate compartment.

Compartment syndrome can be caused by intrinsic and extrinsic causes. Intrinsic causes include edema and hematoma due to fracture. Extrinsic causes include splints and dressings that are circumferentially too tight and intravenous infiltrations. Infiltrations with hyperosmolar fluids such as x-ray contrast are particularly dangerous, because additional water will be drawn in to neutralize the hyperosmolarity.

Measurement of compartment pressures can be a useful adjunct to assessment of the patient. The Stryker pressure measurement device or similar device is kept in many operating rooms for this purpose. The needle is inserted into the compartment in question, a gentle flush with 0.1 to 0.2 cc of saline clears the measurement chamber, and a reading is obtained. Studies have disagreed about whether the criterion is a measured pressure (30–45 mmHg, depending on the series) or within a certain amount of the diastolic blood pressure.[24]

Compartment releases are performed in the operating room under tourniquet control. Release of the volar forearm compartment includes release of the carpal tunnel. As the incision travels distally, it should pass ulnar and then curve back radially just before the carpal tunnel. This avoids a linear incision across a flexion crease and also decreases the chance of injury to the palmar cutaneous branch of the median nerve. One dorsal forearm incision can release the dorsal compartment and the mobile wad. In the hand, the thenar and hypothenar compartments are released each with a single incision. The interosseous compartments are released with incisions over the index and ring metacarpal shafts. Dissection then continues radial and ulnar to each of these bones and provides release of all the muscle compartments. Any dead muscle is débrided. Incisions are left open and covered with a nonadherent dressing. The wounds are reexplored in 2 to 3 days to assess for muscle viability. Often the incisions can be closed primarily, but a skin graft may be needed for the forearm.

If the examiner feels the patient does not have a compartment syndrome, elevation and serial examination are mandatory. When in doubt, it is safer to release an early compartment syndrome than wait to release and risk muscle necrosis. Progression of compartment syndrome can lead to Volkmann's ischemic contracture with muscle loss and scarring that may compress nerves and other critical structures. Medicolegally, it is far easier to defend releasing an early compartment syndrome than delaying treatment until the process has progressed to necrosis and/or deeper scarring.

COMPLICATIONS

Nonunion

Any fractured bone has the risk of failing to heal. Fortunately, in the fingers and hand, this is a rare problem. Tuft injuries, where soft tissue interposes between the fracture fragments, have relatively higher risk of this problem. The nonunited tuft can be treated with débridement and bone grafting or revision amputation depending on the needs and goals of the patient. Phalangeal and metacarpal nonunions are also quite rare. They can similarly be treated with débridement of the nonunion, grafting,

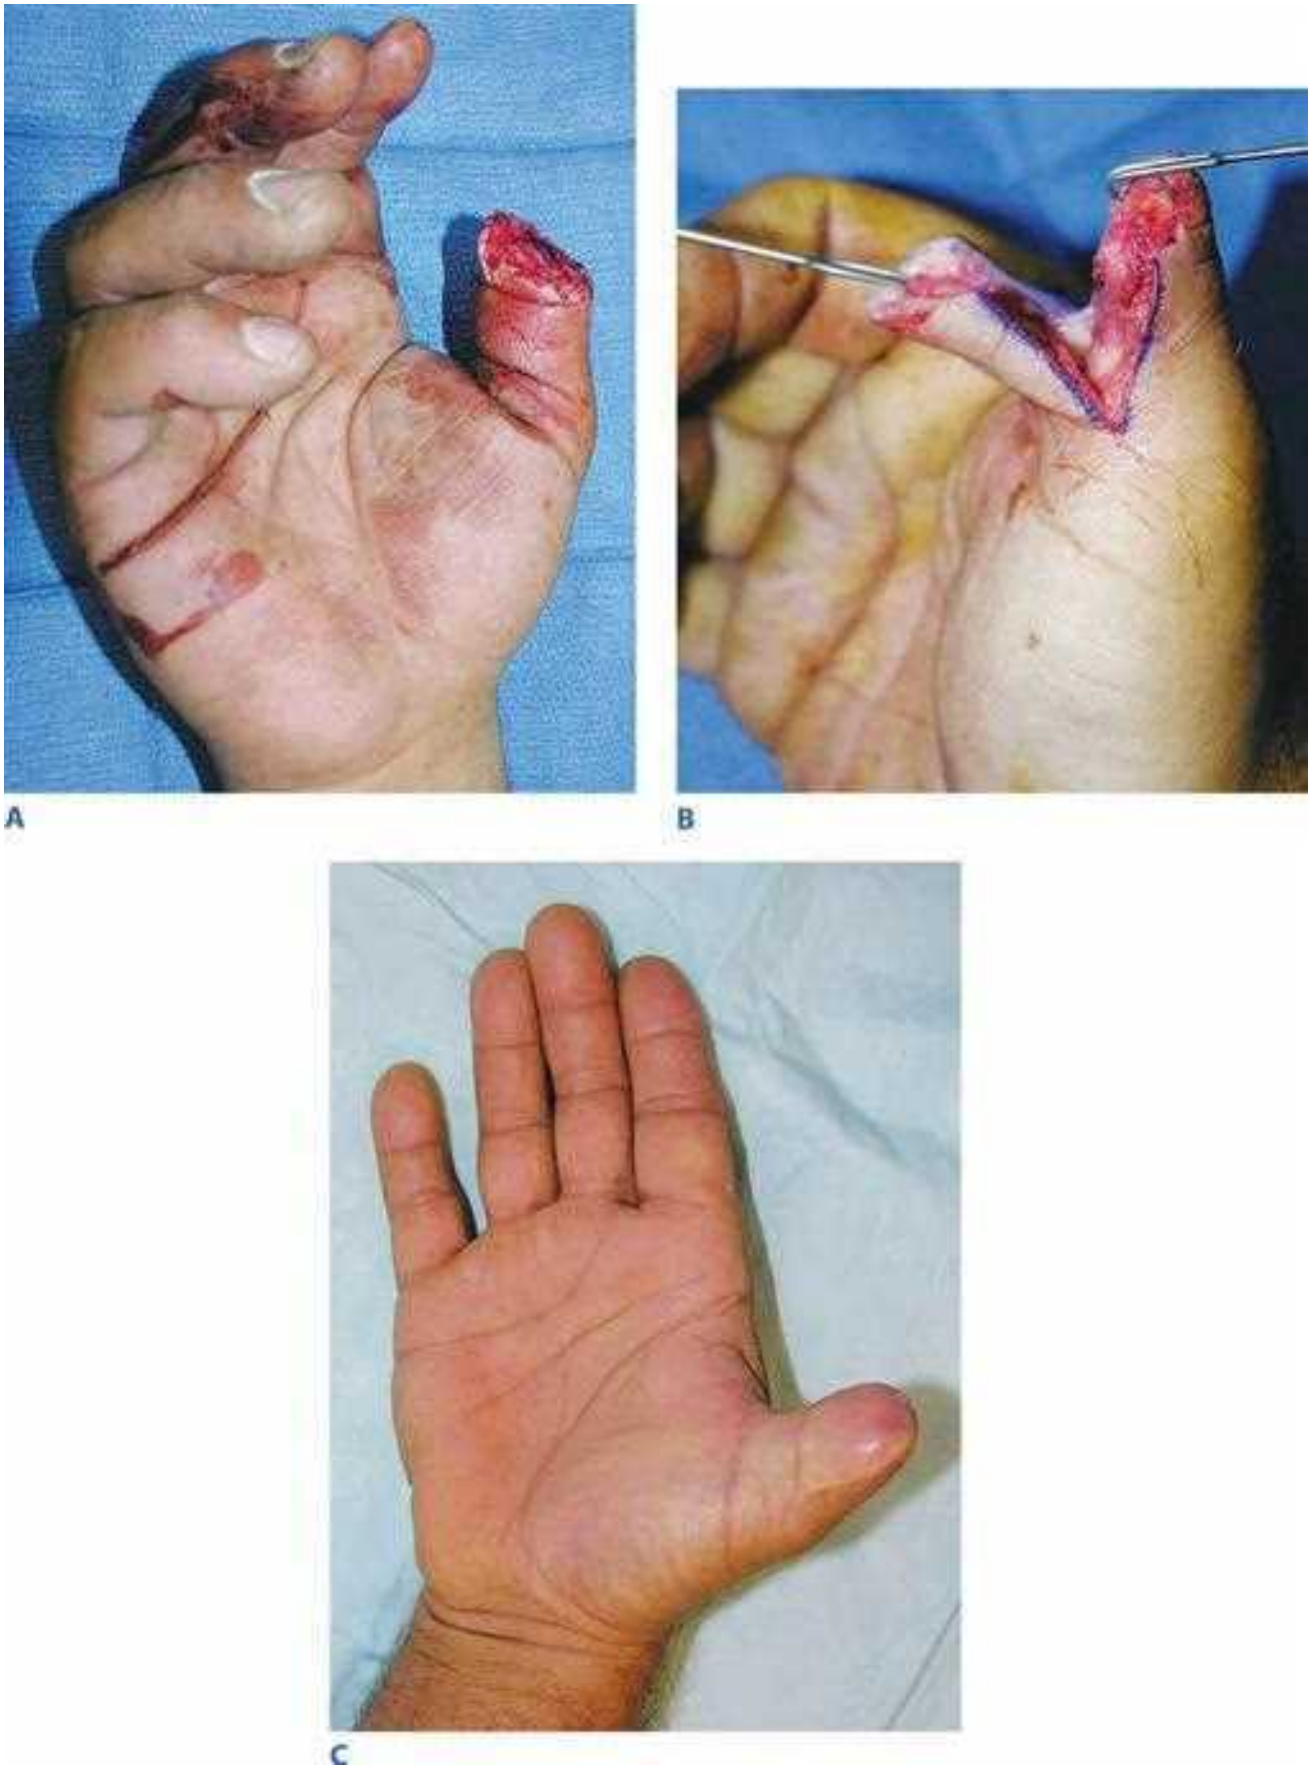

Figure 44-16. Local flaps for digital tip coverage. **A–C.** For thumb injuries, Moberg described elevation of the entire volar skin with both neurovascular bundles for distal advancement. Sensation to the advanced skin is maintained. **D–F.** An 8-year-old girl underwent fingertip replantation that did not survive. A thenar flap was transferred to cover the defect. Some authors advise against its use in patients over 30 years old. **G–I.** In this 45-year-old man, the entire skin of P3 of the long finger was avulsed and unrecoverable. A cross-finger flap was transferred and provides excellent, durable coverage. The border of the flap and surrounding skin is still apparent 4.5 months after surgery.

and rigid fixation.[25] More proximally, the scaphoid bone of the wrist has a significant risk of nonunion even if nondisplaced (see Fig. 44-9A). Any patient suspected of a scaphoid injury, namely those with tenderness at the anatomic snuffbox, should be placed in a thumb spica splint and reevaluated within 2 weeks even if initial X-rays show no fracture. Scaphoid nonunions can be quite challenging to repair,[26] and immobilization at the time of injury in a thumb spica splint is essentially always warranted.

Stiffness

The desired outcome of any hand injury is a painless, mobile, functional hand. Multiple factors can contribute to decreased mobility, including complex injuries of soft tissue and bone, noncompliance of the patient with postoperative therapy, and inappropriate splinting. The surgeon performing the initial evaluation can greatly impact this last factor. The goal of splinting is to keep the collateral ligaments on tension (MPs at 90°, IP joints straight). For severe cases of stiffness, mobilization surgeries such as tenolysis and capsulotomies[27] can be performed, but these rarely produce normal range of motion. Prevention of joint contractures with appropriate splinting and early, protected mobilization is the best option to maximize mobility at the end of healing. Healing of an injured or diseased structure in the hand is not the endpoint of treatment; the goal of any intervention must be to obtain structure healing, relief of pain, and maximization of function.

4▶

Neuroma

Any lacerated nerve will form a neuroma. A neuroma consists of a ball of scar and axon sprouts at the end of the injured nerve.[28] In unfavorable circumstances, this neuroma can become painful. The SRN is particularly notorious for this problem. By providing proximal axon sprouts a target, nerve repair is an excellent preventive technique. In some circumstances, such as injuries requiring amputation, this is not possible. As mentioned earlier, the surgeon should resect the nerve stump as far proximally in the wound as possible to avoid the nerve stump healing in the cutaneous scar to minimize this risk.

For the patient who develops a painful neuroma, nonsurgical treatments are initiated first. The neuroma can be identified by the presence of a Tinel's sign. Therapy techniques of desensitization, ultrasound, and electrical stimulation have all proven useful. Corticosteroid injection to the neuroma has also proven useful in some hands.

When these techniques fail, surgery is contemplated. The neuroma can be resected, but a new one will form to replace it. The nerve ending can be buried in muscle or even bone to prevent the neuroma from residing in a superficial location where it may be impacted frequently.

Regional Pain Syndromes

Injuries to the upper extremity can occasionally result in the patient experiencing pain beyond the area of initial injury. Reflex sympathetic dystrophy and sympathetic mediated pain are two terms that have been used in the past to describe this phenomenon. Both are inaccurate, as the sympathetic nervous system is not always involved. Current terminology for this condition is complex regional pain syndrome (CRPS). Type I occurs in the absence of a documented nerve injury; type II occurs in the presence of one.[29]

CRPSs manifest as pain beyond the area of initial injuries. There is often associated edema and changes in hair and/or sweat distribution. Comparison to the unaffected side is useful to better appreciate these findings. There are currently no imaging studies that can be considered diagnostic for CRPS.[30]

For the patient in whom the diagnosis of CRPS is not clear, no definitive diagnostic study exists. Patients suspected of CRPS should be referred for aggressive hand therapy. Brief trials of oral corticosteroids have been successful in some series. Referral to a pain management specialist including a trial of stellate ganglion blocks is also frequently employed.

NERVE COMPRESSION

Nerves conduct signals along their axonal membranes toward their end organs. Sensory axons carry signals from distal to proximal; motor axons from proximal to distal. Myelin from Schwann cells allows faster conduction of signals. Signals jump from the start of one Schwann cell to the end of the cell (a location called a gap junction) and only require the slower membrane depolarization in these locations.

Nerve compression creates a mechanical disturbance of the nerve.[31] In early disease, the conduction signal is slowed across the area of compression. When compression occurs to a sufficient degree for a sufficient time, individual axons may die. On a nerve conduction study, this manifests as a decrease in amplitude. Muscles receiving motor axons may show electrical disturbance on electromyogram (EMG) when sufficiently deprived of their axonal input.

Compression of sensory nerves typically produces a combination of numbness, paresthesias (pins and needles), and pain. Knowledge of the anatomic distribution of the peripheral nerves can aid in diagnosis. Sensory disturbance outside an area of distribution of a particular nerve (e.g., volar and dorsal radial-sided hand numbness for median nerve) makes compression of that nerve less likely. Diseases that cause systemic neuropathy (e.g., diabetes) can make diagnosis more difficult.

Nerve compression can theoretically occur anywhere along a peripheral nerve's course. The most common sites of nerve compression in the upper extremity are the median nerve at the carpal tunnel, ulnar nerve at the cubital tunnel, and ulnar nerve at Guyon's canal. Other, less common locations of nerve compression are described as well. In addition, a nerve can become compressed in scar due to a previous trauma.

Carpal Tunnel Syndrome

The most common location of upper extremity nerve compression is the median nerve at the carpal tunnel, called carpal tunnel syndrome (CTS). The carpal tunnel is bordered by the scaphoid bone radially, the lunate and capitate bones dorsally, and the hook of the hamate bone ulnarly (see Fig. 44-3). The transverse carpal ligament, also called the flexor retinaculum, is its superficial border. The FPL, four FDS, and four FDP tendons pass through the carpal tunnel along with the median nerve. Of these 10 structures, the median nerve is relatively superficial and radial to the other nine.

An estimated 53 per 10,000 working adults have evidence of CTS. The National Institute for Occupational Safety and Health website asserts, "There is strong evidence of a positive association between exposure to a combination of risk factors (e.g., force and repetition, force and posture) and CTS."[32] There is disagreement among hand surgeons regarding whether occurrence of CTS in a patient who does repetitive activities at work represents a work-related injury.

Initial evaluation of the patient consists of symptom inventory: location and character of the symptoms, sleep disturbance due to symptoms, history of dropping objects, and difficulty manipulating small objects such as buttons, coins, or jewelry clasps.

Physical examination should begin with inspection. Look for evidence of wasting of the thenar muscles. Tinel's sign should be tested over the median nerve from the volar wrist flexion crease to the proximal palm, although this test has significant interexaminer variability.[33] Applying pressure over the carpal tunnel while flexing the wrist has been shown in one series to have the highest sensitivity when compared to Phalen's and Tinel's signs.[34] Strength of the thumb in opposition should also be tested.

Early treatment of CTS consists of conservative management. The patient is given a splint to keep the wrist at 20° extension worn at nighttime. Many patients can have years of symptom relief with this management. As a treatment and diagnostic modality, corticosteroid injection of the carpal tunnel is often employed. Mixing local anesthetic into the solution provides the benefit of early symptom relief (corticosteroids often take 3–7 days to provide noticeable benefit), and report of postinjection anesthesia in the median nerve distribution confirms the injection went into the correct location. Multiple authors have shown a strong correlation to relief of symptoms with corticosteroid injection and good response to carpal tunnel release.[35]

When lesser measures fail or are no longer effective, carpal tunnel release is indicated. Open carpal tunnel release is a time-tested procedure with documented long-term relief of symptoms. A direct incision is made over the carpal tunnel, typically in line with where the ring finger pad touches the proximal palm in flexion. Skin is divided followed by palmar fascia. The carpal tunnel contents are visualized as they exit the carpal tunnel. The transverse carpal ligament is divided with the median nerve visualized and protected at all times. Improvement in symptoms is typically noted by the first postoperative visit, although symptom relief may be incomplete for patients with long-standing disease or systemic nerve-affecting diseases such as diabetes.

Endoscopic techniques have been devised to address CTS. All involve avoidance of incising the skin directly over the carpal tunnel. In experienced hands, endoscopic carpal tunnel release provides the same relief of CTS with less intense and shorter lasting postoperative pain. After 3 months, however, the results are equivalent to open release.[36] In inexperienced hands, there may be a higher risk of injury to the median nerve with the endoscopic techniques; this procedure is not for the occasional carpal tunnel surgeon.

Cubital Tunnel Syndrome

The second most common location of upper extremity nerve compression is the ulnar nerve where it passes behind the elbow at the cubital tunnel. The cubital tunnel retinaculum passes between the medial epicondyle of the humerus and the olecranon process of the ulna. It stabilizes the ulnar nerve in this location during elbow motion. Over time, or sometimes after trauma, the ulnar nerve can become less stabilized in this area. Motion of the elbow then produces trauma to the nerve as it impacts the retinaculum and medial epicondyle.

Cubital tunnel syndrome may produce sensory and motor symptoms.[37] The small finger and ulnar half of the ring fingers may have numbness, paresthesias, and/or pain. The ulnar nerve also innervates the dorsal surface of the small finger and ulnar side of the ring finger, so numbness in these areas can be explained by cubital tunnel syndrome. The patient may also report weakness in grip due to effects on the FDP tendons to the ring and small fingers and the intrinsic hand muscles. Patients with advanced disease may complain of inability to fully extend the ring and small finger IP joints.

Physical examination for cubital tunnel syndrome begins with inspection. Look for wasting in the hypothenar eminence and the interdigital web spaces. When the hand rests flat on the table, the small finger may rest in abduction with respect to the other fingers; this is called Wartenberg's sign. Tinel's sign is often present at the cubital tunnel. Elbow flexion test will often be positive. Grip strength and finger abduction strength should be compared to the unaffected side. Froment's sign can be tested by placing a sheet of paper between the thumb and index finger and instructing the patient to hold on to the paper while the examiner pulls it away without flexing the finger or thumb (this tests the strength of the adductor pollicis and first dorsal interosseous muscles). If the patient must flex the index finger and/or thumb (FDP-index and FPL, both median nerve supplied) to maintain traction on the paper, this is a positive response.

Early treatment of cubital tunnel syndrome begins with avoiding maximal flexion of the elbow. Splints are often used for this purpose. Corticosteroid injection is rarely done for this condition; unlike in the carpal tunnel, there is very little space within the tunnel outside of the nerve. Injection in this area runs a risk of intraneural injection, which can cause permanent scarring of the nerve and dysfunction.

When conservative management fails, surgery has been contemplated. Treatment options include releasing the cubital tunnel retinaculum with or without transposing the nerve anterior to the elbow. While some authors advocate anterior transposition into the flexor-pronator muscle group with the goal of maximizing nerve recovery,[37] recent studies have demonstrated equivalent results between transposition and in situ release of the nerve even in advanced cases.[38] For this reason, the simpler in situ release, either open or endoscopic, is preferred by many surgeons.

Other Sites of Nerve Compression

All nerves crossing the forearm have areas described where compression can occur.[37] The median nerve can be compressed as it passes under the pronator teres. The ulnar nerve can be compressed as it passes through Guyon's canal. The radial nerve, or its posterior interosseous branch, can be compressed as it passes through the radial tunnel (distal to the elbow where the nerve divides and passes under the arch of the supinator muscle). The SRN can be compressed distally in the forearm as it emerges from under the brachioradialis tendon, called Wartenberg's syndrome. As mentioned previously, any nerve can become compressed in scar at the site of a previous trauma.

DEGENERATIVE JOINT DISEASE

As with other joints in the body, the joints of the hand and wrist can develop degenerative changes. Symptoms typically begin in the fifth decade of life. Symptoms consist of joint pain and stiffness and often are exacerbated with changes in the weather. Any of the joints can become involved. As the articular cartilage wears out, pain typically increases and range of motion

decreases. The patient should always be asked to what degree symptoms are impeding activities.

Physical findings are documented in serial fashion from the initial visit and subsequent visits. Pain with axial loading of the joint may be present. Decreased range of motion may be a late finding. Instability of the collateral ligaments of the joint is uncommon in the absence of inflammatory arthritis.

Plain X-rays are typically sufficient to demonstrate arthritis. Initially, the affected joint has a narrower radiolucent space between the bones. As joint degeneration progresses, the joint space further collapses. Bone spurs, loose bodies, and cystic changes in the bone adjacent to the joint all may become apparent. X-ray findings do not always correlate with patient symptoms. Patients with advanced x-ray findings may have minimal symptoms, and vice versa. Treatment is initiated and progressed based on the patient's symptoms regardless of imaging findings.

Initial management begins with rest of the painful joint. Splints are often useful, but may significantly impair the patient in activities and thus are frequently used at nighttime only. Oral nonsteroidal anti-inflammatory medications such as ibuprofen and naproxen are also useful. Patients on anticoagulants and antiplatelet medications may not be able to take these, and some patients simply do not tolerate the gastric irritation side effect even if they take the medication with food.

For patients with localized disease affecting only one or a few joints, corticosteroid injection may be contemplated. Needle insertion can be difficult since these joint spaces are quite narrow even before degenerative disease sets in. Also, many corticosteroid injections are suspensions, not solutions; injected corticosteroid will remain in the joint space and can be seen as a white paste if surgery is performed on a joint that has been previously injected.

Small Joints (Metacarpophalangeal and Interphalangeal)

When conservative measures fail, two principal surgical options exist: arthrodesis and arthroplasty. The surgeon and patient must decide together as to whether conservative measures have failed. Surgery for arthritis, whether arthrodesis or arthroplasty, is performed for the purpose of relieving pain. Arthrodesis, fusion of a joint, provides excellent relief of pain and is durable over time. However, it comes at the price of total loss of motion.

Silicone implant arthroplasty has been available for over 40 years.[39] Rather than a true replacement of the joint, the silicone implant acts as a spacer between the two bones adjacent to the joint. This allows for motion without bony contact that would produce pain. Long-term studies have shown that all implants fracture over time, but usually continue to preserve motion and pain relief.[40]

In the past 15 years, resurfacing implant arthroplasties have become available for the small joints of the hand. Multiple different materials have been used to fabricate such implants. These are designed to behave as a true joint resurfacing (as knee and hip arthroplasty implants are) and have shown promising outcomes in short- and intermediate-term studies.[40] Neither the silicone nor the resurfacing arthroplasties preserve (or restore) full motion of the MP or PIP joints.

Wrist

The CMC joint of the thumb, also called the basilar joint, is another common location of arthritis pain. Pain in this joint particularly disturbs function because the CMC joint is essential for opposition and cylindrical grasp. Patients will typically complain of pain with opening a tight jar or doorknob and strong pinch activities such as knitting. Conservative management is used first, as described earlier. Prefabricated, removable thumb spica splinting can provide excellent relief of symptoms for many patients.

Multiple surgical options exist for thumb CMC arthritis. Many resurfacing implants have been used in the past; often they have shown good short- and intermediate-term results and poor long-term results. Resection of the arthritic trapezium provides excellent relief of pain; however, most authors feel that stabilization of the thumb metacarpal base is necessary to prevent shortening and instability.[41] Recently, one author demonstrated excellent long-term results from resection of the trapezium without permanent stabilization of the metacarpal base.[42] For both of these operations, the thumb base may not be sufficiently stable to withstand heavy labor. For these patients, fusion of the thumb CMC in mild opposition provides excellent pain relief and durability. The patient must be warned preoperatively that he will not be able to lay his hand flat after the surgery. This loss of motion can be problematic when the patient attempts to tuck in clothing or reach into a narrow space.

Degenerative change of the radiocarpal and midcarpal joints is often a consequence of scapholunate ligament injury. Often the initial injury goes untreated, with the patient believing it is merely a "sprain"; the patient is first diagnosed with the initial injury when he presents years later with degenerative changes.

Degenerative wrist changes associated with the scapholunate ligament follow a predictable pattern over many years, called *scapholunate advanced collapse* or *SLAC wrist*.[43] Because of this slow progression (Fig. 44-17A), patients can usually be treated with a motion-sparing procedure. If there is truly no arthritic change present, the scapholunate ligament can be reconstructed.

If arthritis is limited to the radiocarpal joint, two motion-sparing options are available. The proximal carpal row (scaphoid, lunate, and triquetrum) can be removed (proximal row carpectomy [PRC]). The lunate facet of the radius then articulates with the base of the capitate, whose articular surface is similar in shape to that of the base of the lunate. Most series show maintenance of about 66% of wrist motion and 66% of hand strength or more, as compared to the opposite side.[44] Alternatively, the scaphoid can be excised, and four-bone fusion (lunate, capitate, hamate, and triquetrum) can be performed. This maintains the full length of the wrist and the lunate in the lunate facet of the radius. Some series have shown better strength but less mobility with this technique, others have shown equivalent results to the PRC.[45] The four-bone fusion does appear to be more durable for younger patients and/or those who perform heavy labor.

If the patient presents with pancarpal arthritis or motion-sparing measures have failed to alleviate pain, total wrist fusion is the final surgical option. The distal radius is fused, through the proximal and distal carpal rows to the third metacarpal, typically with a dorsal plate and screws. Multiple long-term studies have shown excellent pain relief and durability; this comes at the cost of total loss of wrist motion. This is surprisingly well tolerated in most patients, especially if the other hand/wrist is unaffected. The only activity of daily living that cannot be done with a fused wrist is personal toileting.

Figure 44-17. Arthritis of the hand and wrist. **A.** This patient injured her scapholunate ligament years prior to presentation. The scapholunate interval is widened (*double arrow*), and the radioscaphoid joint is degenerated (*solid oval*), but the radiolunate and lunocapitate joint spaces are well preserved (*dashed ovals*). **B.** This patient has had rheumatoid arthritis for decades. The classic volar subluxation of the metacarpophalangeal joints of the fingers (*dashed oval*) and radial deviation of the fingers are apparent.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an inflammatory arthritis that can affect any joint in the body. Inflamed synovium causes articular cartilage breakdown with pain and decreased range of motion. The goals of hand surgery for the RA patient are relief of pain, improvement of function, slowing progression of disease, and improvement in appearance.[46] In addition, swelling of the joint due to the inflammation can cause laxity and even failure of the collateral ligaments supporting the joints. Recent advances in the medical care of RA have made the need for surgical care of these patients far less common than in previous decades.

MP joints of the fingers are commonly affected. The base of the proximal phalanx progressively subluxates and eventually dislocates volarly with respect to the metacarpal head. The collateral ligaments, particularly on the radial side, stretch out and cause the ulnar deviation of the fingers characteristic of the rheumatoid hand. In more advanced cases, the joint may not be salvageable (Fig. 44-17B). For these patients, implant arthroplasty is the mainstay of surgical treatment. Silicone implants have been used for over 40 years with good results.[47] The silicone implant acts as a spacer between proximal and distal bone, rather than as a true resurfacing arthroplasty. The radial collateral ligament must be repaired to appropriate length to correct the preoperative ulnar deviation of the MP joint. Extensor tendon centralization is then performed, as needed, at the end of the procedure.

For MP joint and PIP joint disease, fusion is an option. However, since RA usually affects multiple joints, fusion is typically avoided due to impaired function of adjacent joints, which would leave a severe motion deficit to the finger.

Failure of the support ligaments of the distal radioulnar joint (DRUJ) leads to the *caput ulnae* posture of the wrist with the ulnar head prominent dorsally. As this dorsal prominence becomes more advanced, the ulna head, denuded of its cartilage to act as a buffer, erodes into the overlying extensor tendons. Extensor tenosynovitis, followed ultimately by tendon rupture, begins ulnarly and proceeds radially. Rupture of the ECU tendon may go unnoticed due to the intact ECRL and ECRB tendons to extend the wrist. EDQ rupture may go unnoticed if a sufficiently robust EDC tendon to the small finger exists. Once the fourth compartment (EDC) tendons begin to fail, the motion deficit is unable to be ignored by the patient.

Surgical solutions must address the tendon ruptures as well as the DRUJ synovitis and instability and ulna head breakdown that led to them.[46] Excision of the ulna head removes the bony prominence. The DRUJ synovitis must also be resected. Alternatively, the DRUJ can be fused and the ulna neck resected to create a pseudoarthrosis to allow for rotation. For both procedures, the remaining distal ulna must be stabilized. Multiple techniques have been described using portions of FCU, ECU, wrist capsule, and combinations thereof.

The ruptured extensor tendons are typically degenerated over a significant length. Primary repair is almost never possible, and the frequent occurrence of multiple tendon ruptures makes repair with graft less desirable due to the need for multiple graft donors.

Strict compliance with postoperative therapy is essential to maximizing the surgical result. Due to the chronic inflammation associated with RA, tendon and ligament repairs will be slower to achieve maximal tensile strength. Prolonged nighttime splinting, usually for months, helps prevent recurrence of extensor lag. Finally, the disease may progress over time. Reconstructions that were initially adequate may stretch out or fail over time. Medical management is the key to slowing disease progression and maximizing the durability of any surgical reconstruction.

DUPUYTREN'S CONTRACTURE

In 1614, a Swiss surgeon named Felix Plater first described contracture of multiple fingers due to palpable, cord-like structures on the volar surface of the hand and fingers. The disease state he described would ultimately come to be known as Dupuytren's

contracture. Dupuytren's name came to be associated with the disease after he performed an open fasciotomy of a contracted cord before a class of medical students in 1831.[48]

The palmar fascia consists of collagen bundles in the palm and fingers. These are primarily longitudinally oriented and reside as a layer between the overlying skin and the underlying tendons and neurovascular structures. There are also connections from this layer to the deep structures below and the skin above. Much is known about the progression of these structures from their normal state (called bands) to their contracted state (called cords), but little is known on how or why this process begins.

Increased collagen deposition leads to a palpable nodule in the palm. Over time, there is increased deposition distally into the fingers. This collagen becomes organized and linearly oriented. These collagen bundles, with the aid of myofibroblasts, contract down to form the cords, which are the hallmark of the symptomatic patient. Detail of the molecular and cell biology of Dupuytren's disease is beyond the scope of this chapter but is available in multiple hand surgery texts.[49]

Most nonoperative management techniques will not delay the progression of disease. Corticosteroid injections may soften nodules and decrease the discomfort associated with them but are ineffective against cords. Splinting has similarly been shown not to retard disease progression.

Disruption of the cord with a needle is an effective means of releasing contractures, particularly at the MP joint level. Long-term studies have demonstrated more rapid recovery from needle fasciotomy, as the procedure is called, but more durable results with fasciectomy.[50] Injectable clostridial collagenase was approved by the U.S. Food and Drug Administration in 2009 and shows good early results.[51]

For patients with advanced disease including contractures of the digits that limit function, surgery is the mainstay of therapy. Although rate of progression should weigh heavily in the decision of whether or not to perform surgery, general guidelines are MP contractures ≥30° and/or PIP contractures ≥20°.[52]

Surgery consists of an open approach through the skin down to the involved cords. Skin is elevated off of the underlying cords. Great care must be taken to preserve as much of the subdermal vascular plexus with the elevated skin flaps to minimize postoperative skin necrosis. All nerves, tendons, and blood vessels in the operative field should be identified. Once this is done, the involved cord is resected while keeping the critical deeper structures under direct vision. Skin is then closed, with local flap transpositions as needed, to allow for full extension of the fingers that have been released (Fig. 44-18).

Alternative cord resection techniques include removal of the skin over the contracture (dermatofasciectomy). This requires a skin graft to the wound and should only be done if skin cannot be separated from the cords and local tissue cannot be rearranged with local flaps to provide closure of the wound.

Complications of surgical treatment of Dupuytren's disease occur in as many as 24% of cases.[53] Problems include digital nerve laceration, digital artery laceration, buttonholing of the skin, hematoma, swelling, and pain, including some patients with CRPS (see earlier section on CRPS). Digital nerve injury can be quite devastating, producing annoying numbness at best or a painful neuroma in worse situations.

Hand therapy is typically instituted within a week of surgery to begin mobilization of the fingers and edema control. The therapist can also identify any early wound problems because he or she will see the patient more frequently than the surgeon. Extension hand splinting is maintained for 4 to 6 weeks, with nighttime splinting continued for an additional 6 to 8 weeks. After this point, the patient is serially followed for evidence of recurrence or extension of disease.

INFECTIONS

Trauma is the most common cause of hand infections. Other predisposing factors include diabetes, neuropathies, and immunocompromised patients. Proper treatment consists of incision and drainage of any collections followed by débridement, obtaining wound cultures, antibiotic therapy, elevation, and immobilization. *Staphylococcus* and *Streptococcus* are the offending pathogens in about 90% of hand infections. Infections caused by intravenous drug use or human bites and those associated with diabetes will often be polymicrobial, including gram-positive and gram-negative species. Heavily contaminated injuries require anaerobic coverage. Although α-hemolytic *Streptococcus* and *Staphylococcus aureus* are the most commonly encountered pathogens in human bites, *Eikenella corrodens* is isolated in up to one-third of cases and should be considered when choosing antimicrobial therapy. Ziehl-Neelsen staining and cultures at 28°C to 32°C in Lowenstein-Jensen medium must be performed if there is a suspicion for atypical mycobacteria.[54]

Cellulitis

Cellulitis is characterized by a nonpurulent diffuse spreading of inflammation characterized by erythema, warmth, pain, swelling, and induration. Skin breakdown is a frequent cause, but often no inciting factor is identified. Group A β-hemolytic *Streptococcus* is the most common offending pathogen and causes a more diffuse spread of infection. *S. aureus* is the second most common offending pathogen and will cause a more localized cellulitis. The diagnosis of cellulitis is clinical. Septic arthritis, osteomyelitis, an abscess, a deep-space infection, and necrotizing fasciitis are severe infectious processes that may initially mimic cellulitis. These must be ruled out appropriately before initiating treatment, and serial exams should be conducted to ensure proper diagnosis. Treatment of cellulitis consists of elevation, splint immobilization, and antibiotics that cover both *Streptococcus* and *Staphylococcus.* Intravenous antibiotics are usually initiated for patients with severe comorbidities and those who fail to improve on oral antibiotics after 24 to 48 hours. Failure to improve after 24 hours indicates a need to search for an underlying abscess or other infectious cause.[54]

5▶

Abscess

An abscess will present much like cellulitis, but they are two clinically separate entities. The defining difference is an area of fluctuance. Skin-puncturing trauma is the most common cause. *S. aureus* is the most common pathogen, followed by *Streptococcus*. Treatment consists of incision and drainage with appropriate débridement, wound cultures, wound packing, elevation, immobilization, and antibiotics. The packing should be removed in 12 to 24 hours or sooner if there is clinical concern, and warm soapy water soaks with fresh packing should be initiated. Most should be allowed to heal secondarily. Delayed primary closure should only be performed after repeat washouts for larger wounds where complete infection has been achieved.

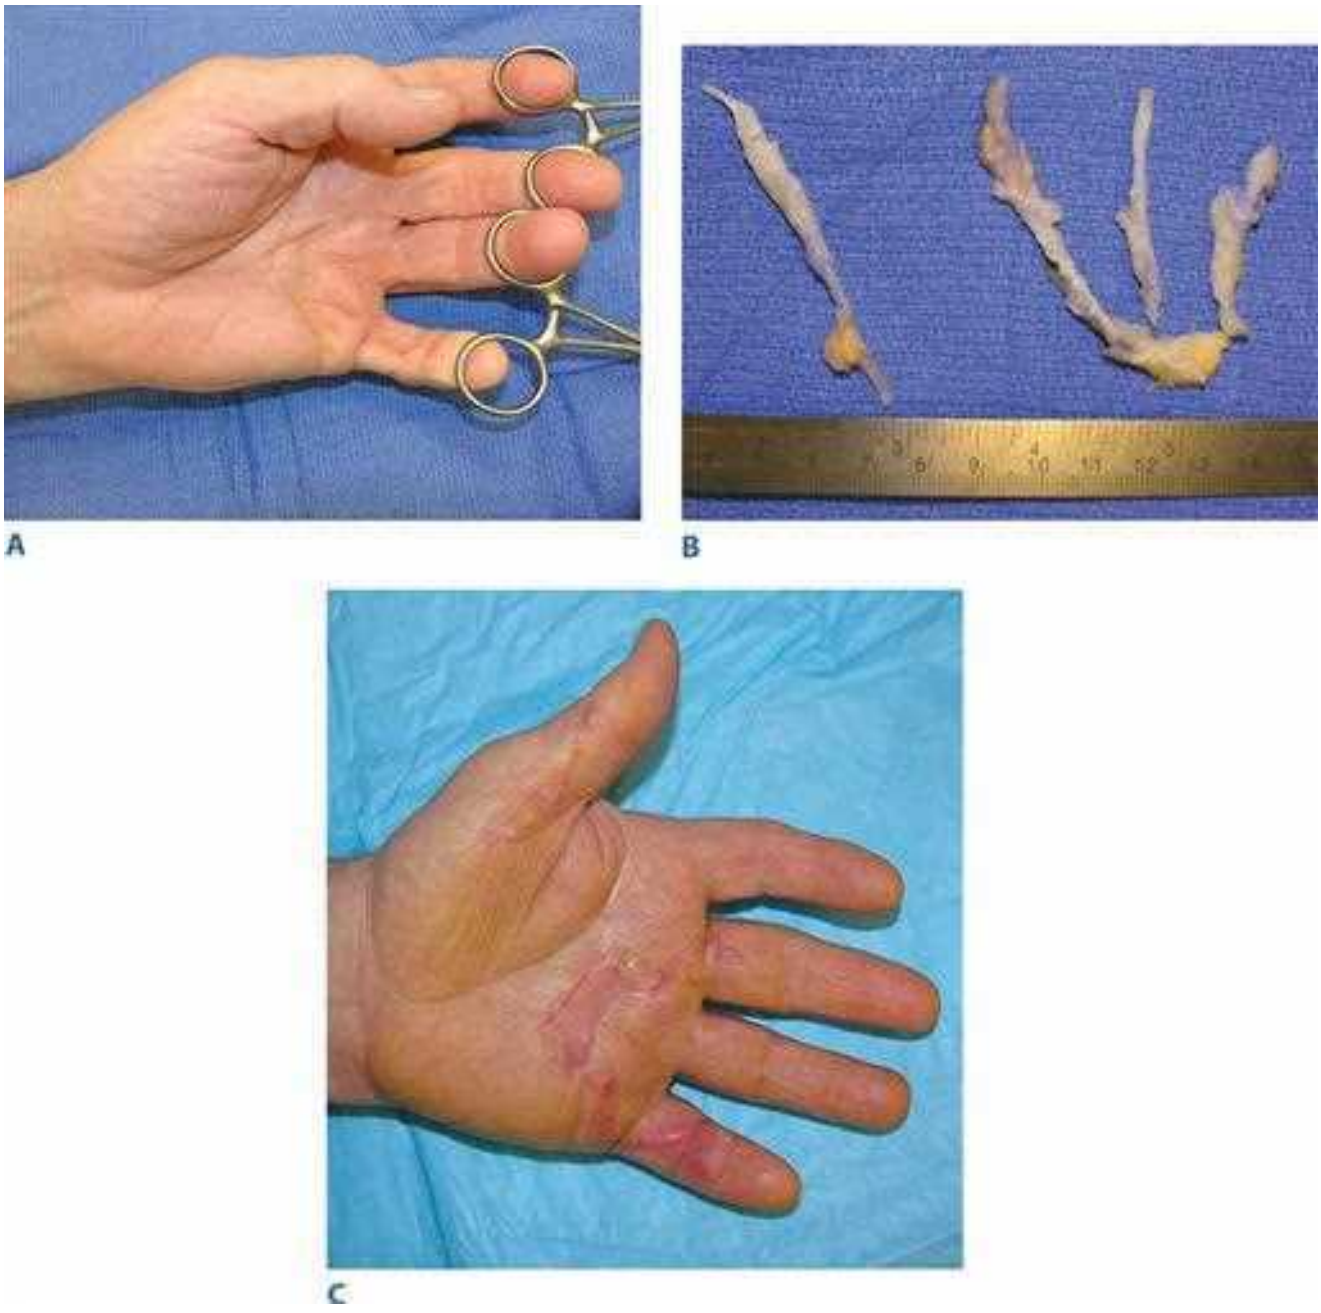

Figure 44-18. Dupuytren's disease. **A.** This patient has cords affecting the thumb, middle, ring, and small fingers. **B.** The resected specimens are shown. **C.** Postoperatively, the patient went on to heal all his incisions and, with the aid of weeks of hand therapy, recover full motion.

Collar-Button Abscess

This is a subfascial infection of a web space and is usually caused by skin trauma that becomes infected; it often occurs in laborers. The adherence of the palmar web space skin to the palmar fascia prevents lateral spread, so the infection courses dorsally, resulting in both palmar web space tenderness and dorsal web space swelling and tenderness. The adjacent fingers will be held in abduction with pain on adduction (Fig. 44-19). Incision and drainage, often using separate volar and dorsal incisions, is mandatory, and follows the same treatment as for any abscess or deep-space infection.

Osteomyelitis

Osteomyelitis in the hand usually occurs due to an open fracture with significant soft tissue injury. The presence of infected hardware, peripheral vascular disease, diabetes, and alcohol or drug abuse are also predisposing factors. Presentation includes persistent or recurrent swelling with pain, erythema, and possible drainage. It will take 2 to 3 weeks for periosteal reaction and osteopenia to be detected on radiographs. Bone scans and MRI are useful modalities to aid in diagnosis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) have low specificity but are useful for monitoring the progress of treatment, with CRP being more reliable. Treatment consists of antibiotics alone in the early stage as long as there is favorable response. All necrotic bone and soft tissue, if present, must be débrided. Initial intravenous antibiotic therapy should cover *S. aureus*, the most common pathogen, and should then be adjusted according to bone cultures. Antibiotic therapy is continued for 4 to 6 weeks once the patient clinically improves and there is no further need for débridement. For osteomyelitis in the setting of an acute fracture with internal fixation in place, the hardware should

A

B

Figure 44-19. **A.** The fingers surrounding the involved (second) web space rest in greater abduction than the other fingers. **B.** Dorsal and volar drainage incisions are made, separated by a bridge of intact web skin; a Penrose drain prevents the skin from closing too early.

be left in place as long as it is stable and the fracture has not yet healed. If the hardware is unstable, it must be replaced. An external fixation device may be useful in this setting. If osteomyelitis occurs in a healed fracture, all hardware and necrotic bone and soft tissue must be removed.[55]

Pyogenic Arthritis

Infection of a joint will progress quickly to severe cartilage and bony destruction if not addressed quickly. Direct trauma and local spread of an infection are the most common causes. Hematogenous spread occurs most commonly in patients who are immunocompromised. *S. aureus* is the most common pathogen, followed by *Streptococcus* species. *Neisseria gonorrhoeae* is the most common cause of atraumatic septic arthritis in an adult less than 30 years of age. Presentation includes exacerbation of pain with any joint movement, severe pain on axial load, swelling, erythema, and tenderness. Radiographs may show a foreign body or fracture, with widened joint space early in the process and decreased joint space late in the process due to destruction. Joint aspiration with cell count, Gram stain, and culture is used to secure the diagnosis. Treatment of nongonococcal septic arthritis includes open arthrotomy, irrigation, débridement, and packing the joint or leaving a drain in place. Intravenous antibiotics are continued until there is clinical improvement, followed by 2 to 4 weeks of additional oral or intravenous antibiotics. Gonococcal septic arthritis is usually treated nonoperatively. Intravenous ceftriaxone is first-line therapy. Joint aspiration may be used to obtain cultures and decrease joint pressure.[56]

Necrotizing Infections

Necrotizing soft tissue infections occur when the immune system is unable to contain an infection, leading to extensive spread with death of all involved tissues. This is different from an abscess, which forms when a functioning immune system is able to "wall off" the infectious focus. Necrotizing infections can result in loss of limb or life, even with prompt medical care.

Bacteria spread along the fascial layer, resulting in the death of soft tissues, which is in part due to the extensive blood vessel thrombosis that occurs. An inciting event is not always identified. Immunocompromised patients and those who abuse drugs or alcohol are at greater risk, with intravenous drug users having the highest increased risk. The infection can by mono- or polymicrobial, with group A β-hemolytic *Streptococcus* being the most common pathogen, followed by α-hemolytic *Streptococcus, S. aureus,* and anaerobes. Prompt clinical diagnosis and treatment are the most important factors for salvaging limbs and saving life. Patients will present with pain out of proportion with findings. Appearance of skin may range from normal to erythematous or maroon with edema, induration, and blistering. Crepitus may occur if a gas-forming organism is involved. "Dirty dishwater fluid" may be encountered as a scant grayish fluid, but often there is little to no discharge. There may be no appreciable leukocytosis. The infection can progress rapidly and can lead to septic shock and disseminated intravascular coagulation. Radiographs may reveal gas formation, but they must not delay emergent débridement once the diagnosis is suspected. Intravenous antibiotics should be started immediately to cover gram-positive, gram-negative, and anaerobic bacteria. Patients will require multiple débridements, and the spread of infection is normally wider than expected based on initial assessment.[54]

Necrotizing myositis, or myonecrosis, is usually caused by *Clostridium perfringens* due to heavily contaminated wounds. Unlike necrotizing fasciitis, muscle is universally involved and found to be necrotic. Treatment includes emergent débridement of all necrotic tissue along with empirical intravenous antibiotics.

Wet gangrene is most common in diabetics with renal failure and an arteriovenous shunt. It is usually polymicrobial. Patients will present with a necrotic digit that is purulent and very malodorous, with rapidly evolving pain, swelling, skin discoloration, and systemic collapse. Emergent treatment is the same as for other necrotizing infections, and amputation of the involved digit or extremity must often be performed.

Infectious Flexor Tenosynovitis

Flexor tenosynovitis (FTS) is a severe pathophysiologic state causing disruption of normal flexor tendon function in the hand. A variety of etiologies are responsible for this process. Most acute cases of FTS are due to purulent infection. FTS also can

occur secondary to chronic inflammation as a result of diabetes, RA, crystalline deposition, overuse syndromes, amyloidosis, psoriatic arthritis, systemic lupus erythematosus, and sarcoidosis.

The primary mechanism of infectious FTS usually is penetrating trauma. Most infections are caused by skin flora, including both *Staphylococcus* and *Streptococcus* species. Bacteria involved vary by etiology of the infection: bite wounds (*Pasteurella multocida*—cat, *E. corrodens*—human); diabetic patients (*Bacteroides*, *Fusobacterium*, *Haemophilus* species, gram-negative organisms); hematogenous spread (*Mycobacterium tuberculosis*, *N. gonorrhoeae*); or water-related punctures (*Vibrio vulnificus*, *Mycobacterium marinum*). Infection in any of the fingers may spread proximally into the wrist, carpal tunnel, and forearm, also known as Parona's space.[57]

Suppurative FTS has the ability to rapidly destroy a finger's functional capacity and is considered a surgical emergency. Suppurative FTS results from bacteria multiplying in the closed space of the flexor tendon sheath and culture-rich synovial fluid medium causing migration of inflammatory cells and subsequent swelling. The inflammatory reaction within the closed tendon sheath quickly erodes the paratenon, leading to adhesions and scarring, as well as increase in pressures within the tendon sheath that may lead to ischemia. The ultimate consequences are tendon necrosis, disruption of the tendon sheath, and digital contracture.

Patients with infectious FTS present with pain, redness, and fever (Fig. 44-20). Physical examination reveals Kanavel's "cardinal" signs of flexor tendon sheath infection: finger held in slight flexion, fusiform swelling, tenderness along the flexor tendon sheath, and pain over the flexor sheath with passive extension of the digit.[58] Kanavel's signs may be absent in patients who are immunocompromised, have early manifestations of infection, have recently received antibiotics, or have a chronic, indolent infection.

If a patient presents with suspected infectious FTS, empiric intravenous antibiotics should be initiated. Prompt medical therapy in early cases may prevent the need for surgical drainage. For healthy individuals, empiric antibiotic therapy should cover *Staphylococcus* and *Streptococcus*. For immunocompromised patients (including diabetics) or infections associated with bite wounds, empiric treatment should include coverage of gram-negative organisms as well.

Adjuncts to antibiotics include splint immobilization (intrinsic plus position preferred) and elevation until infection is under control. Hand rehabilitation (i.e., range-of-motion exercises and edema control) should be initiated once pain and inflammation are under control.

If medical treatment alone is attempted, then initial inpatient observation is indicated. Surgical intervention is necessary if no obvious improvement has occurred within 12 to 24 hours.

Several surgical approaches can be used to drain infectious FTS. The method used is based on the extent of the infection. Michon developed a classification scheme that can be useful in guiding surgical treatment (Table 44-1).[59] Figure 44-20B & C demonstrates drainage of a stage II FTS. A Brunner incision allows better initial exposure but may yield difficulties with tendon coverage if skin necrosis occurs. A 16-gauge catheter or 5-French pediatric feeding tube then is inserted into the tendon sheath through the proximal incision. The sheath is copiously irrigated with normal saline. Avoid excessive fluid extravasation into the soft tissue, because the resulting increase in tissue pressure can lead to necrosis of the digit. The catheter is removed after irrigation. The incisions

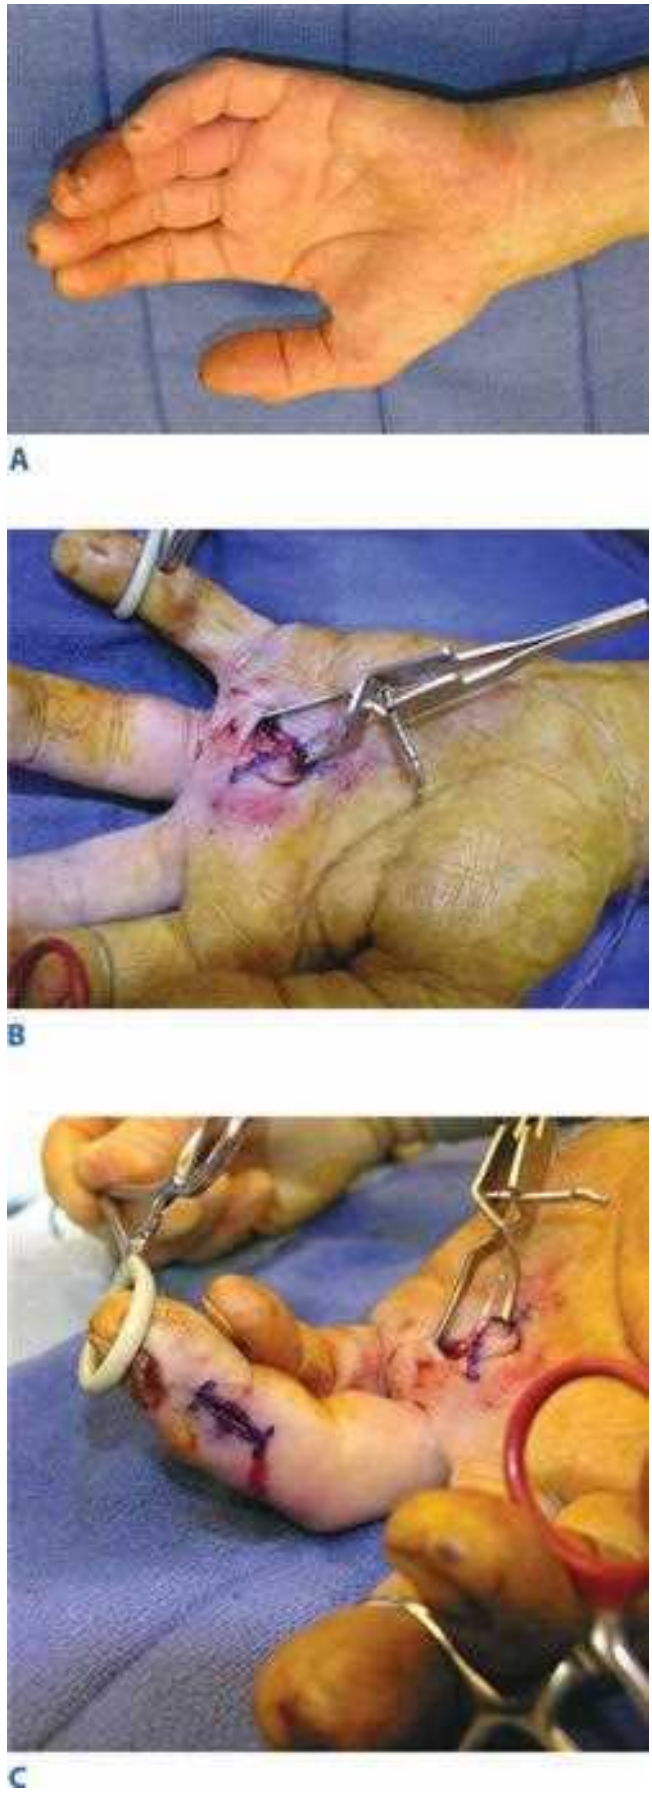

Figure 44-20. Suppurative flexor tenosynovitis of the ring finger. **A.** The finger demonstrates fusiform swelling and flexed posture. **B.** Proximal exposure for drainage. **C.** Distal drainage incision.

Table 44-1

Michon's stages of suppurative flexor tenosynovitis and appropriate treatment

STAGE	FINDINGS	TREATMENT
I	Increased fluid in sheath, mainly a serous exudate	Catheter irrigation
II	Purulent fluid, granulomatous synovium	Minimal invasive drainage ± indwelling catheter irrigation
III	Necrosis of the tendon, pulleys, or tendon sheath	Extensive open débridement and possible amputation

are left open. Some surgeons prefer a continuous irrigation technique for a period of 24 to 48 hours. The catheter is sewn in place, and a small drain is placed at the distal incision site. Continuous or intermittent irrigation every 2 to 4 hours with sterile saline can then be performed through the indwelling catheter.

After surgery, an intrinsic plus splint is applied, the hand is elevated, and the appropriate empiric antibiotic coverage is instituted while awaiting culture results. The hand is reexamined the following day. Whirlpool therapy and range of motion are begun. Drains are removed before discharge from the hospital. The wounds are left open to heal by secondary intention. In severe cases, repeat irrigation and operative débridement may be required.

Antibiotic therapy is guided by culture results as well as clinical improvement. Once there is no further need for debridement, a 7- to 14-day course of oral antibiotics is generally prescribed. Consultation with an infectious disease specialist should be considered early in order to maximize efficiency and efficacy of therapy.

Felon

A felon is a subcutaneous abscess of the fingertip and is most commonly caused by penetrating trauma. *S. aureus* is the most common pathogen. The fingertip contains multiple septa connecting the distal phalanx to the skin. These septa are poorly compliant, and presence of an abscess will increase pressure and lead to severe pain and tissue death. Patients will experience erythema, swelling, and tenderness of the volar digital pad. Oral antibiotics may resolve the infection if diagnosed very early, but incision and drainage is indicated when fluctuance is identified. A digital block should be performed, followed by a longitudinal incision over the point of maximal fluctuance (Fig. 44-21). Transverse and lateral incisions should be avoided, and the incision should never extend across the distal phalangeal joint crease. Deep incision should not be performed as this may cause seeding of bacteria into the flexor tendon sheath. The wound is irrigated and packed, with warm soapy water soaks and packing changes initiated within 24 hours and performed two to three times daily until secondarily healed. Antibiotic coverage should cover for *Staphylococcus* and *Streptococcus* species.[60]

Paronychia

Paronychia is an infection beneath the nail fold. The nail plate can be viewed as an invagination into the dorsal skin extending down to the distal phalanx periosteum. Predisposing factors include anything that causes nail trauma, such as manicures,

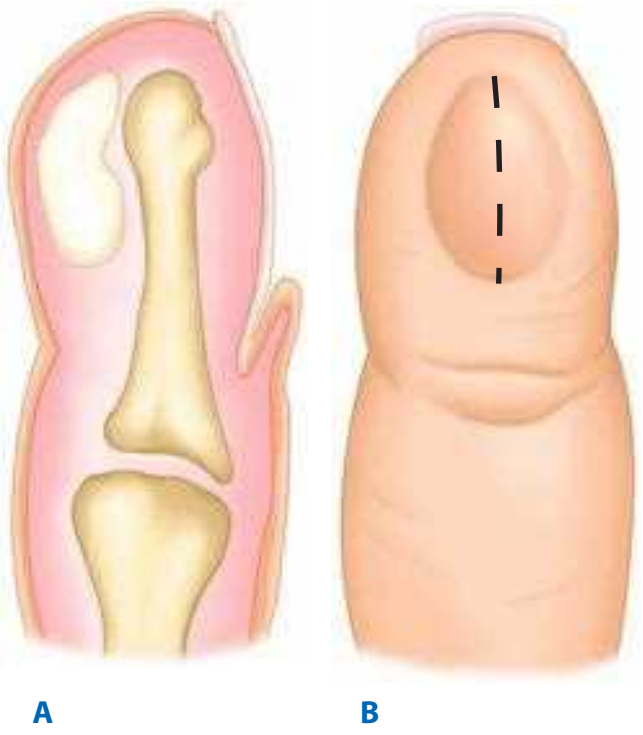

Figure 44-21. Felon. **A.** Lateral view of the digit showing fluctuance between the skin of the pad and the underlying distal phalanx bone. *B.* The authors prefer to drain felons with a longitudinal incision (*dashed line*) directly over the area of maximal fluctuance.

artificial nails, or nail biting. The infection may spread around the nail plate from one side to the other, or it may extend into the pulp and result in a felon. An acute paronychia is usually caused by *S. aureus* or *Streptococcal* species. Patients report pain, erythema, swelling, and possibly purulent drainage involving the periungual tissue. Treatment consists of warm water soaks and oral antibiotics if diagnosed early. If purulence or fluctuance is present, then a freer elevator or 18-gauge needle can be passed along the involved nail fold to decompress the collection (Fig. 44-22). If the infection involves the eponychial

Figure 44-22. Paronychia. **A.** Fluctuance in the nail fold is the hallmark of this infection. **B.** The authors prefer to drain a paronychia using the bevel of an 18-gauge needle inserted between the nail fold and the nail plate at the location of maximal fluctuance.

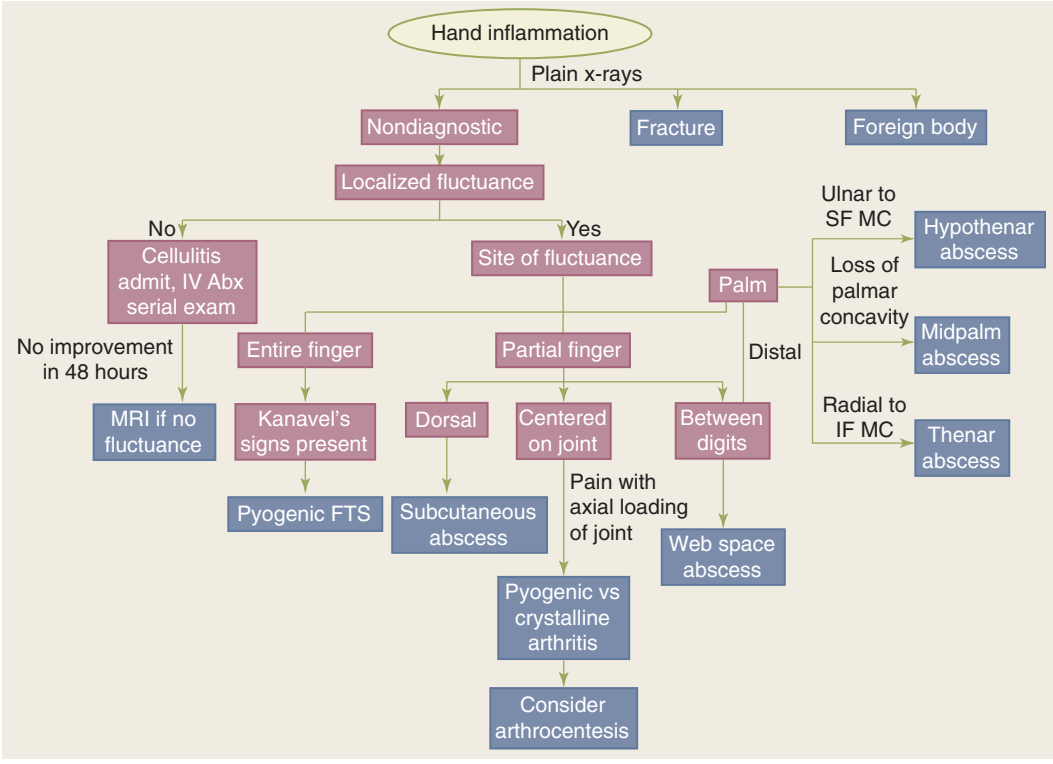

Figure 44-23. Diagnostic algorithm. Diagnostic workup for a patient with hand inflammation to evaluate for infection. See text for details about particular infectious diagnoses. Abx = antibiotics; FTS = flexor tenosynovitis; IF MC = index finger metacarpal; MRI = magnetic resonance imaging; SF MC = small finger metacarpal.

fold, a small proximally based flap of eponychium is created by using a scalpel, followed by irrigation and packing. The nail plate must be removed if the infection extends beneath the nail plate. Packing is kept in place for 24 to 48 hours, followed by warm water soaks and local wound care. Usually, the wound cannot be repacked once the dressing is removed.[60]

A chronic paronychia is most commonly caused by *Candida* species and is most often found in patients who perform jobs involving the submersion of their hands in water or other moist environments. These develop into thickened nails with callus-like formation along the nail folds and may occasionally become red and inflamed. They do not respond to antibiotic treatment, and nail plate removal with marsupialization of the skin proximal to the eponychial fold will allow the wound to heal secondarily. The environmental factors leading to the chronic paronychia must also be corrected in order for treatment to be successful.

All hand infections other than cellulitis will require surgical management. Clinical examination, particularly noting the area of greatest tenderness and/or inflammation, is the single most useful diagnostic tool to localize any purulence requiring drainage. Specific recommendations for differentiating among the possible locations of hand infection are included in the diagnostic algorithm shown in Fig. 44-23.

TUMORS

Tumors of the hand and upper extremity can be classified as benign soft tissue tumors; malignant soft tissue tumors (subclassified into cutaneous and noncutaneous malignancies); benign bony tumors; malignant bony tumors; and secondary metastatic tumors. Initial investigation for any mass starts with a complete history and physical exam. Hand and/or wrist X-rays should be obtained in every patient presenting with a mass unless clearly not indicated (e.g., a superficial skin lesion with no aggressive/malignant features). The workup proceeds in an orderly fashion until a diagnosis is obtained. Once a benign diagnosis is secured (by strong clinical suspicion in an experienced hand surgeon, radiographic evidence, or tissue biopsy), further workup is not needed; this may occur at any point in the workup of a mass.

Most hand masses are benign and can be readily diagnosed without advanced imaging or tissue biopsy. When necessary, additional workup may include baseline laboratory studies, CT and/or MRI of the involved region, and a bone scan or positron emission tomography (PET) scan. Staging of a malignant tumor may occur before biopsy if a malignancy is strongly suspected, or it may occur after formal biopsy. Staging includes a chest X-ray and CT with intravenous contrast of the chest, abdomen, and pelvis to detect possible metastasis. Biopsy of the mass is always the last step of a workup and should occur only after all other available information has been gathered. Any mass that is over 5 cm in size, is rapidly increasing in size (as judged by an experienced surgeon or oncologist), is symptomatic or painful, or has an aggressive clinical or radiographic appearance warrants workup and biopsy to rule out malignancy.

CT scans are useful for detecting bony tumor extension across planes and identifying tumors of small bones, such as the carpal bones. MRI is useful for evaluating soft tissue tumor involvement (e.g., which muscle compartments are involved) as well as intramedullary lesions. Most soft tissue tumors will appear dark on T1-weighted images and bright on T2-weighted images. Hematomas, hemangiomas, lipomas, liposarcomas,

and adipose tissue will appear bright on T1-weighted images and dark on T2-weighted images. Scintigraphy uses methylene diphosphonate attached to technetium-99m. This complex will attach to hydroxyapatite. Immediate uptake is seen in areas of increased vascularity, such as infection, trauma, and neoplasia. Increased uptake 2 to 3 hours later is seen in "pooled" areas where new bone formation has occurred. This modality is useful for detecting areas of tumor invasion or metastases not otherwise seen on prior CT, MRI, or radiographs.

Biopsy is reserved for masses that cannot be diagnosed as benign based on prior clinical and radiographic exams. Needle biopsy is not reliable for primary diagnosis, but it can be useful for recurrent or metastatic disease. Open excisional (if mass is <5 cm in size) or incisional (if mass is >5 cm in size) biopsy is the most common biopsy method. Proper surgical oncologic technique is strictly adhered to in order to prevent tumor spread into uninvolved tissues or compartments. This includes making all incisions longitudinally using sharp dissection and meticulous hemostasis; carrying the incision directly down to the tumor with no development of tissue planes (i.e., making a straight-line path from skin to tumor); incising through the fewest number of muscle compartments; and avoiding critical neurovascular structures. The CT or MRI images will help determine the best surgical approach for biopsy or resection in order to avoid uninvolved compartments and critical structures.[61]

Benign Soft Tissue Tumors

Ganglion Cyst. This is the most common soft tissue tumor of the hand and wrist, comprising 50% to 70% of all soft tissue tumors in this region. They can occur at any age but are most common in the second to fourth decades with a slight predilection toward females. Patients may report a slow-growing soft mass that may fluctuate in size and can sometimes be associated with mild pain. Compressive neuropathies may be seen if they occur in Guyon's canal or the carpal tunnel, but are uncommon. There are no reports of malignant degeneration.[62] History and physical exam are usually sufficient to establish a diagnosis. Occurrence by location is as follows: 60% to 70% occur on the dorsal wrist between the third and fourth extensor compartments and are connected by a stalk to the scapholunate ligament (Fig. 44-24); 18% to 20% occur on the volar wrist; and 10% to 12% occur in the digits as volar retinacular or flexor tendon sheath cysts. The cyst transilluminates. There is always a stalk that communicates with the underlying joint or tendon sheath. The cyst wall is composed of compressed collagen fibers with no epithelial or synovial cells present. Clear viscous mucin fills the cyst and is composed of glucosamine, albumin, globulin, and hyaluronic acid. The etiology is unclear. The most accepted theory currently is Angelides' who proposed that repeated stress of a joint, ligament, or tendon sheath causes an increase of mucin-producing cells and subsequent mucin production. The increased mucin production dissects superficially and coalesces into a cyst. The successful treatment of dorsal ganglion cysts by excising only the stalk supports this theory.[63]

Treatment consists of observation if asymptomatic. If symptoms exist or the patient desires removal for cosmetic appearance, aspiration of the cyst may be performed with a successful cure rate ranging from 15% to 89%. The benefit of injected steroids is inconclusive. Aspiration of a volar wrist ganglion cyst can be dangerous due to the potential of injuring neurovascular structures. Open excision and arthroscopic excision of the cyst stalk are surgical options for cysts that are not amendable to aspiration. Recurrence rate after surgical excision ranges from 4% to 40%.[62]

Figure 44-24. Dorsal wrist ganglion cyst. These typically occur between the third and fourth dorsal extensor compartments and have a stalk connecting the base of the cyst to the scapholunate ligament.

Mucous Cyst. A mucous cyst is a ganglion cyst of the DIP joint. They occur most commonly in the fifth to seventh decades, and the underlying cause is associated osteoarthritis of the DIP joint. They are slow growing and usually occur on one side of the terminal extensor tendon between the DIP joint and the eponychium. The earliest clinical sign is often longitudinal grooving of the involved nail plate followed by a small enlarging mass and then attenuation of overlying skin. X-rays will show signs of osteoarthritis within the DIP joint. Heberden nodes (osteophytes within the DIP joint) are often seen on X-ray.

Possible treatment includes observation, aspiration, or excision. If the cyst is not draining and the overlying skin is intact, the patient may be offered reassurance. A draining cyst poses risk of DIP joint infection due to the tract communicating with the DIP joint and should be excised. If the cyst is symptomatic, painful, or the patient desires removal for cosmetic purposes, excision should be performed. Any osteophytes in the DIP joint must be removed to reduce recurrence. Aspiration is an option for treatment, but this poses the risk of DIP joint infection through seeding of bacteria into the joint or by the development of a draining sinus tract. It is generally not performed.

Giant Cell Tumor of the Tendon Sheath. Also known as a fibrohistocytoma, fibrous xanthoma, localized nodular

synovitis, or pigmented villonodular synovitis, this is the second most common soft tissue mass of the hand and wrist. It is a benign lesion with no clear pathogenesis. The tumor is a growth of polyclonal cells with no risk of metastases. Despite the similarity in name, it is not histopathologically related to giant cell tumor of the bone.[64]

Giant cell tumor of the tendon sheath occurs as a firm slow-growing painless mass over months to years and will often feel bumpy or nodular, which is a distinguishing characteristic helpful for diagnosis. It has a predilection for occurring in close proximity to joints along flexor surfaces of the wrist, hands, and digits (especially the PIP joints of the radial digits) and occurs most commonly between the second and fifth decades (Fig. 44-25A). These tumors do not transilluminate. Direct extension into joints and ligaments can make complete excision difficult. Gross appearance of the tumor will show a well-circumscribed nodular firm mass with a deep brown color due to the large amount of hemosiderin content, which is easily detected on histologic staining (Fig. 44-25B). Multinucleated giant cells and hemosiderin-laden macrophages are characteristic.[64]

This tumor is not visible on radiographs. Approximately 20% will show extrinsic cortical erosion on X-ray. This is a risk factor for recurrence, and removal of the cortical shell should be considered. MRI is useful for delineating involvement with tendons, ligaments, and joints.

The standard treatment is marginal excision. These tumors will often grow next to or around neurovascular bundles, and an Allen's test should always be performed preoperatively to confirm adequate blood supply by both ulnar and radial arteries as well as dual blood supply to an involved digit via the ulnar and radial proper digital arteries. It is important to completely excise the stalk because this will greatly reduce tumor recurrence even in the setting of residual tumor. If tumor is suspected to have extended into the joint, the joint must be opened and all tumor removed. Despite this being a benign lesion, local recurrence is approximately 30% (range, 5%–50%). Some variants can mimic more aggressive processes, and malignancy must be considered if aggressive features are identified, such as direct bony invasion.[64]

A

B

Figure 44-25. Giant cell tumor of tendon sheath. **A.** The mass produces lobulated enlargement of the external finger. **B.** The excised giant cell tumor has a multilobulated, tan-brown appearance.

Lipoma. Lipomas of the hand and wrist may occur in multiple anatomic locations, including subcutaneous tissues; intramuscularly (especially thenar or hypothenar muscles); deep spaces; carpal tunnel or Guyon's canal; and rarely bone or nerve. They typically present as a painless, slow-growing, soft, and mobile mass over a period of months to years. Painful findings suggest close approximation to a neurovascular structure or, less commonly, a malignant lesion such as liposarcoma. Lipomas do not transilluminate. They resemble mature fat histologically. X-rays typically reveal no abnormality. MRI is the most helpful imaging modality to evaluate a lipoma and will show a bright T1 lesion and dark T2 lesion.[65]

Asymptomatic lesions with no aggressive findings may be observed. Marginal excision is recommended for symptomatic, painful, or enlarging lipomas or those that cause dysfunction. MRI is recommended for deep lipomas to evaluate proximity or involvement of critical structures, followed by marginal excision if MRI findings are consistent with a lipoma. If MRI findings are not consistent with a lipoma, incisional biopsy is warranted. Recurrence after marginal excision is rare. Malignant degeneration to liposarcoma is exceedingly rare but has been reported.

Schwannoma. A schwannoma, also known as a neurilemmoma, is a type of benign peripheral nerve sheath tumor. It is the most common benign peripheral nerve sheath tumor of the upper extremity.[66] The majority occur as single solitary masses. Patients with neurofibromatosis type 1 (NF1) or 2 (NF2) may develop multiple schwannomas involving large peripheral nerve trunks or bilateral acoustic schwannomas, respectively. These tumors arise from the Schwann cell and occur most often in the middle decades of life. They grow as painless, slow-growing, firm, round, well-encapsulated masses with a predilection toward flexor surfaces of the forearm and palm (given their presence of large nerves). Schwannomas grow from the peripheral nerve sheath and are usually connected by a pedicled stalk. The tumor is well demarcated and can be readily separated from the nerve fascicles (Fig. 44-26). Unlike neurofibromas, they do not grow within the nerve. Paresthesias or other neurologic findings may occur, but they are usually absent, as is the Tinel's sign. Findings such as pain, paresthesias, or numbness should raise concern for a tumor causing a compressive neuropathy or a tumor that is malignant.[66]

Histologic exam reveals Antoni type A palisades of spindle cells with large oval nuclei with interlacing fascicles. Less cellular regions appear as Antoni type B areas. Mutations of the schwanomin gene on chromosome 22 are found in 50% of sporadic cases and 100% of acoustic schwannomas in patients with NF2.[67]

Surgical treatment is reserved for symptomatic tumors and those that require biopsy to rule out a malignant process. An MRI should be obtained prior to surgery to confirm that the

Figure 44-26. Schwannomas grow as a firm, round, well-encapsulated mass within the epineurium of a peripheral nerve. Schwannomas are able to be separated from the nerve fascicles relatively easily because they do not infiltrate between them (unlike neurofibromas).

tumor is not located within the nerve (i.e., a neurofibroma) and that it is consistent with a schwannoma. Operative treatment involves excisional biopsy. If the tumor is adherent to adjacent soft tissue or not encapsulated, incisional biopsy is performed and excision is delayed pending pathology results. Malignant degeneration is exceedingly rare.[66]

Malignant Soft Tissue Tumors—Cutaneous

Squamous Cell Carcinoma. Squamous cell carcinoma (SCC) is the most common primary malignant tumor of the hand, accounting for 75% to 90% of all malignancies of the hand. Eleven percent of all cutaneous SCC occurs in the hand.[68] It is the most common malignancy of the nail bed. Risk factors include sun exposure, radiation exposure, chronic ulcers, immunosuppression, xeroderma pigmentosa, and actinic keratosis. Marjolin's ulcers represent malignant degeneration of old burn or traumatic wounds into an SCC and are a more aggressive type. Transplant patients on immunosuppression have a four-fold increased risk and patients with xeroderma pigmentosa have a 1000-fold increased risk of developing an SCC. They often develop as small, firm nodules or plaques with indistinct margins and surface irregularities ranging from smooth to verruciform or ulcerated (Fig. 44-27). They are locally invasive, with 2% to 5% lymph node involvement. Metastasis rates of up to 20% have been reported in radiation or burn wounds. Standard treatment is excision with 0.5- to 1.0-cm margins. Other treatment options include curettage and electrodessication, cryotherapy, and radiotherapy.[68]

Basal Cell Carcinoma. Basal cell carcinoma (BCC) is the second most common primary malignancy of the hand, accounting for 3% to 12%; 2% to 3% of all BCCs occur on the hand. Risk factors are similar for SCC and include chronic sun exposure, light complexion, immunosuppression, inorganic arsenic exposure, and Gorlin's syndrome. Presentation includes a small, well-defined nodule with a translucent, pearly border and

Figure 44-27. Squamous cell carcinoma involving the nail fold and nail bed. Note the wart-like and ulcerated appearance.

overlying telangiectasias (Fig. 44-28). Metastasis is very rare. Standard treatment is excision with 5-mm margins. Other treatment options include curettage and electrodessication, cryotherapy, and radiotherapy.[68]

Figure 44-28. Basal cell carcinoma of the dorsal hand with surrounding telangiectasia.

Melanoma. Melanoma accounts for approximately 3% of all primary malignant hand tumors.[69] Risk factors include sun exposure (especially blistering sunburns as a child), dysplastic nevi, light complexion, family history of melanoma, and congenital nevi. Pigmented lesions with irregular borders, color changes, increase in growth, or change in shape are suggestive of melanoma. Breslow thickness is the most important factor in predicting survival for a primary melanoma. Surgical treatment includes excision with 1-cm margins for lesions up to 1 mm in thickness and 2-cm margins for lesions over 1 mm in thickness. Sentinel lymph node biopsy is done for lesions over 1 mm in thickness or for any lesion that is ulcerated and over 0.76 mm in thickness.[70] Any clinically palpable lymph node requires a formal lymph node dissection of the involved basin, as do sentinel lymph nodes positive for melanoma. Lymph node dissection has not been shown to offer any survival benefit, but the information gained from sentinel lymph node biopsy (or lymph node dissection) does offer valuable staging information that is important for prognosis. Subungual melanomas are treated with DIP amputation, with 5-year survival reported at 66%.[71]

Malignant Soft Tissue Tumors—Noncutaneous

Primary soft tissue sarcomas of the upper extremity are very rare, and most hand surgeons will only see several throughout their entire career. Only 14% of all soft tissue sarcomas occur in the entire upper extremity. Statistical inference is limited due to the rare occurrence of these tumors, but mortality rate is very high despite the aggressive treatments. Fewer than 5% of soft tissue sarcomas of the upper extremity will develop lymph node metastasis. Cutaneous malignancies must be considered in the differential diagnosis for any patient with palpable lymph nodes in the setting of any upper extremity mass. Any lesion of the upper extremity that is over 5 cm in diameter, rapidly enlarges, or is painful should be considered malignant until proven otherwise.[72]

Treatment for soft tissue sarcomas can range from palliative debulking to attempted curative resection. Many muscles of the upper extremity and their compartments cross joints (e.g., forearm flexors). Any malignancy within a compartment mandates complete resection of that compartment, and therefore, amputations must often be performed at levels much more proximal than the level of the actual tumor. Many soft tissue sarcomas are not responsive to radiation or chemotherapy, and use of these adjuvant treatments must be decided upon after discussion with medical and radiation oncologists in a multidisciplinary team. Several studies have shown higher mortality rates in patients who undergo initial tumor biopsy of sarcomas at institutions from which they do not ultimately receive treatment. These studies recommend biopsy be performed at the institution at which definitive treatment will be provided.[73] Institutions best suited for such treatment should have pathologists familiar with soft tissue sarcomas, medical and radiation oncologists, surgical oncologists, and a multidisciplinary tumor board.

An in-depth review of each type of soft tissue sarcoma is beyond the scope of this chapter. *Epithelioid sarcoma* is the most common primary soft tissue sarcoma of the upper extremity and usually presents as a benign-like slow-growing mass during the third or fourth decades. It has a propensity for the forearm, palm, and digits. Spread to lymph nodes has been reported. It typically spreads along fascial planes.[74] *Synovial sarcoma* is argued by some to be the most common primary soft tissue sarcoma of the *hand and wrist*, but the paucity of case reports is inconclusive. It is a high-grade malignancy that is painless and slow-growing and usually occurs adjacent to, but not involving, joints. It is most common in the second to fifth decades of life. Tumor size (>5 cm) is positively correlated with mortality. Other sarcomas include malignant fibrous histiocytoma, liposarcoma, fibrosarcoma, dermatofibrosarcoma protuberans, and malignant peripheral nerve sheath tumors, and more information can be found in further selected reading.[75] The majority of metastases to the hand involve secondary bone tumors and are discussed later in the section Secondary Metastatic Tumors.

Benign Bone Tumors

Primary benign bone tumors of the hand and wrist make up a total of 7% of all primary benign bone tumors in the body. Benign tumors of cartilage origin comprise 79% of all primary benign bone tumors of the hand and wrist.[76]

Enchondroma. This is the most common primary benign bone tumor of the hand and wrist and is of cartilage origin. Up to 90% of *all* bone tumors in the hand and wrist are enchondromas, with 35% to 54% of all enchondromas occurring in the hand and wrist. They are often found incidentally on X-rays taken for other reasons (e.g., hand trauma). They are usually solitary and favor the diaphysis of small tubular bones and are most common in the second and third decades of life. The most common location is in the proximal phalanges, followed by the metacarpals and then middle phalanges. Enchondroma has never been reported in the trapezoid. Presentation is usually asymptomatic, but pain may occur if there is a pathologic fracture or impending fracture. The etiology is believed to be from a fragment of cartilage from the central physis. Histology shows well-differentiated hyaline cartilage with lamellar bone and calcification.[76]

Two variants of enchondroma include Ollier's disease (multiple enchondromatosis) and Maffucci's syndrome (multiple enchondromatosis associated with multiple soft tissue hemangiomas). Malignant transformation is very rare in the solitary form, but there is a 25% incidence by age 40 in Ollier's patients and a 100% life-time incidence in Maffucci's patients. When malignant transformation does occur, it is almost uniformly a chondrosarcoma with pain and rapid growth.[77]

Diagnosis is usually made based on history, physical exam, and X-rays. There is a well-defined, multilobulated central lucency in the metaphysis or diaphysis that can expand causing cortical thinning or, sometimes, thickening (Fig. 44-29A). Further imaging is seldom needed, but a CT would be the study of choice.

Observation is indicated for asymptomatic enchondromas with no risk of impending fracture, followed by annual X-rays for 2 years. If a pathologic fracture is found, it is treated with immobilization until fracture union and then surgically treated. If there is any uncertainty as to whether it is an enchondroma, incisional biopsy is indicated and definitive treatment is postponed pending final pathology. Symptomatic lesions and those with impending fracture are treated surgically. Surgical treatment consists of an open incisional biopsy and confirmation by frozen section that it is well-differentiated hyaline cartilage. Curettage and high-speed burring are used to ablate the tumor. Intraoperative fluoroscopy is used to confirm complete ablation (Fig. 44-29B). The defect is then packed with bone graft or bone substitute. Recurrence ranges from 2% to 15%. X-rays should be obtained serially after surgery.[76]

A B

Figure 44-29. Enchondroma. **A.** X-ray of the phalanx demonstrates a well-defined central lucency. Surrounding cortex may thin or thicken. Thinning of the cortex contributes to risk of pathologic fracture. **B.** Intraoperative fluoroscopy after curettage of the tumor. A radiopaque ribbon is used to occupy the defect to help ensure that there is no tumor (similarly radiolucent to the defect after curettage) left behind prior to bone grafting.

Periosteal Chondroma. Periosteal chondromas are benign bone tumors of cartilage origin that arise most commonly within or adjacent to periosteum at the metaphyseal-diaphyseal junction in phalanges. They occur usually in the second or third decade as solitary lesions with pain, swelling, deformity, and possible pathologic fracture. X-rays reveal a subperiosteal lytic, unilobular lesion with erosion into adjacent cortex. There is often a rim of sclerosis. Histologically, they appear as aggressive cartilage with atypia, and it can be difficult to differentiate these from chondrosarcomas.[76]

Diagnosis involves X-rays with incisional biopsy to confirm the benign diagnosis and avoid unnecessary amputation. Treatment includes en-bloc resection of periosteum and corticocancellous bone. Recurrence is less than 4%.

Osteoid Osteoma. This is a tumor of bone origin. Approximately 5% to 15% of all osteoid osteomas occur in the hand and wrist and are most often found in the proximal phalanx or carpus. They usually occur in the second or third decade and present with a deep, dull ache that is classically worse at night and relieved by nonsteroidal anti-inflammatory drugs (NSAIDs). X-rays reveal a central lucency that is usually less than 1 cm in diameter surrounded by reactive sclerosis. Bone scan or CT is helpful to secure the diagnosis.[78]

Treatment consists of NSAID therapy only, and resolution occurs at an average of 33 months. If the patient does not wish to undergo prolonged discomfort with conservative therapy, curettage or percutaneous ablation of the nucleus may be performed.[78]

Giant Cell Tumor of Bone. Giant cell tumors of bone make up only 5% of all benign bone tumors in the body, and only 12% of these occur in the hand or wrist. Although its name is similar to that of "giant cell tumor of tendon sheath," they are two separate tumors and do not share the same clinical or histopathologic characteristics. Approximately 2% occur in the hand and 10% occur in the distal radius; those within the distal radius are more aggressive. They usually occur in the fourth decade with pain and swelling and possibly pathologic fracture.[79]

Giant cell tumor of the bone is unique in that it is benign on histology but does have metastatic potential and can cause death. It should be considered a low-grade malignancy.[79] Workup includes a CT of the chest and total-body scintigraphy to evaluate for metastases and multifocal lesions and MRI to evaluate the extent of local tissue involvement. Treatment consists of amputation of involved phalanges or metacarpals and wide excision of entire carpal rows. Local and systemic surveillance must be done for at least 10 years because metastasis has been reported to occur as late as 10 years postoperatively.[79]

Malignant Bone Tumors

Malignant primary and secondary bone tumors of the hand, like soft tissue malignancies, are exceedingly rare. An in-depth review is beyond the scope of this chapter. The same principles for soft tissue sarcomas of the upper extremity apply here with regard to evaluation, biopsy, and treatment.

Chondrosarcoma comprises 41% of all primary malignant bone tumors of the hand and wrist but only 1.5% of all chondrosarcomas overall. It is most likely to occur from malignant degeneration from a preexisting lesion, with enchondromatosis and osteochondromatosis being the most common. It usually presents as a slow-growing, painless mass in the fourth to sixth decades and can be difficult to differentiate from its benign counterparts. X-ray reveals endosteal erosion, cortical expansion, cortical destruction, and calcification. Metastasis has never been reported for chondrosarcomas of the hand. Chondrosarcomas are not responsive to chemotherapy or radiation.[80]

Osteosarcoma of the hand is exceedingly rare; only 0.18% of osteosarcomas occur in the hand. It usually presents as a painful swelling with pathologic fracture in the fifth to eighth decades of life. Radiation exposure is believed to be a possible risk factor. X-ray findings vary widely, with 90% of tumors occurring at a metaphyseal location. Findings include an osteoblastic or osteolytic lesion, cortical breakthrough with soft tissue extension, a "sunburst" pattern radially, or periosteal elevation (Codman's triangle). The presence or absence of metastasis is the most important prognostic factor, with a 5-year survival of 70% in the absence of metastases and a 5-year survival of 10% if present. Preoperative chemotherapy is usually given, but radiation therapy plays no role.[81]

Secondary Metastatic Tumors

Metastases to the hand or wrist are rare, with only 0.1% of skeletal metastases occurring in the hand. The majority of metastases to the hand are bone lesions, but soft tissue metastases have been reported. The most common primary site is the lung (40%), followed by the kidney (13%) and the breast (11%). Approximately 16% will have no known diagnosis of cancer.[82] The most common sites are the distal phalanges, followed by the proximal and middle phalanges, metacarpals, and carpus. Patients will present with pain, swelling, and erythema. Differential diagnosis includes felon, gout, osteomyelitis, trauma, RA, or skin cancer. Treatment of a hand or wrist metastatic lesion must not interfere with treatment of the primary cancer. Treatment is usually palliative (simple excision or amputation). The average life expectancy for these patients is less than 6 months.[82]

BURNS

The palm of the hand makes up only 1% of total body surface area. A burn involving the entire hand and digits is unlikely to cause life-threatening injury or shock, but seemingly small burns to the hand may cause severe permanent loss of function if not treated appropriately. Burns to the hand can cause serious short- and long-term disability. All burns to the hand are considered severe injuries that warrant transfer to a dedicated burn center for specialized treatment. This management will include a multidisciplinary team consisting of hand surgeons, burn surgeons, burn-specialized nurses, occupational therapists, case managers, and social workers.

First-degree burns involve damage to the epidermis only and present with erythema, no blistering, and full sensation with blanching of skin. These will heal without scarring. Second-degree burns are classified as superficial or deep. Superficial second-degree burns involve damage to the papillary dermis; all skin appendages are preserved, and therefore, these readily reepithelialize with minimal to no scarring. Superficial second-degree burns are sensate and present with pain, erythema, blistering, and blanching of skin. Topical dressings are the mainstay of treatment. Deep second-degree burns involve damage to the reticular dermis with damage to skin appendages, as well as the dermal plexus blood vessels and nerves. These have decreased sensation and no cap refill and appear pale or white. Blistering may be present. Damage to the skin appendages and blood supply in the dermal plexus precludes spontaneous healing without scar. Excision with skin grafting is needed. Third-degree burns involve full-thickness damage through the dermis and are insensate with no blistering. They appear dry, leathery, and even charred.

Acute Management

Advanced Trauma Life Support guidelines should be followed. After primary survey, circulation to the hand should be assessed. Palpation and Doppler ultrasound should be used to evaluate blood flow within the radial and ulnar arteries, the palmar arches, and digital blood flow at the radial and ulnar aspect of each volar digital pad. A sensorimotor exam should be performed. Objective evidence of inadequate perfusion (i.e., deteriorating clinical exam with changes in or loss of pulse or Doppler signal) indicates the need for escharotomy, especially in the setting of circumferential burns. Escharotomy may be performed at bedside with scalpel or electrocautery under local anesthesia or intravenous sedation. The depth of the escharotomy incision should extend into the dermis but not into subcutaneous tissues. In the forearm, axially oriented midradial and midulnar incisions are made for the entire extent of the burn. Escharotomy should proceed as distally as necessary into the wrist and hand to restore perfusion. Digital escharotomies are made via a midaxial (the middle of the longitudinal axis on sagittal view) incision over the radial aspects of the thumb and small finger and the ulnar aspects of the index, middle, and ring fingers.[83] These locations for digital escharotomies avoid painful scars on the heavy-contact surfaces of each respective digit. After primary survey, vascular, and sensorimotor exams are complete, careful documentation should be made of all burns. This is best done with a Lund and Browder chart and includes location, surface area, and initial depth of burn.

The burns should be dressed as soon as examination is complete. Gauze moistened with normal saline is a good initial dressing because it is easy, readily available, and will not leave ointment or cream on the wounds, which can hinder frequent examinations in the initial period. It is critical that no dressing is wrapped in a circumferential manner around any body part. Edema and swelling can lead to extremity ischemia if a circumferential dressing is in place. It is important to maintain body temperature above 37°C, especially in burn patients who have lost thermoregulatory function of the skin and now have moist dressings in place. The hands should be elevated above heart level to decrease edema formation, which can hinder motion and lead to late scar contracture. The hand should be splinted in the intrinsic plus position with the MPs flexed to 90° (placing MP collateral ligaments under tension), the IPs in straight extension (prevents volar plate adhesion), and the wrist in approximately 15° of extension.[84] If the burn involves the thenar eminence, thumb, or first web space, the thumb should be splinted in full abduction (to open up the first web space). Any other web space that is burned should have the adjacent fingers splinted in abduction. This will help prevent web space contracture. In rare cases, Kirschner wires or heavy steel wires/pins are needed to keep a joint in proper position. These are placed percutaneously through the involved joint and serve as a temporary joint stabilizer.

After the primary and secondary surveys are complete, the wound should be evaluated again. Devitalized tissue should be débrided. Wounds should be cleansed twice daily, typically with normal saline. Second-degree superficial burns may be dressed with Xeroform gauze and Bacitracin. Silver sulfadiazine cream is another option for any second- or third-degree wound. It covers gram-positive and gram-negative microbes, but it does not penetrate eschar. It should be applied at least one-sixteenth of an inch thick. Sulfamylon can be used in conjunction with silver sulfadiazine or alone. It deeply penetrates eschar and tissues and has good gram-positive coverage.

After débridement of necrotic skin, grafting will eventually be necessary. Allograft (human cadaver skin) is an expensive but useful temporary dressing for second- and third-degree burns. It can remain in place for up to 14 days before the body will reject it. It typically is left in place for 7 days. Allograft stimulates a wound to begin healing and can also serve as a way of "testing" a wound that needs skin grafting. If the allograft is adherent and there is evidence of temporary ingrowth, this suggests that the wound is ready to receive a skin graft.

Occupational hand therapy has played a major role in preserving hand function following burn injuries. Reestablishment

of hand function is pivotal for burn patients and is directly dependent on their ability or effort to participate with an occupational therapist. Early work with an occupational therapist can minimize the need for later reconstruction.[84] Hand therapy should be initiated as soon as possible. Hand therapists are also able to make customized molded splints that facilitate frequent dressing changes.

Surgical Management

Any burn wound will eventually heal with proper wound care. However, this may involve unacceptable scarring, deformity, contractures, pain, and unstable wounds that are prone to breakdown. The goal is to restore preinjury function as much as possible with a wound that is durable, supple, nonpainful, and allows the patient to return to society as an active member. Local wound care is the ideal treatment for wounds that can heal completely within 14 days while not sacrificing function. Purely cosmetic concerns are addressed after complete scar maturation (~12 months). In other cases, surgical excision and skin grafting are necessary. Skin grafting should be done as soon as it becomes obvious that a wound will not be healed completely by postburn day 14. It should also be considered for wounds that are likely to cause contractures, especially along the joints and web spaces.[84]

Considerable controversy surrounds the need, timing, and method of grafting burns. Careful consideration must be given to the patient's overall status, their preinjury state, and the type of work and recreational activities they enjoyed in order to have a better understanding of which issues should to be addressed.[85] Tangential excision of the wounds should be performed under tourniquet to minimize blood loss and is carried down to viable tissue. Avoid excising through fascia (epimysium) overlying muscles or exposing tendons, bone, joint capsules, or neurovascular structures. Tissues capable of receiving a skin graft include well-vascularized fat, muscle, perineurium, paratenon, perichondrium, and periosteum. Exposure of deep structures without an adequately graftable bed mandates further coverage before skin grafting can occur (discussed later in Reconstruction section).

Once there is an adequate bed, grafting is the next step. If there is any doubt as to whether the wound bed can support a skin graft, a temporary dressing should be placed and the patient reexamined frequently for signs of granulation tissue and wound bed viability. Skin grafts to the dorsum of the hand are typically split-thickness sheet grafts (not meshed). There are no functional differences between a sheet graft and a meshed graft, but sheet grafts have a much better final appearance. Skin grafts to the palmar aspects of the hand should be full-thickness in order to provide the dermal durability needed for daily functions.[84] Skin grafts are secured with staples, sutures, fibrin glue, or even skin glue. It is important to bolster every skin graft. This prevents shearing loss and also keeps the skin graft in contact with the wound bed, preventing fluid collections that can lead to graft loss. A bolster may consist of a tie-over bolster and a splint or a negative-pressure dressing. The hand should be splinted in intrinsic plus for 7 days after skin grafting. Once the graft is adherent, hand therapy should begin, consisting of active and passive range-of-motion exercises and modalities.

Reconstruction

Reconstruction of burn wounds can begin as early as the acute setting and continue into the subacute and late stages. Burns may initially be superficial but later convert to deep burns (especially with grease, oil, and alkali burns) due to infection, tissue desiccation, or continued trauma, or they may be deep from the outset of injury. Débridement or excision of burns may result in exposure of viable muscle, bone, tendon, cartilage, joints, and neurovascular structures, as well as loss of fascial layers that are required for overlying soft tissue to glide during movement. Simply skin grafting these exposed structures will result in unstable wounds that are prone to chronic breakdown. Soft tissue contractures will develop as the skin grafts adhere to the structures, effectively anchoring them in static position. This is especially true for tendons, where gliding capability is paramount for function. Flap coverage is required in these situations. The reversed radial forearm flap is a local flap and is often the first choice for flap coverage of the hand. If the zone of injury or size of defect precludes its use, other skin and fat flaps, including the free lateral arm, free anterolateral thigh, or even free parascapular flaps, may be useful, provided the patient can tolerate a free tissue transfer (see Chapter 45) operation (Fig. 44-30). The digits may also be buried subcutaneously in the lower abdominal skin or groin crease. Vascular ingrowth from the digits into the abdominal or groin skin occurs over 2 to 3 weeks, allowing division of the flap(s) and achieving full-thickness coverage of the wounds.[84,85]

An acellular dermal regenerative substitute (e.g., Integra) may be used for wounds that have exposed structures and require more durability than is offered by a skin graft[86] such as full-thickness loss overlying the extensor tendons of the wrist and hand. Dermal substitute is a good option for wounds that are not extensive enough to warrant a flap and for patients who are poor candidates for an extensive surgery. Integra is composed of acellular cross-linked bovine tendon collagen and glycosaminoglycan with an overlying silicone sheet. It is applied much like a skin graft. After incorporation in 14 to 21 days, it is capable of accepting a skin graft (after removing the silicone sheet). Conceptually, it works by replacing the lost dermis and adds durability to a wound bed. It may be reapplied multiple times to the same area if thicker neodermis is desired. Although cultured autologous keratinocytes have been used, they are expensive, time-consuming, and do not provide prompt or durable coverage. They are not widely used.

Web space contractures are the most common deformity resulting after hand burns. They may occur late despite the best

Figure 44-30. Free anterolateral thigh flap reconstruction of a large dorsal hand wound. Once wound coverage is stable, this flap will need to be surgically revised to achieve proper contour.

Figure 44-31. Z-plasty release of web space contracture. **A.** First web space burn contracture. **B.** Immediate postoperative result.

efforts. In the normal web space, the leading edge of the volar aspect of the web is distal to the dorsal aspect. This is reversed in web space contractures and limits digit abduction. Local modified Z-plasty (double-opposing Z-plasty) is the preferred treatment (Fig. 44-31).

Special Considerations

Chemical burns pose a risk to healthcare providers and should be considered hazardous material. They must also be removed from the patient or continued burn injury will occur. A complete discussion of all chemicals causing burns is beyond the scope of this chapter. Hydrofluoric acid produces a slow onset of severe pain and continues to penetrate deeper structures. It avidly binds tissue and circulating calcium and can lead to hypocalcemia and cardiac arrest. The wound should be irrigated copiously with water followed by topical application of an aqueous mixture of calcium gluconate. Calcium gluconate may also be infiltrated intradermally throughout the wound. Effectiveness of treatment is assessed by relief of pain. Intra-arterial injection of calcium gluconate into the artery supplying blood flow is another alternative if the other measures fail.[87] Alkaline and acid burns require copious irrigation with water, with alkali burns often requiring hours of irrigation. Phenol burns should be irrigated with water and treated topically with polyethylene glycol. Phosphorus burns leave phosphorus particles within the wound. A 0.5% copper sulfate solution is applied to stain the particles black, followed by débridement.[84,85]

VASCULAR DISEASE

Vascular disease encompasses a broad spectrum of disorders leading to compromised perfusion to the hand and digits and may potentially cause ischemia and necrosis. Chronic vascular disorders tend to develop slowly and are typically seen in older patients. This includes progressive thrombosis, aneurysms, systemic vasculopathy, and vasospastic disorders. Disorders unique or common to the hand are discussed in the following sections.

Progressive Thrombotic Disease

Hypothenar hammer syndrome involves occlusion of the ulnar artery at the wrist and is the most common occlusive vascular disorder of the upper extremity. The etiology is believed to be chronic trauma to the ulnar artery as it exits Guyon's canal. The classic example is a construction worker who frequently uses heavy equipment, such as jackhammers, that cause prolonged vibration and repetitive impact on the ulnar aspect of the palm. This causes periadventitial arterial damage that results in scarring and eventual compression, as well as medial and intimal damage.[88] The artery then becomes weakened and prone to aneurysm and/or thrombosis. If a thrombus forms, it may embolize, producing digital ischemia. Symptoms may be chronic or acute and include pain, numbness and tingling, weakness of grip, discoloration of the fingers, and even gangrene or ulcers of the fingertips.

If acute in onset, proximal occlusions may be extracted with a balloon catheter or, sometimes, under direct vision via an arteriotomy. Very distal embolism may require infusion of thrombolytics to dissolve clots and allow reperfusion. Large-vessel acute embolism and reperfusion may result in edema and compartment syndrome, requiring fasciotomy. A high index of suspicion must be maintained.

For the more common scenario of chronic, progressive occlusion, the involved segment of ulnar artery should be resected. There is disagreement in the literature regarding whether simple ligation and excision is sufficient for patients with sufficient distal flow or if all patients should undergo vascular reconstruction.[89] The authors' personal preference is to reconstruct all patients.

Systemic Vasculopathy

Buerger's disease (thromboangiitis obliterans) is an inflammatory occlusive disease affecting small and medium-sized arteries and veins. It is strongly influenced by smoking and will often resolve upon smoking cessation. Typical onset is before 50 years of age. Migratory phlebitis occurs distal to the elbow, resulting in ischemia, ulceration, and necrosis of the digits. It can continue to cause more proximal ischemia and ultimately lead to loss of the hands. Treatment must start with smoking

cessation. Failure to stop smoking will make any surgical intervention unsuccessful. Arteriography is useful to determine arterial flow and whether bypass is possible. If direct bypass is not possible, alternatives include arterialization of the venous system by connecting the dorsal venous network to the brachial artery or possible free microvascular omental transfer beneath the dorsal forearm or hand for indirect revascularization.[90]

Vasospastic Disorders

Raynaud's syndrome results from excessive sympathetic nervous system stimulation. Perfusion is diminished and fingers often become cyanotic. Although the onset of the symptoms is benign, chronic episodes can result in atrophic changes and painful ulceration or gangrene of the digits. Raynaud's disease occurs without another associated disease. This disease predominately affects young women and is often bilateral. The vascular system is structurally intact without any obstructions. There is no ulceration, gangrene, or digit loss. In contrast, Raynaud's phenomenon is associated with an underlying connective tissue disorder, such as scleroderma. Arterial stenosis is present due to disease changes in blood vessels as a result of the specific medical disorder.[90]

Scleroderma is an autoimmune connective tissue disorder resulting in fibrosis and abnormal collagen deposition in tissue. Many organs can be affected, with the skin most commonly and noticeably involved. In this disease, blood vessels are injured by intimal fibrosis leading to microvascular disease. The vessels become subject to Raynaud's phenomenon, and patients develop painful, ulcerated, and sometimes necrotic digits.[91,92]

Sympathectomy can provide pain relief and healing of ulcers for patients with scleroderma and Raynaud's phenomenon. In this procedure, adventitia is stripped from the radial artery, ulnar artery, superficial palmar arch, and digital arteries in various combinations based on the affected digits being treated. The decrease in sympathetic tone allows for vasodilation and increased blood flow. If the patient notes significant distal pain relief and/or previously ischemic tissue improves in color after a test administration of local anesthetic, sympathectomy may provide the same results in a long-term fashion.[91,92]

CONGENITAL DIFFERENCES

Congenital differences in a newborn can be particularly disabling as the child learns to interact with the environment by using the hands. The degree of anomaly can range from minor, such as a digital disproportion, to severe, such as total absence of a forearm bone. In recent years, increasing knowledge of the molecular basis of embryonic limb development has significantly enhanced the understanding of congenital differences. Congenital hand differences have an incidence of 1:1500 births. The two most common differences encountered are syndactyly and polydactyly.[93]

There are numerous classification systems for hand differences. The Swanson classification, adopted by the American Society for Surgery of the Hand, delineates seven groups organized based on anatomic parts affected by types of embryonic failures.[94]

Failure of Formation

The failure of the formation of parts is a group of congenital differences that forms as a result of a transverse or longitudinal arrest of development. Conditions in this group include radial club hand, a deformity that involves some or all of the tissues on the radial side of the forearm and hand, and ulnar club hand, which involves underdevelopment or absence of the ulnar-sided bones.

Failure of Differentiation

The failure of the differentiation of parts comprises conditions where the tissues of the hand fail to separate during embryogenesis. Syndactyly, in which two or more fingers are fused together, is the most common congenital hand deformity and occurs in seven out of every 10,000 live births. There is a familial tendency to develop this deformity. This deformity often involves both hands, and males are more often affected than females. Syndactyly is classified as either simple (soft tissue only) or complex (bone and/or cartilage also involved), and complete (full length of the digits) or incomplete (less than the full length).

Surgical release of syndactyly requires the use of local flaps to create a floor for the interdigital web space and to partially surface the adjacent sides of the separated digits (Fig. 44-32). Residual defects along the sides of the separated fingers are covered with full-thickness skin grafts. Surgery usually is performed at 6 to 12 months of age.

Duplication

Duplication of digits is also known as polydactyly. Radial polydactyly is usually manifests as thumb duplication. Wassel described a classification system for thumb duplications based on the level of bifurcation.[95] When two thumbs are present in the same hand, they are rarely both normal in size, alignment, and mobility. In the most common form of thumb duplication, a single broad metacarpal supports two proximal phalanges, each of which supports a distal phalanx. Optimal reconstruction requires merging of elements of both component digits. Usually the ulnar thumb is maintained. If the duplication occurs at the MP joint, the radial collateral ligament is preserved with the metacarpal and attached to the proximal phalanx of the retained ulnar thumb. Surgery is usually performed at 6 to 12 months of age. Ulnar-sided polydactyly may often be treated by simple excision of the extra digit.

Overgrowth

Overgrowth of digits also is known a macrodactyly, which causes an abnormally large digit. In this situation, the hand and the forearm also may be involved. In this rare condition, all parts of a digit are affected; however, in most cases, only one digit is involved, and it is usually the index finger. This condition is more commonly seen in males. Surgical treatment of this condition is complex, and the outcomes may be less than desirable. Sometimes, amputation of the enlarged digit provides the best functional result.

Undergrowth

Underdeveloped fingers or thumbs are associated with many congenital hand deformities. Surgical treatment is not always required to correct these deformities. Underdeveloped fingers may include the following: small digits (brachydactyly), missing muscles, underdeveloped or missing bones, or absence of a digit.

Constriction Band Syndrome

Constriction band syndrome is a set of congenital differences that occurs when a tissue band forms around the digit(s) or arm in utero, impairing blood flow and growth. This condition may

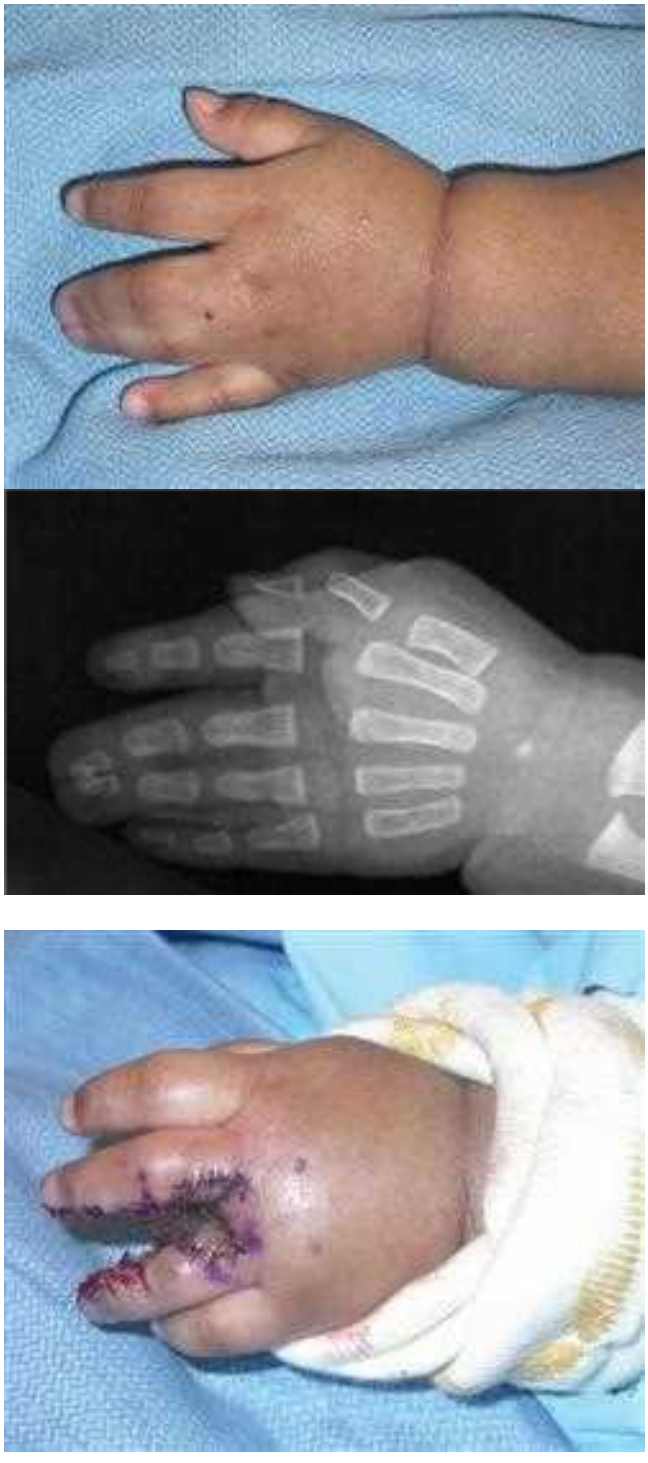

Figure 44-32. Syndactyly. Hand of a 1-year-old patient with complex syndactyly between the long and ring fingers. Complex syndactyly refers to fingers joined by bone or cartilaginous union, usually in a side-to-side fashion at the distal phalanges. The syndactyly is divided with interdigitating full-thickness flaps, a dorsal trapezoidal-shaped flap to resurface the floor of the web space, and full-thickness skin grafts. Note the skin grafts on the ulnar and radial sides of the new web space.

be associated with other problems such as clubfoot, cleft lip, cleft palate, or other craniofacial anomalies. The cause of the ring constrictions is unknown. Some theories suggest that folds or bands in the amniotic membrane may be responsible for this condition.

Generalized Skeletal Anomalies and Syndromes

This is a rare and complex group of unclassified problems.

RECONSTRUCTIVE TRANSPLANTATION OF THE UPPER EXTREMITY

Hand transplantation was first performed in humans in the late 1990s both in Louisville, Kentucky, and Lyon, France.[96] The treating surgeons were able to successfully remove an upper extremity from a brain-dead donor, attach it to an upper extremity amputee, and have the tissue survive. In the subsequent 15 years, many additional centers have achieved technical success with upper extremity transplantation as well.

The technical considerations of hand transplantation have proven to be only the beginning of challenges in bringing this treatment option to the general public. Replantation of an amputated limb was first reported by Malt in 1962.[97] In a limb replantation, there is a zone of injury, and cold preservation of the amputated part does not begin immediately. In a limb transplant, the harvest can be done as proximally as necessary to ensure that only healthy tissue is present on both sides of the repair and to obviate the need for limb shortening, and cold preservation of the amputated part can begin immediately after harvest.

A major concern regarding the use of limb transplantation is the immunosuppression medications required to prevent rejection of the transplanted limb. Unlike organ transplantation, which provides a critical organ without which the recipient could not survive or would require chronic mechanical support (e.g., hemodialysis), the absence of one or even multiple limbs does not represent an immediate threat to a patient's survival. Multiple studies have documented the nephrotoxic and other side effects of tacrolimus (FK 506), the principle antirejection agent used in transplant immunomodulation protocols.[98,99]

Due to these concerns, much research has been directed at minimizing the amount of antirejection medication as well as promoting tolerance or even chimerism. Donor bone marrow transplantation to the limb transplant recipient has been shown to be beneficial toward this purpose and is part of the limb transplant protocol in some centers.[100] Recent research with donor bone marrow infusions has shown that lower levels of immunosuppressive drugs may be possible, as well as fewer immunosuppressive agents.[100] Further research is needed in order to determine the efficacy and utility of donor bone marrow transfusions and how they impact transplant recipients in the short and long term.

The final challenge in consideration of a patient for limb transplantation is selection of an appropriate candidate. There are multiple patient factors that need to be considered to determine if a patient is an appropriate candidate for hand transplantation. These include medical concerns, such as immunologic issues (both antibodies and the presence of occult neoplasms or indolent viruses such as cytomegalovirus), hematologic issues including coagulopathies, and anatomic issues such as quality of skin envelope and amputation level of the bone and neuromuscular structures. Psychological and social factors must also be considered related to the recipient's ability to comply with postoperative medication and therapy protocols as well as to cope with a continuous visible presence of a limb originating from another person.[101]

The promise of upper limb transplantation as a reconstructive technique remains high. Both civilian and military amputees

stand to receive a marked functional benefit from this treatment. With the number of transplants performed worldwide approaching 100 as well as decades of animal research, understanding of how best to use this technique from functional, patient safety, and cost-effectiveness standpoints continues to grow.

chapter 45

Plastic and Reconstructive Surgery

Joseph E. Losee, Michael L. Gimbel, J. Peter Rubin, Christopher G. Wallace, and Fu-Chan Wei

HISTORICAL BACKGROUND

The field of plastic surgery focuses on the restoration of form and function to those who have congenital and acquired deformities. Plastic surgery routinely addresses novel problems and challenges; therefore, the plastic surgeon must have an expert knowledge of anatomy and surgical technique to address new challenges.

The word *plastic* is derived from the Greek *plastikos,* meaning "to mold." Although the term *plastic surgery* can be found in several medical writings from the eighteenth and nineteenth centuries, it was John Staige Davis who established the name of the specialty with the 1919 publication *Plastic Surgery—Its Principles and Practice.*

One of the earliest accounts of reconstructive surgery can be found in the *Sushruta Samhita,* an early text from the sixth or seventh century B.C. by the practitioner Sushruta. In this writing, the reconstruction of an amputated nose with a pedicled forehead flap and the reconstruction of the ear with cheek flaps were described. In addition, in the first century A.D., the Roman physicians Aulus Cornelius Celsus and Paulus Aegineta described operations for facial reconstruction.

The first textbook of plastic surgery is believed to be Gaspara Tagliacozzi's 1597 publication *De Curtorum Chirurgia per Insitionem.* This text describes the reconstruction of the nose with a pedicled arm flap. The nineteenth century saw advances in reconstructive surgery, including Giuseppe Baronio's successful grafting of sheepskin. The techniques for perfecting human skin grafting followed later in the nineteenth century.

Great advances in plastic surgery occurred as a result of the first and second world wars. Out of the fields of dental surgery, otolaryngology, ophthalmology, and general surgery, the discipline of plastic surgery was established. The founders of the field include Sir Harold Gillies, an otolaryngologist who established a center for the treatment of maxillofacial injuries in England; V. H. Kazanjian, a dental surgeon from Boston, who established a center in France for the treatment of facial injuries incurred in World War II; and Vilray P. Blair, from St. Louis, who established centers for the treatment of soft tissue and maxillofacial reconstruction for the U.S. Army. With the onset of World War II, centers of excellence for hand reconstruction appeared as well.

In the last 50 years, advances in plastic surgery have included the transplantation of both autologous and allogeneic tissue, tissue expansion, regional muscle and myocutaneous flap transfers, distant transfer of free flaps using microsurgery, replantation of traumatically amputated extremities and digits, and the emergence of craniofacial surgery. The future of plastic surgery will likely see further advances in the realms of regenerative medicine, fetal surgery, and reconstructive transplantation.

GENERAL PRINCIPLES

Skin Incisions

Human skin exists in a state of tension created by internal and external factors. Externally, skin and underlying subcutaneous tissue are acted on by gravity and clothing. Internally, skin is subjected to forces generated by underlying muscles, joint

Key Points

1. Plastic surgery is the field of surgery that addresses congenital and acquired defects, striving to return form and function.
2. Plastic surgery has been a field of innovation. The future of the specialty likely includes advancements in the areas of regenerative medicine, fetal surgery, and reconstructive transplantation with composite tissue allotransplants.
3. Children diagnosed with cleft and craniofacial anomalies benefit from interdisciplinary care at a specialized center focusing on team care. Long-term follow-up during growth and development is critical for optimal outcomes.
4. Reconstructive surgery attempts to restore form and function through techniques that include skin grafting, use of muscle flaps, bone grafting, tissue expansion, free tissue transfer with microsurgery, and replantation.
5. Aesthetic surgery is surgery performed to reshape the normal structure of the body to improve the patient's appearance and self-esteem. Patients undergoing aesthetic surgery present a unique challenge. The most important outcome parameter is patient satisfaction, and therefore, a thorough understanding of the patient's motivations, goals, and expectations is critical.

extension and flexion, and tethering of fibrous tissues from zones of adherence. As a result, when skin is incised linearly, it gapes to variable degrees. When a circular skin excision is performed, the skin defect assumes an elliptical configuration paralleling the lines of greatest tension. Carl Langer, an anatomist from Vienna, first fully described these tension lines in the mid-1800s based on his studies of fresh cadavers.[1] A. F. Borges described another set of skin lines that, different from Langer's lines, reflect the vectors of relaxed skin tension.[2] Although the term *Langer's lines* often is used interchangeably with the term *relaxed skin tension lines,* the former lines describe skin tension vectors observed in the stretched integument of cadavers exhibiting rigor mortis, whereas the latter lines lay perpendicular to and more accurately reflect the action of underlying muscle[2] (Fig. 45-1). Relaxed skin tension lines may be exploited to create incisions that minimize anatomic distortion and improve cosmesis. In areas of anatomic mobility, such as the neck or over joints, incisions are oriented less for aesthetic reasons and more with the goal of avoiding scar contractures and subsequent functional compromise. In general, incisions are placed perpendicular to the action of the joint.

There are situations, however, in which the direction of the incision has been preestablished, as in acute lacerations, burns, or old contracted and distorting scars. In these circumstances, the principles of proper incision placement can be combined with simple surgical techniques to reorient the scar and lessen the deformity. The Z-plasty technique uses the transposition of random skin flaps both to break up a linear scar and to release a scar contracture through lengthening (Fig. 45-2; Table 45-1). W-plasty is the technique of scar excision and reconstruction in zigzag fashion to camouflage the resulting scar.

Wound Healing

The fundamentals of plastic surgery are based on wound healing physiology. Wound repair consists of an exquisitely regulated symphony of molecular and cellular instruments that act in concert to restore the local tissue environment to prewound conditions. Metabolic imbalances in the wound milieu drive this orchestration and continue to direct it until healing resolves the disturbance. Although a detailed review of wound physiology is presented elsewhere in this text, it is useful to emphasize several points.

Tissue injury disrupts the tissue microenvironment and sets into motion a cascade of events that combine to reestablish the environmental status quo. Disrupted blood vessels fill the wound space with red blood cells and plasma. Injured cells

release factor III (thromboplastin), which accelerates the clotting cascade. Clotting factors in the plasma are activated, and the coagulation cascade forms thrombin and eventually fibrin. Simultaneously, the complement system activates and produces chemoattractive complement protein fragments. Platelets, activated by thrombin and exposed collagen, release a number of growth factors and cytokines. Traumatized vessels contract in response to both direct physical stimulation and prostaglandins released by platelets. Intact local microvasculature vasodilates and leaks plasma in response to inflammatory mediators such as histamine, kinins, and serotonin. These early events, and others, establish inflammation and, finally, homeostasis.[3]

Table 45-1

Tissue lengthening with Z-plasty

TYPE OF Z-PLASTY	INCREASE IN LENGTH OF CENTRAL LIMB (%)
Simple 45°	50
Simple 60°	75
Simple 90°	100
Four-flap with 60° angles	150
Double-opposing	75
Five-flap	125

Platelet activation initiates the first major escalation in the inflammatory response. Within minutes, platelets release signaling molecules from their α-granules to attract macrophages, polymorphonuclear cells (PMNs), fibroblasts, and vascular endothelial cells. Within a few hours of injury, PMNs and macrophages invade the wound and remove tissue debris, coagulation proteins, and bacteria. Although both PMNs and macrophages begin to marginate early, PMNs dominate during the first few days. PMNs also constitute the primary defense against invading organisms that have breached the epithelial barrier. PMNs and macrophages, in concert with the complement system, form the basis of "natural" or "nonspecific" immunity. If there is no infection or foreign material, the neutrophil population diminishes by the second day, whereas macrophages continue to amass.[3]

Macrophages become the major population by the third day after injury. These cells then dominate the wound region for days to weeks. Macrophages are the "masterminds" behind the finely tuned array of repair events that characterizes the proliferative phase of healing. Like neutrophils, activated macrophages continue the task of wound débridement. They are a rich source of degradative enzymes that process the extracellular matrix to make room for remodeling. Tightly coordinated release of the many growth factors, colony-stimulating factors, interleukins, interferons, and cytokines gives the macrophage the ability to regulate migration, proliferation, and specific protein synthesis of multiple cell lines. Macrophages lead the procession of new tissue into the wound dead space. Immature, replicating fibroblasts follow the macrophages. Mature fibroblasts then advance into the wound and are, in turn, followed by newly forming capillary buds, the last cells in the procession.[3]

Thus, injury perturbs the microenvironment and leads to the autoamplifying inflammatory phase. As a result of these processes, three changes occur in the wound: the environment becomes hypoxic, acidotic, and hyperlactated. One biochemical pathway by which this low redox potential state can signal cells to take biologic action is the adenosine diphosphoribose (ADPR) system. Recent evidence has shown that alterations of the polyADPR system affect regulation of collagen and vascular endothelial growth factor (VEGF) transcription.[3] Consequently, the metabolic state that is so deranged in the wound microenvironment is intimately linked to altered cellular function and leads to reparative cell phenotypes.

After inflammation has begun, fibroblasts are attracted by many stimuli and then proliferate and migrate into the site of injury. Fibroblasts are the major producers of collagen in the repair response. Substances that increase collagen deposition and maturation include lactate, oxygen, and growth factors. Lack of these agents as well as steroid treatments decrease collagen in wounds.

Macrophages also usher along angiogenesis, largely through the release of VEGF. VEGF production is upregulated by the same wound metabolic environment that stimulates collagen production. As neovascularization takes place, many of the conditions that signaled the start of the inflammatory and proliferative phases are resolved, and the wound healing response recedes.

Epidermal cells are attracted to the healing wound by the same cytokines that attract other wound cells. Epithelialization proceeds best in a moist environment with high oxygen tension.[3]

Table 45-2

Preoperative management

- Assess and optimize cardiopulmonary function; correct hypertension.
- Treat vasoconstriction: attend to blood volume, thermoregulatory vasoconstriction, pain, and anxiety.
- Assess recent nutrition and provide treatment as appropriate.
- Treat existing infection.
- Assess wound risk using the SENIC index.
- Start administration of vitamin A in patients taking glucocorticoids.
- Maintain tight blood glucose control.

SENIC = Study on the Efficacy of Nosocomial Infection Control.
Source: Modified with permission from Hunt TK, Hopf HW. Wound healing and wound infection: what surgeons and anesthesiologists can do. *Surg Clin North Am.* 1997;77:587. Copyright Elsevier.

Preoperative, intraoperative, and postoperative interventions may be taken by the surgeon to minimize infection and optimize wound healing (Tables 45-2–45-4). These measures all draw on what we understand of the physiologic wound healing process.

Skin Grafts and Skin Substitutes

Skin is comprised of 5% epidermis and 95% dermis. The dermis contains sebaceous glands, whereas sweat glands and hair follicles are located in the subcutaneous tissue. The dermal thickness and concentration of skin appendages vary widely from one location to another on the body. The skin vasculature is superficial to the superficial fascial system and parallels the skin surface. The cutaneous vessels branch at right angles to penetrate subcutaneous tissue and arborize in the dermis, finally forming capillary tufts between dermal papillae.[4]

Skin grafting techniques date back >3000 years to India, where forms of the technique were used to resurface nasal defects in thieves who were punished for their crimes with nose amputation. Modern skin grafting methods include split-thickness grafts, full-thickness grafts, and composite tissue grafts (Table 45-5). Each technique has advantages and disadvantages. Selection of a particular technique depends on the requirements of the defect to be reconstructed, the quality of the recipient bed, and the availability of donor site tissue.

Split-Thickness Grafts. Split-thickness skin grafting represents the simplest method of superficial reconstruction in plastic surgery. Many of the characteristics of a split-thickness graft are determined by the amount of dermis present. Less dermis translates into less primary contraction (the degree to which a graft shrinks in surface area after harvesting and before grafting), more secondary contraction (the degree to which a graft shrinks during healing), and better chance of graft survival. Thin split grafts have low primary contraction, high secondary contraction, and high reliability of graft take, often even in imperfect recipient beds. Thin grafts, however, tend to heal with abnormal pigmentation and poor durability compared with thick split grafts and full-thickness grafts. Thick split grafts have more primary contraction, less secondary contraction, and may take less hardily. Split grafts may be meshed to expand the surface area that can be covered. This technique is particularly useful when a large area must be resurfaced, as in major burns.

Table 45-3

Intraoperative management

- Administer appropriate prophylactic antibiotics at start of procedure. Keep antibiotic levels high during long operations.
- Keep patient warm.
- Maintain gentle surgical technique with minimal use of ties and cautery.
- Keep wounds moist.
- Perform irrigation in cases of contamination.
- Elevate tissue oxygen tension by increasing the level of inspired oxygen.
- Delay closure of heavily contaminated wounds.
- Use appropriate sutures (and skin tapes).
- Use appropriate dressings.

Source: Modified with permission from Hunt TK, Hopf HW. Wound healing and wound infection: what surgeons and anesthesiologists can do. *Surg Clin North Am.* 1997;77:587. Copyright Elsevier.

Table 45-4

Postoperative management

- Keep patient warm.
- Provide analgesia to keep patient comfortable, if not pain free.
- Keep up with third-space losses. Remember that fever increases fluid losses.
- Assess perfusion and react to abnormalities.
- Avoid diuresis until pain is gone and patient is warm.
- Assess losses (including thermal losses) if wound is open.
- Assess need for parenteral/enteral nutrition and respond.
- Continue to control hypertension and hyperglycemia.

Table 45-5

Classification of skin grafts

TYPE	DESCRIPTION	THICKNESS (IN)
Split thickness	Thin (Thiersch-Ollier)	0.006–0.012
	Intermediate (Blair-Brown)	0.012–0.018
	Thick (Padgett)	0.018–0.024
Full thickness	Entire dermis (Wolfe-Krause)	Variable
Composite tissue	Full-thickness skin with additional tissue (subcutaneous fat, cartilage, muscle)	Variable

Source: Modified with permission from Andreassi A, Bilenchi R, Biagioli M, et al. Classification and pathophysiology of skin grafts. *Clin Dermatol.* 2005;23:332. Copyright Elsevier.

Meshed grafts usually also have enhanced reliability of engraftment, because the fenestrations allow for egress of wound fluid and excellent contour matching of the wound bed by the graft. The fenestrations in meshed grafts reepithelialize by secondary intention from the surrounding graft skin. The major drawbacks of meshed grafts are poor cosmetic appearance and high secondary contraction. Meshing ratios used usually range from 1:1.5 to 1:6, with higher ratios associated with magnified drawbacks.

Full-Thickness Grafts. By definition, full-thickness skin grafts include the epidermis and the complete layer of dermis. The subcutaneous tissue is carefully removed from the deep surface of the dermis to maximize the potential for engraftment. Full-thickness grafts are associated with the least secondary contraction upon healing, the best cosmetic appearance, and the highest durability. As a result, they are frequently used in reconstructing superficial wounds of the face and the hands. These grafts require pristine, well-vascularized recipient beds without bacterial colonization, previous irradiation, or atrophic wound tissue.

Graft Take. Skin graft take occurs in three phases: imbibition, inosculation, and revascularization. Plasmatic imbibition refers to the first 24 to 48 hours after skin grafting, during which time a thin film of fibrin and plasma separates the graft from the underlying wound bed. It remains controversial whether this film provides nutrients and oxygen to the graft or merely a moist environment to maintain the ischemic cells temporarily until a vascular supply is reestablished. After 48 hours, a fine vascular network begins to form within the fibrin layer. These new capillary buds interface with the deep surface of the dermis and allow for transfer of some nutrients and oxygen. This phase, called *inosculation,* transitions into revascularization, the process by which new blood vessels either directly invade the graft or anastomose to open dermal vascular channels and restore the pink hue of skin. These phases are generally complete by 4 to 5 days after graft placement. During these initial few days, the graft is most susceptible to interference in engraftment caused by infection, mechanical shear forces, and hematoma or seroma.[4]

Composite Grafts. Composite tissue grafts are donor tissue containing more than just epidermis and dermis. They commonly include subcutaneous fat, cartilage and perichondrium, and muscle. Although less common than skin grafts, grafts of this type are particularly useful in select cases of nasal reconstruction. Excision of the thick skin of the nasal lobule may create too deep a defect to reconstruct with a full-thickness skin graft. The ear lobe composite graft provides thicker coverage with good color match and a fairly inconspicuous donor site (Fig. 45-3). Similarly, the root of the helix of the ear may be used to reconstruct the alar rim, providing skin coverage, cartilaginous support, and internal lining in a single technique.

Flaps

A flap is a vascularized block of tissue that is mobilized from its donor site and transferred to another location, adjacent or remote, for reconstructive purposes. The difference between a graft and a flap is that a graft brings no vascular pedicle and derives its blood flow from recipient site revascularization, whereas a flap arrives with its blood supply intact.

Random Pattern Flaps. Random pattern flaps have a blood supply based on tiny blood vessels in the dermal-subdermal plexus, as opposed to the discrete, well-described vessels of axial pattern flaps (Fig. 45-4).[5] Random flaps are typically used to reconstruct relatively small, full-thickness defects that are not amenable to skin grafting. Unlike axial pattern flaps, random flaps are limited by their geometry. The generally accepted reliable length-to-width ratio for a random flap is 3:1. Exceptions to this rule abound, however. There are many different types of random cutaneous flaps that differ in geometry and mobility. A *transposition flap* is rotated about a pivot point into an adjacent defect (Fig. 45-5). A *Z-plasty* is a type of transposition flap in which two flaps are rotated, each into the donor site of the other, to achieve central limb lengthening (see Fig. 45-2). Another common transposition flap is the *rhomboid (Limberg) flap* (Fig. 45-6). *Rotational flaps* are similar to transposition flaps but differ in that they are semicircular (Fig. 45-7). *Advancement flaps* slide forward or backward along the flap's long axis. Two common variants include the rectangular advancement flap and the V-Y advancement flap (Fig. 45-8). Like transposition flaps, *interpolation flaps* rotate about a pivot point. Unlike transposition flaps, they are inset into defects near, but not adjacent, to the donor site. An example of an interpolation flap is the thenar flap for fingertip reconstruction (Fig. 45-9).

Fasciocutaneous and Myocutaneous Flaps. The *composition* of a flap describes its tissue components. For example, a cutaneous flap contains skin accompanied by a variable amount of subcutaneous fat. A fasciocutaneous flap contains skin and fascia, whereas an adipofascial flap contains subcutaneous fat and fascia without overlying skin. A muscle flap contains muscle only, whereas a myocutaneous flap also contains the overlying skin and intervening tissues. An osseous flap contains vascularized bone only, whereas an osteomyocutaneous flap contains, in addition, muscle, skin, and subcutaneous tissues.

The *contiguity* of a flap describes its position related to its source. Local flaps are transferred from a position adjacent to the defect. Regional flaps are from the same anatomic region of the body as the defect (e.g., the lower extremity region or the head and neck region). Distant flaps are transferred from a different anatomic region to the defect. They may remain attached to the source anatomic region (*pedicled flaps*) or may be transferred as *free flaps* by microsurgery. These are completely detached from the body, and their blood supply is reinstated by microvascular anastomoses to recipient vessels close to the defect.

The term *pedicle* was originally used to describe a bridge of tissue that remained between a flap and its source, similar to how a peninsula remains attached to its mainland. However, as knowledge of flap blood supply and (micro)vascular anatomy has improved over the years, the term pedicle has increasingly become reserved for describing the blood vessels that nourish the flap. Thus its current use is, in essence, *vascular pedicle* in shortened form. As a refinement, it is possible to dissect the pedicle free of its surrounding tissues (termed *skeletonization*) to allow any tortuosity of the supplying blood vessels to be released in order to maximize their reach toward a given defect. This is usually performed in a retrograde direction starting from where the pedicle enters the flap tissues. Similarly, it is possible to detach the desired skin paddle circumferentially from all unneeded surrounding tissues in order to maximize the freedom with which the flap can be inset to reconstruct the defect. Hence, a *pedicled island* flap has had its cutaneous component circumferentially incised while preserving its vascular pedicle. Therefore, a free flap and a pedicled island flap differ only in

that the former requires transection of the vascular pedicle for anastomosis to alternative recipient vessels, whereas the pedicle of the latter remains in continuity.

Such flaps that are supplied by an anatomically defined configuration of vessels are described as having an *axial pattern* blood supply and can be transferred as local, regional, or distant, and pedicled, island pedicled, or free flaps.[6] Arising from the aorta are arteries that supply the internal viscera and other deep vessels that divide to form the main arterial supplies to the trunk, head, and extremities. They ultimately feed interconnecting vessels that supply the vascular plexuses of the fascia, subcutaneous tissue, and skin. These interconnecting vessels reach the skin via either fasciocutaneous (also called *septocutaneous*) vessels that traverse fascial septae between muscles, musculocutaneous perforators that penetrate muscle bellies, or direct cutaneous vessels that traverse neither muscle bellies nor fascial septae.[7] Axial pattern flaps, incorporating suprafascial tissues, are supplied by these fasciocutaneous (septocutaneous), musculocutaneous, or direct cutaneous arteries. The internal viscera are also a source of axial pattern flaps, such as the jejunum flap and omentum flap. The circulation of bone- and muscle-containing flaps also is mainly axial in pattern. It also is possible to design local flaps, such as V-Y advancements and rhomboid flaps, as axial pattern flaps. In contrast to axial pattern flaps, random pattern flaps are only commonly transferred as local flaps by virtue of their lack of a defined vascular pedicle and cannot be transferred as island pedicled or free flaps. Axial pattern flaps may possess some areas with random pattern circulation, usually located at the flap periphery.

The volume of tissue reliably vascularized by the pedicle of an axial pattern flap defines its limits. In other words, the portion of a flap that extends beyond the capabilities of its vascular pedicle to perfuse it reliably will ordinarily undergo necrosis of that portion. This can be clarified conceptually. The arterial tree can be described in terms of its *angiosomes*.[8] An angiosome is a block of tissue that is reliably supplied by a given artery. Neighboring angiosomes overlap, just as the dermatomes of neighboring nerves overlap. An anatomic angiosome is defined by the limits of an artery's ramifications, where it forms anastomoses with a neighboring anatomic angiosome. The vessels that pass

between these anatomic angiosomes are called *choke vessels*. In life, these may open or close in response to physiologic changes to increase or decrease, respectively, an artery's *dynamic angiosome* momentarily. Accordingly, at any given time point, the dynamic angiosome of an artery may be approximated by the volume of tissue stained by an intravascular administration of fluorescein into that artery (indicating the reach of blood flow from that artery into tissues). The *potential angiosome* of an artery is the volume of tissue that can be included in a flap that has undergone *conditioning* (see below). Both the dynamic and potential angiosomes extend beyond the anatomic angiosome of an artery. Although the angiosomal concept provides some guidance to the size and volume limits of a flap harvest, there remains no quantifiable method to predict safe flap harvest limits exactly.

Conditioning refers to any procedure that increases the reliability of a flap by enlarging the angiosome of the pedicle artery from its dynamic toward its potential angiosome. Invoking the *delay phenomenon*, for example, has improved the survival of flaps that otherwise would more frequently be complicated by unpredictable partial necrosis, such as the pedicled transverse rectus abdominis myocutaneous (TRAM) flap. The procedure can be particularly useful in patients at higher risk, such as those who are obese, smoke, or have received radiotherapy. One method of delay for the pedicled TRAM flap is to divide a major portion of its blood supply, the deep inferior epigastric artery on both sides, approximately 2 weeks before transfer. In response, blood from the anatomic angiosome of the superior epigastric artery appears to flow into that of the interrupted deep inferior epigastric artery via intervening choke vessels. As a result, the flap becomes conditioned to rely on the superior epigastric artery. The TRAM flap can then be transferred based on the superior epigastric artery with less risk of its distal portions becoming ischemic and possibly necrotic. Several theories have been proposed to explain the delay phenomenon, including metabolic compensatory responses to relative ischemia and dilatation of choke vessels; however, its mechanisms remain incompletely understood.[9]

Further subclassifications of flap circulation have been introduced for muscular and fasciocutaneous flaps.[10] Individual muscles have been classified by Mathes and Nahai into five types (I–V) according to their blood supply (Table 45-6). This classification is also applied to the respective myocutaneous flaps. Fasciocutaneous flaps also have been classified by these authors into types A, B, and C (Table 45-7). The inclusion of muscle in a flap may serve to increase flap bulk (so as to obliterate dead space) or to provide a functioning component with the harvest of its motor nerve for coaptation to a recipient motor nerve. The purported advantages of muscle-containing flaps over fasciocutaneous flaps for use in previously infected tissue beds or for fracture healing have been debated.

With progressive advancements in flap transfer techniques and in understanding of microvascular flap anatomy, plastic surgeons have steadily increased the number and variety of available flaps, thereby improving the results of flap reconstructions. In addition, this knowledge has reduced the morbidity associated with flap harvest. Perhaps the most important advancement in flap surgery within recent decades has been the introduction of the perforator flap.[11] Perforator flaps evolved from the observation that the muscle component of myocutaneous flaps served as a carrier of blood vessels to the overlying fasciocutaneous tissues. Prior to this, it had been deemed mandatory to include the muscle for reliable harvest of fasciocutaneous tissues supplied by musculocutaneous perforators, even if it was not necessary to include that muscle for the reconstruction. This unfortunately caused an unnecessary muscular deficit at the donor site, and for this reason, fasciocutaneous flaps that were supplied by musculocutaneous perforators instead of septocutaneous vessels were sometimes abandoned. The introduction of intramuscular retrograde dissection techniques, however, allowed the skeletonization of a musculocutaneous perforator from its encasement within a muscle belly, which spared that muscle from flap harvest and preserved its donor site function.[7,11] Further refinement of this concept gave rise to the harvest of cutaneous flaps based on any vessel that penetrated the fascia, which preserved the muscle (when the vessel was a musculocutaneous perforator) as well as the fascia (by suprafascial dissection). Within the last decade, free-style flap harvest has also been introduced.[12] With a handheld Doppler ultrasound probe, the surgeon is able to identify an arterial supply to almost any area of skin with the desired reconstructive characteristics and trace that pedicle in retrograde fashion along whatever direction it takes, preserving donor site fascia and muscle as necessary. Although the exact definition of what a perforator flap is remains contentious, its advantages

Table 45-6

Mathes-Nahai classification of muscular flaps

CLASSIFICATION	VASCULAR SUPPLY	EXAMPLE
Type I	One vascular pedicle	Gastrocnemius
Type II	Dominant and minor pedicles (the flap cannot survive based only on the minor pedicles)	Gracilis
Type III	Two dominant pedicles	Rectus abdominis
Type IV	Segmental pedicles	Sartorius
Type V	One dominant pedicle with secondary segmental pedicles (the flap can survive based only on the secondary pedicles)	Pectoralis major

Table 45-7

Nahai-Mathes classification of fasciocutaneous flaps

CLASSIFICATION	VASCULAR SUPPLY	EXAMPLE
Type A	Direct cutaneous vessel that penetrates the fascia	Temporoparietal fascial flap
Type B	Septocutaneous vessel that penetrates the fascia	Radial artery forearm flap
Type C	Musculocutaneous vessel that penetrates the fascia	Transverse rectus abdominis myocutaneous flap

remain clear: reduced donor site morbidity, reduced flap bulk, and increased flexibility in choosing desired flap components for reconstruction. The circulation of perforator flaps is axial in pattern; consequently, they can be transferred as pedicled island flaps or by microvascular free tissue transfer.

Free Tissue Transfer

A free tissue transfer, often referred to as a *free flap* procedure, is an autogenous transplantation of vascularized tissues. Any axial pattern flap with pedicle vessels of a suitable diameter can be transferred as a free flap. This involves three main steps: (a) complete detachment of the flap, with devascularization, from the donor site; (b) revascularization of the flap with anastomoses to blood vessels in the recipient site; and (c) an intervening period of flap ischemia. Flap circulation must be restored within a tolerable ischemia time.

Given the small diameter of most flap pedicle vessels (usually between 0.8 and 4.0 mm), these anastomoses are usually performed using an operative microscope that provides dedicated illumination and between 6× and 40× magnification. Any surgery performed with the aid of an operative microscope is termed *microsurgery;* such anastomoses are therefore termed *microvascular anastomoses.* High-magnification surgical loupes are usually used for flap harvest, especially for dissecting the flap pedicle, because they allow greater operator freedom. Aside from microvascular anastomosis, microsurgical techniques include microneural coaptation, microlymphatic anastomosis, and microtubular anastomosis.

The first successful free tissue transfer in humans was of a jejunal free flap for cervical esophagus reconstruction in 1957; however, the surgeons did not use microsurgery for the anastomoses. The first *microvascular* free tissue transfers in humans were carried out during the late 1960s and early 1970s. Free flaps were initially considered to be a last-resort option to reconstruct the most complex defects. However, as a result of improved microsurgical techniques and microinstrumentation, as well as proper patient and free flap selection and effective postoperative monitoring methods, the success rates have increased to exceed 95%.[13] Today, free tissue transfer is often the first-choice treatment for many defects and is no longer considered the last-ditch effort. It is now ubiquitously used in appropriate patients by reconstructive plastic surgeons worldwide.

The predetermining factor in free flap failure is occlusion of its blood supply due to thrombosis. As enumerated by Virchow's triad, any factors that alter normal laminar blood flow, cause endothelial damage, or change the constitution of blood (producing hypercoagulability) increase the risk of thrombosis (Table 45-8).[14] Avoidance of this complication, therefore, begins with a thorough patient evaluation for the presence of acquired or inherited thrombophilic tendencies. The patient's hemodynamic status influences that of the free flap and should be optimized. The effect of tobacco smoking on free flap success has been debated, with some larger retrospective studies reporting no difference in thromboembolic complications; however, smoking is well known to affect wound healing.[13,15] Smoking and the use of potentially vasoconstrictive agents, such as caffeine, should be avoided for several weeks before and after a free flap procedure. The restoration of normal laminar blood flow and avoidance of endothelial damage are addressed principally by careful flap insetting and meticulous microvascular surgical technique.

Planning a free flap goes beyond a simple calculation of matching flap and defect dimensions and tissue characteristics. The surgeon must, in addition, consider several important technicalities: what flap pedicle length and size are required (affected by flap choice); which recipient vessels to use; how to orient anastomoses (end to end or end to side), deal with mismatched donor and recipient vessel dimensions, overcome unhealthy donor and/or recipient vessels (e.g., traumatic dissection, scarred surgical field due to previous operation or radiotherapy), inset flap tissues (to maximize functional and cosmetic results without detriment to flap circulation), route the pedicle (to restore normal blood flow without pedicle kinking, twisting, or compression), position the patient (especially if the flap is to be inset over mobile soft tissue or joints), and place postoperative dressings (so as to produce no compression of the flap or pedicle); and what donor site morbidity will likely result (there is a risk-benefit decision between defect severity and flap choice).[16] In addition, the surgeon must have a suitable backup plan to overcome intraoperative troubles; for example, insufficient pedicle length can be addressed with an interpositional vein graft adjoining the donor and recipient vessels, and iatrogenic vessel injury or severely aberrant anatomy may necessitate use of a backup flap or backup recipient vessels.[13]

A clear understanding of the blood supply to the free flap and its tissue components is a prerequisite to harvesting a viable free flap. Pedicle vessels must be identified and protected and handled minimally and atraumatically to avoid thrombogenic factors (see Table 45-8). Meticulous technique also reduces the risk of vasospasm, but the latter can be ameliorated by topical lidocaine or papaverine should it occur. Critical vessels connecting flap components must also be recognized and preserved. Under microscope magnification, the donor and recipient

Table 45-8

Thrombogenic factors that can affect free flap pedicles and anastomoses

ALTERED LAMINAR BLOOD FLOW	ENDOTHELIAL DAMAGE	HYPERCOAGULABILITY
Tension or intimal malalignment at the anastomosis site; twisting, kinking, compression, or vasospasm of pedicle vessels	Iatrogenic damage (e.g., back-walled anastomotic suture, poor vessel handling, too many sutures)	Acquired thrombophilic tendency (e.g., pregnancy, paraneoplastic Trousseau's syndrome, antiphospholipid antibody syndromes)
Intraluminal structures (e.g., atherosclerotic plaque, venous valves, back-walled anastomotic suture)	Previous vessel damage (e.g., atherosclerosis, trauma)	Hereditary thrombophilias (e.g., activated protein C resistance, protein C/protein S deficiency, hyperhomocysteinemia)

vessels should be dissected back to health. The presence of, for example, venous valves, atherosclerotic plaques, intimal trauma, and intraluminal prolapse of adventitial tissue at or adjacent to the anastomosis site increases the risk of thrombosis. The vessel ends should be cleared of periadventitial tissues for 3 to 5 mm with sharp dissection under the microscope. Periadventitial dissection should be limited to this extent, so as to avoid potential devascularization of the vessel wall by removal of the vasa vasorum and prevent the subsequent delayed development of a perianastomotic pseudoaneurysm. Adventitiectomy also helps relieve vasospasm by increasing compliance of the vessel wall and by inducing a local sympathectomy effect. The vessel ends usually are stabilized with a double approximating microvascular clamp for anastomosis. Interrupted sutures or, less commonly, continuous sutures can accomplish the anastomosis. The microneedle typically has a three-eighths circle curvature and is between 30 and 150 µm in size. Its monofilament microsuture is usually between 9-0 and 11-0 caliber. The dimensions of the vessels to be anastomosed define the choice of microneedle and microsuture. Less commonly, suture alternatives such as fibrin adhesives or laser welding (these remain largely experimental) and mechanical anastomotic devices (e.g., venous couplers) may be used. Triangulating or bisecting suturing techniques can help to achieve an even placement of sutures. Normally, each suture should include the full thickness of both vessel walls, none should catch the opposite vessel wall (which causes disastrous luminal occlusion and intimal trauma), and the size of each bite should approximate the vessel wall thickness. The configuration of the anastomosis can be either end-to-end (Fig. 45-10), if the distal circulation can be adequately preserved, or end-to-side (Fig. 45-11), if the distal circulation must be preserved, as in the case of an extremity supplied by one dominant vessel. An end-to-side orientation may also be useful to overcome dramatically mismatched donor-recipient vessel dimensions. Whatever the method chosen, microanatomic differences between the vessels should be respected so as to achieve accurately approximated intimal surfaces in a tension-free anastomosis, devoid of redundancy that might promote kinking.[13]

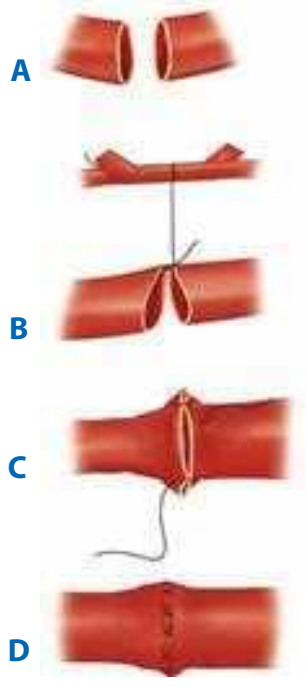

Figure 45-10. **A** through **D.** End-to-end anastomosis.

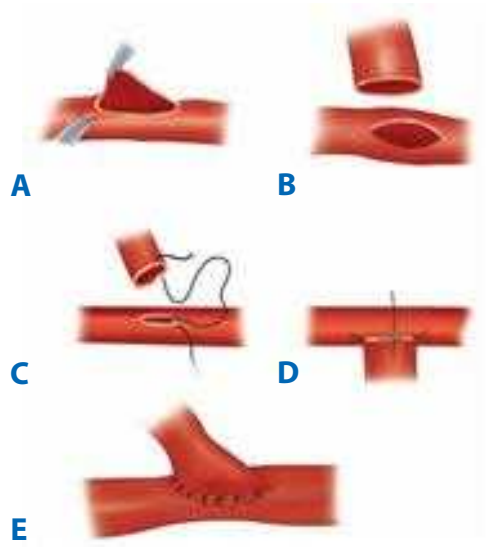

Figure 45-11. **A** through **E.** End-to-side anastomosis.

The clinical monitoring of a free flap should start during flap harvest, especially before its pedicle is divided. A free flap that is struggling to maintain normal perfusion characteristics during harvest most likely has insufficient circulation, which may be due to arterial or venous compromise or a combination of both (Table 45-9). Flap compromise may be due to reversible factors such as pedicle kinking, tensioning, or twisting; patient hemodynamic compromise; or an overly large flap harvest for the chosen pedicle vessels. If poor flap perfusion continues despite the absence or correction of all these factors, an inherent flap problem or a critical vascular injury to the flap or its pedicle must be considered, and it may not be safe to continue its harvest. This is one example of a situation in which a backup plan may require execution.

Clinical flap monitoring continues after successful restoration of arterial inflow and venous outflow. The mainstay of postoperative free flap monitoring is clinical assessment (see Table 45-9), although supplementary instrument monitoring

Table 45-9

Clinical signs of arterial and venous compromise in a free flap[a]

CLINICAL SIGN	ARTERIAL COMPROMISE	VENOUS COMPROMISE
Color	Becoming paler	Increasingly reddish or purplish
Temperature	Becoming cooler	Becoming warmer
Tissue turgor	Reducing	Increasing
Capillary refill time	Becoming slower	Becoming faster
Pinprick bleeding	Increasingly sluggish	Quickening (and darkening)

[a]Note that venous and arterial compromise may coexist, and one may lead to the other.

also can be helpful. Doppler ultrasound assessment of arterial and venous signals is useful for monitoring buried or concealed flaps. If flap perfusion was healthy before division of its donor site pedicle, then poor perfusion after anastomoses is likely due to either a technical error or insufficient systemic hemodynamics. The latter usually is correctable by ensuring that the patient and the patient's environment are suitably warm and by initiating intravenous colloid challenge or, if indicated, blood transfusion. Numerous potential technical errors, which have been described in the earlier paragraphs on planning and anastomosis technique, may occur. Routine postoperative patient monitoring includes measurement of total fluid inputs, urinary catheter output (which should be >1 mL/kg per hour), core temperature, and arterial blood pressure (systolic pressure should be >100 mmHg), as well as pulse oximetry. The patient and free flap are best monitored in an intensive care setting by experienced staff until both are stable enough for routine ward assessments.[17]

Occlusion of the anastomosis most commonly arises from intraluminal thrombosis or from external compression of the pedicle, such as from surrounding tissues, fluid accumulation (e.g., hematoma and tissue edema), or overly tight dressings or skin sutures. Because there is a threshold of ischemia beyond which a flap will sustain irreversible tissue and/or microcirculatory damage, it is important that the early signs of flap circulatory compromise be recognized as quickly as possible and the underlying problem diagnosed and corrected promptly if flap health is to be restored successfully.[17] Different tissues tolerate differing durations of ischemia in correlation with their tissue-specific basal metabolic rate. Although cooling free flaps (to reduce basal metabolic rate) has a variably protective effect in experimental settings, it appears that this practice contributes little to improving free flap success in the clinical setting as long as warm ischemia times are kept to <4 hours for most tissues; exceptions include bowel flaps, which are more susceptible to ischemia.[13]

Given that the predisposing factor for free flap failure is thrombus formation, it is understandable that plastic surgeons have looked to anticoagulant therapies in an effort to improve success rates. Although such drugs, including the dextrans, aspirin, heparins, and also some fibrinolytics, appear beneficial in experimental settings, large clinical trials have failed to show any conclusive associations between their use and either free flap success or failure rates.[18] It seems intuitive to use these drugs for failing free flaps as an adjunctive measure alongside operative reexploration and surgical intervention. The surgeon must be aware of their contraindications and recognize that their side effects, apart from bleeding, are occasionally serious. Venous congestion may be addressed by surgical measures as well as by application of medicinal *Hirudo medicinalis* leeches (with concomitant *Aeromonas hydrophila* prophylaxis) or by chemical "leeching" (topical heparin combined with dermal punctures).

Unfortunately, the "no-reflow" phenomenon is occasionally witnessed and leads to irreversible flap failure. This describes a situation in which no venous return drains into the pedicle vein of the flap, even though adequate arterial inflow passes the arterial anastomoses and is seen to enter the flap tissues. The no-reflow phenomenon sometimes follows an extended ischemic insult and appears to be a self-perpetuating cycle of endothelial cellular swelling, inflammatory vasoconstriction, impaired microcirculatory flow, stasis, microcirculatory thromboses, progressive ischemia, and flap failure.[13]

Despite these potential problems, free flap success rates exceed 95% in experienced hands. There is no doubt that increasing microsurgical experience is critical to improving free flap success rates. The laboratory setting is an excellent environment in which to progress beyond the early portion of one's learning curve through supervised microsurgical training and execution of microvascular anastomoses and microvascular free flap procedures in small animals.

Tissue Expansion

Although skin grafts and local flaps are very useful in reconstructing many superficial defects, they are not without their drawbacks. Both leave donor site defects with cosmetic and/or functional sequelae. Grafts are limited in color match and durability, whereas local flaps may supply insufficient tissue and produce contour irregularities. The advent of tissue expansion has created the potential to increase the amount of local, well-matched tissue that can be advanced or transposed as a flap while decreasing donor site morbidity.

The most common method of skin expansion involves the placement of an inflatable silicon elastomer balloon with an integrated or remote port beneath the skin and subcutaneous tissue followed by serial inflation with saline. After completion of expansion, usually over weeks to months, the expander is removed and the redundant overlying skin may be advanced into an adjacent defect. Expanders are available in a multitude of shapes and sizes that can be tailored to the reconstruction. In breast reconstruction, the tissue expander is replaced with a permanent implant instead of using the tissue as a flap to re-create the volume of the breast mound. Histologically, expanded skin demonstrates thickened dermis with enhanced vasculature and diminished subcutaneous fat. Studies have shown that the skin expansion is due not merely to stretch or creep but also to actual generation of new tissue.[19]

The technique of tissue expansion comes with its share of potential complications, including infection, hematoma, seroma, expander extrusion, implant failure, skin necrosis, pain, and neurapraxia. Furthermore, an inflated expander is a very visible, albeit temporary, deformity that may cause patients much distress.

Despite these imperfections, tissue expansion has become a major treatment modality in the management of giant congenital nevi, secondary reconstruction of extensive burn scars, scalp reconstruction, and breast reconstruction. The technique has permitted the plastic surgeon to perform reconstructions with tissue of similar color, texture, and thickness with minimal donor site morbidity.

PEDIATRIC PLASTIC SURGERY

Cleft Lip and Palate

Orofacial clefting is the most common congenital anomaly and is known to occur in 1 in 500 live white births.[20] The incidence is lower in African Americans and higher in Native Americans and Asians. Clefting of the lip and/or palate is felt to occur around the eighth week of embryogenesis, either by failure of fusion of the medial nasal process and the maxillary prominence or by failure of mesodermal migration and penetration between the epithelial bilayer of the face. The cause of orofacial clefting is felt to be multifactorial. Factors that likely increase the incidence of clefting include increased parental age, drug use and infections during pregnancy, smoking during pregnancy, and

a family history of orofacial clefting. The increased chance of clefting when there is an affected parent is approximately 4%.

The *primary palate* is defined as all tissue anterior to the incisive foramen, including the anterior hard palate (premaxilla), alveolus, lip, and nose. The secondary palate includes everything posterior to the incisive foramen, including the majority of the hard palate and the soft palate (velum). Clefting can involve the lip and nose, with or without a palatal cleft. Clefts of the lip and/or palate are first classified as unilateral or bilateral and then as complete or incomplete (Fig. 45-12). Complete clefts of the lip affect the entire lip and extend up into the nose. Incomplete clefts affect only a portion of the lip and contain a bridge of tissue connecting the central and lateral lip elements, referred to as *Simonart's band.*

Treatment Protocol. Considerable controversy remains over the details of the timing, technique, and protocol for treating children with orofacial clefting. The treatment protocol described in this chapter is accepted at many large cleft centers around the United States. All infants born with cleft-craniofacial anomalies benefit from care by a specialized team dedicated to the treatment of congenital anomalies. Today, this is widely accepted as the standard of care. Often, patients are seen prenatally after a diagnosis is made using sophisticated antenatal ultrasonography. The prenatal consultation has proven to be beneficial to parents, serving to dispel fears and uncertainties, and assuring them that treatment exists. After the infant's birth, a team evaluation occurs, and input is obtained from the surgeon, speech and language pathologist, social worker, craniofacial orthodontist, geneticist, otorhinolaryngologist, and pediatrician. For infants born with orofacial clefting, initial concerns relate to successful feeding and breathing. Infants with palatal clefts cannot generate negative pressure when suckling and therefore need milk dispensed into their mouths from a specialized nurser when they make suckling motions.

Once adequate nutrition and a safe airway are ensured, attention is turned to the cleft anomaly. Attempts to lessen the deformity and set the stage for the surgical repair of the lip and nose begin with a process known as *presurgical infant orthopedics (PSIO),* which includes procedures such as nasoalveolar molding (NAM) (Fig. 45-13). NAM repositions the neonatal alveolar segments, brings the lip elements into close approximation, stretches the deficient nasal components, and turns wide complete clefts into the morphology of narrow "incomplete" clefts. After PSIO with NAM, the definitive single-stage cleft lip and nose repair is performed at 3 to 6 months of age. With this initial operation, the lip deformity is repaired and a primary nasoplasty reconstructs the cleft lip nasal deformity. If the family does not have access to PSIO or have the resources for this time-intensive therapy, a cleft lip adhesion can be performed as an initial stage in the repair. The preliminary cleft lip adhesion unites the upper lip and nasal sill, truly converting complete clefts into incomplete clefts. A cleft lip adhesion is performed in the first or second month of life, and the definitive cleft lip and nose repair follows at 4 to 6 months. After the definitive cleft lip and nose repair, the cleft palate is repaired in a single stage at 9 to 12 months of age.

Unilateral Cleft Lip. The unilateral cleft lip is classically associated with a cleft lip nasal deformity. The cleft lip nasal deformity includes lateral, inferior, and posterior displacement of the alar cartilage. This results from the deficient and clefted underlying skeleton as well as the unopposed pull of the clefted orbicularis oris muscle abnormally inserted on the alar base (Fig. 45-14A). The maxillary minor segment (the smaller alveolar/maxillary segment on the clefted side) is collapsed medially. The process of unilateral cleft lip repair can be thought of as "philtral subunit reconstruction." The goal of the operation is to level Cupid's bow and reconstruct the central philtrum of the lip, ideally placing the incision and subsequent scar as close to the normal philtral

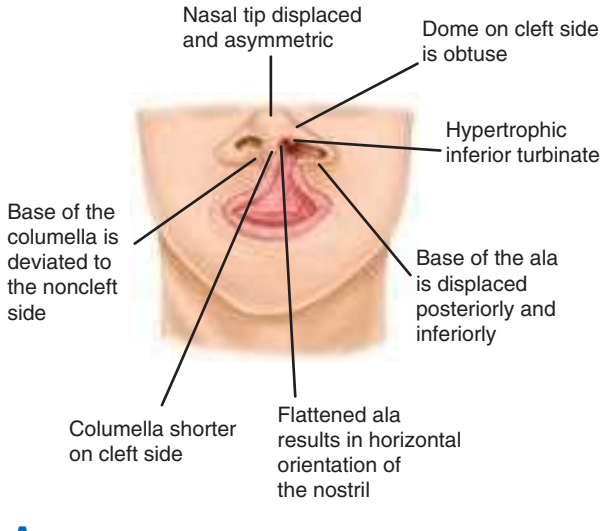

Figure 45-14. **A.** Unilateral cleft lip and nose deformity. **B.** The rotation-advancement repair.

column as possible. The surgical repair is performed under general anesthesia, and local anesthesia containing epinephrine is used. Many different techniques of cleft lip and nose repair have been proposed; however, most of the commonly used procedures are variations of a "rotation-advancement" procedure.[21] The rotation-advancement procedure, as championed by Millard (Fig. 45-14B), rotates the philtral subunit of the central lip downward to level Cupid's bow as the lateral lip element is advanced into the defect created by the downward rotation of the philtrum. Some surgeons choose to perform primary closure of the alveolar cleft at the time of primary lip and nose repair, called a *gingivoperiosteoplasty.* If the alveolar cleft is to be repaired, the gingivoperiosteoplasty is performed by raising mucoperiosteal flaps within the alveolar cleft margin and reapproximating them across the alveolar cleft defect. This creates a bony tunnel closed with periosteal flaps and facilitates the generation of bone in the alveolar defect. It is accepted today that some form of primary nasoplasty should be performed at the time of primary definitive lip repair. Techniques to release and reposition the nasal tip cartilages, as well as the ala, are performed with variations of tip rhinoplasties using suture methods. Some surgeons choose to use postoperative internal and/or external splints to maintain the nasal correction achieved at surgery during the healing process.

Bilateral Cleft Lip. In the complete bilateral cleft lip and nose deformity, the central lip element, called the *prolabium,* is entirely separate from the rest of the upper lip. The prolabium is displaced on top of the central alveolar segment, called the *premaxilla,* containing the unerupted four central incisors. Often, the premaxilla and prolabium are outwardly displaced. This is referred to as a *flyaway premaxilla.* For the child with a complete bilateral cleft lip and nose, PSIO is a very important step in preparing the child for definitive lip and nose surgery by retracting the premaxilla into the maxillary arch, repositioning the lip segments, and stretching the rudimentary columella. Bilateral cleft lip and nose repairs often are versions of straight-line repairs, with the Mulliken technique being the more commonly performed (Fig. 45-15). In the bilateral cleft lip deformity, the new philtrum is made from the prolabium and is united to the lateral lip elements on top of the repaired orbicularis oris muscle.[22]

Cleft Palate. During the eighth to twelfth weeks of gestation, the mandible becomes more prognathic, the tongue drops from beneath the clefted lateral palatine processes, and the palatal

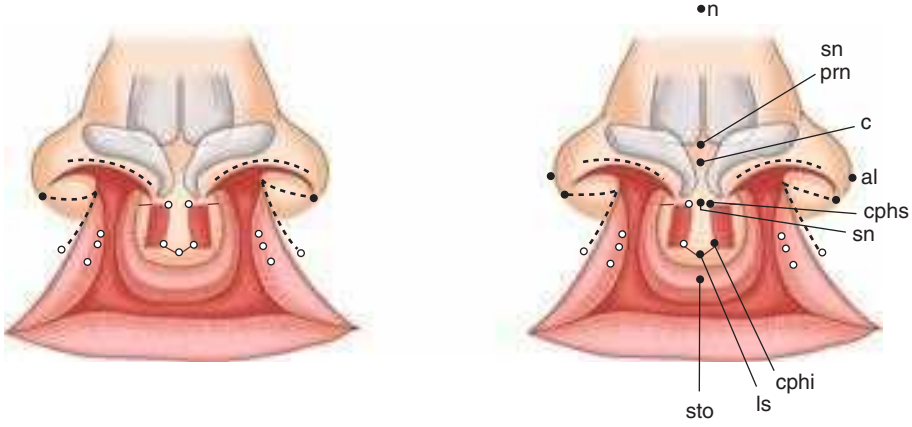

Figure 45-15. Mulliken bilateral cleft lip and nose repair. al = ala nasi; c = highest point of columella nasi; cphi = crista philtri inferior; cphs = crista philtri superior; ls = labiale superius; n = nasion; prn = pronasale; sn = subnasale; sto = stomion.

shelves migrate upward into a more horizontal position and fusion occurs. A cleft palate results from the failure of fusion of the two palatal processes. As with labial clefting, isolated clefts of the palate are multifactorial in etiology, and isolated clefts of the palate are more likely to be associated with other anomalies. Between 8% and 10% of isolated clefts of the palate are associated with the 22q deletion of velocardiofacial syndrome.[23]

The main goal of cleft palate surgery is to help the patient attain normal speech, which results from velopharyngeal competence. During speech, the soft palate, or velum, is moved posteriorly and superiorly, primarily by the levator palatini muscle sling that suspends the velum from the skull base. Velopharyngeal competence is obtained during attempted speech when the velum approximates the posterior pharyngeal wall, preventing air and liquid from regurgitating into the nasal cavity. Velopharyngeal competence allows intraoral pressure to be built up for speech sounds. A cleft palate precludes this from occurring and results in velopharyngeal incompetence (VPI). Because it is impossible for the oral and nasal cavities to be partitioned in the patient with a cleft palate, it is also difficult for the patient to develop negative intraoral pressure for an effective suck. Therefore, specialized nursers are used to dispense liquid into the infant's mouth during the suckling motions. Children with clefts of the palate have an increased incidence of otitis media; this may be related to the abnormality of the velar musculature and ineffective function of the eustachian tube. The increased incidence of otitis media can result in hearing loss if not treated appropriately. In addition, VPI and nasal air escape during speech results in hypernasal speech.

As with the repair of cleft lip and nose, the timing, technique, and protocols for cleft palate repair are controversial. Most agree that palate repair should be performed before the development of speech. The cleft palate usually is repaired when the infant is between 6 and 18 months of age. Cleft palate repair also is performed under general anesthesia, with the head slightly hyperextended and a retractor, such as the Dingman mouth gag, placed intraorally to retract the tongue and endotracheal tube. An epinephrine solution is injected into the palate. Techniques of hard palate closure include the use of unipedicled hard palate mucoperiosteal flaps as in the Wardill-Veau-Kilner repair or bipedicled hard palate mucoperiosteal flaps as in the von Langenbeck repair. Both the unipedicled and bipedicled hard palate palatoplasty techniques rely on the greater palatine neurovascular pedicle. Soft palate or velar closure techniques are divided into straight-line and Z-plasty procedures. With either a straight-line or Z-plasty velar repair, the levator palatini muscle should be independently repaired; this is called an *intravelar veloplasty.* The clefted levator is identified coursing sagittally in an anterior-posterior direction, abnormally inserted onto the posterior edge of the hard palate. In intravelar veloplasty, it is released from the posterior edge of the hard palate in the midline and dissected free from abnormal attachments to the aponeurosis of the tensor veli palatini muscle and superior constrictor laterally. After its complete release, the levator palatini muscle is united in the midline, with reconstruction of the levator muscle sling that suspends the velum from the skull base and aids in velopharyngeal competence.

The authors prefer the double opposing Z-plasty technique of soft palate or velar reconstruction known as the *Furlow palatoplasty.*[24] The procedure uses four triangular flaps, two oral and two nasal, with the posteriorly based flaps containing the released levator muscles. The Z-plasty lengthens the soft palate, prevents longitudinal scarring from a straight-line repair, and produces a secondary pharyngoplasty effect by narrowing the velopharyngeal port (Fig. 45-16).

Complications of palatoplasty include wound healing problems resulting in a breakdown of the suture line and the development of a fistula. The literature reports fistula rates ranging from approximately 1% to 20%. Treatment of palatal fistulae is particularly challenging, because the recurrence rates have been noted to approach 96%. The second most common complication of palatoplasty is the incomplete correction of speech and the development of postoperative VPI. The literature reports postoperative VPI rates ranging from 10% to 40%. Some of the best rates of velopharyngeal competence have been reported with the Furlow double opposing Z-plasty palatoplasty. Postoperative VPI is treated with pharyngoplasty—either a posterior pharyngeal flap pharyngoplasty or a sphincter pharyngoplasty. A posterior pharyngeal flap is a static flap formed from the posterior pharyngeal wall including mucosa and a portion of the superior constrictor muscle. The midline superiorly based pharyngeal flap is inset into the posterior free edge of the soft palate, permanently attaching it to the posterior pharyngeal wall. The sphincter pharyngoplasty has been reported to involve creation of a dynamic sphincter made with the bilateral posterior tonsillar pillars containing the palatopharyngeus muscle. The superiorly based tonsillar pillars are elevated from the lateral pharynx and inset into a horizontal incision on the posterior pharyngeal wall at the level of the adenoid pad.

Craniofacial Anomalies

History, Overview, and Classification System. Craniofacial surgery is the subspecialty of plastic surgery dealing with hard and soft tissue deformities of the craniofacial skeleton, treating the congenital, developmental, and acquired defects of the cranial and/or facial skeleton. Craniofacial surgery addresses the functional and equally important appearance-related issues surrounding these deformities. Attempting to separate the functional impairment from the appearance-related issues is arbitrary, because it can be argued that the most important function of a face is to look like a face.[25] Numerous studies have established the importance of facial form and the significant emotional impact that facial deformities have on a person's life and sense of self.

The field of craniofacial surgery finds its origins in the aftermath of the world wars and the need to treat massive facial injuries. In 1967, Dr. Paul Tessier, now recognized as the father of craniofacial surgery, first publicly presented his concepts of using wide exposure and a transcranial route to treating craniofacial deformities with large segmental movements of bone. An American disciple of Dr. Tessier, Dr. Linton Whitaker of the Children's Hospital of Philadelphia, working with the Committee on Nomenclature and Classification of Craniofacial Anomalies of the American Cleft Palate-Craniofacial Association, presented a simple and practical classification system for craniofacial anomalies (Table 45-10).

It is the standard of care today that an interdisciplinary team of experts with specialized knowledge and training in treating children with craniofacial anomalies care for children who have such anomalies. The preoperative workup and evaluation must be thorough and should include imaging (computed tomography [CT], magnetic resonance imaging [MRI], and cephalography), photography, blood work, anesthesia consultation, and other components as the condition dictates. Craniofacial procedures are often long, complicated surgeries of significant magnitude, with an attendant risk of blood loss, serious morbidity, and even mortality. Significant blood loss is a realistic possibility, and

preparation for blood conservation and transfusion must be made. The routine surgical approach to the craniofacial skeleton can be via a coronal incision, and after a bifrontal craniotomy, the orbital and facial skeleton can be addressed. Bone grafts for reconstruction can be split calvarial grafts or, alternatively, grafts from the ribs or iliac crest. Rigid fixation is obtained with bioresorbable plates, screws, and sutures. Despite the magnitude of the procedures, significant morbidity (e.g., blindness, brain injury, significant infection, cerebrospinal fluid leak, intracranial hematoma) or mortality is rare.

Craniofacial Clefts. The rare craniofacial clefts have been subclassified by Tessier (Fig. 45-17). The Tessier classification

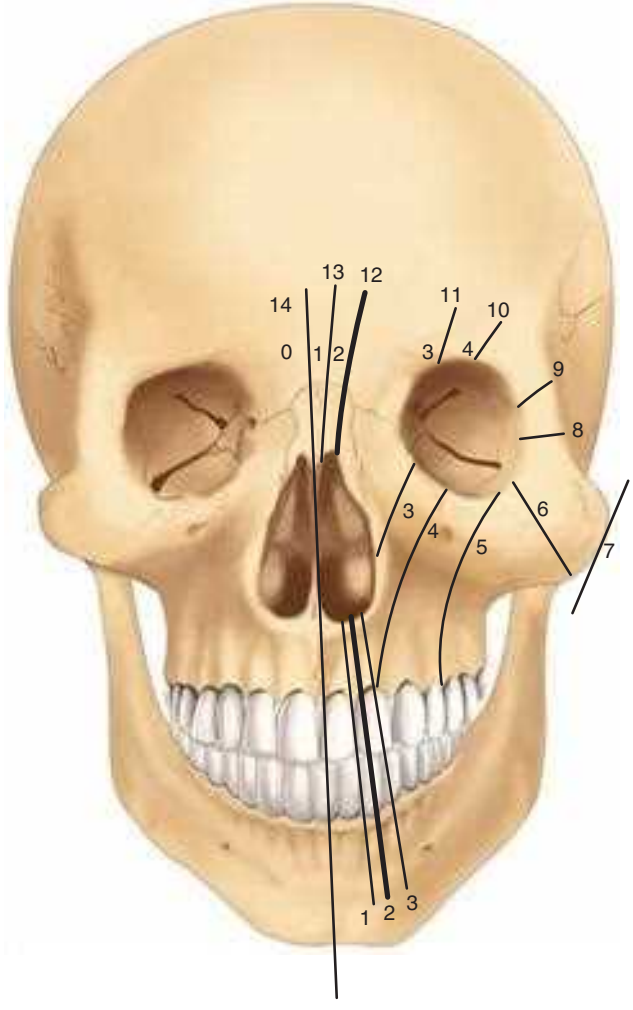

Figure 45-17. Tessier's classification of craniofacial clefts.

Figure 45-18. Craniofacial cleft. *(Reproduced with permission from Losee J, Kirschner R, eds.* Comprehensive Cleft Care. *1st ed. New York: McGraw-Hill Professional; 2008, Chap. 27, Fig. 3. Copyright © The McGraw-Hill Companies, Inc.)*

of craniofacial clefts considers the orbit as the center around which the clefts radiate as the spokes of a wheel, numbered from 0 to 14. The facial clefts (0 to 7) and their cranial extensions (8 to 14) are often associated and total 14 (Fig. 45-18). Treacher Collins syndrome (Fig. 45-19), also known as *mandibulofacial dysostosis,* is a type of craniofacial clefting disorder representing bilateral 6-7-8 clefts. This autosomal dominant disorder with variable penetrance has the following manifestations: hypoplasia of the zygomas, asymmetry and hypoplasia of the mandible, ear anomalies, and colobomas of the lower eyelids. Craniofacial microsomia, also known as *hemifacial microsomia,* can be classified as a form of clefting as well (Fig. 45-20). Manifestations of this anomaly usually involve the hard and soft tissue of one half of the craniofacial skeleton. Deformities range in severity from complete absence of an affected facial component (globe, mandible, ear) to mild asymmetries. Ear deformities range from complete absence of the ear to only preauricular skin tags. Similarly, the eye deformities range from complete absence of the globe to various anomalies including epibulbar dermoids. Hypoplasia of the temporal skull, maxilla and zygoma, and orbit are seen in varying degree and affect the underlying skeleton as well as the overlying soft tissues. The classical deformity of hemifacial microsomia affects the mandible. Hypoplasia of the hemimandible, as well as the maxilla, results in dental malocclusions (Fig. 45-20C). Mandibular hypoplasia may range from

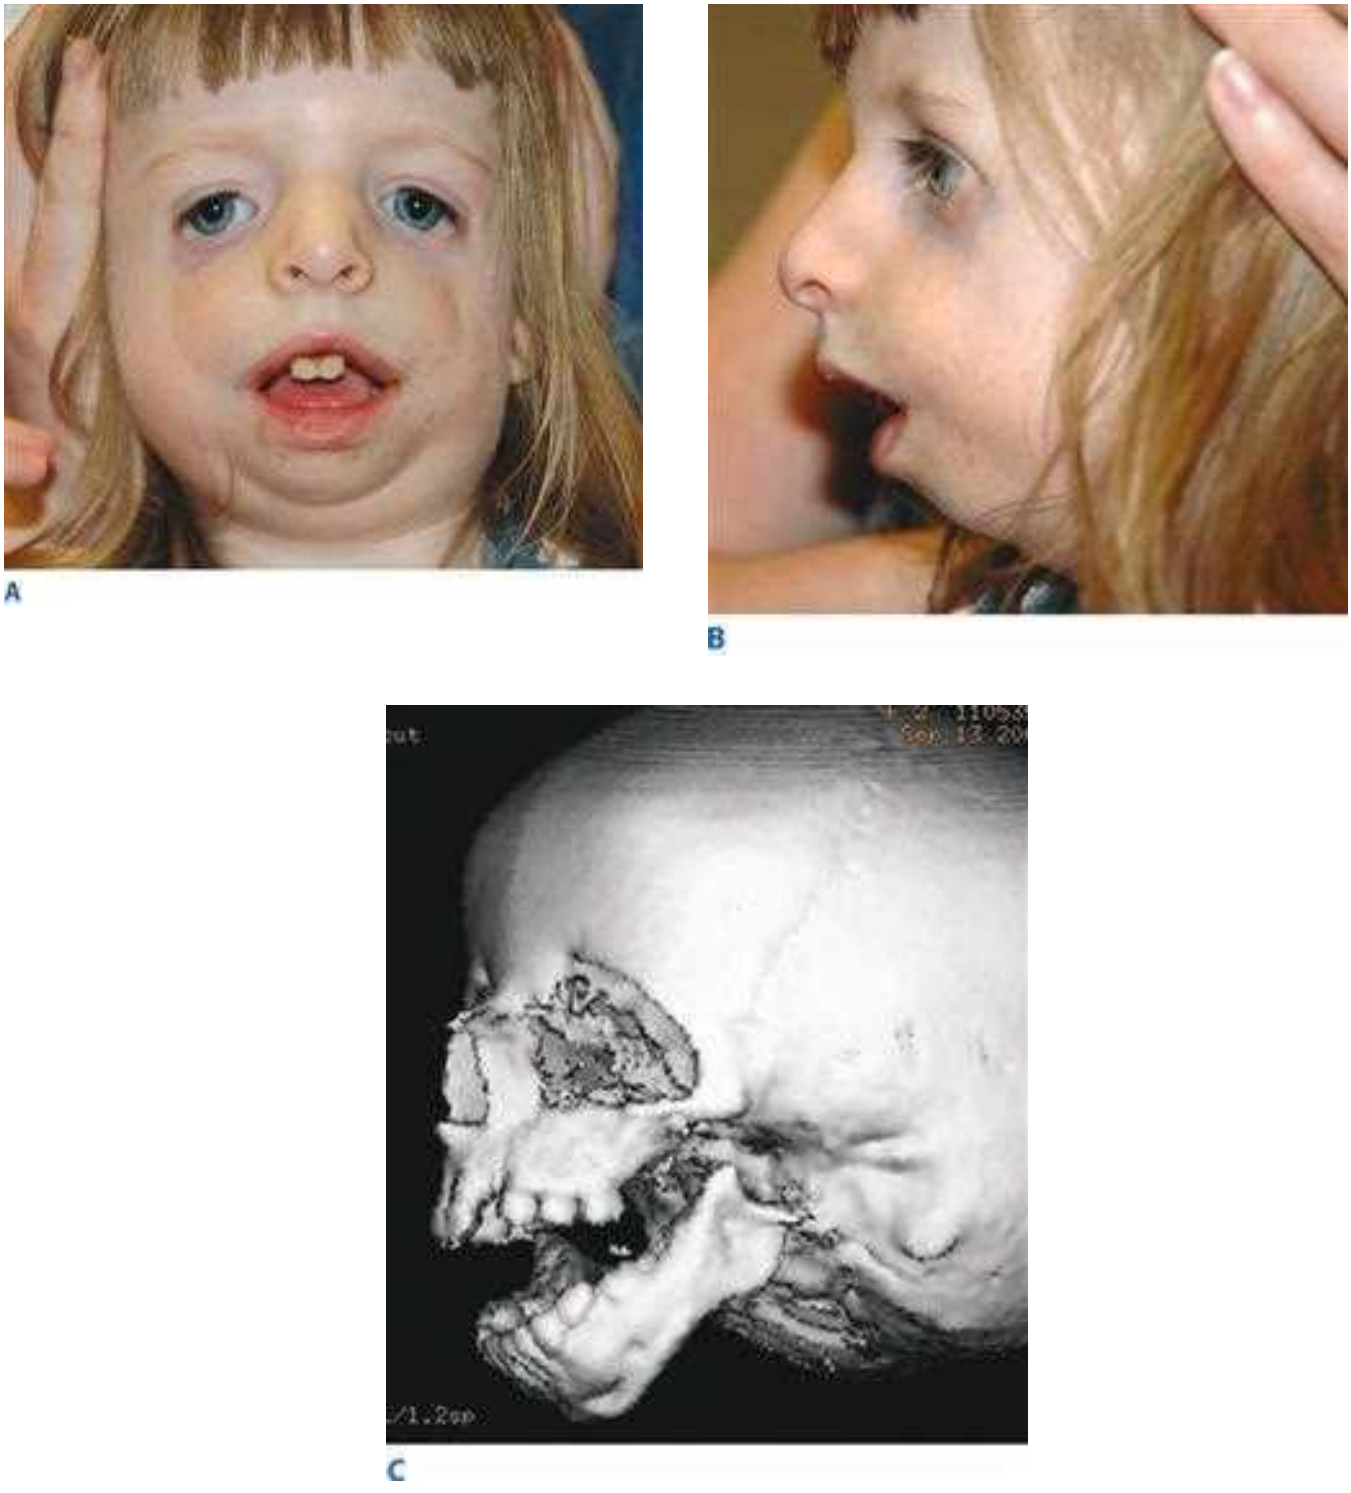

Figure 45-19. Child with Treacher Collins syndrome. **A.** Frontal view. **B.** Lateral view. **C.** Three-dimensional computed tomographic scan of the craniofacial skeleton.

minor underdevelopment of otherwise normal components to complete absence of the condyle, ramus, and proximal body.

Treatment of hemifacial microsomia includes management of the airway and attention to other functional conditions. Treatment of the mandibular deformity includes distraction osteogenesis during growth and orthognathic procedures at skeletal maturity. Ear deformities are reconstructed with techniques using costal cartilage and local soft tissue. Soft tissue deficiencies of the hemiface can be treated with fat injections, dermal-fat grafts, or free tissue transfer. Orbital hypertelorism is yet another type of midline craniofacial (0-14) clefting. *Orbital hypertelorism* is defined as a lateralization of the entire orbit, increasing the intraorbital distance and resulting from midline conditions such as encephaloceles, frontonasal dysplasia, and syndromic craniosynostosis. The treatment of severe orbital hypertelorism includes a transcranial approach to four-wall

orbital box osteotomies, resection or treatment of the abnormal midline process, mobilization, medialization of the orbital complexes, and nasal reconstruction with a cantilever nasal bone graft.

Craniosynostosis. The craniosynostoses are a group of disorders that result from the abnormal obliteration or premature fusion of the cranial sutures. The craniosynostoses can be subdivided into simple or single-suture craniosynostoses, and complex, syndromic, or multiple-suture craniosynostoses. The cranial sutures allow for the normal growth of the skull, and therefore, the classic presentation of craniosynostosis is an abnormal head shape. The resultant abnormal head shapes are secondary to an inhibition of skull growth at right angles to the fused suture and a compensatory overexpansion of the skull perpendicular to the fused suture into areas with open sutures. These abnormal head shapes provide a basis for the classification of craniosynostoses. In addition to appearance-related deformities resulting from craniosynostosis, important functional aspects include the potential for intracranial hypertension, which may result from brain growth restricted by an unyielding skull. The chances of intracranial hypertension increase with the number of sutures affected. Blindness and mental deficiencies secondary to an increase in intracranial pressure can likely be prevented by the surgical expansion of the cranium to release the fused suture, correct the abnormal head shape, and remodel the skull. The standard procedure used today in the correction of these synostotic deformities is fronto-orbital advancement. Fronto-orbital advancement, performed using a transcranial approach, includes a frontal craniotomy and orbital repositioning. The complex or multisutural synostoses are often syndromic, resulting from gain-of-function mutations of the fibroblast growth factor receptors (*FGFR1, FGFR2, FGFR3*). These syndromes of craniosynostosis include Apert's, Crouzon's, Pfeiffer's, and Saethre-Chotzen syndromes. The syndromic craniosynostoses not only include bicoronal synostosis but also involve the midface, with resulting exorbitism and midface hypoplasia. Multilevel airway anomalies, obstructive sleep apnea, corneal exposure, intracranial hypertension, feeding difficulties, and severe malocclusion are some of the associated anomalies found in children with syndromic craniosynostoses. In addition to fronto-orbital advancement, facial osteotomies (i.e., Le Fort III craniofacial disjunction) are required to treat the orbital, midfacial, and occlusal deformities.

Atrophy and Hypoplasia. The categories of craniofacial atrophy and hypoplasia encompass many conditions such as Pierre Robin sequence and Romberg's progressive hemifacial atrophy. Pierre Robin sequence is characterized by three pathognomonic findings: microretrognathia, glossoptosis, and respiratory distress. Pierre Robin sequence may or may not be associated with a palatal cleft. It is thought by some to occur secondary to a fixed and flexed fetal head position that inhibits mandibular growth and results in micrognathia. The micrognathia prevents the natural caudal migration of the tongue from between the clefted palatal shelves, and the resulting deformity as described earlier. The functional consequences include intermittent respiratory obstruction and obstructive sleep apnea that may affect feeding, growth, and safety of the airway. Treatment of a child mildly affected with Pierre Robin sequence may include simply positioning the child prone until the child "grows out" of the condition. However, if the child is severely affected and unable to feed adequately or has an unsafe airway, surgical intervention

is required. For decades, tracheotomy was the initial and definitive treatment of choice; however, today many initially attempt a tongue-lip adhesion, treating the glossoptosis and alleviating respiratory obstruction by suturing the tongue tip to the lower lip. The tongue-lip adhesion is taken down at the time of palatoplasty. Should the tongue-lip adhesion not adequately correct the obstruction, then neonatal mandibular distraction can be used to correct the underlying microretrognathia and relieve the obstructive symptoms (Fig. 45-21). Another syndrome of atrophy and hypoplasia is Romberg's progressive hemifacial atrophy, also known as *Parry-Romberg syndrome* (Fig. 45-22). Romberg's disease is a disorder of unknown etiology, beginning in childhood or adolescence, in which hemifacial atrophy of the skin, subcutaneous fat, muscle, bone, and cartilage progresses for a variable period of time before spontaneously ceasing or "burning out" 2 to 10 years after beginning. Most believe treatment should be delayed until at least 1 year after the process of atrophy has ceased. Some hematologists and oncologists have treated the early presentation of Romberg's disease with chemotherapy. After the cessation of atrophy, reconstruction of the craniofacial skeleton and soft tissues may begin with bone and/or cartilage grafts, alloplastic implants, dermal-fat grafts, fat grafting, and possibly free tissue transfers.

Hyperplasia, Hypertrophy, and Neoplasia. The categories of craniofacial hyperplasia, hypertrophy, and neoplasia encompass a wide variety of conditions affecting the craniofacial skeleton. These include vascular anomalies (discussed later in this chapter), neurofibromatosis, hemifacial hypertrophy, and bony conditions such as osteomas and fibrous dysplasia. Fibrous dysplasia can be monostotic, affecting a single location, or polyostotic, affecting more than a single location in the skeleton; it may be associated with skin pigmentation abnormalities and endocrine involvement, and be termed *polyostotic* or *McCune-Albright syndrome.* Treatment of fibrous dysplasia of the craniofacial skeleton includes block resection and reconstruction with bone grafts. If extensive involvement exists and block resection is not possible or feasible, partial resection and contouring of the affected bone is possible, as long as there is the understanding that long-term outcomes and the behavior of the disease are unpredictable.

Vascular Anomalies

Vascular anomalies are vascular birthmarks that all appear similar: flat or raised, in various shades of red and purple.[26] For centuries, they have been named by similarly colored food and drink (i.e., strawberry hemangioma, port-wine stain). Today these vascular birthmarks have been biologically classified as either *hemangiomas* or *vascular malformations.* The Greek suffix *-oma* means "swelling" or "tumor" and today connotes a lesion characterized by hyperplasia. Hemangiomas are congenital vascular anomalies that undergo a phase of rapid growth followed by slow regression, based on endothelial cell kinetics. Malformations are abnormal vascular channels lined with quiescent endothelium, usually are seen at birth, never regress, and have the potential to expand. The differential diagnosis of vascular anomalies is routinely made by a detailed accurate history and clinical examination. For deep lesions, radiographic studies may help determine the diagnosis. Biopsy is used if the diagnosis is uncertain or there is concern over the potential of malignancy.

Hemangiomas. The infantile hemangioma is the most common birthmark, affecting 10% to 12% of whites, with a 3:1 to 5:1 predilection for females and an increased incidence in

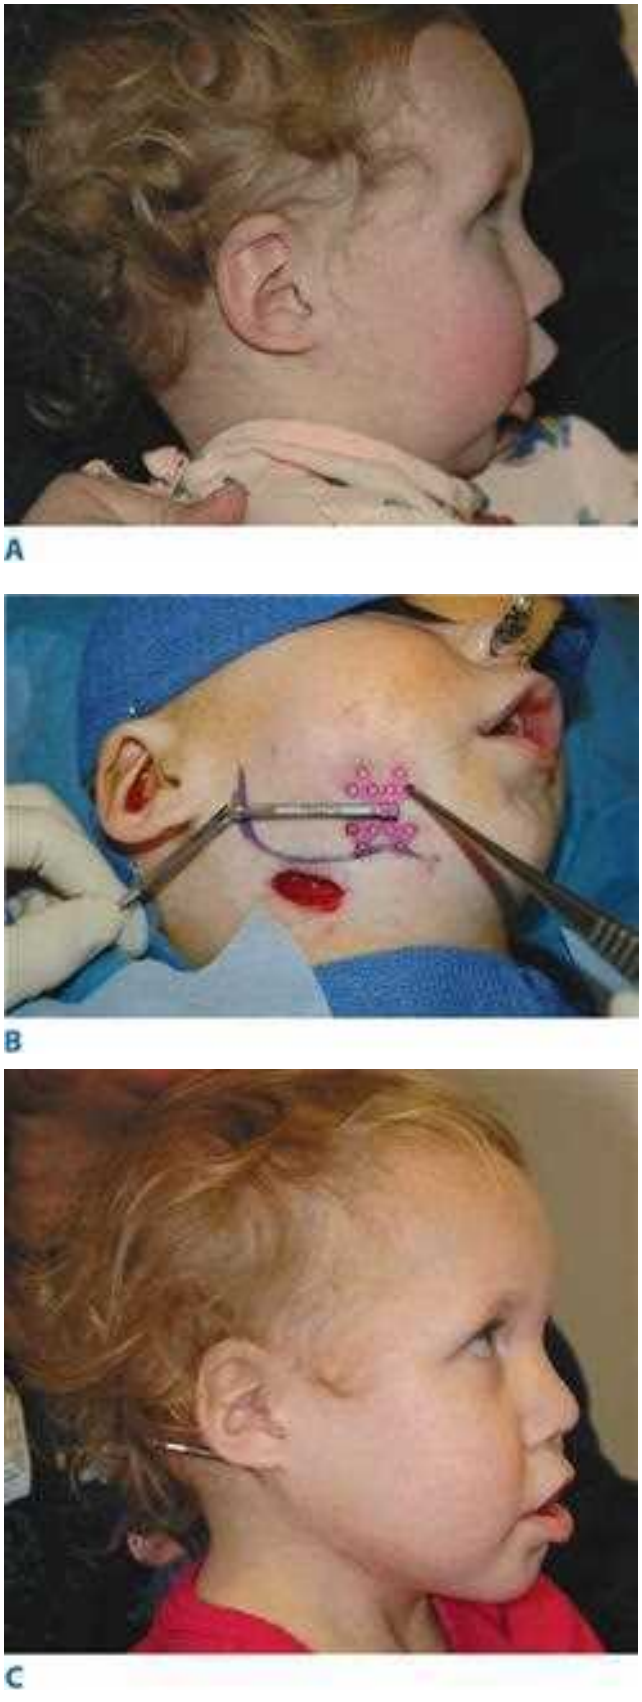

Figure 45-21. A. Lateral view of a child with Pierre Robin sequence and mandibular microretrognathia. **B.** Intraoperative photo of a submandibular incision and planning for the placement of a buried mandibular distractor. **C.** Lateral view of the child after mandibular distraction with slight overcorrection of retrognathia. The distractor is still in place as evident from the activating rod seen exiting the skin retroauricularly.

Figure 45-22. Frontal view of a child with left-sided Romberg's progressive hemifacial atrophy.

preterm infants (23%) (Fig. 45-23). Hemangiomas are solitary in 80% of cases and multiple in 20%. In children with multiple (more than three) cutaneous hemangiomas, abdominal ultrasound is suggested to rule out hemangiomatosis with visceral involvement. Hemangiomas do not cause bleeding disorders; however, more invasive lesions such as kaposiform hemangioendothelioma can result in Kasabach-Merritt syndrome, characterized by platelet trapping and disordered bleeding.

Hemangiomas are usually first noted around 2 weeks of life as a flat pink spot, often confused with a superficial scratch.

Figure 45-23. Hemangioma of the ear and retroauricular region.

Around the second month of life, they enter the *proliferating phase* in which rapid growth is seen caused by plump, rapidly dividing endothelial cells. If the hemangioma is superficial, the skin becomes crimson and raised; if the lesion is deep, a dark blue or purple color is noted with less superficial swelling. Hemangioma growth frequently peeks before the first year, and then the lesions enter the *involuting phase* in which growth is commiserate with the child. The involuting phase is characterized by diminishing endothelial activity and luminal enlargement. The lesion begins to "gray," losing its intense reddish color and taking on a purple-gray shade with overlying "crepe paper" skin. The involution phase continues until 5 to 10 years of age. Regression of the lesion is then complete. The *involuted phase* begins in 50% of children by 5 years of age and in 70% by 7 years. If there was cutaneous ulceration during the proliferative phase, a cutaneous scar may persist, along with the yellow-gray crepe paper–like skin with fibro-fatty deposition. In 50% of children, near-normal skin is restored.

The treatment of hemangiomas is largely observational, with reassurance of parents that regression and involution will occur. Cutaneous ulceration secondary to a proliferating hemangioma occurs in 5% of cases and more frequently with lip or urogenital lesions. Local wound care, topical application of lidocaine for pain, and laser cauterization may be beneficial treatment modalities. Problematic or endangering hemangiomas (i.e., periocular lesions threatening amblyopia, airway lesions, facially disfiguring lesions) occur in 10% of cases. The first-line treatment for problematic hemangiomas is systemic corticosteroid therapy, which is particularly effective (85% response rate). Second-line therapies include interferon and vincristine, each with its own attendant effectiveness and morbidity. Laser therapy has been claimed by some to be effective in the treatment of early hemangiomas; however, there has been no conclusive proof that laser therapy either diminishes lesion bulk or induces involution. Laser therapy has been effective in lightening affected skin. Surgery for hemangiomas in the proliferating phase is largely limited to treatment of problematic lesions (i.e., eyelid lesions threatening amblyopia). Hemangioma surgery usually is reserved for the treatment of secondary deformities and residual fibro-fatty depositions, among other indications.

Vascular Malformations. Vascular malformations are subclassified by vessel type, such as lymphatic, capillary, venous, or arterial, and by rheologic characteristics, such as slow flow and fast flow. Slow-flow lesions include capillary malformations (CMs) and telangiectasias, lymphatic malformations (LMs), and venous malformations (VMs). Fast-flow lesions include arterial malformations (AMs) and arteriovenous malformations (AVMs). In addition, there are combined malformations. One such combined lesion occurs in Klippel-Trénaunay syndrome in which CMs, LMs, and VMs are found and may be associated with soft tissue and skeletal hypertrophy in one or more of the limbs (Fig. 45-24A).

CMs are pink-red macular vascular stains that are present at birth and persist throughout life. These lesions tend to become more verrucous and darker throughout life. CMs are effectively treated with a pulsed-dye laser, and the results often are better with treatment in infancy and young childhood. Laser therapy often is repetitive and prolonged. CMs of the head and neck, historically called *port-wine stains,* may be associated with Sturge-Weber syndrome, which includes vascular involvement of the leptomeninges and ocular pathology (Fig. 45-24B).

A

B

C

D

Figure 45-24. **A.** Klippel-Trénaunay syndrome, with combined vascular anomaly (capillary malformation, lymphatic malformation, venous malformation) of the leg. **B.** Sturge-Weber syndrome, with V1 and V2 capillary malformation of the left face. **C.** Lymphatic malformation of the neck, previously referred to as *cystic hygroma.* **D.** Venous malformation of the forehead.

LMs are anomalous lymphatic channels that never regress and have the potential to affect underlying muscle and bone, causing significant swelling and bony overgrowth. They have historically been called *lymphangiomas* or *cystic hygromas* (Fig. 45-24C). LMs can be classified as microcystic, macrocystic, or both. LMs expand or contract with the flow of lymph, infection, or intralesional hemorrhage. Superficial LMs that affect the skin often produce cutaneous vesicles that may coalesce and weep lymph fluid. Sclerotherapy remains a major treatment modality for LMs, and lesions that are macrocystic can be aspirated before sclerotherapy. Although surgery rarely removes the entire lesion, surgical resection is the only possibility for cure. These resections often are challenging, lengthy, and associated with significant blood loss, and the potential exists for regeneration of lymph channels and recurrence of the LMs postoperatively.

VMs are frequently bluish, soft, and compressible, and swell when dependent (Fig. 45-24D). VMs grow with the child, expand slowly, and may enlarge during puberty. Patients often complain about stiffness and pain with thrombosis. VMs can affect the skin, muscle, and bone. MRI is the modality of choice for imaging these lesions. Preoperative sclerosis followed by surgical extirpation is the treatment of choice for VMs that cause functional or appearance-related disability. VMs have the tendency to recanalize and re-expand. Use of elastic support stocking and low-dose aspirin therapy are important adjunctive treatment modalities for VMs involving the legs.

Pure AMs are rare and more commonly present as AVMs. AVMs appear as red violaceous skin with a palpable mass beneath. Local warmth, bruit, and thrill are frequently present. AVMs have the likely consequences of ischemic changes, ulceration, intractable pain, and intermittent bleeding. The natural history of AVMs has been described as consisting of four stages: quiescence, expansion, destruction, and decompensation. Usually, treatment for AVM is initiated when signs and symptoms of ischemic pain, ulceration, bleeding, or hemodynamic instability (stages 3 and 4) are evident. Surgical treatment includes arterial embolization to temporarily occlude the nidus 24 to 72 hours before surgical extirpation. The nidus and overlying affected skin must be widely excised, and reconstruction can be performed afterward.

Congenital Melanocytic Nevi

Congenital melanocytic nevi (CMNs) contain nevus cells and are usually present at birth. Lesions are frequently light to dark brown and round or oval, and vary greatly in size, pattern, and anatomic location. The most common location of CMNs is the trunk, followed by the extremities and head and neck. Frequently, larger lesions are associated with multiple smaller satellite lesions. Over time, these lesions may become less (or sometimes more) pigmented and develop hypertrichosis and a variegated texture, including nodularity. Small CMNs are <1.5 cm in diameter, and large ones are >10 cm. Giant CMNs usually are >20 cm in their greatest dimension in adulthood, and this correlates with a 9-cm scalp lesion or a 6-cm trunk lesion in an infant. All CMNs should be monitored for worrisome changes that indicate the need for biopsy, including ulceration, uneven pigmentation, change in shape, and nodularity. There is controversy over the actual incidence of malignant transformation of CMNs; however, most experts believe that melanoma may arise directly from a CMN. No convincing study to date has proven that excision of a CMN reduces the rate of malignant transformation to melanoma; however, many clinicians feel that excision serves at least to debulk the lesion. The reported lifetime risk for melanoma arising in small or large CMNs is between 0% and 5%; the risk for giant CMNs is estimated to be between 5% and 10%.[27] In addition to being at risk for melanoma, patients with large or giant CMNs are at risk for neurocutaneous melanocytosis (leptomeningeal melanosis), and this condition includes collections of melanocytes in the leptomeninges. Neurocutaneous melanocytosis carries a lifetime nonreducible risk of central nervous system melanoma and other morbidity and mortality from seizures, hydrocephalus, and other central nervous system conditions. MRI screening for infants born with large or giant CMNs is recommended to make the diagnosis of neurocutaneous melanocytosis.

Many different treatments have been advocated for the child with CMN; however, the overwhelming goals are to remove (or at least reduce) the risk of malignant transformation, preserve function, and improve cosmesis. Dermabrasion, chemical peels, and laser therapy have been reported to improve the appearance; however, none of these modalities completely removes nevus cells. To address malignant potential, only complete excision is a possible solution, and this is difficult, because nevus cells may extend beyond the skin and into the deep subcutaneous tissue and even the underlying muscle. The surgical options include direct excision and primary closure, serial excision, excision and skin grafting, and staged tissue expansion with subsequent lesion excision and flap reconstruction (Fig. 45-25). Treatment options have particular indications with respect to the location of the nevus. Scalp lesions are best treated with tissue expansion. Full-thickness skin grafting is best used for ear and eyelid reconstruction. Tissue expansion is associated with increased morbidity in lower extremity reconstruction, and therefore excision and grafting, even with previously expanded full-thickness skin grafts, is often the treatment of choice. In summary, CMNs often are treated surgically to decrease the risk of malignant degeneration to melanoma as well as to correct the significant appearance-related deformity.

4▶ RECONSTRUCTIVE SURGERY

Facial Reconstruction after Fracture

General Principles. As technologic advances raise the level of energy involved in modern systems of transportation, recreation, and weaponry, so follow increases in the degree of maxillofacial destruction related to misadventures with this technology. The first phase of care for the patient with maxillofacial trauma is activation of the advanced trauma life support protocol. Concomitant injuries beyond the face are the rule rather than the exception. The most common life-threatening considerations in the facial trauma patient are airway maintenance, control of bleeding, identification and treatment of aspiration, and identification of other injuries. Once the patient's condition has been stabilized and life-threatening injuries treated, attention is directed to diagnosis and management of craniofacial injuries.

Physical examination of the face with attention to lacerations, bony step-offs, instability, tenderness, ecchymosis, facial asymmetry, and deformity guides the examiner to underlying hard tissue injuries. Traditional specialized radiography has largely been replaced by widely available high-resolution CT. Coronal, sagittal, and three-dimensional reconstructions of images further elucidate complex injuries.

Figure 45-25. **A.** Congenital melanocytic nevus (CMN) of the posterior shoulder. **B.** Treatment of CMN of the posterior shoulder with tissue expansion. **C.** Appearance of the posterior shoulder after removal of tissue expanders, excision of the CMN, and flap coverage.

Mandible Fractures. Mandibular fractures are common injuries that may lead to permanent disability if not diagnosed and properly treated. The mandibular angle, ramus, coronoid process, and condyle are points of attachment for the muscles of mastication, including the masseter, temporalis, lateral pterygoid, and medial pterygoid muscles (Fig. 45-26). Fractures are frequently multiple, and disturbances in dental occlusion reflect the forces of the many muscles of mastication on the fracture segments. Dental occlusion is perhaps the most important basic relationship to understand about fracture of the midface and mandible. The Angle classification system describes the relationship of the maxillary teeth to the mandibular teeth. Class I is normal occlusion, with the mesial buccal cusp of the first maxillary molar fitting into the intercuspal groove of the mandibular first molar. Class II malocclusion is characterized by anterior (mesial) positioning, and class III malocclusion is posterior (distal) positioning of the maxillary teeth with respect to the mandibular teeth (Fig. 45-27).

Nonsurgical treatment may be used in situations in which there is minimal displacement, preservation of the pretraumatic occlusive relationship, and normal range of motion. The goals of surgical treatment include restoration of pretraumatic dental occlusion, reduction and stable fixation of the fracture, and repair of soft tissue. Operative repair involves seating of the

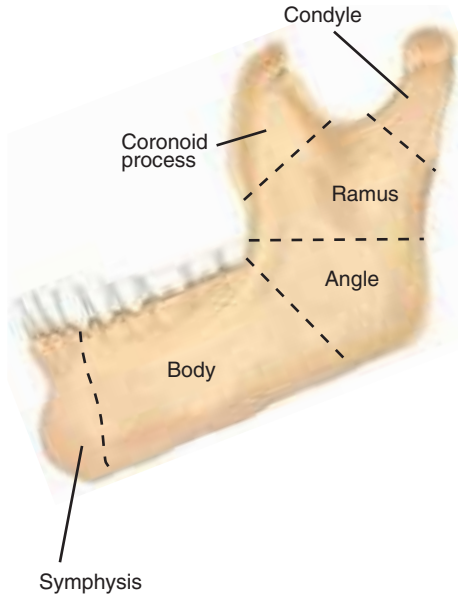

Figure 45-26. Mandibular anatomy. *(Reproduced with permission from Thornton J, Hollier L. Facial fractures II: lower third.* Selected Readings Plast Surg. *2002;9:1.)*

condyles within the glenoid fossa, achievement of maxillary-mandibular fixation with arch bars or intermaxillary screws to establish proper dental occlusion, and intraoral, extraoral, or combination surgical exposure of fracture lines. The mandibular plating approach follows one of two schools of thought: rigid fixation as espoused by the Association for Osteosynthesis/Association for the Study of Internal Fixation (AO/ASIF) and less rigid but functionally stable fixation (Champy technique). Regardless of the stabilization approach, one of the

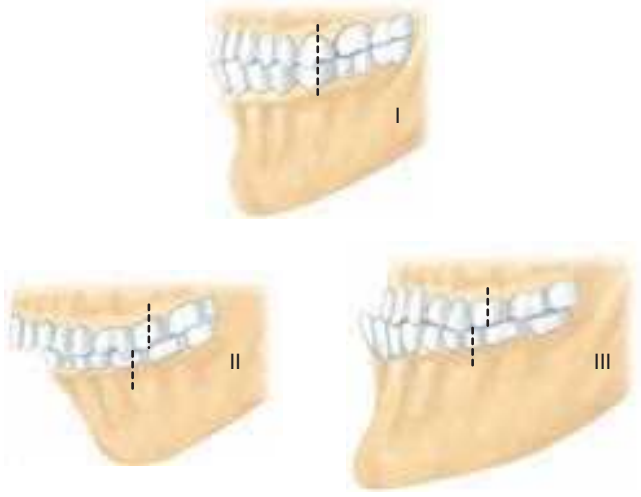

Figure 45-27. Angle classification. Class I: The mesial buccal cusp of the maxillary first molar fits into the intercuspal groove of the mandibular first molar. Class II: The mesial buccal cusp of the maxillary first molar is mesial to the intercuspal groove of the mandibular first molar. Class III: The mesial buccal cusp of the maxillary first molar is distal to the intercuspal groove of the mandibular first molar. *(Reproduced with permission from Thornton J, Hollier L. Facial fractures II: lower third.* Selected Readings Plast Surg. *2002;9:1.)*

postoperative objectives is release from maxillary-mandibular fixation and resumption of range of motion as soon as possible to minimize the risk of ankylosis. Other potential complications include infection, nonunion, malunion, malocclusion, facial nerve branch injury, infra-alveolar or mental nerve injury, and dental fractures.

Orbital Fractures. Treatment of all but the simplest orbital injuries should include evaluation by an eye specialist to assess visual acuity and rule out globe injury. Orbital fractures may involve the orbital roof, floor, or lateral or medial walls. The most common orbital fracture is the orbital floor blow-out fracture caused by direct pressure to the globe and sudden increase in intraorbital pressure. Because the medial floor and inferior medial wall are made of the thinnest bone, fractures occur most frequently at these locations. These injuries may be treated expectantly if they are sufficiently small and without complication. However, larger blow-out fractures and those associated with enophthalmos (increased intraorbital volume), entrapment of inferior orbital tissues, or diplopia lasting >2 weeks generally require surgical treatment.[28] There are many approaches to the orbital floor, including the transconjunctival, subciliary, and lower blepharoplasty incisions. All provide access to the orbital floor and allow for repair with a multitude of different autogenous and synthetic materials. Late complications include persistent diplopia, enophthalmos, ectropion, and entropion.

Lateral and inferior orbital rim fractures also are not uncommon and are often associated with the zygomaticomaxillary complex fracture pattern, as discussed later.

Special mention should be made of two uncommon complications after orbital fracture. Superior orbital fissure syndrome results from compression of structures contained in the superior orbital fissure in the posterior orbit. These include cranial nerves III, IV, and VI, and the first sensory division of cranial nerve V. Compression of these structures leads to symptoms of eyelid ptosis, globe proptosis, paralysis of the extraocular muscles, and anesthesia in the cranial nerve V1 distribution. If the optic nerve (cranial nerve II) is also involved, symptoms include blindness and the syndrome is dubbed *orbital apex syndrome.* Both of these syndromes are medical emergencies, and steroid therapy and surgical decompression are considered.

Zygoma and Zygomaticomaxillary Complex Fractures. The zygoma forms the lateral and inferior borders of the orbit. It articulates with the sphenoid bone in the lateral orbit, the maxilla medially and inferiorly, the frontal bone superiorly, and the temporal bone laterally (Fig. 45-28). Zygoma fractures may involve the arch alone or many of its bony relationships. Isolated arch fractures manifest as a flattened, wide face with associated edema and ecchymosis. Nondisplaced fractures may be treated nonsurgically, whereas displaced and comminuted arch fractures may be reduced and stabilized indirectly (Gilles approach) or, for more complicated fractures, directly through a coronal incision.

The zygomaticomaxillary complex (ZMC) fracture involves disruption of the zygomatic arch, the inferior orbital rim buttress, the zygomaticomaxillary buttress, the lateral orbital wall, and the zygomaticofrontal buttress. The fracture segment tends to rotate laterally and inferiorly, creating an expanded orbital volume, limited mandibular excursion, an inferior cant to the palpebral fissure, and a flattened malar eminence. ZMC fractures are almost always accompanied by numbness in the infraorbital nerve distribution and subconjunctival hematoma.

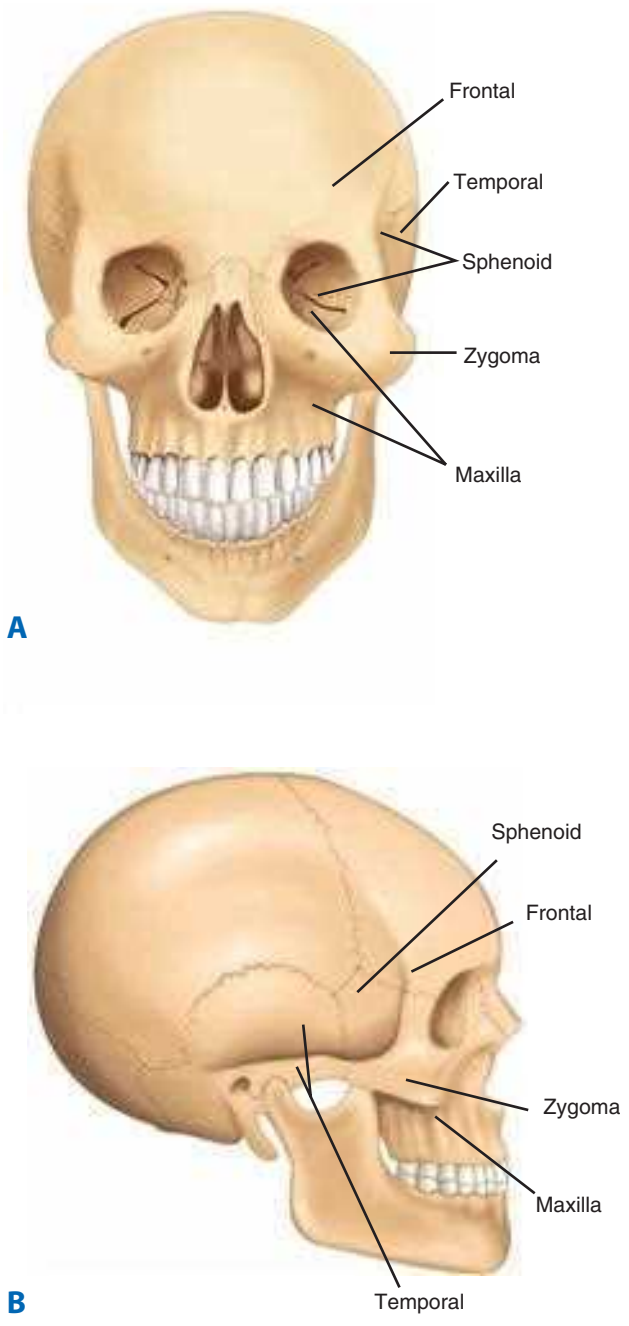

Figure 45-28. Facial bone anatomy. *(Reproduced with permission from Hollier and Thornton.[28])*

Displaced fractures are treated by exposure through multiple incisions to gain access to all of the buttresses requiring fixation. These include the upper eyelid incision (zygomaticofrontal buttress and lateral orbital wall), the subtarsal or transconjunctival incision (orbital floor and infraorbital rim), and the maxillary gingivobuccal sulcus incision (zygomaticomaxillary buttress). Again, significantly complex zygomatic fractures require wide exposure through a coronal approach.[5]

Naso-Orbital-Ethmoid Fractures. Naso-orbital-ethmoid (NOE) fractures are often part of a constellation of panfacial fractures and intracranial injuries. Anatomically, the fracture pattern involves the medial orbits, nasal bones, nasal processes of the frontal bone, and frontal processes of the maxilla. These injuries result in severe functional deficit and cosmetic deformity from collapse of the nose, ethmoids, and medial orbits; displacement of medial canthal ligament fixation; and nasolacrimal apparatus disruption. Telecanthus is produced by splaying apart of the nasomaxillary buttresses to which the medial canthal ligaments are attached. Treatment typically involves plating or wiring all bone fragments meticulously, potentially with primary bone grafting, to restore their normal configuration. Key to the successful repair of an NOE fracture is the careful re-establishment of the nasomaxillary buttress and restoration of the pretrauma fixation points of the medial canthal ligaments. If comminution is severe, this may be achievable using transnasal wiring of the ligaments.

Frontal Sinus Fractures. The region of the frontal sinus is a relatively weak structural point in the upper face. For this reason, it is a common location for fracture in facial trauma. The paired sinuses each have an anterior bony table that determines the contour of the forehead and a posterior table that separates the sinus from the dura. Each sinus drains through the medial floor into its frontonasal duct, which empties into the middle meatus within the nose. Treatment of a frontal sinus fracture depends on the fracture characteristics (Fig. 45-29).

Nasal Fractures. The nose is the most common facial fracture site due to its prominent location, and such fracture can involve the cartilaginous nasal septum, the nasal bones, or both. It is important to perform an intranasal examination to determine whether a septal hematoma is present. If present, a septal hematoma must be incised, drained, and packed to prevent pressure necrosis of the nasal septum and long-term midvault collapse. Closed reduction of nasal fractures may be performed under local or general anesthesia. Unfortunately, many, if not most, show some deformity upon final healing, requiring rhinoplasty if airway obstruction is present or if improved appearance is desired.

Panfacial Fractures. Fractures of multiple bones in various locations fall into the category of panfacial fracture. These may involve frontal and maxillary sinus fractures, NOE fractures, orbital and ZMC fractures, palatal fractures, and complex mandible fractures. The difficulty in the repair of these injuries lies not in the technical aspects of fixation but in the reestablishment of normal relationships between facial features in the absence of all pretraumatic reference points. Without proper correction of bony fragment relationships, facial width is exaggerated and facial projection is lost. The key point in approaching the patient with a panfacial fracture is first to reduce and repair the zygomatic arches and frontal bar to establish the frame and width of the face. The nasomaxillary and zygomaticomaxillary buttresses may then be repaired within this correct frame. Next, the maxilla may be reduced to this framework, followed by palatal fixation if needed. Finally, now that the midface relationships have been corrected, maxillary-mandibular fixation can be applied with the mandible in correct occlusion followed by plating of any mandibular fractures.[29]

Ear Reconstruction

Acquired defects of the auricle have many causes, and many different choices for reconstruction are available. Reconstructive approach often is determined by the size and location of the defect. Small helical lesions may be simply excised as a wedge and closed primarily. Larger defects of the upper and middle thirds of the ear may use antihelical and conchal cartilage reduction patterns to reduce the circumference of the helix to allow

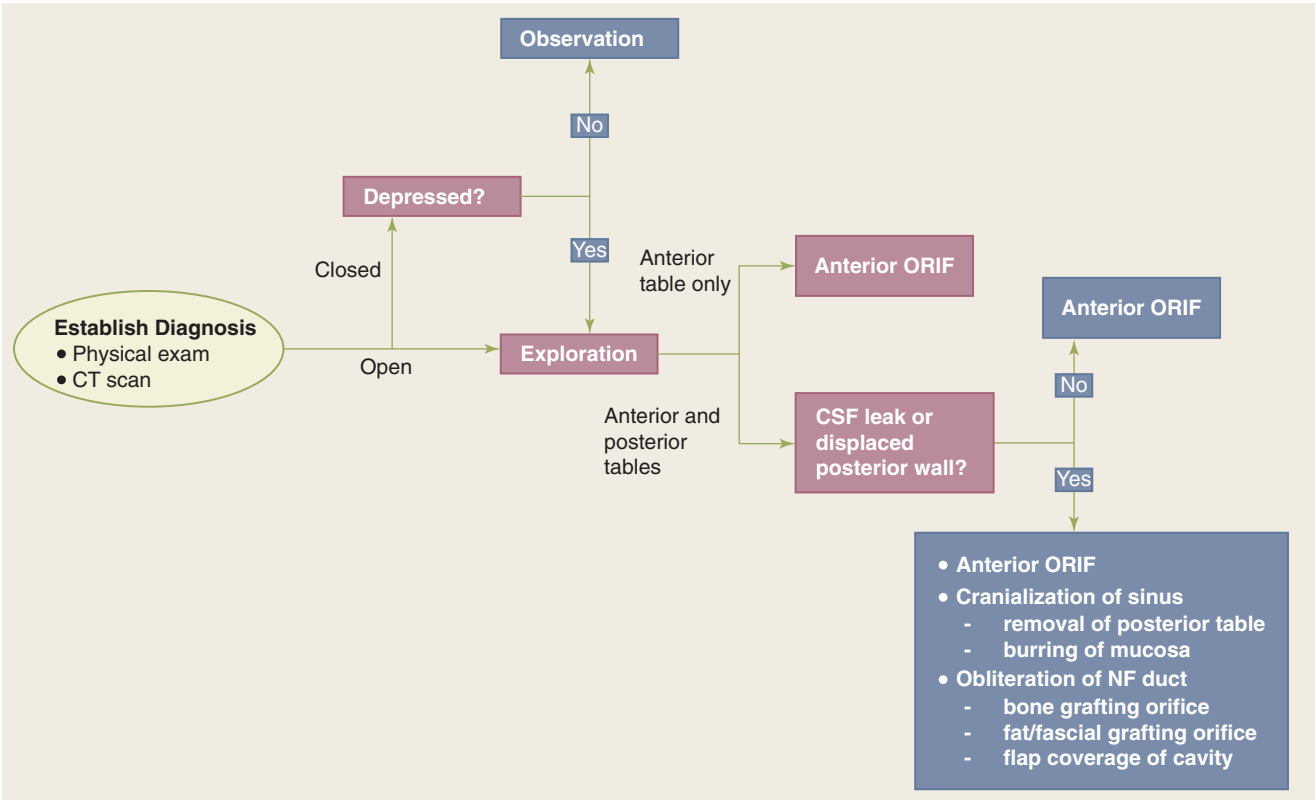

Figure 45-29. Algorithm for the treatment of frontal sinus fracture. CSF = cerebrospinal fluid; CT = computed tomography; NF = nasofrontal; ORIF = open reduction, internal fixation.

primary closure. When helical defects are too large for this solution, local flaps may be used to close or re-create the missing tissue. Postauricular flaps created in staged procedures may be manipulated to create a skin tube mimicking the furled helix and bridging the gap of a defect. Alternatively, use of an Antia-Buch chondrocutaneous advancement flap combined with cartilaginous reduction allows for closure of defects[30] (Fig. 45-30). Even larger defects of the upper and middle thirds of the ear may be reconstructed with large local skin flaps combined with contralateral cartilage grafts or contralateral composite grafts. Although ear lobe defects are relatively simple to close primarily, lower third auricular defects that involve more than just the lobe are complex and require cartilaginous support, often combined with local skin flaps.

Nasal Reconstruction

Reconstruction of the nose requires appreciation of the nine aesthetic subunits that are defined by normal anatomic contours and lighting patterns (Fig. 45-31). In general, if a defect involves ≥50% of a subunit, the remainder of the subunit should be excised and included in the reconstruction. The nose can be thought of as being composed of three layers: skin cover, structural support, and mucosal lining. When a defect or anticipated defect is evaluated, it is useful to consider what layers of tissue will be missing so that a reconstruction can be devised that replaces each layer. Healing by secondary intention is successfully used in concavities such as the alar groove. Split- or full-thickness skin grafts may be used for superficial defects of the nasal dorsum or sidewall. Composite grafts may be used for the nasal tip or alar rim (see Fig. 45-3). Local random pattern flaps are useful in closing small defects of the dorsum and tip and may be combined with cartilage grafts if structural support is needed. Axial pattern flaps are commonly used for larger defects. These flaps have the advantage of being able to cover and revascularize underlying cartilage grafts and enjoy a close color match to surrounding skin. Workhorse flaps used in nasal reconstruction include the nasolabial flap and the paramedian forehead flap (Fig. 45-32). Even larger defects may require scalping flaps or free radial forearm flaps. Split calvarial cantilever bone grafts may provide the nasal dorsum support. Lining is generally achieved with scar tissue turnover flaps, mucoperichondrial flaps from within the nasal vestibule, or skin grafting of the underside of transposed flaps.

Lip Reconstruction

The lips are important for articulate speech, eating, maintenance of oral competence, facial expression, and aesthetic harmony of the lower face. Three layers of tissue form the upper and lower lips: skin, muscle, and mucosa. Blood supply is through the facial artery and its branches to the lip, the superior and inferior labial arteries. Lip defects can arise from trauma, burns, neoplasms, congenital lesions, clefts, or infection. As with almost all types of reconstruction, choice of technique is heavily dependent on defect size, location, and deficient structures. The goals of lip reconstruction are restoration of the competent oral sphincter with vermilion apposition, preservation of sensation, and avoidance of microstomia, all while preserving a near-normal static and dynamic appearance. In the upper and lower lip, vermilion-only defects can be corrected with advancement of the labial mucosa, often called a *lip shave*. In defects of less than one-third the horizontal length, enough redundancy is present to allow primary closure. More complex decisions must be made for defects that are between one-third and two-thirds of the total lip length.

Gimbel.)*

The two categories of lip flap technique are transoral cross-lip flaps and circumoral advancements flaps. Cross-lip flaps include the Abbé flap and the Estlander flap. The Abbé flap was originally designed to reconstruct central upper lip (tubercle) defects with lower lip full-thickness tissue vascularized by one of the labial arteries (Fig. 45-33). The technique requires a second-stage procedure for division of the pedicle. The Estlander flap is similar in principle but is based laterally at the oral commissure and is used to reconstruct lateral upper or lower lip lesions. Both the Estlander and Abbé flaps are denervated, but sensation and perhaps even motor function return over months.[31] The Karapandzic technique is an advancement-rotation flap technique designed for central lower lip defects. Although good function, sensation, and mobility are preserved, a side effect is reduction in the size of the oral aperture. The Webster-Bernard technique uses cheek tissue advancement flaps to replace defects with full-thickness or partial-thickness cheek incisions extended laterally from the commissure (Fig. 45-34). When performed bilaterally, both the Karapandzic and the Webster-Bernard methods can be used to reconstruct a complete upper or lower lip.

In addition, microvascular free tissue transfer reconstruction may be necessary in cases where there is no remaining lip. The radial forearm free flap is the most commonly used for this purpose, usually transferred with the palmaris longus tendon for lip support.

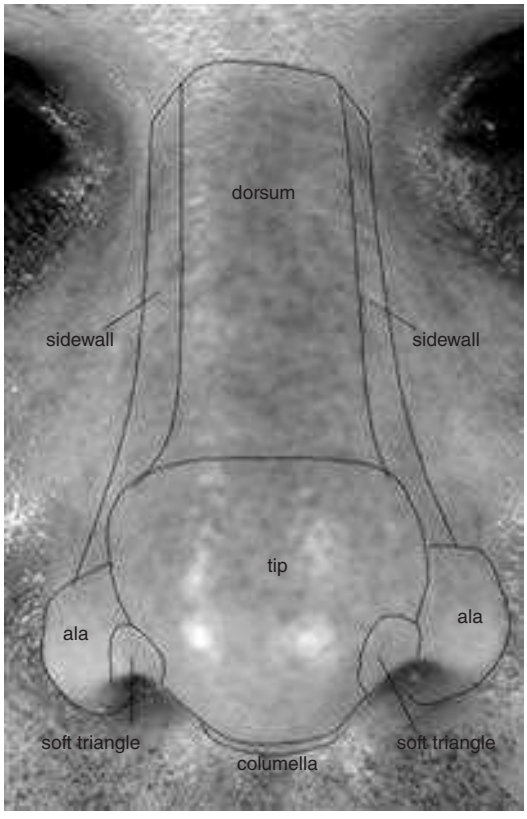

Figure 45-31. Nasal aesthetic subunits. *(Photograph reproduced with permission from M. Gimbel.)*

Eyelid Reconstruction

The eyelids protect the eye from exposure and are another crucial aesthetic structure of the face. They consist of an anterior lamella (skin and orbicularis oculi muscle) and a posterior lamella (tarsus and conjunctiva). The eyelid blood supply is robust, and ischemia is rarely a concern in reconstruction.

Upper Eyelid. Defects comprising <25% of the upper eyelid can generally be closed primarily in pentagonal approximating fashion (Fig. 45-35). For defects involving 25% to 50% of the upper eyelid, lateral canthotomy (release of the lateral canthal tendon) and cantholysis (release of the superior limb of the lateral palpebral tendon) can be performed to allow advancement and are often combined with use of a lateral semicircular flap (Fig. 45-36). Defects larger than 50% of the upper eyelid may be reconstructed with a Cutler-Beard full-thickness advancement flap or a modified Hughes tarsoconjunctival advancement flap (Fig. 45-37).

Lower Eyelid. Lower eyelid reconstruction considerations parallel those for the upper eyelid. In addition, special attention must be given to the prevention of scleral visibility and ectropion, which can arise from excessive vertical tension due to either technique or scarring. Similar reconstructive methods may be used, including direct closure, semicircular flaps and canthal release, and advancement flaps. Grafts may also be used if the defect is partial thickness. Full-thickness contralateral upper eyelid skin grafts are suitable for replacing the anterior lamella. The posterior lamella requires sturdy, nonkeratinized graft tissue, such as cartilage (tarsal, ear, or

nasal septal) or hard palate mucosal grafts, to allow globe apposition.[32]

Ptosis. In the normal eyelid, the orbicularis oculi muscle, Müller's muscle, and levator palpebrae muscle act in concert to open and close the palpebral aperture and to maintain the level of the upper eyelid with respect to the pupil. Eyelid ptosis is created by derangement of this cooperative action. Ptosis may be congenital or acquired. Congenital ptosis is caused by lid anomalies, ophthalmoplegia, and synkinesis, whereas acquired ptosis can be neurogenic, myogenic, or traumatic in nature. Horner's syndrome is a form of neurogenic ptosis caused by interrupted sympathetic innervation that leads to ptosis, miosis, and anhydrosis. A thorough evaluation of the ptotic patient includes a general eye and visual acuity examination, attention to signs of exposure or irritation, measurement of marginal-reflex distance, observation of the height of the supratarsal fold, and assessment of levator function. Severity of ptosis and degree of levator dysfunction are critical in deciding the appropriate corrective procedure (Table 45-11). Mild ptosis may be addressed with the Fasanella-Servat procedure, which involves excision of the superior tarsal edge, conjunctiva, and levator aponeurosis, and mullerectomy. Other corrections of mild ptosis usually involve variations on this procedure. Moderate ptosis with fair to good levator function may be treated with some form of a levator aponeurosis shortening procedure. Severe ptosis with poor levator

function requires use of an alternate eyelid motor. The frontalis muscle fascial sling technique, which uses strips of fascial grafts sutured to the frontalis muscle, is one such solution.

Skull and Scalp Reconstruction

Scalp Reconstruction. The scalp is formed of five layers: *S*kin, sub*C*utaneous tissue, galea *A*poneurotica, *L*oose areolar tissue, and *P*ericranium (SCALP). The scalp is well vascularized bilaterally by branches of the external carotid artery, including the superficial temporal arteries, the occipital arteries, and the posterior auricular arteries. In addition, the bilateral supraorbital and supratrochlear arteries contribute to the forehead and anterior scalp blood supply. These vessels run in the subcutaneous tissue layer, just superficial to the galea. Because of this rich blood supply, scalp lacerations can lead to dramatic blood loss, an event that usually can be curtailed by a simple running/locking suture closure.

Partial-thickness scalp loss due to trauma usually occurs at the level of the loose areolar tissue plane and is treated initially with débridement of devitalized tissue. If a partial-thickness defect is small enough, primary closure or skin graft can be used. Although the cosmetic result is often less than desirable, all layers of the scalp will accept a skin graft, including the calvaria if it is burred down to its diploë. Because the scalp is relatively inelastic, scoring of the galeal layer often facilitates closure of full-thickness defects, but care must be taken to avoid lacerating the blood vessels just superficial to the galea. Larger areas of loss (4–8 cm) may be covered with large scalp flaps, as classically described by Orticochea.[33] Grafting of defects or donor sites leaves a visible area of alopecia. Tissue expansion has been very successful in replacing scarred or grafted regions with hair-bearing skin. Defects larger than 8 to 10 cm are best treated with microsurgical free tissue transfer. Total or subtotal scalp avulsions are rare injuries that usually occur when a person's long hair becomes caught in rotating machinery. These potentially devastating injuries are ideally treated by scalp replantation, because the avulsed segment usually has preserved vessels (Fig. 45-38).

Calvarial Reconstruction. Autogenous bone remains the material of choice for reconstruction of skull defects. Its advantages include resistance to infection and ability to heal with strength. All autogenous bone sources have the disadvantage of donor site morbidity. Bone grafts can be harvested from a normal area of the calvaria, of which the outer table may be used as a graft for defects of limited size. Care must be taken during harvest to avoid compromise of the inner table. Rib bone may also be used, either as a split-rib graft or as a microsurgical free osseous flap. Unfortunately, use of ribs to reconstruct the skull may give an unappealing "washboard" appearance to the scalp. Another disadvantage of bone grafts, although not flaps, is graft resorption over time.

Alternative materials to autogenous bone exist for calvarial reconstruction, including methyl methacrylate, titanium, and hydroxyapatite (with or without bone morphogenic protein). Although they have the advantage of no donor site, these plastics and metals are associated with a higher risk of infection necessitating removal. Various formulations of calcium phosphate hydroxyapatites are being actively studied as bone replacement materials.

Head and Neck Reconstruction

The head and neck region has a compact arrangement of critical and complex structures encasing the essential routes to the gastrointestinal and respiratory systems. The tissues of the face, mouth, and cavities serve as a primary communication interface with the external environment through facial and verbal expression. Therefore, cancer resections with adequate safety margins can be severely and multiply debilitating. The management of head and neck cancer patients demands an integrated multidisciplinary team approach that includes the skills of ablative and reconstructive surgeons, medical and radiation oncologists, pathologists, nutritionists, and functional and psychological rehabilitation specialists.

Eyelid ptosis classification

Classification of ptosis severity	
Mild	1–2 mm
Moderate	3 mm
Severe	4+ mm
Classification of levator function	
Excellent	12–15 mm
Good	8–12 mm
Fair	5–7 mm
Poor	2–4 mm

Tumor-Ablative Surgery. The freedom available to the ablative surgeon to completely excise a tumor is limited, at least partly, by the capability of the reconstructive surgeon to restore anatomic continuity and achieve successful wound healing. A neck dissection to remove cervical lymphatics and nodes may be performed for prophylactic or curative intent, for more accurate prognostication by operative staging, and/or for solidification of plans for adjunctive treatments. It is important to be familiar with the tumor-node-metastasis (TNM) classification and staging of head and neck cancers. The N and M parameters are fairly constant for most head and neck cancers, whereas the T parameter varies according to tumor location.

Figure 45-38. Twenty-five-year-old woman with 70% scalp avulsion after a pedestrian-automobile accident. *Top row:* Defect and specimen intraoperatively. *Bottom row:* Appearance 9 weeks after microsurgical scalp replantation. *(Photographs reproduced with permission from M. Gimbel.)*

Principles of Reconstruction. The reconstructive surgeon aims to restore lost anatomic components adequately. Residual deficits, seemingly inconsequential, may progress to psychological morbidity, societal malacceptance, and social withdrawal. Uncomplicated and timely wound healing is important to allow adjuvant therapies when indicated and smooth discharge to home and occupation.

Each defect can be addressed by a number of methods, but the technique must be decided for each individual patient. Although a more complex reconstruction might offer improved outcomes, it may bring an increased risk of complications. Some patients may therefore benefit from use of a simpler method with more acceptable anesthetic and operative risk rather than a gold-standard reconstruction. Such an approach may be appropriate, for example, for an elderly patient with an advanced T4 cancer and short life expectancy. Reconstruction is impossible for some functional losses, such as the enucleation of an eye, but replacement by a reasonably aesthetic prosthesis may be achievable.[34]

Reconstructive Options by Region. Before the 1970s, autogenous tissue reconstructions were largely restricted to local or regional pedicled flaps, including the trapezius, pectoralis, and deltopectoral workhorse flaps. With microvascular free tissue transplantation, defects that were previously deemed nearly impossible to reconstruct can now be addressed in a single operation. Consequently, head and neck cancers that were historically unresectable have become more operable.

Intraoral Structures The reconstructive choice for floor of mouth, tongue, and other intraoral defects is dictated by the dimension of the defect, the volume of tissue lost, and residual tongue mobility. The tongue and adjacent mucosal surfaces heal exceptionally well, so small defects may be treated by primary closure or even left to heal spontaneously. Smaller defects, less than one-fourth glossectomy, may be treated with a skin graft or perhaps primary closure if tongue mobility is preserved. Larger defects, more than one-third glossectomy, call for reconstruction by free tissue transfer, commonly a free radial forearm or anterolateral thigh flap for smaller- or larger-volume defects,

respectively. Total glossectomy defects are a major challenge, and no ideal method exists to restore tongue motor functions. The primary goal is to protect the airway from aspiration. Swallowing and articulation are often suboptimal after total glossectomy reconstructions. Options include bulkier myocutaneous free flaps harvested from the anterolateral thigh, the back (latissimus dorsi), or the abdomen (rectus abdominis), or pedicled regional flaps (e.g., latissimus dorsi).[35]

The reconstructive choice for other intraoral soft tissue defects should also take into consideration the specific characteristics of the defect, such as its thickness and dimensions, and involvement of the oral commissure, facial skin, and/or neck. Buccal defects, for example, may be adequately treated with a radial forearm free flap or a thin anterolateral thigh flap. Thicker defects may be more appropriately reconstructed with a fasciocutaneous anterolateral thigh free flap. Those that extend through the full thickness of the cheek to involve the external facial skin may be reconstructed with a cutaneous or myocutaneous anterolateral thigh free flap that has been folded to address the internal mucosal, external skin, and intervening soft tissue defects simultaneously.[36] When the contour of the neck is expected to be sunken and asymmetric after a neck dissection, it is possible to improve symmetry by insetting part of the flap into the neck. This maneuver also obliterates dead space and helps protect the adjacent major neurovascular structures.

Mandible and Midface Mandibular defects may arise from the ablation of tumors involving the bone itself or from the need to satisfy clearance margins for adjacent soft tissue tumors. Segmental mandibular defects can be classified as isolated bone defects, compound defects (bone and oral lining *or* skin), composite defects (bone, oral lining, *and* skin), or extensive composite defects (bone, oral lining, skin, and soft tissues).[37] The primary goals of mandibular reconstruction are to restore bony continuity, masticatory (with accurate dental occlusion) and speech functions, and facial contour, and to maintain tongue mobility. Occasionally, a small segmental mandibular defect may be amenable to reconstruction with a nonvascularized bone graft, but these are poorly suited to the forces of mastication and are prone to resorption and failure amid radiotherapy or infection.

The best option for most segmental mandibular defects is the fibula bone free flap with an adjoined skin island supplied by reliable septocutaneous vessels (occasionally musculocutaneous perforators) from the peroneal artery and vein; this is termed a *fibula osteoseptocutaneous free flap*.[38] Its many desirable characteristics include (a) the ability to withstand multiple osteotomies (as long as the periosteal blood supply is protected) so that the bone can be folded to re-create the contour of any mandibular region, (b) an unmatched supply of sturdy bone length (22–26 cm in the adult) sufficient to reconstruct even angle-to-angle defects, (c) a bicorticocancellous structure that can tolerate the forces of mastication as well as the incorporation of osseointegrated dental implants, (d) acceptable donor site morbidity when the flap is appropriately harvested, and (e) a donor site location that allows a two-team approach for simultaneous tumor ablation and flap harvest.[39,40] Reasonable alternatives include vascularized bone flaps from the iliac crest, radius, or ribs. Extensive composite mandibular defects may demand more than one free flap (such as one anterolateral thigh free flap with one fibula osteoseptocutaneous free flap) to reconstruct the entire anatomy in one operation.[41] Later, dental rehabilitation can be achieved with conventional dentures if alveolar ridge height and soft tissue quality allow. However, for select patients, osseointegrated dental implants offer a far superior alternative. These can be secured into the neomandible, either at the time of reconstruction (primarily; Fig. 45-39) or more commonly at a later stage (secondarily), and ultimately will support a dental prosthesis that can closely match the native dentition for excellent aesthetic and masticatory outcomes.[42]

Similar principles are also applicable to other bony defects in the head and neck region, including maxillary and other midfacial defects, although non–load-bearing, facial, bone-only defects may be more amenable to nonvascularized bone grafting such as from the calvarium. The goals of midface reconstruction include the restoration of facial contour and projection, achievement of accurately occlusive maxillary dentition, provision of appropriate infraocular support, and sealed separation of adjacent nasal and oral cavities.

Esophagus and Hypopharynx The goals of reconstruction for esophageal and hypopharyngeal defects, which may be circumferential or partial, are to maintain luminal patency, restore speech and swallowing, and avoid strictures, fistulas, and gastrointestinal anastomotic leaks. Reconstructive options for partial defects include primary closure, if luminal narrowing is insignificant, and skin (or dermal) grafts for partial-lining defects. A regional muscle flap may be useful for patching small full-thickness defects, but larger defects call for free tissue transfer of a jejunal flap or a tubed fasciocutaneous flap.[43] The jejunal flap involves the harvest of a proximal segment based on its mesenteric blood supply and inset into the neck in the isoperistaltic direction. Disadvantages of the jejunal flap include halitosis, slow swallowing transit times, and a "wet" voice. Tubed fasciocutaneous free flap options, including the anterolateral thigh and radial forearm flaps, are also popular; however, they may have a greater risk of stricturing than the free jejunal flap. Nevertheless, proponents of such flaps favor the resultant vocal qualities and faster transit times.

Recipient Vessels in the Head and Neck for Free Flaps Commonly used recipient arteries for free tissue transfer in the head and neck include the ipsilateral superior thyroid, lingual, facial, superficial temporal, and transverse cervical arteries. End-to-side anastomosis with the carotid artery is associated with potentially lethal carotid blow-out injury. Anastomoses with contralateral vessels are useful when ipsilateral vessels are not available, such as in patients with recurrent cancer who have undergone previous free flap procedures or irradiation.[36] Vein grafts can be avoided by using carefully planned flaps that offer longer pedicles (such as the anterolateral thigh of fibula osteoseptocutaneous free flaps) but may occasionally be necessary. For venous drainage, tributaries of the superficial and deep jugular systems are convenient. Finally, protection of the major vessels and nerves of the neck is possible after neck dissection by overlaying residual free flap tissues. This also aids in improving the contour and symmetry of the neck for aesthetic purposes and obliterates any dead space.

Complications Apart from the general complications that may be encountered with any major operation, there are several specific potential complications of head and neck ablative and reconstructive surgery. Specific intraoperative complications include air embolus, pneumothorax, and injuries to important

vessels, lymphatics, or cranial nerves. Specific perioperative complications include carotid artery blow-out, flap necrosis, infections, saliva or chyle leakage, airway problems, and acute psychiatric disturbances. Examples of later complications are prolonged pain syndromes, fistulas, scar contractures, and problems associated with radiotherapy such as flap shrinkage (potentially with metalwork exposure) and osteoradionecrosis.

Facial Reanimation

Facial nerve paralysis is a debilitating and emotionally depressing condition that presents many functional and aesthetic problems. Loss of mimetic muscle activity leads to poor articulation and drooling from oral incompetence, exposure keratopathy from dysfunctional lacrimation and paralytic ectropion, and impaired socialization from facial disfigurement and difficulty expressing emotion. Facial nerve dysfunction has a number of possible causes, including oncologic resection, temporal bone or skull base surgery, trauma, congenital conditions (Möbius' syndrome), and idiopathic origin. The main considerations in treatment are management of forehead and brow symmetry, eyelid closure, oral competence and symmetry, and smile dynamics. The long-term goals include normal static appearance, symmetry with movement, and restoration of voluntary muscular control. Although the best results usually require multistaged, complex surgeries, the elderly patient is better served by a single-stage procedure that provides immediate improvement.

Neural Techniques. Traumatic injuries to the facial nerve without segmental nerve loss are best treated with primary end-to-end neurorrhaphy of the facial nerve stumps. The success of this repair depends on accurate approximation of nerve ends and achievement of a tension-free epineural repair with fine sutures. In segmental facial nerve loss due to trauma or oncologic resection, interpositional nerve grafts lead to the most successful reconstruction and may approach the results of primary repair. Grafting ideally is performed at the time of the injury rather than in delayed fashion. Donor nerves include the cervical plexus, great auricular nerve, and sural nerve. Timing of reanimation after nerve repair depends on distance of the repair from the motor end plates. Axonal regeneration proceeds at approximately 1 mm/d, whereas motor end plates deteriorate at approximately 1% per week and are gone by 2 to 3 years. In general, facial tone returns approximately 6 months after repair and voluntary motion a few months later.[44] Problems associated with facial nerve repair and grafting are weakness, mass movement (synkinesia), and dyskinesia. If the proximal facial nerve stump is available but the distal stumps are not, the cervical plexus can be harvested and proximally anastomosed to the facial nerve stump and distally implanted into the mimetic muscles to allow neurotization and partial restoration of function.

Nerve transfer techniques borrow other local cranial nerves to innervate the distal facial nerve stump if grafting cannot be done. This requires the availability of distal facial nerve or nerve branch stumps. Typically used donor nerves include the ipsilateral hypoglossal nerve, spinal accessory nerve, and cross-face sural nerve graft from a contralateral facial nerve branch (redundant buccal or zygomatic branch). Disadvantages of this technique include those of nerve repair or grafting plus loss of donor nerve function and facial hypertonia. Transfer of the complete hypoglossal nerve creates ipsilateral tongue paralysis and hemitongue atrophy with mild to moderate intraoral dysfunction.[44]

Muscle Transposition Techniques. All of the aforementioned neural techniques rely on the presence of a functional distal neuromuscular unit. When the distal neuromuscular unit is deficient, as in congenital facial paralysis or in situations in which reconstruction is not undertaken until 2 to 3 years after the original insult, muscle transposition is considered. Muscle transposition techniques require intense muscular retraining to achieve the intended dynamics. A classic muscle dynamic facial sling uses the temporalis muscle, innervated by the trigeminal nerve and perfused by the deep temporal branch of the internal maxillary artery. The muscle is released along with its aponeurosis from the temporal fusion line, reflected inferomedially, and attached to the modiolus at the oral commissure, the nasolabial fold, and potentially the orbicularis oculi. Disadvantages include lack of spontaneous movement, temporomandibular joint dysfunction, and soft tissue fullness over the zygomatic arch. Other transferable muscle units include the masseter muscle and the anterior belly of the digastric muscle.[44]

Innervated Free Tissue Transfer. Microsurgical free innervated muscle transfer may be considered in the same situations as local muscle transfers but is especially appropriate when concomitant soft tissue augmentation is needed. Muscles described for this purpose include the gracilis, latissimus dorsi, serratus anterior, and pectoralis minor muscles. The procedure may be performed in a single stage if the proximal facial nerve stump is available for anastomosis or if a long enough donor muscle nerve is present to reach the contralateral facial nerve branches. Often, however, it is a staged procedure beginning with establishment of a local neural source via cross-facial nerve grafting. The extent of axonal regeneration through the graft is monitored using Tinel's test. After sufficient axonal progression, approximately 6 to 12 months, the free muscle transfer is performed via vascular anastomoses to the superficial temporal or facial vessels, recipient and donor nerve coaptation, and fixation of the muscle to the zygoma superolaterally and to the nasolabial fold, upper lip orbicularis, and lower lip orbicularis inferomedially. Disadvantages of free muscle transfer include donor site morbidity, lengthy surgical times, and the need for specialized microsurgical skills.

Ancillary Procedures. One of the most important goals of treatment for facial paralysis is rehabilitation of the periocular region. This objective may be simply achieved with implantation of gold or platinum upper eyelid weights, which allows gravity to assist with lid closure. Static fascial slings are used to improve symmetry when comorbid conditions preclude more extensive and staged surgeries. Sling materials include tensor fasciae latae, Gore-Tex, and human acellular dermal allograft. Nonsurgical techniques play a significant role in improving facial symmetry, both as a primary intervention and an adjunct to surgery. Contralateral mimetic muscle hypertonicity is tempered with botulinum toxin injections. Finally, soft tissue rejuvenative techniques such as cervicofacial rhytidectomy, blepharoplasty, browlift, and midface lift can improve the soft tissue effects of facial nerve paralysis (Fig. 45-40).

Breast Reconstruction

Breast cancer is the most common malignancy and the second leading cause of cancer-related death among women in the United States. One in eight women will develop breast cancer sometime during their life. Breast reconstruction began as a means to reduce chest wall complications and deformities from mastectomy. Reconstruction has now been shown to benefit women in terms of psychological well-being and quality of life.[45] The goal of breast reconstruction is to re-create form and symmetry while avoiding delay in adjuvant cancer treatment. A number of studies have shown that breast reconstruction, both immediate and delayed, does not impede standard oncologic treatment, does not delay detection of recurrent cancer, and does not change the overall mortality associated with the disease.[46-48]

Preoperative counseling of the breast cancer patient regarding reconstruction options should include discussion of the timing and type of reconstruction, alternatives to surgical reconstruction, and realistic expectations. The plastic surgeon and surgical oncologist must maintain close communication to achieve optimal results.

Timing of Reconstruction. *Immediate reconstruction* is defined as initiation of the breast reconstructive process at the time of the ablative surgery. This is usually done in patients with early-stage disease for whom there is low expectation of postoperative radiation therapy. Immediate reconstruction takes advantage of the preserved, supple skin envelope made possible by the skin-sparing mastectomy approach. In general, this allows a more aesthetically pleasing and symmetric reconstruction. It is also psychologically advantageous to the patient to avoid living with the mastectomy deformity, as in delayed reconstruction. Furthermore, the cost to the medical system is less with immediate reconstruction because fewer operations are required than for staged procedures. Disadvantages include the potential delay of adjuvant therapy due to surgical site complication, partial necrosis of mastectomy skin flaps, and the possibility that unanticipated postoperative radiation therapy is required. Breast reconstructions by all techniques are adversely affected by radiation therapy, and many surgeons feel reconstruction should be delayed until at least 6 months after treatment.

Delayed breast reconstruction is initiated at least 3 to 6 months after mastectomy. This approach avoids mastectomy flap unreliability and radiation therapy unpredictability. However, the patient is subjected to an additional operative procedure, and overall cosmetic result is often worse (especially with autologous tissue reconstruction).

Partial Breast Reconstruction. Over the last decade, many women have chosen breast conservation therapy (BCT) consisting of segmental mastectomy with sentinel lymph node biopsy and/or axillary lymph node dissection combined with postoperative whole-breast irradiation. Although this less invasive cancer treatment is quite beneficial to many women, significant breast deformity can result from the tissue removal and radiation-induced changes, especially in women with small breasts. *Oncoplastic surgery* refers to the set of techniques developed to lessen breast deformity from partial mastectomy, both

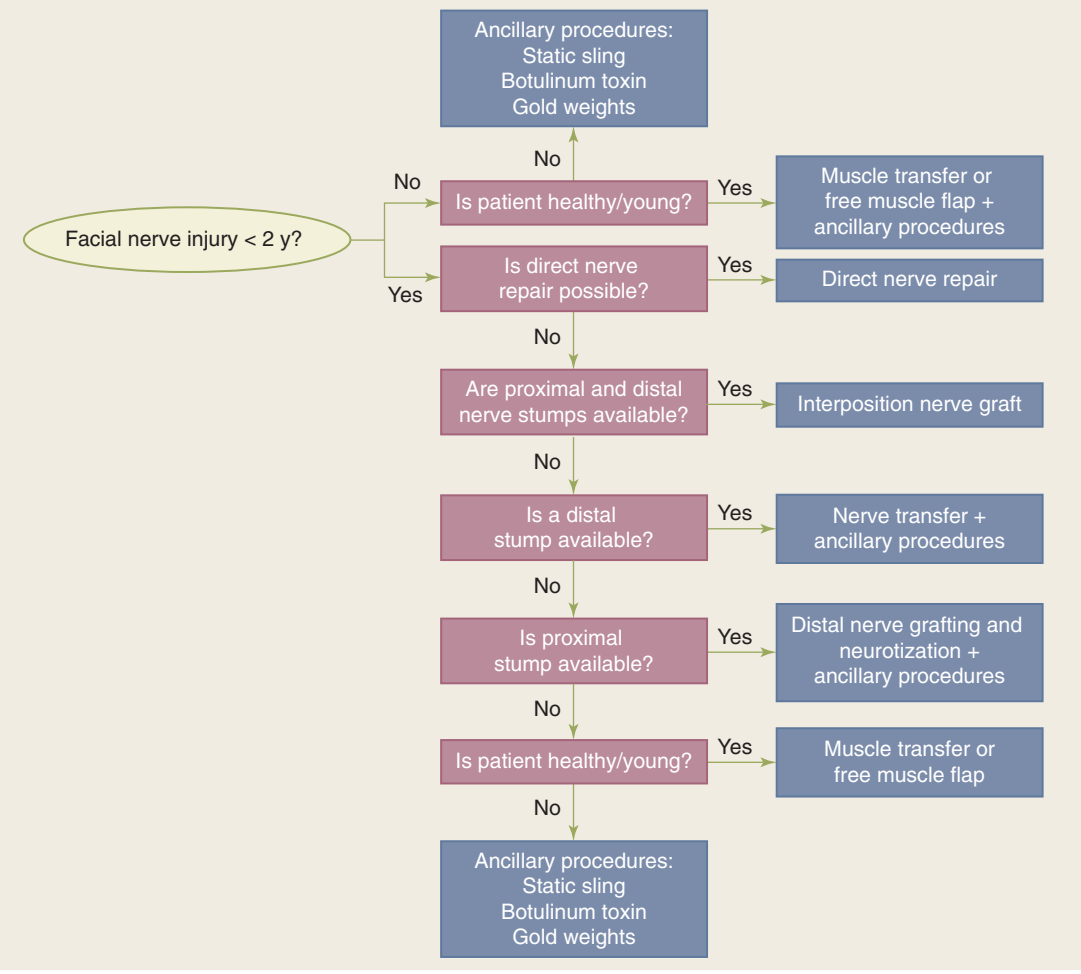

Figure 45-40. Facial reanimation treatment algorithm.

in the delayed and the immediate settings. One of the most common methods of minimizing defect visibility in large-breasted women is to rearrange the breast parenchyma at the time of tumor extirpation using reduction mammoplasty techniques. Dermatoglandular pedicles supporting the nipple-areolar complex can be designed in any number of orientations to avoid the defect location. This procedure, combined with traditional contralateral breast reduction, can result in excellent cosmetic outcomes, often better than the preoperative appearance (Fig. 45-41). The lateral thoracodorsal flap, based on the lateral intercostal perforators at the inframammary fold, is particularly useful in correcting lateral breast defects[49]

One drawback of these oncoplastic techniques when performed at the time of segmental mastectomy is the chance that, if the specimen margins are not clear, the reconstruction must be taken down to allow for reexcision. The oncologic implications of reusing the flap in this setting are unclear. Another shortcoming is the potential for fat necrosis, especially distally, in these nonaxial pattern flaps.

Implant-Based Reconstruction. By necessity or patient choice, many women undergo mastectomy for local control of breast cancer. In fact, recently in response to the increased recognition of multifocal disease and experience with poor aesthetic results after BCT in small-breasted patients, some women have chosen mastectomy despite being candidates for BCT. The simplest method of reconstructing the breast is placement of an implant into the mastectomy defect. Occasionally an implant may be placed at the time of mastectomy as a one-stage mound reconstruction. Usually, however, the first stage involves placement of a silicone shell tissue expander under the chest wall musculature (pectoralis major, serratus anterior, superior rectus sheath), followed by expansion of the skin and pocket regularly over the following few months. The patient then returns to the operating room for removal of the expander and placement of a saline or silicone breast implant (Figs. 45-42 and 45-43). After exhaustive investigation, silicone implants have been proven as safe and effective as saline implants in breast augmentation and reconstruction. After another few months, the nipple is reconstructed.

The advantages of the tissue expander/implant–based reconstruction are absence of donor site morbidity, short operative times, and short recovery periods. The disadvantages include the need for more reconstructive stages and longer cumulative time to completion of reconstruction. Implant breast reconstructions tend to lack the natural breast feel and ptotic appearance. This is particularly noticeable in unilateral reconstructions. Some of these disadvantages have been mitigated by the advent of nipple-sparing mastectomy and immediate, acellular dermal matrix-assisted implant reconstruction (Fig. 45-44). Complications related to prosthetic-based breast reconstruction include infection, malposition, hematoma, seroma, and rupture

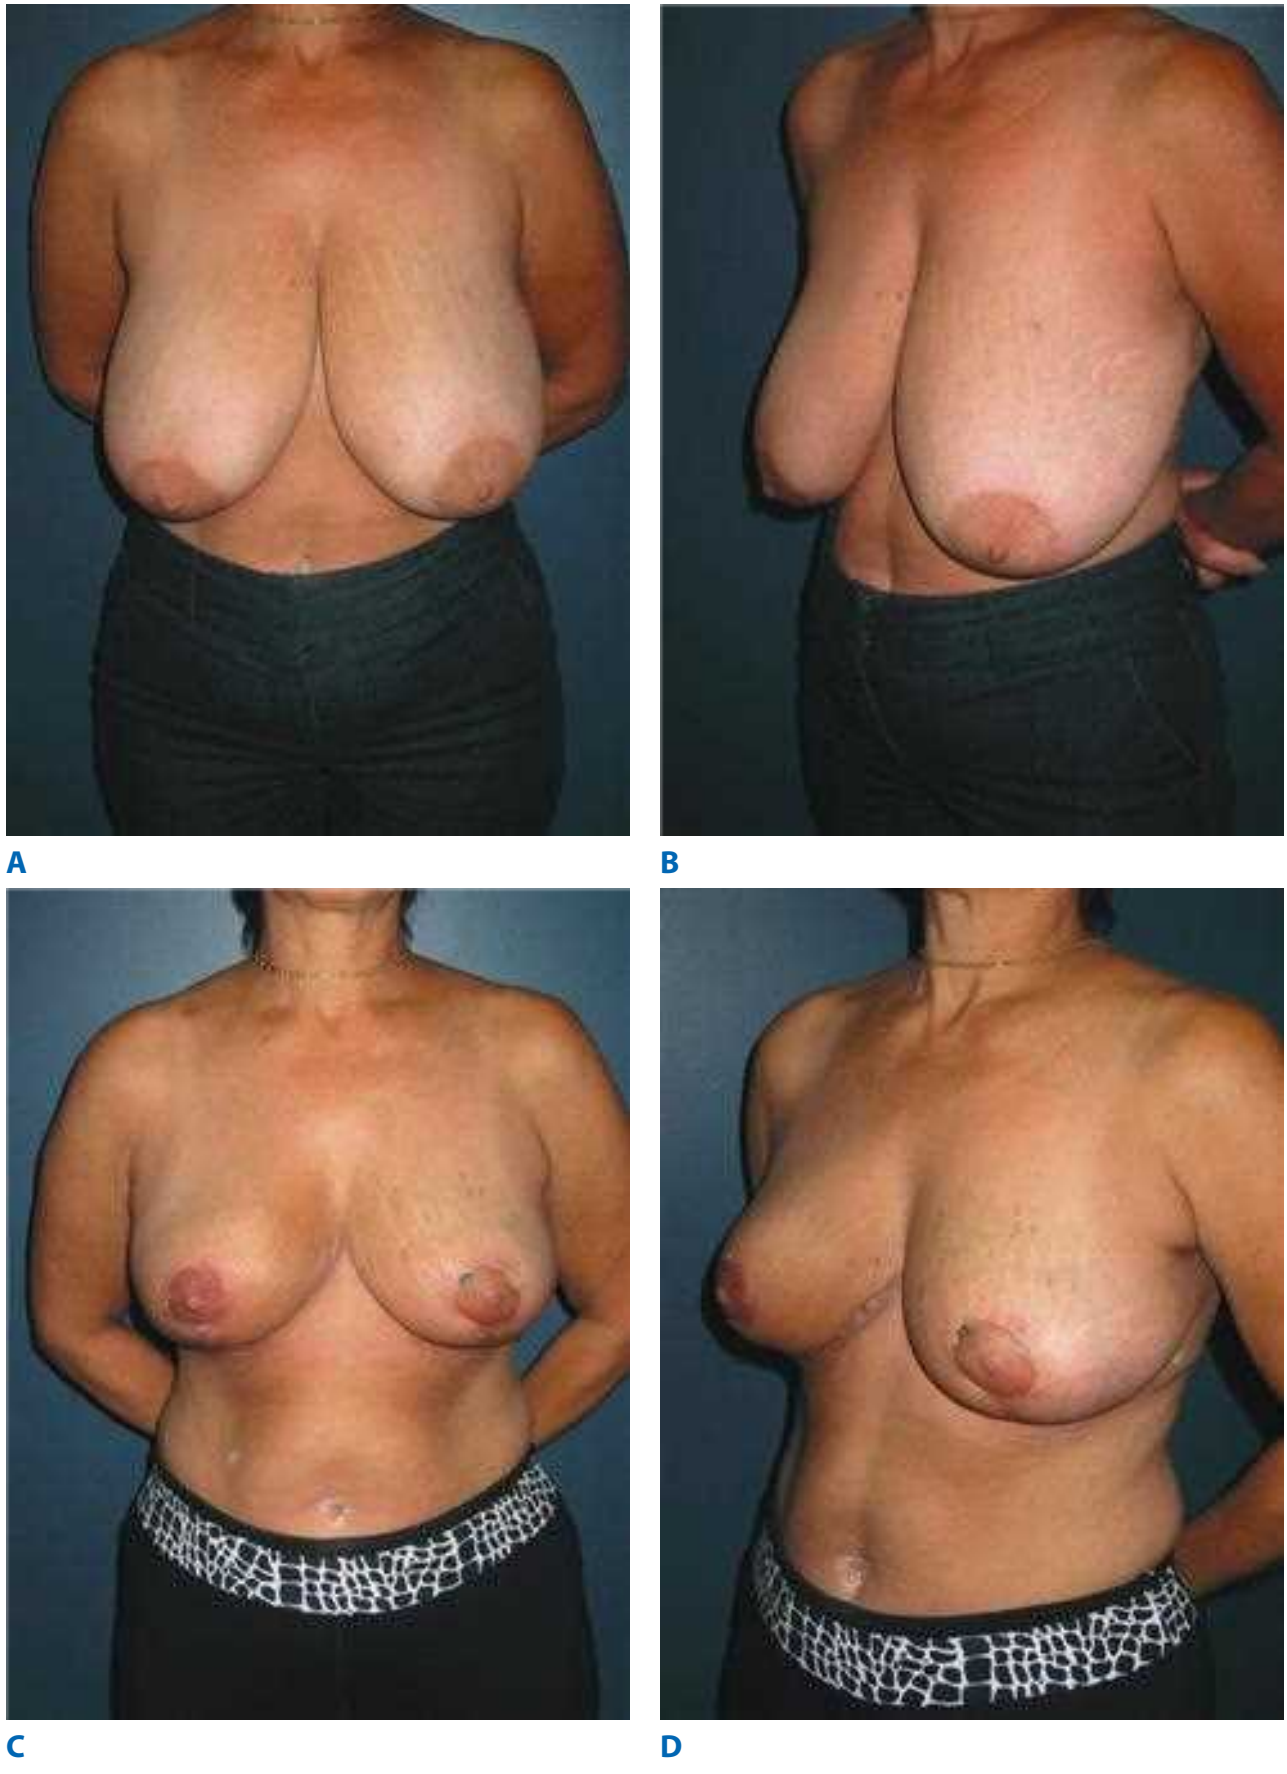

Figure 45-41. Preoperative (*top row*) and 3-week postoperative (*bottom row*) photos of a 52-year-old patient with cancer at the 6 o'clock position of the left breast. Oncoplastic superomedial pedicle reduction on the left breast was performed simultaneously with a left segmental mastectomy of the lesion and a contralateral symmetrization reduction. *(Photographs reproduced with permission from M. Gimbel.)*

and deflation. Long term, the most common problem requiring reoperation is the formation of dense scarring around the implant (capsular contracture) causing firmness, visible deformity, and even discomfort. In addition, implants are medical devices that undergo mechanical wear, ultimately leading to leakage and deflation. All in all, the chance that a woman will need additional unanticipated surgery on her reconstructed breast within 5 years of prosthetic-based reconstruction is approximately 35%.[50]

The cosmetic results worsen and the rate of complications increases when implants are placed in an irradiated chest wall, regardless of whether the radiation therapy occurs before or after reconstruction.

Total Autologous Tissue Reconstruction. An entirely different way to reconstruct the breast avoids the placement of implants in favor of using only the patient's own redundant tissue. Indications for total autologous breast reconstruction are many and varied, including patient preference, previous or anticipated chest wall radiation treatment, a ptotic contralateral breast, and previous failed implant reconstruction. Contraindications are lack of a suitable donor site due to scarring or minimal adiposity, morbid obesity, and serious comorbidities that preclude a longer surgery and recovery period.

The most commonly used donor site is the abdomen. Most women in the breast cancer patient population have redundant skin and fat in the lower abdomen that may be transferred to the chest wall and fashioned into a breast mound. Many techniques have been developed to transfer this tissue, both as pedicled myocutaneous flaps and as free flaps. The workhorse abdominal flap for breast reconstruction is the pedicled transverse rectus abdominis myocutaneous (TRAM) flap. This flap is based on the superior epigastric vessels that run on the undersurface of the rectus abdominis muscle. A transversely oriented skin paddle with underlying fat is isolated based on its perforating vessels that course through the rectus muscle to join the main superior epigastric pedicle. The flap, along with the rectus muscle and blood supply, is tunneled under the anterior chest wall and

delivered into the mastectomy defect, where it is then shaped into a breast mound. The donor site is closed in a manner similar to an abdominoplasty. The advantages of this and all total autologous reconstruction techniques are creation of a breast that looks and feels natural, that changes volume along with the patient's weight (and the contralateral natural breast), and that avoids the potential complications of breast implants. In addition, patients are often pleased to have the incidental benefit of an abdominoplasty. The pedicled TRAM flap procedure is also relatively quick for a total autologous reconstruction. Downsides include the potential for partial or complete flap failure, fat necrosis, fullness in the upper abdomen from the tunneled pedicle, abdominal wall bulge or hernia, and abdominal wall weakness.

The free TRAM flap was introduced to improve on the sometimes limited volume of tissue that can be carried by the relatively indirect blood supply of the pedicled TRAM's superior epigastric vessels. The free TRAM flap is similar to the pedicled TRAM flap but is based on the deep inferior epigastric vessels, which are the dominant blood supply to the lower abdomen. The flap is harvested as a free flap, and the deep inferior epigastric artery and vein are anastomosed to recipient vessels in the chest, usually the internal mammary or the thoracodorsal vessels. A refinement to this method is the muscle-sparing free TRAM flap procedure, in which less fascia and rectus abdominis muscle is harvested with the flap to minimize donor site morbidity. The ultimate muscle-sparing free TRAM flap is the deep inferior epigastric perforator flap (Fig. 45-45). In this case, the fascia is opened but no muscle is included with the flap, and the perforating vessels of the deep inferior epigastric system are dissected between the muscle fibers to join the main pedicle. When patients are carefully selected, muscle-sparing techniques decrease abdominal wall morbidity and increase useful pedicle length for microsurgery without significantly compromising flap perfusion[51] (Fig. 45-46A,B). Finally, in some patients, the lower abdominal tissue may be transferred to the breast as a free flap without violating the abdominal wall fascia at all. The superficial inferior epigastric artery is often capable of supporting enough abdominal tissue volume to reconstruct the breast. Because this artery and its accompanying vein do not traverse the anterior rectus sheath, the flap can be harvested with no more abdominal wall morbidity than an abdominoplasty. Unfortunately, this artery is frequently absent or too diminutive in size to be used in the majority of patients. Despite the many advantages of microsurgical total autologous breast reconstruction, it is associated with longer operative times than pedicled TRAM procedures, requires expertise in microsurgery, and has the potential for complete flap failure due to microvascular thrombosis.

Implant and Autologous Tissue Reconstruction. The pedicled latissimus dorsi myocutaneous flap procedure is a straightforward, reliable method used for breast reconstruction. It is often reserved for reconstructing breasts when other methods have previously failed. The latissimus flap is relegated to second-choice status because it carries the major disadvantage of autologous tissue reconstruction (donor site morbidity) as well as all of the potential complications associated with breast implants. That aside, the latissimus flap/implant–based reconstruction can produce excellent cosmetic results with relatively low donor site morbidity (Fig. 45-47). The latissimus dorsi muscle with overlying skin paddle is elevated based on its thoracodorsal vessel pedicle, tunneled through the axilla, and delivered into the mastectomy site. After partial insetting, either a tissue expander or permanent implant is usually placed behind the muscle to give adequate volume to the reconstruction (Fig. 45-48). Drawbacks specific to this method include contour irregularity of the back, high rate of donor site seroma, and shoulder weakness (uncommon).

Accessory Procedures. After creation of the breast mound, refinements and accessory procedures are performed after approximately 3 months. These may include breast mound revision, scar revisions, fat grafting, and nipple-areola complex reconstruction. Scores of methods have been described for reconstructing the nipple. These include local flap techniques (e.g., star flap, skate flap, C-V flap), grafting techniques (contralateral nipple/areola sharing, groin skin, labia skin), and tattooing.

Radiation-Related Considerations. With some notable exceptions, most surgeons advocate avoidance of implant-based breast reconstruction in chest walls that have previously received radiation or are likely to receive radiation due to the relatively high rate of complications and disappointing results. Delayed total autologous reconstructions bring healthy nonirradiated tissue to replace the damaged fibrotic tissue and are the preferred mode of breast reconstruction in this setting. Similarly, latissimus dorsi/implant reconstructions replace much of the irradiated skin, which probably explains to some degree why, in the face of previous irradiation, implants fair better with an overlying latissimus flap than without.

The question of whether total autologous reconstructions should be done before or after anticipated radiation therapy is still controversial. Those in favor of delaying the reconstruction argue that an irradiated flap will exhibit shrinkage and fibrosis that subtracts from the overall aesthetic result. Those in favor of performing immediate reconstruction in this setting feel that, because immediate reconstructions have inherently better aesthetics, the imperfect result due to irradiation it is still comparable to the result of delayed reconstruction without the additional operation. To date, no prospective study has been performed comparing the two approaches.

Trunk and Abdominal Reconstruction

In the trunk, as in most areas of the body, choice of reconstructive method is determined by the location and size of the defect and the properties of the deficient tissue. A distinction is made between partial-thickness and full-thickness defects in deciding between grafts, flaps, synthetic materials, or a combination of techniques. Unlike the head and the lower leg, the trunk harbors a relative wealth of regional transposable axial pattern flaps that allow sturdy reconstruction, only rarely requiring distant free tissue transfer. Indeed, the trunk serves as the body's arsenal, providing its most robust flaps to rebuild its largest defects.

Thoracic Wall. The chest wall is a rigid framework designed to resist both the negative pressure associated with respiration and the positive pressure from coughing and from transmitted intra-abdominal forces. Furthermore, it protects the heart, lungs, and great vessels from external trauma. Reconstructions of chest wall defects must emulate these functions.

Gimbel.)*

B

Figure 45-46. (*Continued*)

The pectoralis major muscle is the workhorse pedicled flap for coverage of the sternum, upper chest, and neck. It is a Mathes and Nahai type V flap with one dominant pedicle (pectoral branch of the thoracoacromial artery) and several secondary segmental pedicles (intercostal perforators and the pectoral branch of the lateral thoracic artery).[52] The muscle may be advanced or transposed on its dominant pedicle or used as a turnover flap based on its internal mammary perforators. Both methods are useful in covering the sternum after dehiscence or infection. Before the turnover flap is elevated, previous operative notes should be reviewed carefully to determine whether the internal mammary artery is still a viable perfusion source; the artery, especially the left, is frequently used for heart revascularization. The muscle may also be used for obliteration of

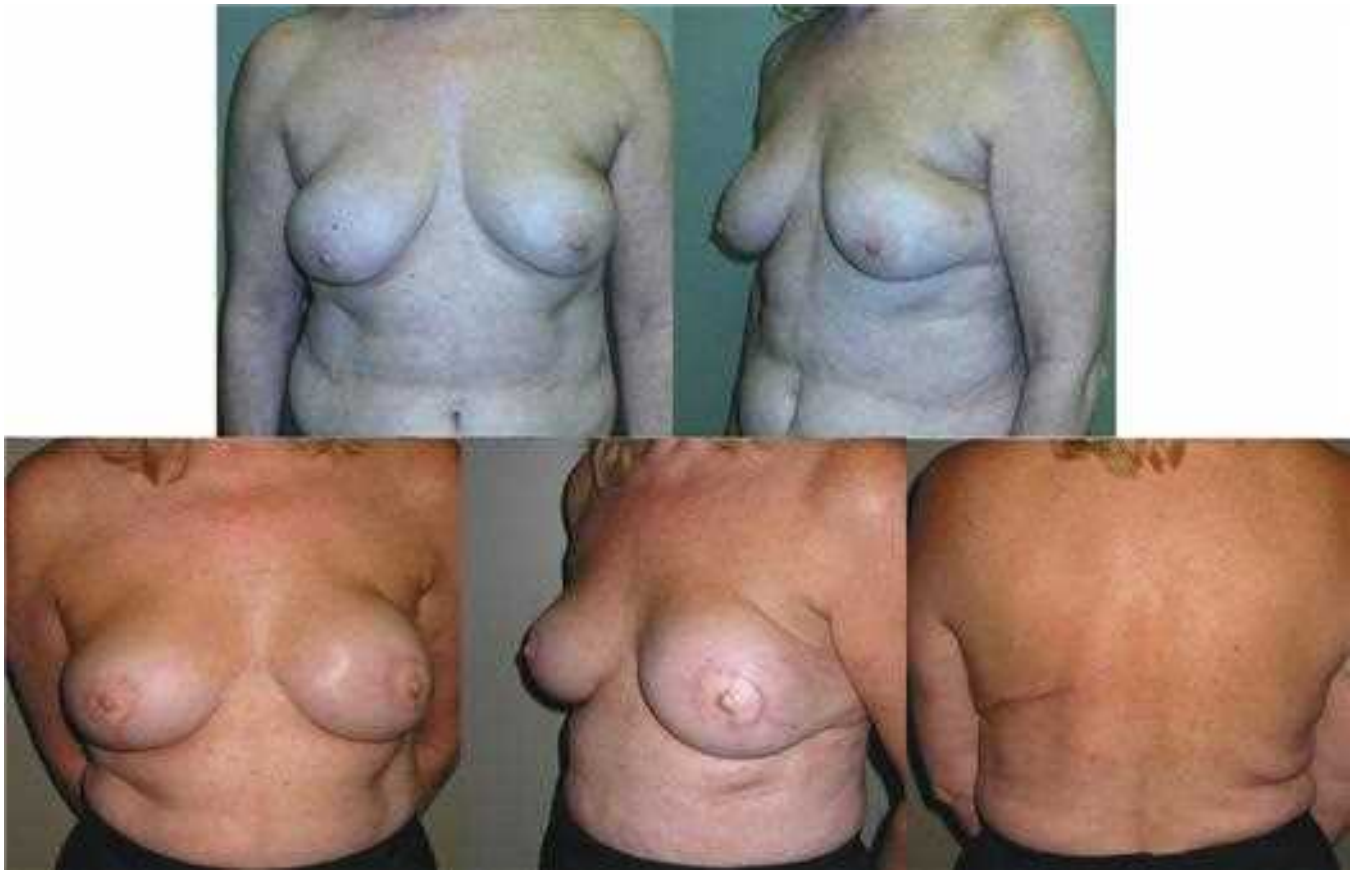

Figure 45-47. Preoperative and postoperative photos of a 58-year-old woman with a left latissimus dorsi flap/silicone implant breast reconstruction and right symmetrization mastopexy. *(Photographs reproduced with permission from M. Gimbel.)*

intrathoracic dead space infections and as a myocutaneous flap for head and neck reconstruction. Although it is a reliable flap, the loss of the pectoralis major muscle results in upper extremity weakness and cosmetic deformity from loss of the anterior axillary fold.[53]

The rectus abdominis muscle is a type III axial pattern flap that can be based on the superior epigastric vessels or the deep inferior epigastric vessels.[51] When elevated as a myocutaneous flap it can be designed with a transverse (TRAM) or vertical rectus abdominis myocutaneous skin paddle. Although the vertical rectus abdominis muscle flap has better vascularized skin due to its multiple longitudinally oriented perforators, the TRAM flap provides a larger area of donor skin that can be primarily closed with an easily concealable scar. The rectus abdominis muscle is frequently used for lower sternum reconstruction when the pectoralis muscle is insufficient. It can also be used in pedicle or free flap configuration for repair of large chest wall defects from cancer resection (Fig. 45-49).

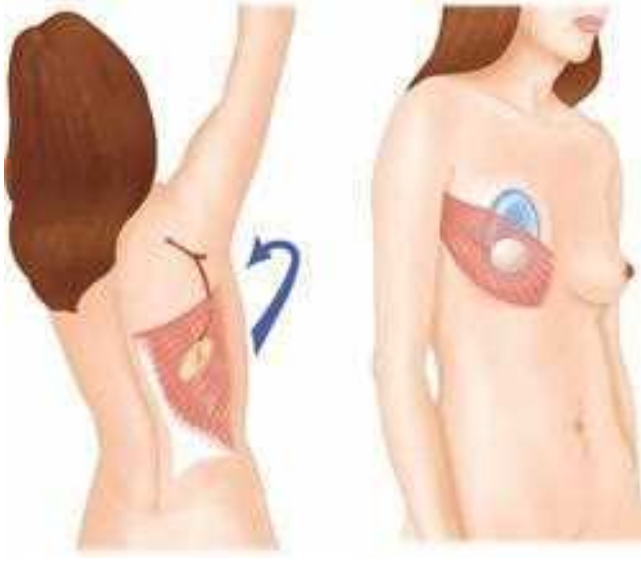

Figure 45-48. Latissimus dorsi flap/implant–based breast reconstruction. *(Illustrations reproduced with permission from M. Gimbel.)*

The latissimus dorsi myocutaneous flap is probably the most widely used flap in nonsternal chest wall reconstructions due to its broad size, location, reliability, and pedicle length. The flap is based on the thoracodorsal vessels arising from the subscapular system. Its secondary blood supply comes from the posterior intercostal and lumbar vessels.[52] The arc of rotation of this flap can extend to most areas on the ipsilateral torso as well as to the abdomen, head and neck, and upper arm. The serratus anterior muscle can be included on the same vascular pedicle to further increase its surface area. Use of this donor site is relatively well tolerated, but shoulder weakness can be significant. The major drawbacks of the latissimus flap are its conspicuous scar and the high risk of seroma.[53]

The trapezius muscle flap, based on the transverse cervical vessels, is generally used as a pedicled flap to cover the upper midback, base of neck, and shoulder. The superior portion of the muscle along with the acromial attachment and spinal accessory nerve are preserved to maintain shoulder elevation function.

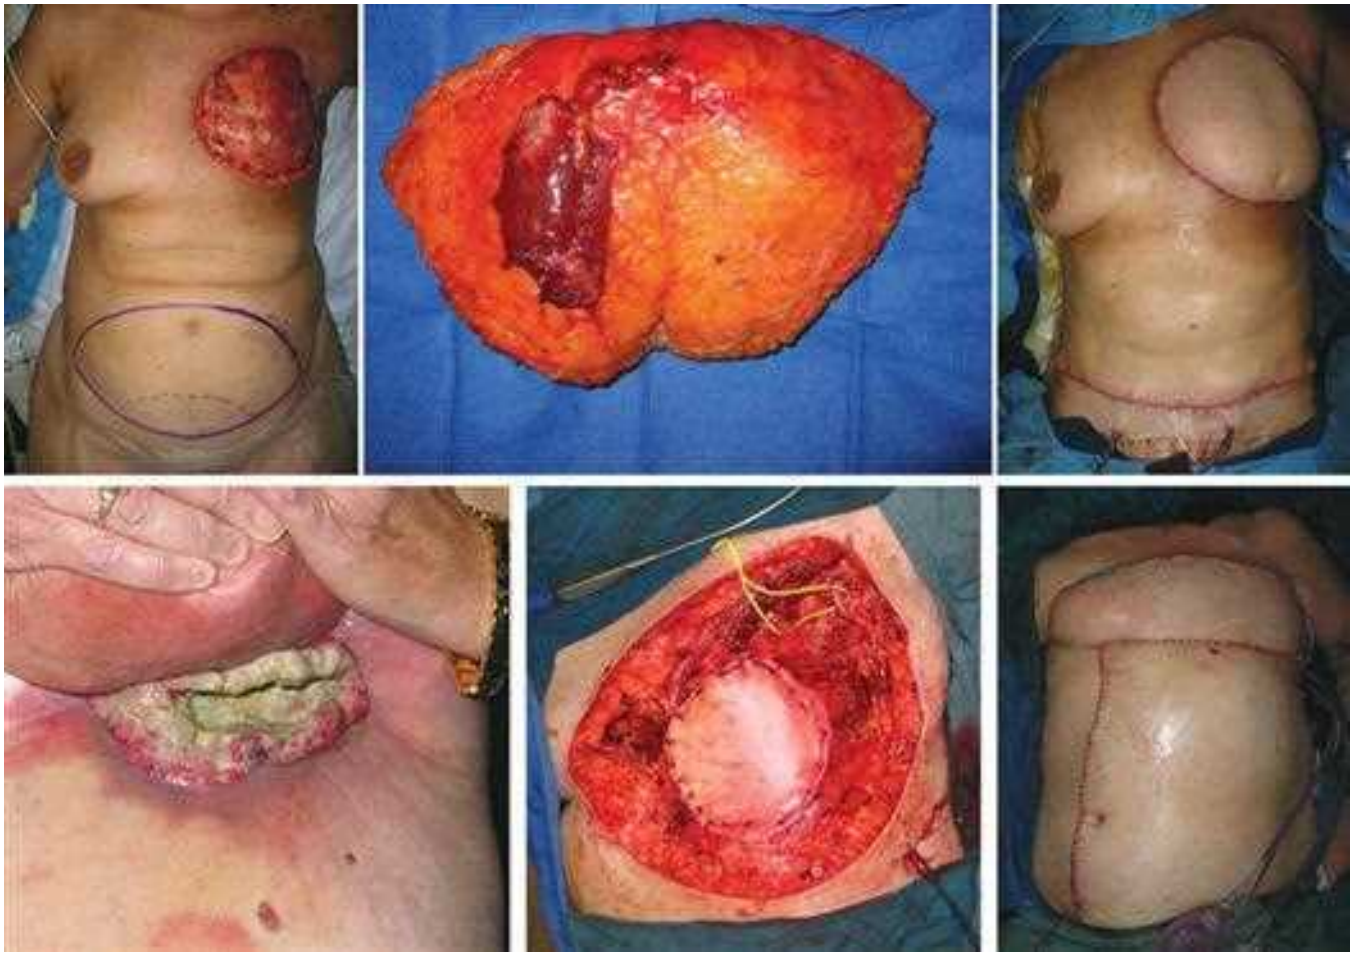

Figure 45-49. *Top row:* Free transverse rectus abdominis muscle reconstruction of a large partial-thickness chest wall defect. *Bottom row:* Full-thickness chest wall defect reconstructed in two layers with human acellular dermal allograft and overlying pedicled vertical rectus abdominis muscle flap. *(Photographs reproduced with permission from M. Gimbel.)*

Other useful flaps of the thoracic region include the scapular/parascapular fasciocutaneous flap, the external oblique flap, the medially or laterally based thoracoepigastric skin flaps, and the omental flap.

When a full-thickness defect of the chest wall involves more than two adjacent ribs, the inherent rigidity of soft tissue flaps may provide insufficient chest wall integrity. Although cadaveric bone and autologous bone grafts have been used in the past to lend structural support, the availability of well-tolerated synthetic and biologic materials has become more common. These materials include polypropylene (Prolene), polyethylene (Marlex), and polytetrafluoroethylene (Gore-Tex) meshes, methyl methacrylate, and acellular dermal allograft. Even if these avascular foreign bodies must be removed due to chronic infection, often a thick fibrous layer of tissue will have formed that can maintain chest wall stability.[53]

Abdominal Wall. The abdominal wall also protects the internal vital organs from trauma, but with layers of strong torso-supporting muscles and fascia rather than with osseous structures. The goals of reconstruction are restoration of structural integrity, prevention of visceral eventration, and provision of dynamic muscular support. Defects in the abdominal wall may arise from trauma, oncologic resection, congenital deformities, and infection. By far the most common reason for abdominal wall deficiency, however, is incisional fascial dehiscence and herniation after laparotomy. When a reconstruction plan is being formulated, careful physical examination and review of the medical history will help prevent selection of an otherwise sound strategy that, because of previous incisions and trauma, is destined for failure.

Partial Defects of the Abdominal Wall. Large defects of the abdominal skin and subcutaneous tissue are usually easily controlled with skin grafts, local advancement flaps, or tissue expansion. Myofascial defects are more difficult to manage. The abdominal wall fascia requires a minimal-tension closure to avoid dehiscence, recurrent incisional hernia formation, or abdominal compartment syndrome.[54] Prosthetic meshes are frequently used to replace the fascia in clean wounds and in operations that create myofascial defects. When the area of fascial deficiency is contaminated, as in infected mesh reconstructions, enterocutaneous fistulas, or viscus perforations, prosthetic mesh is avoided because of the risk of infection. A delayed reconstruction can be prefaced by insetting a resorbable polyglactin (Vicryl) mesh that will eventually granulate to allow skin grafting. The ensuing hernia is repaired later with prosthetics under cleaner conditions. The separation-of-components procedure has enjoyed much success in closing large midline defects without resorting to mesh. This procedure involves advancement of bilateral myofascial flaps consisting of the anterior rectus fascia/rectus abdominis/internal oblique/transversus abdominis muscle complex.

Mobility of this myofascial unit is created by release of the external oblique muscle at the semilunate line. Midline defects measuring up to 10 cm superiorly, 18 cm centrally, and 8 cm inferiorly can be closed using separation of components.[55] This technique is less effective in closing lateral defects, for which regional muscle and fascial flaps are usually better suited (rectus abdominis flap, internal oblique flap, external oblique flap).[54]

Full-thickness abdominal defects and large myofascial defects require large robust pedicled flaps or free flaps for closure. The tensor fasciae latae pedicled flap, based on the ascending branch of the lateral circumflex femoral vessels, is useful in reconstructing the lower two-thirds of the abdomen. Bilateral flaps can be used for very large defects, although the skin-grafted donor site is unsightly. The rectus femoris flap and the vastus lateralis flap can be used for smaller lower abdominal defects. The "mutton-chop" flap, which is an extended rectus femoris flap with fascia lata included distally, has been used successfully in closing massive defects.[56,57] Large defects of the upper abdominal wall may be repaired with pedicled extended latissimus dorsi flaps with attached pregluteal fascia. Very large full-thickness defects, especially superiorly, are best treated with free tissue transfer of large myofascial units such as the latissimus dorsi or the tensor fasciae latae. These can also be innervated flaps to reestablish contractile force and strength in the abdominal wall.

Extremity Reconstruction

Posttraumatic Reconstruction. With the beginnings of modern orthopedic and plastic surgery, improvements in the understanding of anesthesia, trauma resuscitation, infection, and the availability of early antibiotics, the requirement to amputate almost all open (compound) lower extremity fractures as a life-saving procedure gradually decreased while attempts at limb salvage became more realistic. The introduction and maturation of microsurgical techniques witnessed increasing successes in distal extremity replantations and free flap reconstructions. Soft tissue reconstruction thus advanced alongside evolving techniques of bone fixation, joint reconstruction, general vascular surgery, and acute multitrauma management. Current lower extremity reconstruction incorporates the use of vascularized bone, bone distraction techniques, composite tissue flaps, and functioning muscle transfers tailored to the given defect.[58] The future may behold the use of cadaveric vascularized composite allografts or even tissue-engineered vascularized composite tissue constructs.

Common causes of high-energy lower extremity trauma include road traffic accidents, falls from a height, direct blows, sports injuries, and gunshots. Understanding the anatomy of the lower limb compartments, nerve and vascular supplies, muscle functions, skeletal structure, and mechanics is essential for accurate bony and soft tissue restoration for function and appearance. Several limb-salvage scoring systems have been suggested to aid in the decision regarding whether to amputate or attempt limb salvage, but their routine use remains controversial; nevertheless, they can provide guidance during this life-altering decision process.[59] Compound fractures are often classified according to the system devised by Gustilo and colleagues (Table 45-12).[60]

In addition to following standard multiple trauma evaluation and resuscitation guidelines, the multidisciplinary team must assess the injured limb for neurovascular status, soft tissue defects and degloving, configuration of fractures, and

Table 45-12

Gustilo and Anderson classification of compound fractures

CLASSIFICATION	DESCRIPTION
Grade I	Wound <1 cm; minimal contamination, comminution, and soft tissue damage
Grade II	Wound >1 cm; moderate soft tissue damage and minimal periosteal stripping
Grade IIIa	Substantial contamination and severe soft tissue damage but adequate fracture coverage; usually due to high-energy trauma
Grade IIIb	Substantial contamination, periosteal stripping, severe soft tissue damage, and inadequate fracture coverage; usually due to high-energy trauma
Grade IIIc	Any open fracture with an associated arterial injury requiring repair

presence of compartment syndrome. Neurovascular status and evidence for compartment syndrome require frequent reassessment, particularly following interventions such as fracture reduction, splintage, and surgery. Bony stabilization may be critical to controlling fracture hemorrhage. Doppler ultrasound examination may help assess vascular integrity. Angiography is a lengthier procedure that provides more detailed information, but the team must be cognizant that delay to revascularization increases the risk of massive reperfusion injury and multiple organ failure.[61] Compartment syndrome must be released with urgent fasciotomies when present. Its most critical early feature is increasingly severe pain especially on passive stretch of the compartment's musculature; pulselessness, pallor, paresthesia, and paralysis are late signs. Compartment pressure monitors are useful in patients who are unconscious or have proximal nerve blocks in place. Antitetanus vaccine and antibiotics should be provided as soon as possible according to contemporary guidelines.[62] An evaluation of the patient as a whole allows treatment to be planned within the context of comorbidities, socioeconomic considerations, and rehabilitative potential. The loss of plantar sensation historically favored below-knee amputation, but this is no longer an absolute recommendation.[61]

With the availability of microvascular free tissue transplantation, radical débridement (i.e., wound excision) can be adequate even for the largest wound. Early one-stage wound coverage and bony reconstruction is generally advocated and should be performed jointly by extremity trauma orthopedic and plastic surgical teams whenever possible.[61,62] It is reasonable for reconstruction to be deferred briefly if there remain tissues of questionable viability so that these can be reassessed and débrided as required. Placement of a temporary negative pressure dressing between débridements helps reduce bacterial ingress and the inflammatory response. If débridement produces an irregular dead space that cannot be completely obliterated, or if tissues remain questionable even after a second look, the resultant cavity may be filled with antibiotic-impregnated beads or available vascularized soft tissues to act as a spacer

until definitive reconstruction is possible. This applies also to segmental bone losses within a soft tissue envelope of doubtful viability. In these situations, soft tissue coverage preferably is still achieved early; bony reconstruction can be completed at a later date, when both the bone and soft tissue envelope are stable and healthy. It remains debated whether fasciocutaneous or muscular flaps are superior for treating compound fractures. Dead space is critical to obliterate, and this is more readily achieved using muscle. Fasciocutaneous flaps may be superior for coverage of metaphyseal fractures, particularly around the ankle. Reviewed experimental data in animals suggest that diaphyseal tibial fractures with periosteal stripping are better covered by muscle instead of fasciocutaneous flaps.[63] Perforator-based chimeric flaps, such as the anterolateral thigh flap with a chimeric portion of vastus lateralis, can be designed to incorporate the best features of both tissue types for the given defect.

Once meticulous débridement is complete, the order of surgical repair is fracture stabilization followed by vascular repair and reconstruction of a stable soft tissue envelope. The choice of method for soft tissue coverage is determined by the location and extent of the injury (Table 45-13). Coverage for weight-bearing areas should be durable, stable (nonshearing), and sensate. Properly fitted footwear provides essential protection against pressure-related complications. Split-thickness skin grafts are reasonable for coverage of exposed healthy muscle or soft tissue. Local flaps may be used to cover smaller defects. Island pedicled perforator-based flaps are more versatile in design and inset, preserve viable muscles by excluding them from flap harvest, and can be a useful option when there is no significant degloving injury (Fig. 45-50). Using retrograde pedicle dissection, they can be harvested in freestyle fashion both to avoid the zone of injury and to suit the defect requirements.[64] Free tissue transplantation is preferred for larger or more complex defects, particularly in the middle and lower thirds of the leg where there are less soft tissues available for reconstruction. Free flaps need not be limited to providing only soft tissue coverage; incorporation of vascularized bone, such as of fibula or iliac crest, can aid in fracture management.[65] Chimeric flap configurations can improve flap insetting into composite defects. Flow-through designs, such as the anterolateral thigh flow-through free flap, can be used to bridge segmental vascular defects to revascularize the distal extremity.[66] Muscular flaps can be motor innervated to restore lost muscle functions at the recipient site.[67] Other techniques such as bone distraction and tissue expansion may be indicated in select circumstances. Traditional cross-leg flaps are almost never used now; they cause complete immobilization and increase the risk of deep vein thrombosis and contracture formation.

Osteomyelitis often complicates inadequately débrided compound leg fractures. Delayed coverage also appears to increase the risk of this dreaded complication. Generous irrigation, débridement, removal of dead bone (even in a segment), expedient antibiotic therapy, and healthy soft tissue coverage are important in both acute compound fracture and established posttraumatic osteomyelitis. Large segmental bone losses can be addressed with microvascular free transplantation of osseous flaps or distraction lengthening.[61,68]

When limb salvage either is not possible or is not in the best interests of the patient, attention is directed to providing soft tissue stump coverage suitable for weight bearing and allowing ambulation with a properly fitted prosthesis. Ideally, local tissues are used; however, when they are unavailable or inadequate, the amputated part can be a useful source of skin grafts or tissues for microvascular free transfers to the stump, which preserves length and avoids a more proximal amputation.

Table 45-13

Some lower extremity reconstructive options for soft tissue coverage after fracture

AREA OF DEFECT	RECONSTRUCTIVE OPTIONS
Femur	Sartorius muscle/MC flap (anterior defects) TFL muscle/MC flap (posterior defects) Vastus lateralis/medialis muscle/MC (mid to lower thigh defects) ALT/AMT and posterior thigh fasciocutaneous flap Free osseous flaps (e.g., double-barreled fibula osteoseptocutaneous flap) useful for segmental femur defects
Knee and proximal third of tibia	Gastrocnemius muscle (medial or lateral head, or both) with SSG Island pedicled fasciocutaneous flaps (e.g., distally based anterolateral thigh flap; medial sural artery perforator flap) Free tissue transfer for larger defects
Middle third of tibia	Soleus muscle with SSG Gastrocnemius head(s) with SSG Tibialis anterior muscle "open-book flap" (preserves function) Island pedicled fasciocutaneous flaps (e.g., posterior tibial and peroneal perforator flaps) Free tissue transfer for larger defects
Distal third of tibia	Free tissue transfer usually the first choice Reverse flow sural neurofasciocutaneous flap Island pedicled fasciocutaneous flaps (e.g., posterior tibial and peroneal perforator flaps) Local muscle flaps for smaller defects

ALT = anterolateral thigh; AMT = anteromedial thigh; MC = myocutaneous; SSG = split-thickness skin graft; TFL = tensor fasciae latae.

Reconstruction after Oncologic Resection. The refinements in surgical ablation techniques, in adjuvant radiation therapy and chemotherapy, and in limb reconstruction methods have opened the possibility for curative limb-sparing treatments instead of amputation. Extensive soft tissue and segmental long bone defects from radical tumor resection and radiation-compromised wound healing can often be reconstructed now by liberal importation of fresh tissues through microvascular free tissue transplantation tailored to the defect.

Diabetic Ulceration. The pathophysiology of primary diabetic lower limb complications has three main components: peripheral neuropathy (motor, sensory, and autonomic), peripheral vascular disease, and immunodeficiency. Altered foot

Figure 45-50. Perforator-based island pedicled anterolateral thigh flap for soft tissue coverage of the upper third lateral leg. **A.** Soft tissue defect with exposed tibial metaphysis after débridement. Note the arterial handheld Doppler signal (*red dot*) around which the flap has been designed. The flap has been reverse-planned and the pivot point determined along the axis of the descending branch of the lateral circumflex femoral artery (*black line*). **B.** The flap has been harvested and its pedicle skeletonized to maximize freedom of flap motion; note the additional backup vein in case venous supercharge might be required. **C.** Satisfactory flap perfusion following inset. **D.** Flap perfusion became compromised postoperatively but (**E**) improved with bedside maneuvers; if improvement did not occur, backup venous supercharge would have been available. **F.** The regional fasciocutaneous flap has provided durable, color- and texture-matched soft tissues for reconstruction around the knee; importantly, the pliability of the flap tissues has allowed for a full range of knee movement to be maintained. *(Photographs reproduced with permission from L. Lin.)*

biomechanics and gait caused by painless collapse of ligamentous support, foot joints, and foot arches change weight-bearing patterns. Blunted pain allows cutaneous fissuring and ulceration to progress. Multiflora infections are established amid local immunodeficiency and microvasculopathy. Frank neuroarthropathic Charcot's foot deformities may ultimately result. Cutaneous ulcerations may chronically deteriorate relatively painlessly, involving deeper tissues, including bone. Persistent soft tissue infection and osteomyelitis, worsened by peripheral vascular compromise and immunodeficiency, traditionally ends in gangrene and amputation. More than 60% of nontraumatic lower extremity amputations occur in diabetics.[69] Indeed, the age-adjusted lower extremity amputation rate in diabetics (5.5 per 1000 diabetics) was approximately 28 times that of people without diabetes (0.2 per 1000 people).[69] Improved patient education and medical management, timelier detection of diabetic foot problems and referral for treatment, and the use of more refined techniques for wound management play important roles in improving the chances of limb preservation.[70]

Diabetic patients with lower limb disease often have significant multisystemic comorbidities that must be optimized for surgery; strict perioperative control of blood glucose levels is mandatory. Clinical examination must include documentation of sensory deficits, vascular insufficiencies, and evidence of osteomyelitis. Plain radiographs, MRI, nuclear bone scans, and angiography or duplex imaging may be indicated. A patient with significant vascular disease may be a candidate for lower extremity endovascular revascularization or open bypass.[71] Nerve conduction studies may diagnose surgically reversible neuropathies at compressive sites and aid in decisions about whether to perform sensory nerve transfers to restore plantar sensibility.[70] Antibiotic and fungal therapies should be guided by tissue culture results.

Plastic surgical management starts with thorough débridement of devitalized or infected tissues, purulent cavities, and osteomyelitic bone. Methods of wound closure are dictated by the extent and location of the postdébridement defect (Table 45-14). Vacuum-assisted closure may be appropriate for superficial defects. Skin grafts should be used cautiously and not in weight-bearing areas. Local and regional flaps can be used after careful evaluation of their vascularity given concurrent peripheral vascular disease and possible recent distal vascular bypass procedures. Microvascular free tissue transfers are appropriate when defects are large or when local flaps are not available. Combination lower extremity bypass and free flap coverage has proved beneficial for the treatment of the diabetic foot in terms of healing and reduction of disease progression.[72] Orthopedic surgeons should be consulted to improve foot biomechanics and address bony prominences to reduce the risk of recurrent ulceration. Proper footwear (including orthotic devices and off-loading shoe inserts), hygiene, and toenail and skin care are essential.[70]

Table 45-14

Some reconstructive options for the diabetic foot

AREA OF DEFECT	RECONSTRUCTIVE OPTIONS
Forefoot	V-Y advancement Toe island flap Single toe amputation Lisfranc's amputation
Midfoot	V-Y advancement Toe island flap Medial plantar artery flap Free tissue transfer Transmetatarsal amputation
Hindfoot	Lateral calcaneal artery flap Reversed sural artery flap Medial plantar artery flap ± flexor digitorum brevis Abductor hallucis muscle flap Abductor digiti minimi muscle flap Free tissue transfer Syme's amputation
Foot dorsum	Supramalleolar flap Reversed sural artery flap Thinner free flaps (e.g., temporoparietal fascia, radial forearm, groin, thinned anterolateral thigh flaps)

Lymphedema. The lymphatic system provides a high-volume transport mechanism, clearing proteins and lipids from the interstitial space to the systemic vasculature by means of differential pressure gradients. Factors that contribute to circulatory lymphatic flow include segmental lymphangion contractility, skeletal muscle activity, and one-way valves that prevent backflow.[73,74] The lymphatics course throughout the body alongside the venous system, into which they eventually drain via the major thoracic and cervical ducts. With lymphatic obstruction, abnormal connections form between the superficial and deep lymphatics and between the lymphatic and venous systems. Lymphatic stagnation, hypertension, and valvular incompetence contribute to edema, inflammatory fibrovascular proliferation, and collagen deposition, causing firm, nonpitting swelling with peau d'orange cutaneous changes. Lymphoscintigraphy reveals the lymphatic anatomy and quantifies lymphatic flow. MRI provides anatomic information regarding lymphatic trunks, nodes, and obstructive lesions. It is essential to rule out neoplastic lymphatic invasion, especially after oncologic ablation, as a cause of secondary lymphedema. Lymphangiosarcoma is a rare cause of lymphedema that is deadly if diagnosed late.[75]

Primary lymphatic obstruction may arise from congenital malformations of the lymphatic system such as lymphatic hypoplasia, functional insufficiency, or absence of lymphatic valves. Identified genetic causes include the autosomal dominant Milroy's disease. Lymphedema praecox accounts for >90% of cases of primary lymphedema, generally appears during puberty but sometimes as late as the third decade, and occurs more commonly in females. It is usually unilateral and limited to the foot and calf. Lymphedema tarda appears after the age of 35 years and is relatively rare. Secondary (acquired) lymphedema is much more common, with filariasis being the leading cause worldwide.[76] In Western countries, secondary lymphedema is more commonly the result of neoplasms and their surgical treatments and radiotherapy.[76]

The mainstays of management for lower extremity lymphedema are patient education and nonsurgical measures, including one or more of the following: use of external compressive garments and devices, limb elevation, administration of antibiotics for episodes of cellulitis, and specialized complex physical therapy.[77,78]

Until recently, the efficacy of available surgical options was generally poor, so they were reserved for cases in which aggressive nonsurgical measures had failed. The classic Charles procedure involved radical excision of lymphedematous suprafascial tissues with skin grafting for coverage; cosmetic outcomes were often disastrous, and functional problems arose due to high rates of contracture, wound breakdown, and ulcerations. This method was later modified into multiple staged excisions of subcutaneous tissues. Other techniques include liposuction and bridging procedures.[78] Microsurgical lymphatic-lymphatic, lymphatic-venous, lymphatic-venous-lymphatic, and lymph node–venous anastomoses were all tried historically, with some techniques showing efficacy early on but long-term results showing high variability.[79] Recently, however, with an increased understanding of its pathophysiology and improved preoperative investigations, objective staging of lymphedema severity has become more accurate and allowed microsurgeons to tailor treatments for properly selected patients.[80,81] These factors, alongside improvements in microsurgical techniques, instrumentation, and long-term postoperative care, have provided better surgical results and a resurgence in interest in microsurgical treatment for lymphedema.[76] Nonsurgical techniques can be, and usually are, combined with any of the surgical methods.

Pressure Sore Treatment

A *pressure ulcer* is defined as tissue injury, usually over a bony prominence, due to pressure or a combination of pressure and shear forces. These wounds occur in patients debilitated by age, illness, immobilization from orthopedic injuries, or spinal cord injury. Prevention of pressure ulcers first requires identification of susceptible patients. Once such patients are identified, measures to prevent development of ulceration include frequent position changes (by both the patient and caretakers), use of pressure reduction equipment (low air loss mattresses and seat cushions, heel protectors), nutritional optimization, hygienic control of incontinence, and medical and/or surgical treatment of muscle spasm and joint contracture. Once an ulcer has developed, these same factors must be carefully evaluated and deficiencies corrected before embarking on a complex reconstructive treatment plan. Successful reconstruction also requires a medically stable, cooperative, motivated patient with adequate social support.

Pressure ulcers are described by their stage, based on depth of tissue injury (Table 45-15).[82] Stage I and II ulcers are treated conservatively with dressing changes and basic pressure ulcer prevention strategies as already discussed. Patients with stage III or IV ulcers should be evaluated for surgery. The wound is examined for soft tissue infection or abscess, osteomyelitis, and involvement of deeper structures or spaces (e.g., joint space, urethra, spinal canal) to determine the urgency and specific requirements of the problem. Blood laboratory work and imaging studies are performed to help establish whether soft tissue or bone infection is present. Radiographs are usually adequate to rule out osteomyelitis; CT and MRI are helpful when plain films are equivocal. Wet gangrenous tissue and abscesses should be surgically débrided without delay to prevent or treat sepsis. In patients who do not meet the strict reconstruction criteria, débridement to healthy tissue without subsequent reconstruction may be the optimal treatment. If bone is present at the wound base, it should be débrided only to bleeding bone and left with a smooth contour. Complete ischiectomy should not be performed for ischial decubitus ulcers, because removal of one ischium only transfers subsequent pressure trauma to the contralateral ischium or the perineum. If osteomyelitis is present, which is best proven by culture of specimens obtained by intraoperative bone biopsy, long-term antibiotic therapy guided by microorganism sensitivity is indicated. A special note should be made regarding surgical treatment of spinal cord injury patients with T5 or higher injuries. In these patients, manipulation of a pressure ulcer and even simple urinary retention can trigger autonomic hyperreflexia. This dangerous condition is characterized by critically high blood pressure elevation and sympathetic discharge. Effective management is immediate recognition and reversal of trigger factors along with prompt administration of pharmacologic agents to prevent complications such as intracranial and retinal hemorrhage, seizure, cardiac irregularities, and death.

Table 45-15

National pressure ulcer advisory panel staging system

CLASSIFICATION	DESCRIPTION
Stage I	Intact skin with nonblanchable redness
Stage II	Partial-thickness loss of dermis; may present as blister
Stage III	Full-thickness loss of dermis with visible subcutaneous fat (no deeper structures exposed)
Stage IV	Full-thickness loss of dermis with exposed bone, tendon, or muscle
Unstageable	Full-thickness loss of dermis with ulcer base obscured by eschar

Direct closure of a pressure ulcer is rarely performed because it usually creates tension in the healing tissues already stressed by nonphysiologic external pressure, predisposing the closure to breakdown. Skin grafting is useful for shallow ulcers with well-vascularized beds that are not subjected to high mechanical shear. Unfortunately, these requirements remove most pressure ulcers from skin graft candidacy. The mainstay of deep pressure ulcer reconstruction is coverage with well-vascularized local flaps. There is debate over whether myocutaneous flaps are better than fasciocutaneous flaps for resurfacing regions prone to excess pressure and shear. Although myocutaneous flaps have excellent bulk and blood supply, muscle has low tolerance for ischemic injury. From an anatomic viewpoint, there is no pressure point on the human body where bone is padded by muscle. On the other hand, although fasciocutaneous flaps provide reasonable bulk and are teleologically appropriate, some argue that subcutaneous fat and fascia have low resistance to pressure and shear forces and have less robust perfusion than muscle.[83]

The anatomic location of the pressure ulcer naturally has a profound impact on flap choice. Regardless of the wound site, however, the flap design should be very large, more than needed for closure, so that if the ulcer recurs the flap can be readvanced. In addition, care should be taken to place suture lines, the weakest part of the reconstruction, away from pressure points. Over the last few decades, patterns have developed in the selection of particular flaps for particular pressure sores. Sacral decubiti are well treated with gluteus maximus myocutaneous flaps (Fig. 45-51). In ambulatory patients, either the superior or the inferior gluteus muscle is spared to preserve hip extension function. The downside of using the gluteal muscle is the relatively

Figure 45-51. Flap reconstruction of pressure ulcers. *Top row:* Preoperative and 1-month postoperative photos of a stage IV sacral decubitus ulcer treated with a myocutaneous gluteus maximus flap. *Bottom row:* Preoperative and 1-month postoperative photos of a stage IV trochanteric ulcer treated with a myocutaneous V-Y tensor fasciae latae flap. *(Photographs reproduced with permission from M. Gimbel.)*

bloody dissection. A common alternative is the gluteal fasciocutaneous advancement or rotational flap. Ischial pressure sores are generally due to sitting in a wheelchair with improper cushioning or insufficient position changes. A good first-choice flap for ischial wound reconstruction is the hamstring V-Y myocutaneous flap. The gluteus maximus flap may also be transposed inferiorly to cover this wound. A fasciocutaneous alternative is the posterior thigh flap, based on the continuation of the inferior gluteal artery. Trochanteric ulcers develop from prolonged positioning in the lateral decubitus position or from poorly fitting seat or wheelchair equipment. The tensor fasciae latae myocutaneous flap is an expendable muscle unit in ambulatory patients that has a reliable blood supply. It can be advanced superiorly or transposed on its long arc of rotation (see Fig. 45-51). Good second-choice flaps are the rectus femoris muscle flap and the vastus lateralis myocutaneous flap. When pressure sores are neglected, they can become confluent, forming large areas of deep tissue destruction. This dire situation may require hip disarticulation and use of the upper leg soft tissue as a total thigh flap for coverage.

The postoperative care after flap reconstruction of pressure ulcers is as important for success as the surgery itself. The authors recommend transfer of the patient from the operating room table onto an air-fluidized bed, where the patient will remain for the next 7 to 10 days in the hospital. Meticulous instructions must be given to the nursing staff and therapists regarding the positioning and rolling of the patient to prevent stressing the suture lines during these maneuvers. Nutrition and muscle spasm control are carefully maintained. The posthospitalization care plan, which should have been arranged preoperatively, is confirmed to avoid lapses in proper care. Patients with ischial sores are advised to abstain from sitting for 6 weeks to allow for sufficient healing. Care of the pressure ulcer patient is a labor-intensive process that requires attention to detail by the surgeon, nurses, therapists, caseworkers, and family. Unfortunately, small gaps in care inevitably lead to large gaps in the debilitated patient's integument.

Reconstructive Transplant Surgery

Composite tissue allotransplantation (CTA), such as hand and face transplantation, has become a clinical reality and offers enormous potential for many reconstructive problems, including amputation of extremities. However, as with solid organ transplantation, there remains the issue of allograft rejection. In contrast to visceral organ transplantation, which involves homogeneous tissues, CTA may involve a combination of skin, subcutaneous tissue, nerve, blood vessels, muscle, tendon, and bone, and thus carry the antigenicities of all these tissue types. The basic principles of immunosuppression for solid organ

transplantation have been applied to CTA and include therapy with a variety of combinations of T-cell–depleting agents, monoclonal antibodies, calcineurin inhibitors, antimetabolites, and rapamycin. The complications associated with immunosuppression are well known, including opportunistic infections, metabolic disturbances, and malignancies. Patients selected to undergo CTA, specifically hand transplantation, are young and healthy and therefore more resistant to immunosuppressive side effects than typically less robust solid organ recipients.

As with any surgical procedure, the benefits, success rate, and complications must be understood. Unlike solid organ transplantation, CTA is not a lifesaving procedure. There remains much debate over the risks associated with lifelong administration of potentially dangerous immunosuppressive agents to patients who have no life-threatening illness. The ultimate goal in CTA research is immune tolerance in which the recipient of the allograft remains fully immunocompetent yet does not mount an immunologic response to the transplanted allograft. Accomplishment of this goal would allow the decrease or possible elimination of immunosuppressive medications. If immune tolerance is achieved, CTA clinical applications will broaden dramatically as they become the next frontier in reconstructive surgery[84] (Fig. 45-52).

AESTHETIC SURGERY

The American Medical Association defines *cosmetic surgery* as "surgery performed to reshape normal structures of the body to improve the patient's appearance and self-esteem." 5▶ *Reconstructive surgery* is performed on structures of the body that are abnormal due to congenital defects, developmental abnormalities, trauma, infection, tumors, or disease. It is generally performed to improve function but may also be done to approximate a normal appearance.[85] In practical terms, there are both reconstructive and cosmetic elements to almost every plastic surgery case, and the definition of "normal" structure is sometimes unclear. Nevertheless, there are patients for whom it is a priority to make surgical changes to their bodies in the clear absence of a functional deformity. Aesthetic surgery patients present a unique challenge to the plastic surgeon, because the most important outcome parameter is not truly appearance, but patient satisfaction. Optimally, a good cosmetic outcome will be associated with a high level of patient satisfaction. For this to be the case, the plastic surgeon must do a careful analysis of the patient's motivations for wanting surgery, along with the patient's goals and expectations. The surgeon must make a reasonable assessment that the improvements that can be achieved through surgery will meet the patient's expectations. The surgeon must appropriately counsel the patient about the magnitude of the recovery process, the exact location of scars, and potential complications. If complications do occur, the surgeon must manage these in a manner that preserves a positive doctor-patient relationship.

Assessment of Facial Aesthetics

A thorough evaluation of the patient who presents for facial aesthetic surgery should start with elicitation of the patient's chief complaint, and the examination should be focused on that region. Physical examination of the entire face should note skin quality as well as the presence of redundant skin on the neck, jowls, and eyelids. Depth of the nasolabial folds and the presence of "marionette" lines on the chin should be noted. Brow position should be evaluated, along with the distance from brow to hairline. Bulging fat in the lower eyelid region and the presence of a "tear trough" deformity, or deep fold at the lid-cheek junction, should be evaluated. Facial fat atrophy and descent, a hallmark of facial aging, should be noted.

Blepharoplasty and Browlift

Excess skin and adipose deposits of the upper eyelid are approached through an incision based on the supratarsal crease.

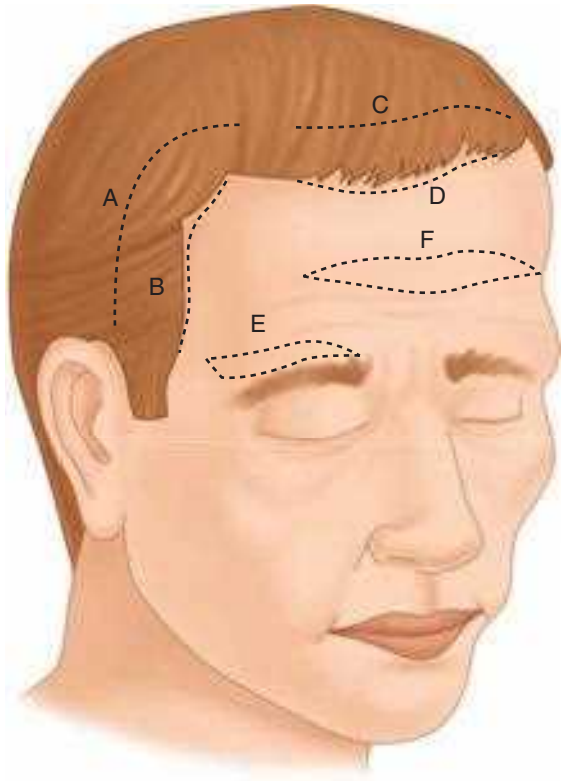

Figure 45-53. Incisions for browlift. *A,* Temporal scalp incision; *B,* temporal hairline incision; *C,* midline scalp incision; *D,* mid-hairline incision; *E,* direct eyebrow incision; *F,* direct forehead incision.

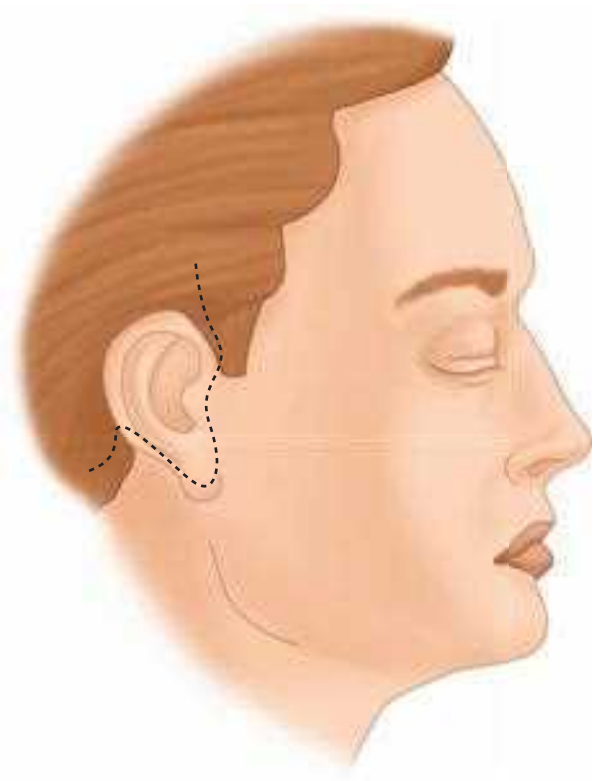

Figure 45-54. Incisions for cervicofacial rhytidectomy.

Careful attention to marking will avoid the complication of overresection. A strip of orbicularis muscle is often excised to accentuate the supratarsal fold. Fat deep to the orbital septum is resected selectively. In the lower lid, excess skin is removed through a subciliary incision. Lower eyelid fat may be either excised or repositioned. Complications can include hematoma, lower lid retraction, and injury to ocular muscles. If a hematoma forms in the retro-orbital region, a true surgical emergency exists. Permanent vision loss can occur if it is not immediately decompressed. Brow ptosis, judged relative to the superior orbital rim, can be corrected through a number of incisions (Fig. 45-53).[86]

Facelift

Correction of jowls, nasolabial folds, and redundant neck skin can be accomplished with a facelift procedure that both removes skin and tightens the superficial musculoaponeurotic system (SMAS) layer. The SMAS lies deep to the subcutaneous tissue and contains the muscles of facial expression. The facial nerves are in a plane just deep to the SMAS. The SMAS can be simply plicated or a portion of it excised and closed. A sub-SMAS dissection technique can help to elevate and develop this layer in separate fashion, with care being taken to avoid injury to the underlying facial nerves. The incisions for most facelift techniques are preauricular with extension into the temporal hairline superiorly and into the retroauricular region posteriorly and inferiorly (Figs. 45-54 and 45-55). The platysmal layer is continuous with the SMAS layer and can be plicated through a small neck incision to eliminate the appearance of vertical bands along the muscle edge. The most common facelift complication is hematoma, which may require operative drainage to prevent skin flap necrosis. Injury to facial nerves, most often temporal branch and marginal mandibular branch, is seen in approximately 1% of cases.[87]

Rhinoplasty

The key to understanding rhinoplasty is appreciating the complex nasal anatomy (Fig. 45-56) and the way in which altering this framework will impact the appearance of the nose. Evaluation of the rhinoplasty patient not only should include the aesthetic complaints, but also should consider the function of the nasal airways. Nasal airway obstruction can occur from several structural problems. A deviated septum can severely impede airflow, as can problems with the internal nasal valve. Obstruction at the internal nasal valve, which is the junction of the upper lateral cartilage and septum, can be identified by applying lateral traction on the cheek skin to open the valve and observing whether airflow improves (Cottle sign). Airway obstruction can be addressed surgically at the time of rhinoplasty. Aesthetic deformities of the dorsum of the nose are treated by a combination of osteotomies, which serve to reposition the nasal bones, and rasping of the bone. Aesthetic deformities of the tip of the nose are treated by reducing the width of the lower lateral cartilages and/or sewing the cartilages together to reduce tip width. Small tips can be augmented with cartilage grafts harvested from septum or auricle (Fig. 45-57). Complications of rhinoplasty include induction of new nasal airway obstruction and a variety of aesthetic deformities.[88]

Suction Lipectomy

Liposuction involves the removal of adipose tissue through minimal incisions using a hollow suction cannula. Although the scarring is quite innocuous, a key principle of liposuction is that fat is being removed without skin tightening. Therefore, one relies on the patient's inherent skin elasticity to provide retraction over the treated adipose depot. Assessment of skin tone is

Figure 45-55. Facelift. **A.** Preoperative appearance. **B.** Postoperative appearance.

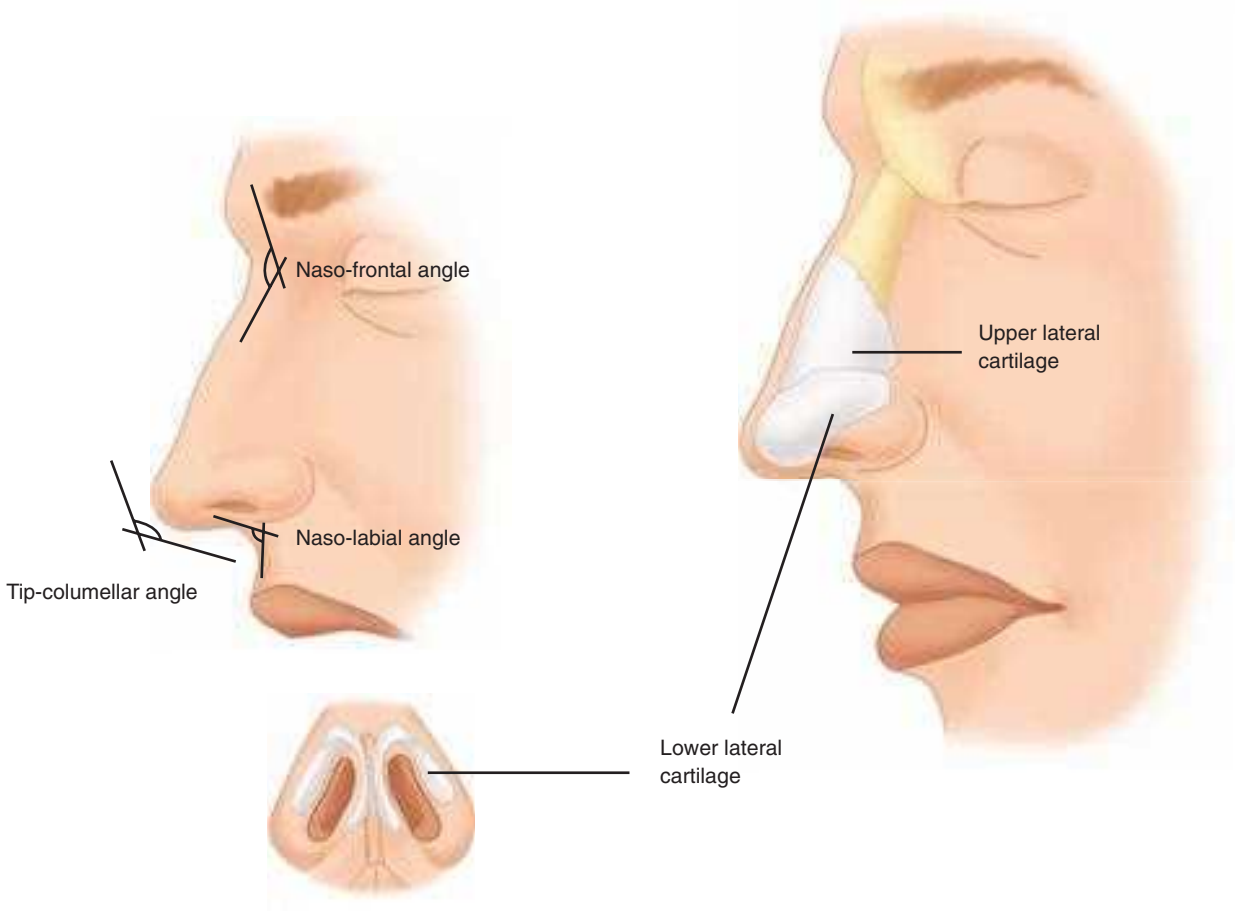

Figure 45-56. Rhinoplasty anatomy.

A

B

Figure 45-57. Rhinoplasty. **A.** Preoperative appearance. **B.** Postoperative appearance.

a vital part of the patient evaluation. If there is skin laxity in the area to be treated, it may worsen after liposuction. Importantly, liposuction should be used as a tool for contouring prominent adipose depots and is not considered a weight loss treatment. The best candidates for liposuction are individuals who are close to their goal weight and have focal adipose deposits that are resistant to diet and exercise (Fig. 45-58). The suction cannula removes fat by avulsing small parcels of adipose tissue into small holes at the cannula tip. With standard suction lipectomy, fat is removed only when the cannula is actively moved through the tissue planes. Minimal tissue effects are seen when the cannula is stationary. In general, larger-diameter cannulas remove adipose tissue at a faster rate but carry a higher risk of causing contour irregularities such as grooving and uneven removal of fat. Newer liposuction technology uses an ultrasonic probe to emulsify the fat via cavitation before suction. Advocates of ultrasonic liposuction report that the technique provides a more even and uniform removal of adipose tissue. Recognizing that no one technique is best for all patients and all anatomic regions, many surgeons use ultrasonic energy selectively.

A major advance in the field of liposuction was the development of tumescent local anesthesia. This method involves the infiltration of very dilute lidocaine and epinephrine (lidocaine 0.05% and epinephrine 1:1,000,000) in large volumes throughout the subcutaneous tissues. Tumescent volumes may range from one to three times the anticipated aspirate volume. The dilute lidocaine provides sufficient anesthesia to allow the liposuction to be performed without additional agents, although many surgeons prefer to use sedation or even general anesthetic when large volumes of fat are to be removed. When general anesthesia is used, the lidocaine dose may be reduced or even eliminated. With tumescent anesthesia, the absorption of the dilute lidocaine from the subcutaneous tissue is very slow, with peak plasma concentrations occurring approximately 10 hours after the procedure.[89] Therefore, the standard lidocaine dosing limit of 7 mg/kg may be safely exceeded. Current recommendations suggest a limit of 35 mg/kg of lidocaine with tumescent anesthesia.[90] A very important component of the tumescent anesthetic solution is the dilute epinephrine, which limits blood loss during the procedure.

Safety issues are paramount for liposuction because of potential fluid shifts postoperatively and hypothermia. If ≥5000 mL of aspirate is to be removed, the procedure should be performed in an accredited acute care hospital facility. After the procedure, vital signs and urinary output should be monitored overnight in an appropriate facility by qualified and competent staff who are familiar with perioperative care of the liposuction patient.[90]

Autologous Fat Grafting

The concept of reinjecting fat tissue harvested by liposuction has been put into practice for decades. Key to the technique is a processing step in which the sterilely collected fat is separated from the aqueous (primarily tumescent fluid) and free lipid fractions. This can be done by centrifugation or filtering. The adipose grafts are then injected into the tissues using specially designed blunt-tipped cannulas. Small aliquots of graft material are injected with each cannula pass, and the fat is interposed within the vascularized tissues of the recipient bed in small channels. Autologous fat grafting has been used primarily for facial aesthetic augmentation of the midface, but has been gaining popularity for breast aesthetic applications, buttock augmentation, and breast reconstruction.

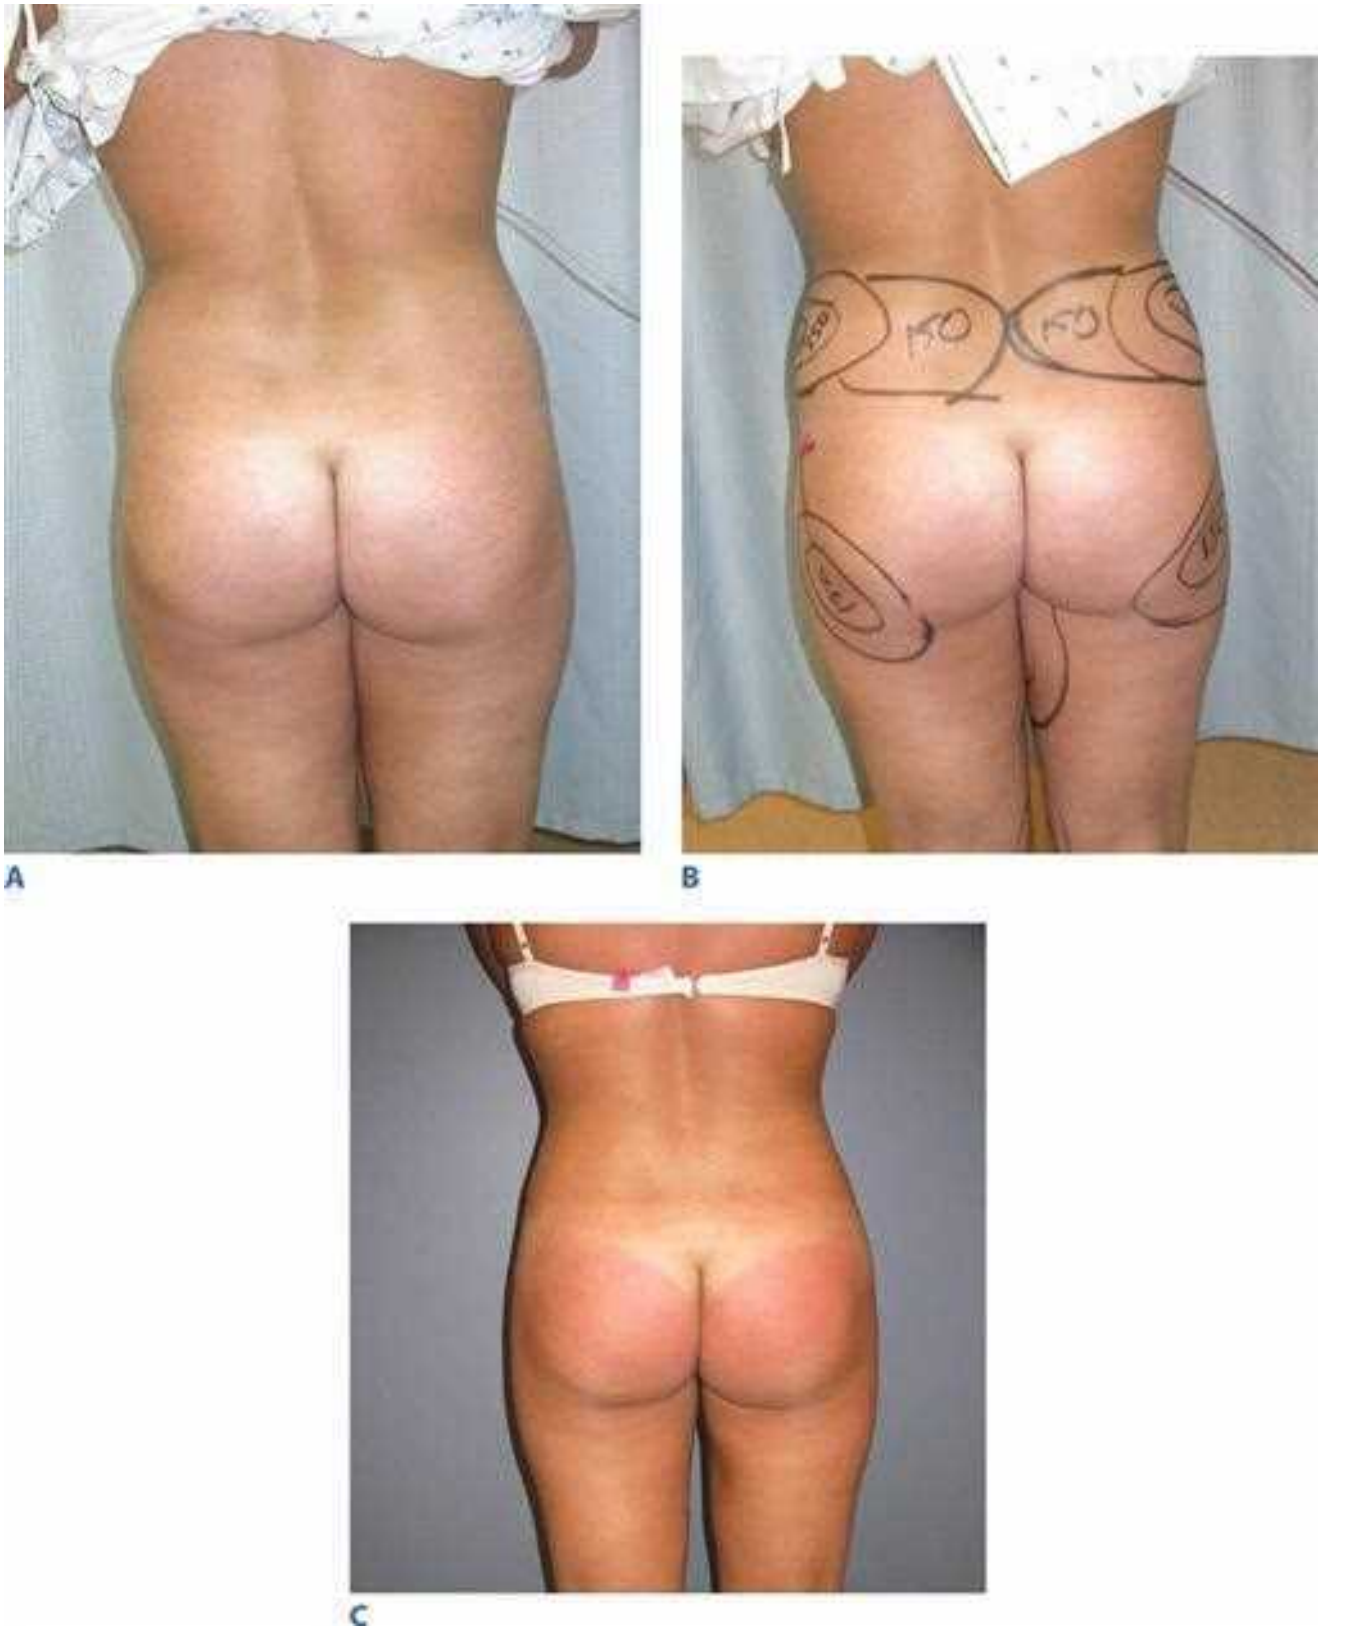

Figure 45-58. **A** and **B.** Preoperative photos of a 22-year-old woman with focal adipose deposits on the trunk and extremities. **C.** Patient 3 months after surgery.

Excisional Body Contouring

When significant skin laxity is present, improvement in contour can be achieved only through skin excision. Therefore, all body-contouring surgery represents a trade of excess skin for scar, and this must be emphasized during patient consultation. The patient willing to accept scars in exchange for improved contour is likely to be satisfied with the procedures. With the increased number of bariatric surgery procedures over the past decade, body-contouring surgery has become very popular and is emerging as a new subspecialty of plastic surgery.

Figure 45-59. **A.** Preoperative photo of 35-year-old woman after gastric bypass and massive weight loss. **B.** Patient 12 months after a fleur-de-lis abdominoplasty.

Abdominoplasty/Panniculectomy. Abdominoplasty/panniculectomy is the most common body-contouring procedure and can range from a limited-incision skin removal in the lower abdomen to a major skin excision with transposition of the umbilicus and placation of the rectus muscles to further enhance contour.[91] Some patients may benefit from a concurrent vertical incision to remove skin in two vectors (Fig. 45-59). Possible complications include skin necrosis, persistent paresthesias of the abdominal wall, seroma, and wound separation. Necrosis of the umbilicus may complicate preservation of that structure if the stalk is excessively long or an umbilical hernia is repaired. Adding a vertical resection increases the incidence of skin necrosis, especially at the confluence of scars in the lower abdomen.

Brachioplasty (Arm Lift). Brachioplasty, or arm lift, leaves a visible longitudinal scar on the upper arm. Therefore, it is reserved for patients with excessive skin in that region. The patient willing to accept the scar can be happy with the results. Complications include distal seroma and wound separation. Paresthesias in the upper arm and forearm may occur secondary to injury of sensory nerves passing through the resection area, although this rarely affects function. Scar contracture in the axilla may limit shoulder excursion in rare cases and require revision.

Thigh and Buttock Lift. Treatment of loose skin on the thighs and buttocks involves a spectrum of operations customized to the individual patient. The outer thighs can be lifted at the same time that an abdominoplasty is performed with one continuous scar along the belt line. The same scar can be continued all the way around the back to lift the buttocks as well. This combination of abdominoplasty, thigh lift, and buttock lift is commonly referred to as a *circumferential lower body lift.* The inner thighs can be contoured by lifting the skin and placing the incisions along the groin crease. Firmly anchoring the deep thigh fascia to Colles' fascia is essential to help prevent spreading of the labia. In cases of severe excess skin on the inner thighs, a long vertical incision is necessary. Complications of thigh and buttock lift include seroma, wound separation, skin necrosis, and change in the shape of the genital region (with possible sexual dysfunction). Blood loss during the procedure may necessitate transfusion.

Reduction Mammaplasty

Breast reduction is performed to treat symptoms of macromastia, most commonly consisting of the triad of upper back pain, bra strap grooving, and rashes under the fold of the breasts. Although this procedure has reconstructive indications, the aesthetic outcome is of considerable importance. Fundamental to the success of the procedure is the establishment of symmetric and proper nipple position. Nipple ptosis is graded by the nipple position relative to the inframammary fold (IMF). Grade 1 ptosis describes a nipple ≤1 cm below the IMF. Grade 2 ptosis describes a nipple 1 to 3 cm below the IMF. Grade 3 ptosis describes a nipple position >3 cm below the IMF. *Pseudoptosis* or *bottoming out* is a term used to describe the descent of the breast tissue below the nipple and is a potential long-term complication of breast reduction. In addition to classification of

nipple ptosis, a thorough preoperative evaluation also includes measurement of the distance from sternal notch to nipple bilaterally, as well as measurement of the distance from nipple to IMF. The base width of the breast should also be considered. Many patients are found to have significant baseline asymmetries in these measurements. Preoperative breast cancer screening consistent with current American Cancer Society guidelines should be performed for all patients undergoing elective breast reshaping surgery. The planned new nipple position should be symmetrical at the IMF along the breast meridian. There are many technical variations of the breast reduction procedure, but nearly all of them have common elements of reshaping the skin envelope in three dimensions and moving the nipple to a new location on a vascularized tissue pedicle. The pedicle is de-epithelialized to preserve the subdermal vascular plexus. Fig. 45-60 shows the classic "keyhole" Wise pattern reduction technique. The skin resection is designed to create a conical shape, and the nipple is transposed on an inferiorly based pedicle.[92] This results in an inverted T-shaped

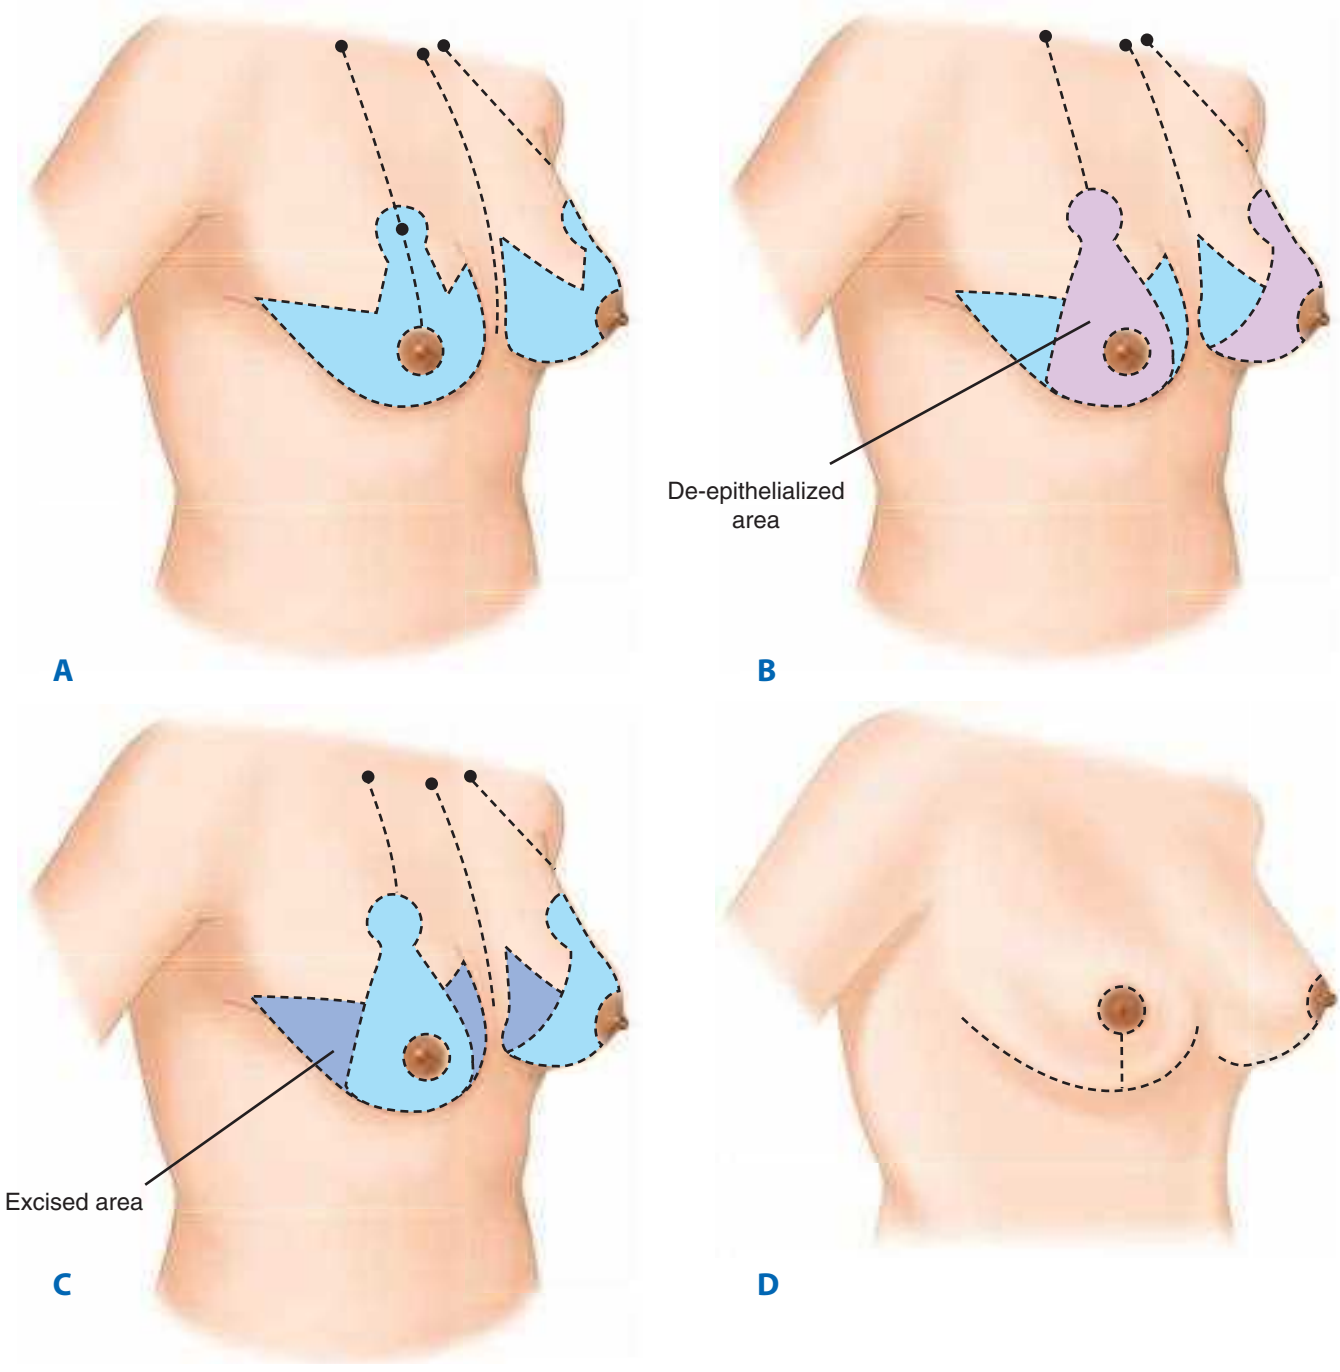

Figure 45-60. Inferior pedicle reduction mammaplasty. **A.** Markings for Wise pattern reduction. **B.** Purple area is region to be de-epithelialized. **C.** Dark blue region is area to be resected. A segment of the inferior pedicle is de-epithelialized. The inferior pedicle is dissected straight down to the chest wall, with maintenance of an 8- to 10-cm pedicle width. Lateral and medial segments are resected. After this is accomplished, the superior flap is dissected to the clavicle. Breast subcutaneous tissue and parenchyma are resected from the superior pole. The vertical limbs are brought together and to the meridian of the inframammary fold. The nipple is then set in its new superior position. **D.** T-shaped incision on final closure.

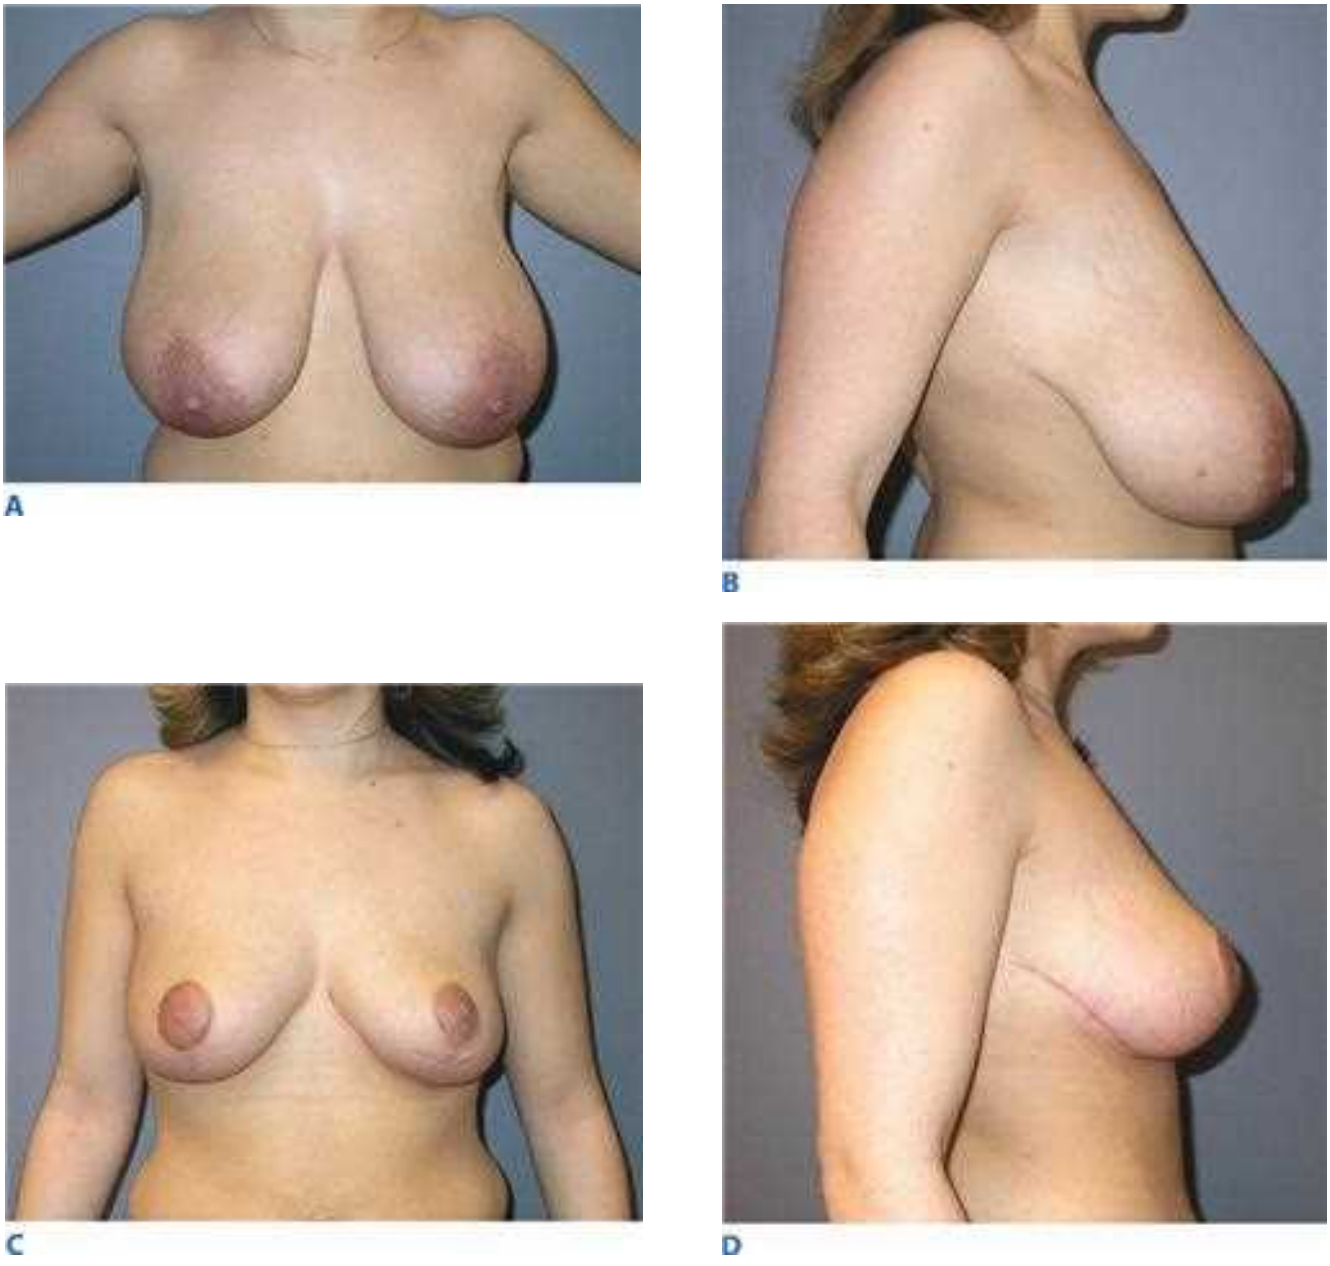

Figure 45-61. **A** and **B.** Preoperative photos of a 25-year-old woman with symptoms of upper back pain, bra strap grooving, and rashes under the folds of her breasts treated with a Wise pattern inferior pedicle reduction. **C** and **D.** Patient 6 months after surgery.

scar. Fig. 45-61 shows a patient treated using this technique. All breast reduction techniques keep the scars on the lower half of the breast so they are covered by clothing. Techniques have been designed to minimize scar length and even eliminate the horizontal component in the IMF. Fig. 45-62 depicts a vertical scar skin resection pattern with the nipple preserved on a superior pedicle.[93,94] For excessively large breasts, the required pedicle length may be too long to provide adequate blood supply to the nipple. In such cases, the nipple is removed and replaced onto a viable tissue bed as a full-thickness skin graft. Complications of breast reduction include decreased nipple sensation, nipple loss (rare), skin necrosis, hematoma, and fat necrosis. This last complication can result in a firm mass of scar within the breast that may need careful evaluation and follow-up to distinguish it from a neoplastic mass. Long-term complications include inability to breastfeed and pseudoptosis, as mentioned earlier.

Mastopexy

In contradistinction to breast reduction, in which patients are treated for symptoms related to heavy breasts, mastopexy is a three-dimensional reshaping of the breast performed with no or minimal volume removal. The principles are the same, however. The skin envelope is contoured, and the nipple location is optimized. Because the degree of ptosis may be less severe than in breast reduction cases, the patterns of skin resection can vary widely. Minimal patterns may involve excision of just a crescent of skin from above the areola or a periareolar ("donut") resection. The Wise keyhole pattern can be used for larger skin excisions.

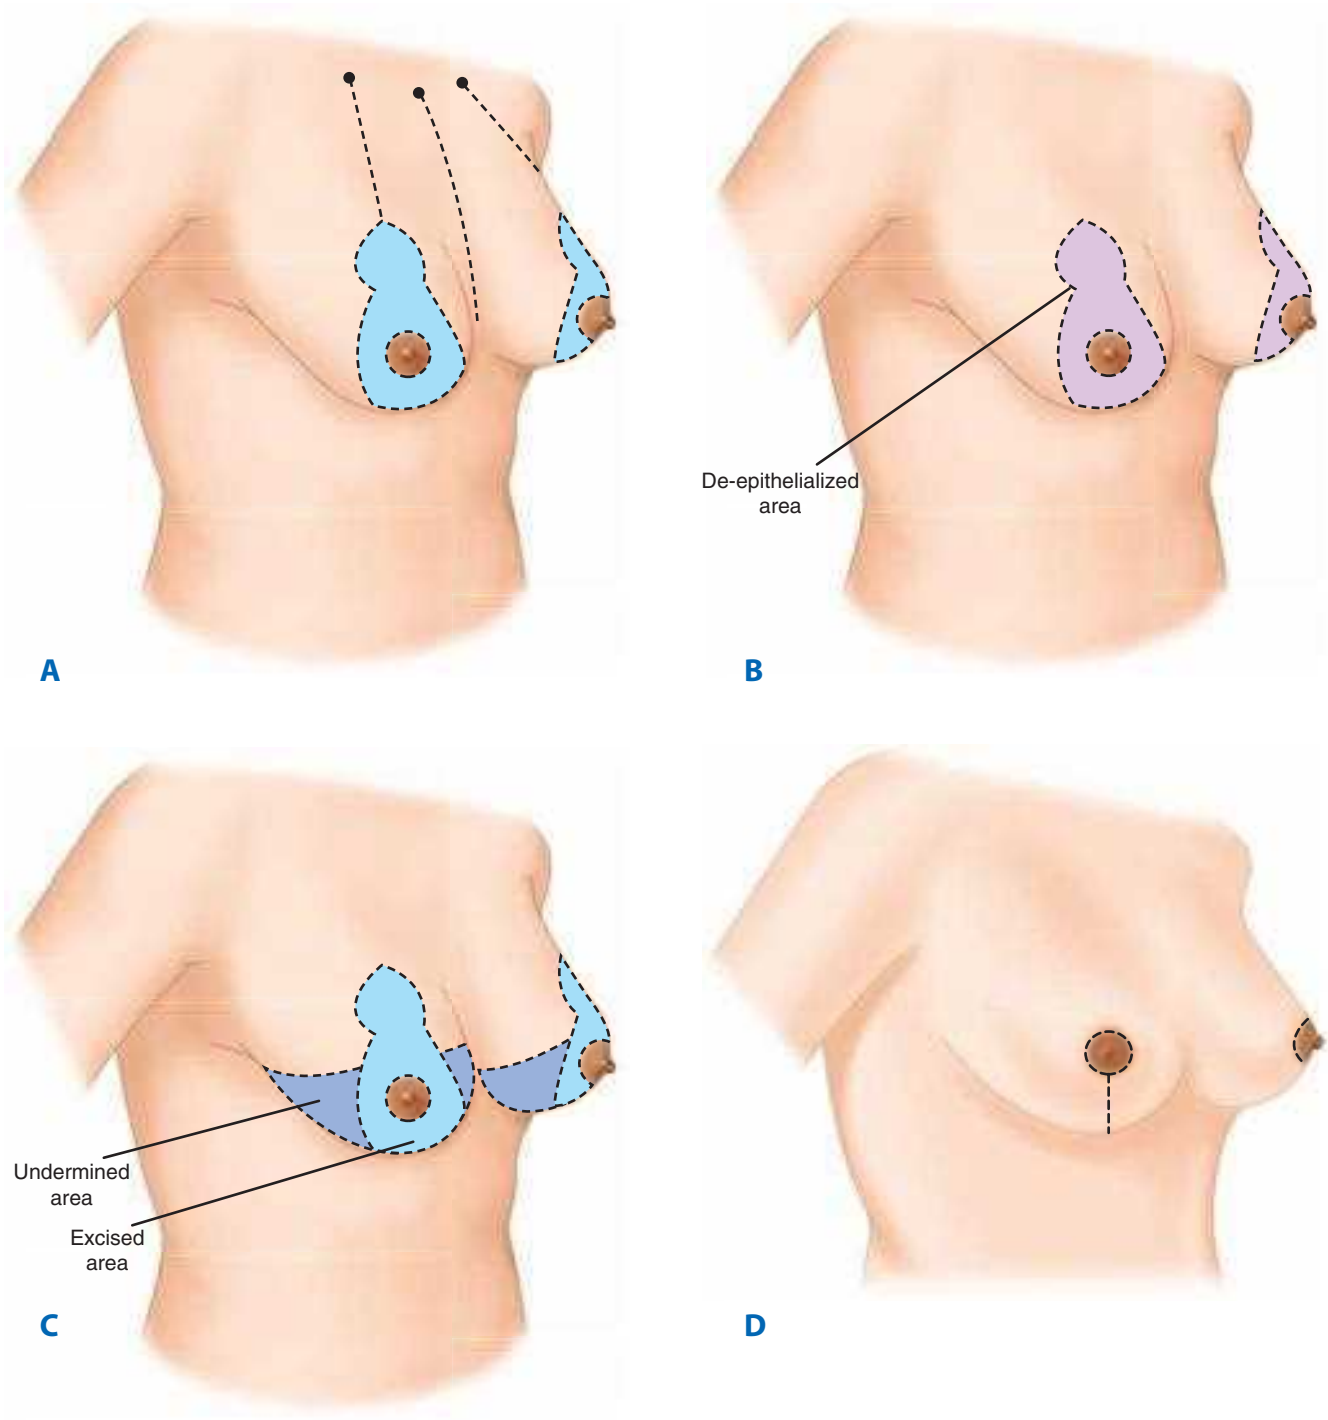

Figure 45-62. Vertical reduction mammaplasty, Lejour technique. **A.** Markings for vertical reduction. **B.** Purple area is region to be de-epithelialized. **C.** Dark blue region represents inferior pole to be resected. The shaded regions are the lateral and medial segments that are to be undermined; these areas can also be liposuctioned. The superior pedicle is de-epithelialized and dissected to the chest wall. The tissue and parenchyma from the inferior pole are resected. The pillars from the lateral and medial segments are sewn together. The nipple is transposed on its pedicle to its new position. **D.** Closure of the vertical mammaplasty. There is bunching up of skin and tissue along the vertical limb that will resolve over time; in addition, the new inframammary fold will declare itself superior to the original one.

Augmentation Mammaplasty

Although the use of prosthetic implants can successfully increase breast size, the surgeon must fully understand both the risks of the biomaterials and the way in which a specific implant of given shape and size can be surgically integrated into the existing breast mound to achieve the desired result.[95] To address the latter point, the surgeon must first consider the possible surgical approaches for implant placement. The three commonly used incisions for placement of cosmetic breast implants are inframammary, periareolar, and axillary (Fig. 45-63).[96] A transumbilical breast augmentation technique has been advocated by some surgeons more recently, but critics of this approach point out that there is poor control over the dissection of the implant pocket and that direct access to the

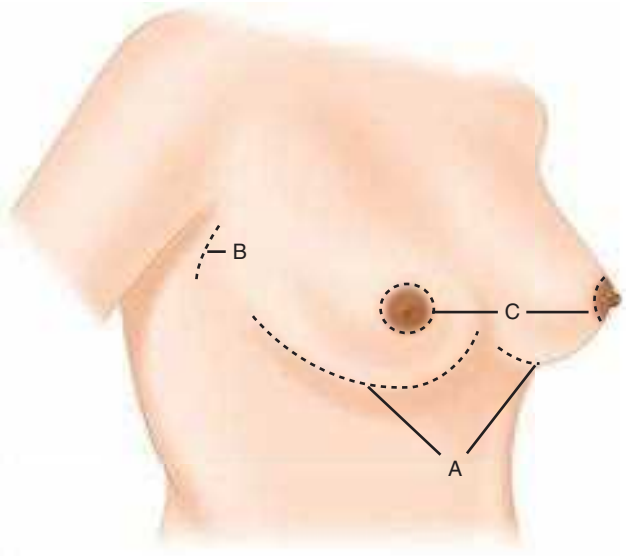

Figure 45-63. Incisions for augmentation mammaplasty. *A,* Inframammary; *B,* axillary; *C,* periareolar.

tissues of the breast is inadequate to control bleeding vessels. In addition, only saline implants can be used with transumbilical breast augmentation because the prefilled silicone implants are too large to pass through the incision and narrow tunnel. The implants may be placed in a subglandular or subpectoral position (Fig. 45-64). Many surgeons prefer the subpectoral placement because it provides greater soft tissue coverage in the upper pole of the breast and can hide contour irregularities related to the implant. This soft tissue coverage is especially important with saline implants, because visible rippling can occur. The next issue to consider is existing nipple position. If a patient has mild ptosis, the sheer volume of the implant may raise the nipple to an acceptable level. For more severe ptosis, a concurrent mastopexy is necessary. Some surgeons advocate performing the mastopexy as a second stage after the implant has settled into position.

Potential complications related to the implant itself are numerous, and the patient must be fully informed of these possibilities before undergoing surgery. One important point is that there is a high likelihood that the patient will require a second operation to address an implant problem. The implant complications are essentially all local. Although there was concern in the past that implants might be associated with systemic connective tissue disorders, large epidemiologic studies have not supported such a link. The fears over implant safety were so strong that the Food and Drug Administration (FDA) declared a moratorium on the use of silicone gel implants in 1992. At that time, saline-filled implants were still allowed for general cosmetic use. Data were compiled on silicone gel implants, and these devices were approved by the FDA for general use in 2006.[97] A potential implant complication is rupture of the device. For saline implants, this results in rapid deflation. For silicone gel implants, the rupture may be not be obvious and can be confirmed by MRI. Another complication is capsular contracture, which results in a tight envelope of scar that can distort the shape of the implant and cause pain in severe cases. A complication more common to saline devices is the appearance of rippling in the upper pole of the device. Implant malposition can also distort the breast shape and require reoperation. Safety data printed on the official FDA-approved package insert from one of the device manufacturers show the incidence of reoperation to be 29.9% over 7 years in a study of 901 women undergoing primary breast augmentation with saline-filled implants (postapproval study). The rate of severe capsular contracture (grade 3 or 4 on a 4-point scale) was 15.7%, and the rate of implant rupture was 9.8%.[98] For silicone gel–filled implants, the reoperation rate was observed to be 23.5% over 4 years in a study of 455 women undergoing primary breast augmentation. The rate of severe capsular contracture (grade 3 or 4 on a 4-point scale) was 13.2%, and the rate of implant rupture (evaluated by MRI) was 2.7%. The three most common reasons for operation, in order, were capsular contracture (28.9%), implant malposition (15.6%), and ptosis (14.1%). For secondary augmentation, complication rates were much higher, with the reoperation rate over 4 years rising to 35.2%. The rate of capsular contracture was 17.0%, and the rate of implant rupture was 4.0%.[99]

Another concern regarding breast implants is the issue of whether adequate mammography can be performed after augmentation. Displacement techniques can be used by the mammographer to view the breast tissue. Although patients are advised that implants may affect mammography, a study surveying women who did and did not undergo breast augmentation found no statistical difference in survival or detection of carcinoma between the two cohorts.[100]

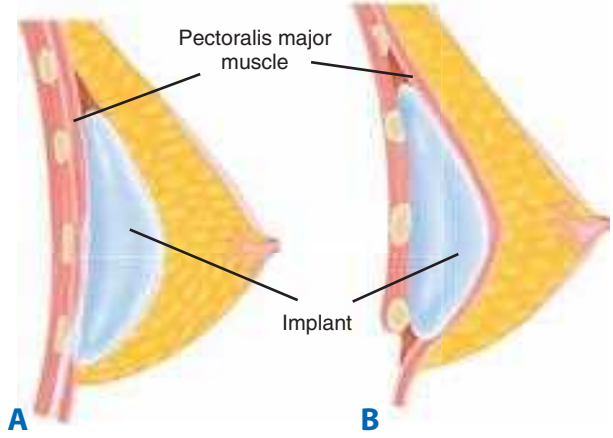

Figure 45-64. Placement of breast implant. **A.** Subglandular. **B.** Subpectoral.

Gynecomastia

Male breast excess or gynecomastia can be caused by a host of medical diseases and pharmacologic agents. Medical conditions associated with gynecomastia include liver dysfunction, endocrine abnormalities, Klinefelter's syndrome, renal disease, testicular tumors, adrenal or pituitary adenomas, secreting lung carcinomas, and male breast cancer. Causative pharmacologic agents include marijuana, digoxin, spironolactone, cimetidine, theophylline, diazepam, and reserpine. Although these numerous causes must be considered, a majority of patients present with either idiopathic enlargement of the breast parenchyma (more common in teenagers) or simple skin ptosis and excess adipose deposits on the chest wall (considered pseudogynecomastia; more common in adult males). To obtain a flat chest, both liposuction and/or skin excision techniques can be used.[101]

chapter 46

Anesthesia for the Surgical Patient

Robert S. Dorian

TRUE COLLABORATION

The discipline of anesthesia embodies control of three great concerns of humankind: consciousness, pain, and movement. The field of anesthesiology combines the administration of anesthesia with the perioperative management of the patient's concerns, pain management, and critical illness. The fields of surgery and anesthesiology are truly collaborative and continue to evolve together, enabling the care of sicker patients and rapid recovery from outpatient and minimally invasive procedures.

BRIEF HISTORY OF ANESTHESIA

The discovery of anesthesia is one of the seminal American contributions to the world. Along with infection control and blood transfusion, anesthesia has enabled surgery to occupy its fundamental place in medicine. Before the advent of modern anesthesia in the 1840s, many substances and methods were tried in the search for pain relief and better operating conditions. Opium, alcohol, exposure to cold, compression of peripheral nerves, constriction of the carotid arteries to produce unconsciousness, and hypnosis (mesmerism) all proved less than satisfactory and dictated rapid and crude surgical procedures. Patients had to be restrained by several attendants, and only the most stoic could tolerate the screams heard in the operating theater. Charles Darwin, who witnessed two such operations, "rushed away before they were completed. Nor did I ever attend again, for hardly any inducement would have been strong enough to make me do so; this being long before the blessed days of chloroform. The two cases fairly haunted me for many a long year."[1]

Modern Beginnings

Although Humphrey Davy (1778–1829) suggested using nitrous oxide for the relief of pain in surgical procedures in 1800, this was not pursued until 1844 by dentist Horace Wells (1815–1848). Wells astutely observed that a man who was injured after inhaling nitrous oxide during an exhibition of the "laughing gas" displayed no awareness of pain. After experimenting on himself, Wells attempted to demonstrate the analgesic effects of nitrous oxide for a dental procedure at Harvard Medical School in 1845. The public demonstration was a failure because nitrous oxide has analgesic properties, but does not suffice as the sole anesthetic agent in every patient. Wells never recovered from his humiliating experience and eventually committed suicide. However, he does hold a place in history as the first person to recognize and use the only anesthetic from the 1800s that is still in use today—nitrous oxide.

In 1842, Crawford Long (1815–1878), a physician in rural Georgia, used diethyl ether to induce surgical anesthesia for the removal of two small neck tumors. Diethyl ether had been known for over 800 years but was not used for analgesic purposes. It became an inexpensive and popular recreational drug in the mid-nineteenth century and was used by American medical students at "ether frolics." Although Long did experiments to verify the analgesic effects of ether, he did not publish his work until 1848, in the *Southern Medical Journal*, too late to be the unquestioned discoverer of anesthesia.[2]

Ether Day

William Morton (1819–1868) was a dentist and partner of Horace Wells. After taking a course in anesthesia from Wells, Morton left the partnership in Hartford, Connecticut, and established himself in Boston. He continued his interest in anesthesia,

Key Points

1. The incremental interchange of ideas across the specialties of anesthesia and surgery demonstrates the collaborative nature of science in general and medicine in particular. Many surgeons contributed to the growth in anesthesia; more comprehensive anesthesia, in turn, allowed more complex surgery to develop.
2. The role of the anesthesiologist has expanded to become the perioperative physician. The anesthesiologist evaluates the patient preoperatively, provides the anesthetic, and is involved in postoperative pain relief.
3. New and improved airway and intubation devices, such as the laryngeal mask airway and the video laryngoscope, along with the American Society of Anesthesiologists' airway management algorithm, have led to improved management and control of routine and difficult airways.
4. The specialties of critical care medicine and pain medicine have grown out of the expanded field of anesthesiology. The postanesthesia care unit gave rise to the intensive care unit; the treatment of acute and chronic pain syndromes by anesthesiologists contributed to the growth of pain medicine as a specialty.
5. The study of proteomics will lead to anesthetics tailored to individuals, maximizing effects and reducing side effects of various anesthetic drugs.

but with diethyl ether replacing nitrous oxide. Ether proved a good choice, as it supports respiration and the cardiovascular system at analgesic levels and is potent enough to administer in room air without hypoxia. He practiced the administration of ether on a dog and then used it when extracting teeth from patients in his office. On October 16, 1846, Morton gave the first public demonstration of ether as an anesthetic for Johns Collins Warren, distinguished surgeon and a founder of Massachusetts General Hospital. In attendance in the surgical amphitheater were several surgeons, medical students, and a newspaper reporter. After anesthesia was induced using a makeshift inhaler, Warren successfully removed a vascular mass from the patient's neck with no ill effects. Warren was an originator of the *Boston Medical and Surgical Journal* (now *The New England Journal of Medicine*), and by November 1846, the demonstration was published in an article by Henry J. Bigelow.[3] The stature of Warren and Bigelow lent considerable credence to the advent of surgical anesthesia; as news spread rapidly, surgeons around the world were quick to adopt this "American invention." Massachusetts General Hospital has restored and preserved the original amphitheater where the demonstration took place, now called the *Ether Dome*. It is designated as a Registered National Historic Landmark commemorating the first public demonstration, rather than discovery, of the use of ether as an anesthetic.

The First Anesthesiologists

John Snow (1813–1858) made science out of the art of anesthesia. He was a respected London physician who applied a scholarly, scientific method to investigate the clinical properties and pharmacology of ether, chloroform, and other anesthetic agents. Snow was an astute observer and published a detailed account of the five degrees of etherization in 1847. He vastly improved the apparatus for administering ether and mastered the clinical techniques of anesthetizing patients. As the leading anesthetist of his day, he gave anesthetics to the royal family, including chloroform during labor to Queen Victoria for the birth of Prince Leopold. The Queen's endorsement of "that blessed chloroform" removed the moral and social stigma against relieving pain during childbirth and brought anesthesia into public awareness. Chloroform, popularized in England by James Simpson (1811–1870), had a narrow therapeutic index and placed great clinical demands on the anesthetist. Ether, with its ability to maintain the cardiovascular and respiratory systems, remained in common use in the United States and often was administered by house staff, medical students, or nurses. Snow encouraged the administration of anesthesia by a physician and felt that a physician dedicated specifically to that purpose was appropriate and necessary. Snow and other exceptional British physicians specializing in anesthesia (Joseph Clover [1825–1882] and Sir Frederick Hewitt [1857–1916]) created a standard of excellence in the latter half of the nineteenth century. This atmosphere of professionalism led to the formation of anesthesia societies and the publication of papers in the prestigious *British Medical Journal* and *The Lancet* in England years before such organizations existed in America.[4]

Cocaine: The First Local Anesthetic

The ancient Incas chewed coca leaves as a stimulant and may have been aware of its local anesthetic properties, allegedly facilitating trephination of the skull by chewing a clump of coca leaves and dripping the resultant saliva into the wound. The active alkaloid of the coca leaf was synthesized in 1860 and called *cocaine* by German chemist Albert Niemann, who noted that it "benumbs the nerves of the tongue, depriving it of feeling."[5] Sigmund Freud (1856–1939) of Vienna received a supply of cocaine from Merck, studied its properties, and wrote the famous monograph "Uber Coca" in 1884. Freud was primarily interested in the stimulant and euphoric effects of cocaine and attempted to use it to treat morphine addiction. Freud and Karl Koller (1857–1944), an ophthalmologic intern, began to perform physiologic experiments with cocaine, measuring its effects on muscle strength. Although they both noted that the drug caused numbness of the tongue when swallowed, it was Koller who first instilled it into his own cornea; report of its use as a local anesthetic galvanized the medical world. Soon after, young American surgeons William Halsted (1852–1922) and Richard Hall described intradermal injection of cocaine and were the first to use it for regional blocks of the facial nerves, brachial plexus, and internal pudendal and posterior tibial nerves.[6] Halstead later became the first professor of surgery and chief surgeon at Johns Hopkins University, where he remained for more than 30 years. One of the founding fathers of modern surgery, he pioneered radical mastectomy with lymphadenectomy and the use of rubber gloves. While experimenting on themselves, Halstead and other early researchers became addicted to cocaine.[7] Its toxic effects were the stimulus to find other local anesthetics—procaine was synthesized in 1905 and lidocaine in 1943.

The New York neurologist Leonard Corning (1855–1923) observed the regional blocks of Halstead and Hall, analytically studied local anesthesia effects on dogs, applied his knowledge

to humans, and published the first textbook on local anesthesia in 1886. After experimenting on the spinal nerves of a dog, he intradurally injected a solution of cocaine into a patient, called it *spinal anesthesia*, and commented that it might be useful in surgery. His suggestion went unheeded for more than 10 years, until August Bier (1861–1949), a prominent German surgeon, gave the first deliberate spinal anesthetic.[8] This incremental interchange of ideas and advances across the Atlantic and across the specialties of anesthesia and surgery demonstrates the collaborative nature of science in general and medicine in particular. The development of surgery and anesthesia exemplifies the dichotomy of two fledgling specialties that are mutually dependent, yet increasingly autonomous.

The Twentieth Century

Developments in anesthesia on both sides of the Atlantic progressed rapidly in the twentieth century. The convergence of technologies that produced the hollow needle and syringe, coupled with the synthesis of barbiturates, gave rise to intravenous (IV) anesthesia in the early 1900s. Barbital, followed by hexobarbital and thiopental in 1934, produced rapid and more pleasant induction of anesthesia than the inhaled gases. The concept of "balanced anesthesia" began in 1925, when John Lundy (1894–1973) proposed the use of thiopentone for induction, followed by inhaled agents for maintenance of anesthesia. Lundy directed the department of anesthesiology at the Mayo Clinic for 28 years. He established the first recovery room and blood bank, authored the first textbook on modern anesthesia, and helped found the American Board of Anesthesiology.

Nitrous oxide, diethyl ether, and chloroform, all discovered fortuitously by observation, remained the dominant inhalation agents until the accidental discovery of cyclopropane's anesthetic properties in 1923. Although rapid acting and pleasant smelling, cyclopropane was limited by its flammability and cardiac irritability. Because it was known that fluorination would reduce or eliminate flammability of chemical compounds, British chemist Charles Suckling set out to synthesize an anesthetic that was stable, potent, volatile, and not flammable. He successfully produced halothane in 1953. Introduced into clinical practice in 1956 after extensive testing in Manchester, England, and paired with an accurate calibrated vaporizer, halothane quickly became the most widely used fluorinated anesthetic. Enflurane and isoflurane, synthesized in the United States by Ross Tyrell, were introduced into clinical practice in 1972 and 1981, respectively. The newest agents, desflurane and sevoflurane, were introduced into clinical practice in the early 1990s. They possess a low solubility and are characterized by rapid onset and recovery, making them particularly well suited to outpatient surgery.

The motto of the American Society of Anesthesiologists (ASA) is "Vigilance," and to that end, there has been continued progress in objective mechanical measurement of patient well-being. The early anesthesiologists used clinical signs such as patient color, depth of respiration, and pulse rate to monitor depth of anesthesia and patient homeostasis. Harvey Cushing, who eventually became Moseley Professor of Surgery at the Peter Bent Brigham Hospital, began the first anesthesia records or "ether charts" in 1895 while a medical student. They recorded pulse, respiratory rates, pupillary diameter, and the amounts of ether and other drugs administered. He later introduced the use of the portable sphygmomanometer of Riva-Rocci to measure blood pressure and the precordial stethoscope to monitor breath and heart sounds. Monitoring has since progressed to its current state with incremental developments in electrocardiography, pulse oximetry, and mass spectrometry, all mandatory for the safe administration of any anesthetic.

The control of the patient's airway and respiration as the purview of the anesthesiologist evolved with techniques of endotracheal intubation as pioneered by Sir Ivan Magill (1888–1986) and the invention of the cuffed endotracheal tube by Arthur Guedel (1883–1965). This later merged with the invention of mechanical ventilation and its introduction to the operating room as the embodiment of today's anesthesia machine. It was this expertise at control of respiration that paved the way for the most revolutionary modern development in anesthesia—the use of muscle relaxants. Curare, a nondepolarizing muscle relaxant, was popularized by Harold Griffith of Montreal. His report of the successful use of curare was a galvanizing event that revolutionized the practice of anesthesia, as the relaxation of abdominal muscles could be controlled to facilitate surgery.[9] The depolarizing relaxant succinylcholine was introduced in 1949, and research has continued to provide the newer nondepolarizing drugs mivacurium, pancuronium, rocuronium, atracurium, and cisatracurium.

Anesthesiology Today—The Perioperative Physician

The specialty of anesthesia is no longer limited to the operating room. It is natural that anesthesiology, born out of the quest to relieve pain, gave rise to the field of acute and chronic pain medicine. The anesthesiologist consulting on the acute pain service may recommend oral, intramuscular, or IV analgesia with a variety of agents, or patient-controlled analgesia. Postsurgical patients also may be treated with nerve blocks: regional (e.g., brachial plexus, popliteal, and femoral) or neuraxial (epidural or intrathecal). The discipline of chronic pain addresses patients who suffer for months or years with cancer or other debilitating diseases. Treatment modalities escalate from orally administered drugs, to diagnostic and therapeutic nerve blocks, to more invasive measures like dorsal column nerve stimulators and radiofrequency or cryosurgical nerve ablation.

Daily management of the airway, fluids and transfusions, ventilation, drug delivery, monitoring, and caring for the sickest patients in the postanesthesia care unit prepared anesthesiologists to become major contributors to the development of critical care medicine. Of the 28 founding members of the Society of Critical Medicine, 10 were anesthesiologists.[10]

The American Board of Anesthesiology became an independent board in 1941 and, since then, has granted board certification to more than 25,000 diplomates. Certificates in Anesthesia Pain Management and Anesthesia Critical Care Medicine are granted to those completing additional postgraduate training. The ASA has more than 35,000 members, and its official journal, *Anesthesiology*, has a monthly circulation of 40,000 worldwide.

BASIC PHARMACOLOGY

Pharmacokinetics

Pharmacokinetics or the *time dependency* of a drug describes the relationship between the dose of a drug and its plasma or tissue concentration. It is what the body does to the drug. It relates to absorption, distribution, metabolism, and elimination. The route of administration, metabolism, protein binding, and

tissue distribution all affect the pharmacokinetics of a particular drug.

Administration, Distribution, Metabolism, and Elimination. *Administration* of a drug affects its pharmacokinetics, as there will be different rates of drug entry into the circulation. For example, the oral and IV routes are subject to first-pass effect of the portal circulation; this can be bypassed with the nasal or sublingual route. Other routes of drug administration include transdermal, intramuscular, subcutaneous, or inhalation.

Distribution is the delivery of a drug from the systemic circulation to the tissues. Once a drug has entered the systemic circulation, the rate at which it will enter the tissues depends on several factors:

- Molecular size of the drug, capillary permeability, polarity, and lipid solubility. Small molecules will pass more freely and quickly across cell membranes than large ones, but capillary permeability is variable and results in different diffusion rates. Renal glomerular capillaries are permeable to almost all non–protein-bound drugs; capillaries in the brain are fused (i.e., they have tight junctions) and are relatively impermeable to all but the tiniest molecules (the blood-brain barrier). Un-ionized molecules pass more easily across cell membranes than charged molecules; diffusability also increases with increasing lipid solubility.
- Plasma protein and tissue binding. Many drugs bind to circulating proteins like albumin, glycoproteins, and globulins. Disease, age, and the presence of other drugs will affect the amount of protein binding; drug distribution is affected because only the unbound free portion of the drug can pass across the cell membrane. Drugs also bind reversibly to body tissues; if they bind with high affinity, they are said to be sequestered in that tissue (e.g., heavy metals are sequestered in bone).[11]
- The fluid volume in which a drug distributes is termed the *volume of distribution* (Vd). This mathematically derived value gives a rough estimation of the overall physical distribution of a drug in the body. A general rule for volume distribution is that the greater the Vd, the greater the diffusability of the drug. Because drugs have variable ionization rates and bind differently to plasma proteins and tissues, the Vd is not a good predictor of the actual concentration of the drug after administration. Determining the apparent Vd (dose/concentration) is an attempt to more accurately ascertain the drug dose administered and its final concentration.

Metabolism is the permanent breakdown of original compounds into smaller metabolites. Drug *elimination* varies widely; some drugs are excreted unchanged by the body, some decompose via plasma enzymes, and some are degraded by organ-based enzymes in the liver. Many drugs rely on multiple pathways for elimination (i.e., metabolized by liver enzymes and then excreted by the kidney).

When a drug is given orally, it reaches the liver via the portal circulation and is partially metabolized before reaching the systemic circulation. This is why an oral dose of a drug often must be much higher than an equally effective IV dose. Some drugs (e.g., nitroglycerine) are hydrolyzed presystemically in the gut wall and must be administered sublingually to achieve an effective concentration.

It is important to remember that the response to drugs varies widely. The disposition of drugs is affected by age; weight; sex; pregnancy; disease states; and the concomitant use of alcohol, tobacco, and other licit and illicit drugs. Genetic polymorphism, or variations in genes that cause differing drug effects, is another explanation of varying drug response. This will be discussed later in the Future Direction of Anesthesia section on proteomics. This as yet unpredictable response to drugs underscores the importance of the most important monitor in the operating room—the anesthesiologist, who continuously assesses the patient's vital signs and adjusts the doses of anesthetic agents to match the surgical stimulus.

Pharmacodynamics

Pharmacodynamics, or how the plasma concentration of a drug translates into its effect on the body, depends on biologic variability, receptor physiology, and clinical evaluations of the actual drug. It is what the drug does to the body. An *agonist* is a drug that causes a response. A *full agonis*t produces the full tissue response, and a *partial agonist* provokes less than the maximum response induced by a full agonist. An antagonist is a drug that does not provoke a response itself, but blocks agonist-mediated responses. An *additive effect* means that a second drug acts with the first drug and will produce an effect that is equal to the algebraic summation of both drugs. A *synergistic effect* means that two drugs interact to produce an effect that is greater than expected from the two drugs' algebraic summation.[12]

Hyporeactivity means a larger than expected dose is required to produce a response, and this effect is termed *tolerance*, *desensitization*, or *tachyphylaxis*. Tolerance usually results from chronic drug exposure, either through enzyme induction (e.g., alcohol) or depletion of neurotransmitters (e.g., cocaine).

Potency, Efficacy, Lethal Dose, and Therapeutic Index

The *potency* of a drug is the dose required to produce a given effect, such as pain relief or a change in heart rate. The average sensitivity to a particular drug can be expressed through the calculation of the effective dose; ED_{50} would have the desired effect in 50% of the general population. The *efficacy* of any therapeutic agent is its power to produce a desired effect. Two drugs may have the same efficacy but different potencies. The difference in potency of the two drugs is described by the ratio $ED_{50}b/ED_{50}a$, where *a* is the less potent drug. If the $ED_{50}b$ equals 4 and the $ED_{50}a$ equals 0.4, then drug *a* is 10 times as potent as drug *b*. For example, 10 mg of morphine produces analgesia equal to that of 1 mg of hydromorphone. They are equally effective, but hydromorphone is 10 times as potent as morphine.

Dose-response curves show the relationship between the dose of a drug administered (or the resulting plasma concentration) and the pharmacologic effect of the drug. The pharmacologic effect might be secretion of a hormone, a change in heart rate, or contraction of a muscle. Between 20% and 80% of the maximum effect, the logarithm of the dose and its response has a linear relationship. The term *dose* only applies to the amount administered and not the actual concentration. If the concentration of an antagonist is increased (in the presence of a fixed concentration of agonist), the dose-response curve will be shifted to the right, and a higher agonist concentration will be required to achieve the desired effect. A basic dose-response curve is shown in Fig. 46-1.

The *lethal dose* (LD_{50}) of a drug produces death in 50% of animals to which it is given. The ratio of the lethal dose and

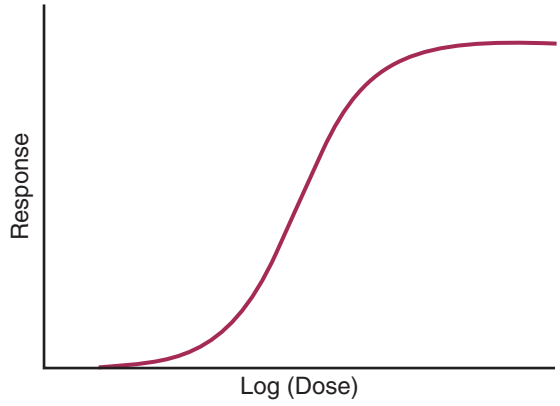

Figure 46-1. Basic dose-response curve.

effective dose, LD_{50}/ED_{50}, is the *therapeutic index*. A drug with a high therapeutic index is safer than a drug with a low or narrow therapeutic index.

ANESTHETIC AGENTS

Anesthesia can be *local*, *regional*, or *general* (Table 46-1). Local anesthesia is accomplished using a local anesthetic drug that can be injected intradermally and is used for the removal of small lesions or to repair traumatic injuries. Local anesthesia is the most frequent anesthetic administered by surgeons and may be accompanied by IV sedation to improve patient comfort.

General Anesthesia

General anesthesia describes a triad of three major and separate effects: unconsciousness (and amnesia), analgesia, and muscle relaxation (see Table 46-1). IV drugs usually produce a single,

Table 46-1

Anesthetic agents, their actions, and their clinical uses

EFFECT	MONITOR	IV DRUGS	POTENT GASES	WEAK GAS	LOCAL ANESTHETICS[c]	
Unconscious (amnesia) (anxiolysis)	EEG and/or clinical signs	Benzodiazepines Midazolam Lorazepam Diazepam Barbiturates Etomidate Ketamine[a]	Sevoflurane Desflurane Isoflurane Enflurane Halothane	Nitrous oxide[b]		
Analgesia	Heart rate Blood pressure Respiratory rate	Opioids Fentanyl Morphine Hydromorphone Nonopioid Ketamine[a] Parecoxib Dexmedetomidine Acetaminophen IV Ketorolac	Sevoflurane Desflurane Isoflurane Enflurane Halothane	Nitrous oxide[b]	Amides Lidocaine Bupivacaine Ropivacaine Prilocaine Mepivacaine Peripheral nerve blocks (brachial plexus, femoral, etc.) Central nerve blocks (spinal, epidural)	Esters Cocaine Procaine Chloroprocaine Tetracaine Benzocaine
Muscle relaxation (paralysis)	Nerve stimulator	Depolarizer Succinylcholine Nondepolarizers Pancuronium Vecuronium Rocuronium Atracurium	Sevoflurane Desflurane Isoflurane Enflurane Halothane			

EEG = electroencephalogram; IV = intravenous.

[a]Note that the IV agents are quite specific in their effects, except for ketamine, which has both amnestic and analgesic qualities.

[b]The potent inhalational anesthetics contribute to all three components of anesthesia, but nitrous oxide has weak amnestic and analgesic properties and provides no muscle relaxation at all.

[c]The local anesthetics produce excellent analgesia and muscle relaxation but contribute nothing to amnesia or anxiolysis; these anesthetics must be supplemented with an IV sedative.

discrete effect, while most inhaled anesthetics produce elements of all three. General anesthesia is achieved with a combination of IV and inhaled drugs, each used to its maximum benefit. The science and art of anesthesia are dynamic processes. As the amount of stimulus to the patient changes during surgery, the patient's vital signs are used as a guide and the quantity of drugs is adjusted, maintaining an equilibrium between stimulus and dose. General anesthesia is what patients commonly think of when they are to be "put under" and can be a cause of considerable preoperative anxiety.[13]

Intravenous Agents

Unconsciousness and Amnesia The IV agents that produce unconsciousness and amnesia are frequently used for the induction of general anesthesia. They include barbiturates, benzodiazepines, propofol, etomidate, and ketamine. Except for ketamine, the following agents have no analgesic properties and do not cause paralysis or muscle relaxation.

Barbiturates The most common barbiturates are thiopental, thiamylal, and methohexital. The mechanism of action is at the γ-aminobutyric acid (GABA) receptor, where they inhibit excitatory synaptic transmission. They produce a rapid, smooth induction within 60 seconds, and wear off in about 5 minutes. In higher doses and in patients with intravascular depletion, they cause hypotension and myocardial depression. The barbiturates are anticonvulsants and protect the brain during neurosurgery by reducing cerebral metabolism.

Propofol Propofol is an alkylated phenol that inhibits synaptic transmission through its effects at the GABA receptor. With a short duration, rapid recovery, and low incidence of nausea and vomiting, it has emerged as the agent of choice for ambulatory and minor general surgery. Additionally, propofol has bronchodilatory properties that make its use attractive in asthmatic patients and smokers. Propofol may cause hypotension and should be used cautiously in patients with suspected hypovolemia and/or coronary artery disease (CAD), the latter of which may not tolerate a sudden drop in blood pressure. It can be used as a continuous infusion for sedation in the intensive care unit setting. Propofol is an irritant and frequently causes pain on injection.

Benzodiazepines The most important uses of the benzodiazepines are for reduction of anxiety and to produce amnesia. Frequently used IV benzodiazepines are diazepam, lorazepam, and midazolam. They all inhibit synaptic transmission at the GABA receptor but have differing durations of action. The benzodiazepines can produce peripheral vasodilatation and hypotension but have minimal effects on respiration when used alone. They must be used with caution when given with opioids; a synergistic reaction causing respiratory depression is common. The benzodiazepines are excellent anticonvulsants and only rarely cause allergic reactions.

Etomidate Etomidate is an imidazole derivative used for IV induction. Its rapid and almost complete hydrolysis to inactive metabolites results in rapid awakening. Like the above IV agents, etomidate acts on the GABA receptor. It has little effect on cardiac output and heart rate, and induction doses usually produce less reduction in blood pressure than that seen with thiopental or propofol. Etomidate is associated with pain on injection and more nausea and vomiting than thiopental or propofol.

Ketamine Ketamine differs from the above IV agents in that it produces analgesia as well as amnesia. Its principal action is on the *N*-methyl-D-aspartate receptor; it has no action on the GABA receptor. It is a dissociative anesthetic, producing a cataleptic gaze with nystagmus. Patients may associate this with delirium and hallucinations while regaining consciousness. The addition of benzodiazepines has been shown to prevent these side effects. Ketamine can increase heart rate and blood pressure, which may cause myocardial ischemia in patients with CAD. Ketamine is useful in acutely hypovolemic patients to maintain blood pressure via sympathetic stimulation but is a direct myocardial depressant in patients who are catecholamine depleted. Ketamine is a bronchodilator, making it useful for asthmatic patients, and rarely is associated with allergic reactions.

Analgesia. The IV analgesics most frequently used in anesthesia today have little effect on consciousness, amnesia, or muscle relaxation. The most important class is the *opioids*, so called because they were first isolated from opium, with morphine, codeine, meperidine, hydromorphone, and the fentanyl family being the most common. The most important *nonopioid* analgesics are ketamine (discussed earlier in the Ketamine section) and ketorolac, an IV nonsteroidal anti-inflammatory drug (NSAID).

Opioid Analgesics The commonly used opioids—morphine, codeine, oxymorphone, meperidine, and the fentanyl-based compounds—act centrally on μ-receptors in the brain and spinal cord. The main side effects of opioids are euphoria, sedation, constipation, and respiratory depression, which also are mediated by the same μ-receptors in a dose-dependent fashion. Although opioids have differing potencies required for effective analgesia, *equianalgesic doses of opioids result in equal degrees of respiratory depression*. Thus, there is no completely safe opioid analgesic. The synthetic opioid fentanyl and its analogues sufentanil, alfentanil, and remifentanil are commonly used in the operating room. They differ pharmacokinetically in their lipid solubility, tissue binding, and elimination profiles and thus have differing potencies and durations of action. Remifentanil is remarkable in that it undergoes rapid hydrolysis that is unaffected by sex, age, weight, or renal or hepatic function, even after prolonged infusion. Recovery is within minutes, but there is little residual postoperative analgesia.

Naloxone and the longer-acting naltrexone are pure opioid *antagonists*. They can be used to reverse the side effects of opioid overdose (e.g., respiratory depression), but the analgesic effects of the opioid also will be reversed.

Nonopioid Analgesics *Ketamine*, an *N*-methyl-D-aspartate receptor antagonist, is a potent analgesic, but is one of the few IV agents that also causes significant sedation and amnesia. Unlike the μ-receptor agonists, ketamine supports respiration. It can be used in combination with opioids, but the dysphoric effects must be masked with the simultaneous use of sedatives, usually a benzodiazepine like midazolam.

Ketorolac is a parenteral NSAID that produces analgesia by reducing prostaglandin formation via inhibition of the enzyme cyclooxygenase (COX). Intraoperative use of ketorolac reduces postoperative need for opioids. Two forms of COX have been identified: COX-1 is responsible for the synthesis of several prostaglandins as well as prostacyclin, which protects gastric mucosa, and thromboxane, which supports platelet function. COX-2 is induced by inflammatory reactions to produce more prostaglandins. Ketorolac (as well as many oral NSAIDs, aspirin, and indomethacin) inhibits both COX-1 and COX-2, which causes the major side effects of gastric bleeding, platelet dysfunction, and hepatic and renal damage.

Parecoxib is a parenteral, predominantly COX-2 NSAID that presumably produces analgesia and reduces inflammation without causing gastrointestinal bleeding or platelet dysfunction.

Dexmedetomidine is an IV α_2-adrenergic agonist, administered as a continuous infusion, and has sedative and analgesic properties. It is useful for sedation in an intensive care unit setting and as an adjunct to general anesthesia. Side effects are hypotension and bradycardia.

IV *acetaminophen* is an analgesic drug and antipyretic of moderate potency; its site of action is in the central nervous system (CNS), not peripherally. It does not have anti-inflammatory properties and is not considered an NSAID.[14] When used as part of postoperative analgesic therapy, it will reduce the amount of opioids required, reducing side effects (e.g., constipation, sedation, respiratory depression).

Neuromuscular Blocking Agents. Neuromuscular blocking agents have no amnestic, hypnotic, or analgesic properties; patients must be properly anesthetized *before* and *in addition to* the administration of these agents. A paralyzed but unsedated patient will be aware, conscious, and in pain, yet be unable to communicate their predicament. Inappropriate administration of a neuromuscular blocking agent to an awake patient is one of the most traumatic experiences imaginable. Neuromuscular blockade is not a substitute for adequate anesthesia, but is rather an adjunct to the anesthetic. Depth of neuromuscular blockade is best monitored with a nerve stimulator to ensure patient immobility intraoperatively and to confirm a lack of residual paralysis postoperatively.[15]

Unlike the local anesthetics, which affect the ability of nerves to conduct impulses, the neuromuscular blockers have no effect on either nerves or muscles, but act primarily on the *neuromuscular junction*.

There is one commonly used *depolarizing* neuromuscular blocker—succinylcholine. This agent binds to acetylcholine receptors on the postjunctional membrane in the neuromuscular junction and causes depolarization of muscle fibers.

Although the rapid onset (<60 seconds) and rapid offset (5–8 minutes) make succinylcholine ideal for management of the airway in certain situations, total body muscle fasciculations can cause postoperative aches and pains, an elevation in serum potassium levels, and an increase in intraocular and intragastric pressure. Its use in patients with burns or traumatic tissue injuries may result in a high enough rise in serum potassium levels to produce arrhythmias and cardiac arrest. Unlike other neuromuscular blocking agents, the effects of succinylcholine cannot be reversed. Succinylcholine is rapidly hydrolyzed by plasma cholinesterase, also referred to as *pseudocholinesterase*. There are many reasons for a patient to have low pseudocholinesterase levels, such as liver disease, concomitant use of other drugs, pregnancy, and cancer. These factors are usually not clinically problematic, delaying return of motor function only by several minutes. Some patients have a genetic disorder manifesting as atypical plasma cholinesterase; the atypical enzyme has less-than-normal activity, and/or the patient has extremely low levels of the enzyme. The incidence of the homozygous form is approximately 1 in 3000; the effects of a single dose of succinylcholine may last several hours instead of several minutes. Treatment is to keep the patient sedated and unaware he or she is paralyzed, continue mechanical ventilation, test the return of motor function with a peripheral nerve stimulator, and extubate the patient only after he or she has fully regained motor strength. Two separate blood tests must be drawn: *pseudocholinesterase level* to determine the amount of enzyme present, and *dibucaine number*, which indicates the quality of the enzyme. Patients with laboratory-confirmed abnormal pseudocholinesterase levels and/or dibucaine numbers should be counseled to avoid succinylcholine as well as mivacurium, which is also hydrolyzed by pseudocholinesterase. First-degree family members should also be tested. Succinylcholine is the only IV triggering agent of malignant hyperthermia (discussed later in the Malignant Hyperthermia section).

There are several competitive *nondepolarizing* agents available for clinical use. The longest acting is *pancuronium*, which is excreted almost completely unchanged by the kidney. Intermediate-duration neuromuscular blockers include *vecuronium* and *rocuronium*, which are metabolized by both the kidneys and liver, and *atracurium* and *cisatracurium*, which undergo breakdown in plasma known as *Hofmann elimination*. The agent with shortest duration is *mivacurium*, the only nondepolarizer that is metabolized by plasma cholinesterase, and like succinylcholine, is subject to the same prolonged blockade in patients with plasma cholinesterase deficiency. All nondepolarizers reversibly bind to the postsynaptic terminal in the neuromuscular junction and prevent acetylcholine from depolarizing the muscle. Muscle blockade occurs without fasciculation and without the subsequent side effects seen with succinylcholine. The most commonly used agents of this type and their advantages and disadvantages are listed in Table 46-2.

The reversal of neuromuscular blockade is not a true reversal of the drug (as with protamine reversal of heparin) but a reversal of the effect of the neuromuscular blockade. Neuromuscular blocking reversal agents, usually neostigmine, edrophonium, or pyridostigmine, increase acetylcholine levels by inhibiting acetylcholinesterase, the enzyme that breaks

Table 46-2

Advantages and disadvantages to common nondepolarizing neuromuscular blocking agents

AGENT	DURATION (H)	ADVANTAGES	DISADVANTAGES
Pancuronium	>1	No histamine release	Tachycardia; slow onset; long duration
Vecuronium	<1	No cardiovascular effects	Intermediate onset
Rocuronium	<1	Fast onset; no cardiovascular effects	—
Mivacurium	<1	Fast onset; short duration & histamine release	—

down acetylcholine. The subsequently increased circulating levels of acetylcholine prevail in the competition for the postsynaptic receptor, and motor function returns. Use of the peripheral nerve stimulator is required to follow depth and reversal of motor blockade, but it is essential to correlate data from the nerve stimulator with clinical signs that indicate return of motor function, including tidal volume, vital capacity, hand grip, and 5-second sustained head lift.

Inhalational Agents. Unlike the IV agents, the inhalational agents provide all three characteristics of general anesthesia: unconsciousness, analgesia, and muscle relaxation. However, it would be impractical to use an inhalation-only technique in larger surgical procedures, because the doses required would cause unacceptable side effects, so IV adjuncts such as opioid analgesics and neuromuscular blockers are added to optimize the anesthetic. All inhaled anesthetics display a dose-dependent reduction in mean arterial blood pressure except for nitrous oxide, which maintains or slightly raises the blood pressure. Nitrous oxide, although not potent enough to use alone, provides partial anesthesia and allows a second agent to be used in smaller doses, reducing side effects.

Minimum alveolar concentration (MAC) is a measure of anesthetic potency. It is the ED_{50} of an inhaled agent (i.e., the dose required to block a response to a painful stimulus in 50% of subjects). The higher the MAC, the less potent an agent is. The potency and speed of induction of inhaled agents correlate with their lipid solubility, and this is known as the *Meyer-Overton rule*. Nitrous oxide has a low solubility and is a weak anesthetic agent, but has the most rapid onset and offset. The "potent" gases (e.g., desflurane, sevoflurane, enflurane, and halothane) are more soluble in blood than nitrous oxide and can be given in lower concentrations, but have longer induction and emergence characteristics.

Sevoflurane and desflurane are the two most recently introduced inhalational agents in common use. Because of their relatively lower tissue and blood solubility, induction and recovery are more rapid than with isoflurane or enflurane.

All of the potent inhalational agents (e.g., halothane, isoflurane, enflurane, sevoflurane, and desflurane), as well as the depolarizing agent succinylcholine, are triggering agents for malignant hyperthermia. Table 46-3 lists the advantages and disadvantages of each agent.

Local Anesthetics

Local anesthetics are divided into two groups based on their chemical structure: the amides and the esters. In general, the amides are metabolized in the liver, and the esters are metabolized by plasma cholinesterases, which yield metabolites with slightly higher allergic potential than the amides (Table 46-4).

Amides. Lidocaine, bupivacaine, mepivacaine, prilocaine, and ropivacaine have in common an amide linkage between a benzene ring and a hydrocarbon chain that, in turn, is attached to a tertiary amine. The benzene ring confers lipid solubility for penetration of nerve membranes, and the tertiary amine attached to the hydrocarbon chain makes these local anesthetics water soluble. Lidocaine has a more rapid onset and is shorter acting than bupivacaine; however, both are widely used for tissue infiltration, regional nerve blocks, and spinal and epidural anesthesia. Ropivacaine is the most recently introduced local anesthetic. It is clinically similar to bupivacaine in that it has a slow onset and a long duration, but is less cardiotoxic. All amides are 95% metabolized in the liver, with 5% excreted unchanged by the kidneys.

Esters. Cocaine, procaine, chloroprocaine, tetracaine, and benzocaine have an ester linkage in place of the amide linkage mentioned earlier in the Amides section. Unique among local anesthetics, cocaine occurs in nature, was the first used clinically, produces vasoconstriction (making it useful for topical application, e.g., for intranasal surgery), releases norepinephrine from nerve terminals resulting in hypertension, and is highly addictive. Cocaine is a Schedule II drug. Procaine, synthesized in 1905 as a nontoxic substitute for cocaine, has a short duration and is used for infiltration. Tetracaine has a long duration and is useful as a spinal anesthetic for lengthy operations. Benzocaine is for topical use only. The esters are hydrolyzed in the blood by pseudocholinesterase. Some of the metabolites have a greater allergic potential than the metabolites of the amide anesthetics, but true allergies to local anesthetics are rare.

Table 46-3

Advantages and disadvantages of common inhalational agents

AGENT	MAC (%)	ADVANTAGES	DISADVANTAGES
Nitrous oxide	105	Analgesia; minimal cardiac and respiratory depression	Sympathetic stimulation; expansion of closed air space
Halothane	0.75	Effective in low concentrations; minimal airway irritability; inexpensive	Cardiac depression and arrhythmia hepatic necrosis; slow elimination
Enflurane	1.68	Muscle relaxation No effect on cardiac rate or rhythm	Strong smell; seizures
Isoflurane	1.15	Muscle relaxation; no effect on cardiac rate or rhythm	Strong smell
Desflurane	6	Rapid induction and emergence	Coughing; high cost
Sevoflurane	1.71	Rapid induction and emergence; pleasant smell; ideal for mask induction	High cost; metabolized by liver

MAC = minimum alveolar concentration.

In: Cousins MJ, Bridenbaugh PO, eds. *Cousins and Bridenbaugh's Neural Blockade in Clinical Anesthesia and Pain Medicine*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:49.

The common characteristic of all local anesthetics is a reversible block of the transmission of neural impulses when placed on or near a nerve membrane. Local anesthetics block nerve conduction by stabilizing sodium channels in their closed state, preventing action potentials from propagating along the nerve. The individual local anesthetic agents have different recovery times based on lipid solubility and tissue binding, but return of neural function is spontaneous as the drug is metabolized or removed from the nerve by the vascular system.

Toxicity of local anesthetics results from absorption into the bloodstream or from inadvertent direct intravascular injection. Toxicity manifests first in the more sensitive CNS and then the cardiovascular system.

Central Nervous System Toxicity. As plasma concentration of local anesthetic rises, symptoms progress from restlessness to complaints of tinnitus. Slurred speech, seizures, and unconsciousness follow. Cessation of the seizure via administration of a benzodiazepine or thiopental and maintenance of the airway are the immediate treatment. If the seizure persists, the trachea must be intubated with a cuffed endotracheal tube to guard against pulmonary aspiration of stomach contents.

Cardiovascular System Toxicity. With increasingly elevated plasma levels of local anesthetics, progression to hypotension, increased P-R intervals, bradycardia, and cardiac arrest may occur. Bupivacaine is more cardiotoxic than other local anesthetics. It has a direct effect on ventricular muscle, and because it is more lipid soluble than lidocaine, it binds tightly to sodium channels (it is called the *fast-in, slow-out local anesthetic*). Patients who have received an inadvertent intravascular injection of bupivacaine have experienced profound hypotension, ventricular tachycardia and fibrillation, and complete atrioventricular heart block that is extremely refractory to treatment. The toxic dose of lidocaine is approximately 5 mg/kg; that of bupivacaine is approximately 3 mg/kg.

Calculation of the toxic dose before injection is imperative. It is helpful to remember that for any drug or solution, 1% = 10 mg/mL. For a 50-kg person, the toxic dose of bupivacaine would be approximately 3 mg/kg, or $3 \times 50 = 150$ mg. A 0.5% solution of bupivacaine is 5 mg/mL, so 150 mL/5 mg/mL = 30 mL as the upper limit for infiltration. For lidocaine in the same patient, the calculation is $50 \text{ kg} \times 5 \text{ mg/mL} = 250$ mg toxic dose. If a 1% solution is used, the allowed amount would be 250 mg/10 mg/mL = 25 mL.

Additives to Local Anesthetics. Epinephrine has one physiologic and several clinical effects when added to local anesthetics. Epinephrine is a vasoconstrictor, and by reducing local bleeding, molecules of the local anesthetic remain in proximity to the nerve for a longer time period. Onset of the nerve block is faster, the quality of the block is improved, the duration is longer, and less local anesthetic will be absorbed into the bloodstream, thereby reducing toxicity. Although epinephrine 1:200,000 (5 g/mL) added to a local anesthetic for infiltration will greatly lengthen the time of analgesia, epinephrine-containing solutions should not be injected into body parts with end-arteries, such as toes or fingers, as vasoconstriction may lead to ischemia or loss of a digit. When added to the local anesthetic, sodium bicarbonate will raise the pH, favoring the nonionized uncharged form of the molecule. This speeds the onset of the block, especially in local anesthetics that are mixed with epinephrine. The pH of such solutions is around 4.5; therefore, the addition of sodium bicarbonate results in a relatively large increase in pH.[16]

Regional Anesthesia: Peripheral vs. Central

Peripheral Nerve Blocks. Local anesthetic can be injected *peripherally*, near a large nerve or plexus, to provide anesthesia to a larger region of the body. Examples include the brachial plexus for surgery of the arm or hand, blockade of the femoral and sciatic nerves for surgery of the lower extremity, ankle block for surgery of the foot or toes, intercostal block for analgesia of the thorax postoperatively, or blockade of the cervical plexus, which is ideal for carotid endarterectomy. Risks of peripheral regional nerve blocks are dependent on their location.

For example, nerve blocks injected into the neck risk puncture of the carotid or vertebral arteries, intercostal nerves are in close proximity to the vascular bundle and have a high rate of absorption of local anesthetic, and nerve blocks of the thorax run the risk of causing pneumothorax. All peripheral nerve blocks may be supplemented intraoperatively with IV sedation and/or analgesics.

Central Nerve Blocks: Spinal and Epidural. Local anesthetic injected *centrally* near the spinal cord—spinal or epidural anesthesia—provides anesthesia for the lower half of the body. This is especially useful for genitourinary, gynecologic, inguinal hernia, or lower extremity procedures. Spinal and epidural anesthesia block the spinal nerves as they exit the spinal cord. Spinal nerves are mixed nerves; they contain motor, sensory, and sympathetic components. The subsequent block will cause sensory anesthesia, loss of motor function, and blockade of the sympathetic nerves from the level of the anesthetic distally to the lower extremities. Subsequent vasodilation of the vasculature from sympathetic block may result in hypotension, which is treatable with IV fluids and/or pressors.

Spinal Anesthesia Local anesthetic is injected directly into the dural sac surrounding the spinal cord. The level of injection is usually below L1 to L2, where the spinal cord ends in most adults. Because the local anesthetic is injected directly into the cerebrospinal fluid surrounding the spinal cord, only a small dose is needed, the onset of anesthesia is rapid, and the blockade is thorough. Lidocaine, bupivacaine, and tetracaine are commonly used agents of differing durations; the block wears off naturally via drug uptake by the cerebrospinal fluid, bloodstream, or diffusion into fat. Epinephrine as an additive to the local anesthetic will significantly prolong the blockade.

Possible complications include hypotension, especially if the patient is not adequately prehydrated; high spinal block requires immediate airway management; and postdural puncture headache sometimes occurs. Spinal headache is related to the diameter and configuration of the spinal needle and can be reduced to approximately 1% with the use of a small 25- or 27-gauge needle.

Cauda equina syndrome is injury to the nerves emanating distal to the spinal cord resulting in bowel and bladder dysfunction and lower extremity sensory and motor loss. It has mainly been seen in cases in which indwelling spinal microcatheters and high (5%) concentrations of lidocaine were used. Indwelling spinal catheters are no longer used.

Epidural Anesthesia Epidural anesthesia could also be called *extradural anesthesia*, because local anesthetics are injected into the epidural space surrounding the dural sac of the spinal cord. Much greater volumes of anesthetic are required than with spinal anesthesia, and the onset of the block is longer—10 to 15 minutes. As in spinal anesthesia, local anesthetic bathes the spinal nerves as they exit the dura; the patient achieves analgesia from the sensory block, muscle relaxation from blockade of the motor nerves, and hypotension from blockade of the sympathetic nerves as they exit the spinal cord. Note that regional anesthesia, whether peripheral or central, provides only two of the three major components of anesthesia—analgesia and muscle relaxation. Anxiolysis, amnesia, or sedation must be attained by supplemental IV administration of other drugs (e.g., the benzodiazepines or propofol infusion).

Complications are similar to those of spinal anesthesia. Inadvertent injection of local anesthetic into a dural tear will result in a high block, manifesting as unconsciousness, severe hypotension, and respiratory paralysis requiring immediate aggressive hemodynamic management and control of the airway. Indwelling catheters are often placed through introducers into the epidural space, allowing an intermittent or continuous technique, as opposed to the single-shot method of spinal anesthesia. By necessity, the epidural-introducing needles are of a much larger diameter (17- or 18-gauge) than spinal needles, and accidental dural puncture more often results in a severe headache that may last up to 10 days if left untreated.

ANESTHESIA MANAGEMENT

Preoperative Evaluation and Preparation

The ASA has adopted basic standards for the evaluation of patients before surgery. These standards require the anesthesiologist to determine the medical status of the patient by developing a plan of anesthetic care and to discuss this plan with the patient and/or legal guardian.

The preoperative visit results in a summary of all pertinent findings, including a detailed medical history, current drug therapy, complete physical examination, and laboratory and specific testing results. Based on these findings, the anesthesiologist may find that the patient is not in optimal medical condition to undergo elective surgery. These findings and opinions are then discussed with the patient's primary physician, and the surgery may be delayed or cancelled until the patient's medical condition is further tested and optimized.

The detailed medical history obtained at the preoperative visit should include the patient's previous exposure and experience with anesthesia, as well as any family history of problems with anesthesia. History of atopy (medication, foods, or environmental) is an important aspect of this evaluation in that it may predispose patients to form antibodies against antigens that may be represented by agents administered during the perioperative period. A careful review of major organ systems and their function also should be performed.

The physical examination is targeted primarily at the CNS, cardiovascular system, lungs, and upper airway. Specific areas to investigate are shown in Table 46-5.

Table 46-5

Preoperative physical examination

CENTRAL NERVOUS SYSTEM	CARDIOVASCULAR SYSTEM	RESPIRATORY SYSTEM	ORAL AIRWAY
Consciousness; neurocognition; peripheral sensory	Blood pressure; standing and sitting, bilateral; peripheral pulses; heart auscultation; heart rate; murmur; rhythm	Auscultation of lungs; wheezes; rales	Cervical spine mobility; visualize uvula; artificial teeth; thyromental distance

Concurrent medications must be fully explored, and adverse interactions with agents administered during the perioperative period need to be considered. However, concurrent medications that produce desired effects (i.e., β-blockade, antihypertensive, and antiasthma medications) can and should be continued throughout the perioperative period; patients should be counseled to continue these medications up to and including the morning of surgery. Careful documentation will allow the anesthesiologist to make informed decisions about the perioperative selection of drugs and therapy as well as monitoring techniques.

Preoperative laboratory data and specific testing for elective surgery should be patient and situation specific. Examples include serum potassium for a patient on diuretics, glucose in a diabetic patient, or hemoglobin concentration in any surgery with a high risk of blood loss. Coagulation tests are not necessary if the patient is not receiving anticoagulants or has no signs or symptoms of abnormal clotting. Otherwise healthy patients usually do not need preoperative laboratory testing, and tests performed within the previous 6 months are usually sufficient.[17] Other tests that should be generated by history and physical examination include chest radiograph if there is evidence of chest disease and pulmonary function tests in patients who are morbidly obese, severe asthmatics, or patients undergoing pulmonary resection surgery. An electrocardiogram should be performed in all symptomatic patients and in asymptomatic men age 45 years or older and asymptomatic women age 50 years or older. Urine pregnancy testing should be performed on the day of surgery in all women of childbearing age.

Risk Assessment

An integral part of the preoperative visit is for the anesthesiologist to assess patient risk. Risk assessment encompasses two major questions: (a) Is the patient in optimal medical condition for surgery? and (b) Are the anticipated benefits of surgery greater than the surgical and anesthetic risks associated with the procedure?

Research into quantifying preoperative factors that correlate with the development of postoperative morbidity and mortality has recently gained great interest. Originally designed as a simple classification of a patient's physical status immediately before surgery, the ASA physical status scale is one of the few prospective scales that correlate with the risk of anesthesia and surgery (Table 46-6).

Criticism of the ASA scale is primarily due to its exclusion of age and difficulty of intubation (discussed later in this chapter). Cullen and associates examined 1095 patients undergoing total hip replacement, prostatectomy, or cholecystectomy, and found that both age and ASA scale accurately predict postoperative morbidity and mortality[18] (Table 46-7). The ASA scale remains useful and should be applied to all patients during the preoperative visit.

Table 46-6

American Society of Anesthesiologists physical status classification system

P1 A normal healthy patient
P2 A patient with mild systemic disease
P3 A patient with severe systemic disease
P4 A patient with severe systemic disease that is a constant threat to life
P5 A moribund patient who is not expected to survive without the operation
P6 A declared brain-dead patient whose organs are being removed for donor purposes

Table 46-7

American Society of Anesthesiologists physical status and mortality

SCORE	MORTALITY (%)
P1	0.1
P2	0.2
P3	1.8
P4	7.8
P5	9.4

Evaluation of the Airway. The airway examination is an effort to identify those patients in whom management of the airway and conventional endotracheal intubation may be difficult. It is vitally important to recognize such patients before administering medications that induce apnea.

Mallampati Classification. The amount of the posterior pharynx one can visualize preoperatively is important and correlates with the difficulty of intubation. A large tongue (relative to the size of the mouth) that also interferes with visualization of the larynx on laryngoscopy will obscure visualization of the pharynx. The Mallampati classification (Fig. 46-2, Table 46-8) is based on the structures visualized with maximal mouth opening and tongue protrusion in the sitting position.

Other predictors of difficult intubation include obesity, immobility of the neck, interincisor distance <4 cm in an adult, a large overbite, or the inability to shift the lower incisors in front of the upper incisors. The thyromental distance (i.e., the distance from the thyroid cartilage to the mentum [tip of the chin]) should be >6.5 to 7 cm.

Consideration of Patients with Comorbidities. A thorough knowledge of the pathophysiology of concurrent medical conditions regardless of the reason for surgery is essential for optimal perioperative care. Optimal anesthesia extends beyond pharmacology and technical procedures. Specifically, ischemic heart disease, renal dysfunction, pulmonary disease, metabolic and endocrine disorders, CNS diseases, and diseases of the liver and biliary tract can have major impact on the management of anesthesia.

Ischemic Heart Disease. Ischemic heart disease is the result of the heart demanding more oxygen (O_2) than its supply can provide. A supply problem may be due to many factors, including hypoxia, anemia, hypotension and coronary artery atherosclerosis, thrombosis, or spasm. Additionally, the problem may be an increase in myocardial O_2 demand (tachycardia). In the vast majority of cases, the most responsible lesion is a reduction in the luminal area of coronary arteries due to atherosclerosis.

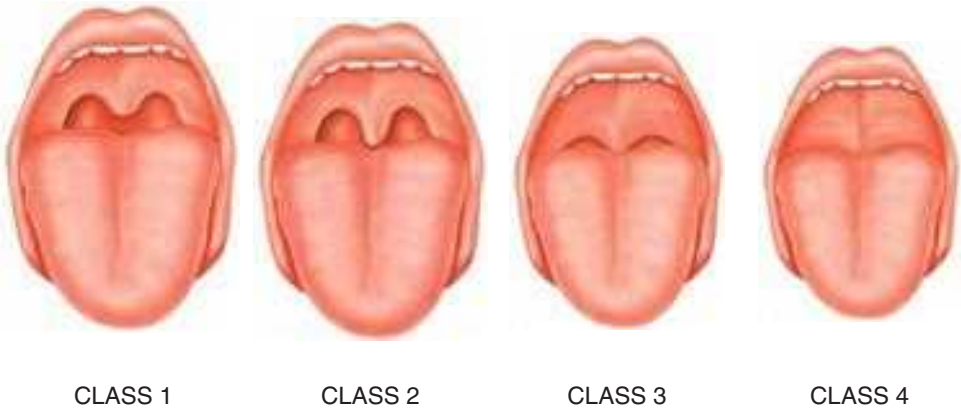

Figure 46-2. The Mallampati classification.

An estimated 14 million people in the United States have ischemic heart disease. Of these, as many as 4 million have few or no symptoms and are unaware that they are at risk for angina pectoris, myocardial infarction, or sudden death.

An important goal of the preoperative visit is for the anesthesiologist to ascertain the patient's severity, progression, and functional limitations induced by ischemic heart disease. Furthermore, this visit can elucidate the possibility of previously undiagnosed ischemic heart disease. A thorough investigation of risk factors for ischemic heart disease is essential during the preoperative visit. The risk of perioperative death due to myocardial infarction in patients without ischemic heart disease is approximately 1%.[19] In contrast, the risk in patients with known or suspected ischemic heart disease is approximately 3%,[19] and in patients undergoing surgery for peripheral vascular disease, the combined risk of death due to cardiac causes is 29%.[20]

Major Risk Factors for Coronary Artery Disease. The risk of *hypercholesterolemia* is proportional to the increased serum level of low-density lipoprotein cholesterol. Reduction achieved via decreased dietary fat or pharmacotherapy reduces risk.

Hyperlipidemia may be familial and thus may account for the fact that a strong family history of premature CAD is a significant risk factor. High-density lipoprotein cholesterol is protective.

Although definitely a risk factor, hypertension alone probably does not cause plaques. Rather, it may act synergistically with hypercholesterolemia by first causing mechanical wall stress and damage.

Smoking causes endothelial damage, and therefore promotes plaque thrombosis. Cessation greatly reduces the risk of CAD.

Table 46-8

Mallampati classification

Class I: soft palate, fauces, uvula, pillars
Class II: soft palate, fauces, portion of uvula
Class III: soft palate, base of uvula
Class IV: hard palate only

Diabetes mellitus is a strong independent risk factor. A hypothesis is that glycosylation products cause release of growth factors that stimulate smooth muscle proliferation.

Other Risk Factors. *Hyperhomocysteinemia* is becoming an established independent risk factor, but is still under evaluation. Reduction of levels by folate therapy may be beneficial.

Advanced age, male sex, obesity, and a sedentary lifestyle can also put a person at risk for developing ischemic heart disease.[21]

Drugs used for the medical management of patients with ischemic heart disease should be continued throughout the perioperative period. Withdrawal of an antihypertensive drug or suspension of β-blockade can induce unwanted increases in sympathetic nervous system activity.[12] Induction of anesthesia in patients with ischemic heart disease can be safely accomplished with a number of IV drugs. As many as 45% of patients have been shown to have myocardial ischemia during the stress of tracheal intubation, and direct laryngoscopy should be used for the shortest time possible to minimize the magnitude of stimulation.[22]

The intraoperative anesthetic technique should allow for the prompt control of hemodynamic variables; the maintenance of the balance between myocardial O_2 delivery and myocardial O_2 demand is probably the single most important factor in managing patients with ischemic heart disease. In this regard, muscle relaxants with minimal to no effects on heart rate and blood pressure, such as vecuronium and rocuronium, are attractive choices for neuromuscular blockade. Additionally, controlled myocardial depression using a volatile anesthetic in patients with a normal left ventricular ejection fraction may help to minimize the stimulation of the sympathetic nervous system and subsequent increases in myocardial O_2 requirements. In patients with impaired left ventricular function, continued myocardial depression with volatile anesthetics may not be tolerated; the addition of short-acting opioids such as fentanyl is beneficial. In cardiac surgical patients, it is not uncommon for high-dose opioids to be used as the predominant anesthetic.

Pulmonary Disease. Chronic pulmonary disease has developed into a worldwide public health problem. Chronic obstructive

pulmonary disease (COPD), distinguished from asthma, which is characterized by reversible airway smooth muscle constriction, is a progressive disease that leads to the destruction of the lung parenchyma.

Infection, noxious particles, and gases can exacerbate COPD. Historically, certain lung function parameters (i.e., significantly abnormal spirometry or arterial blood gas analysis) were once considered contraindications for anesthesia. However, anesthetic techniques have improved, and it has been shown that patients with severe lung disease can safely undergo anesthesia.[23] Zollinger and Pasch found no specific parameters of lung function that were predictive of postoperative lung complications. The highest predictive parameter found was upper abdominal surgery and thoracic surgery.[24]

General anesthesia can be performed safely in patients with pulmonary disease.[25] Inhaled anesthetics are often used due to their bronchodilating properties.[26] Some authors have advocated pretreatment with salbutamol, a long-acting β-agonist, which may prevent bronchoconstriction during anesthetic induction.[27,28]

Regional and local anesthesia have the benefit of avoiding tracheal irritation and stimulating bronchospasm. However, patients with COPD may become hypoxic while lying strictly supine, and sensory levels of anesthetic above T10 are associated with the impairment of respiratory muscle activity necessary for patients with COPD to maintain adequate ventilation.[12]

Intraoperatively, mechanical ventilation using a slow breathing rate (at eight breaths per minute) should be used to allow for passive exhalation in the presence of increased airway resistance. This slow breathing, facilitated by high inspiratory flow rate, may allow for improved maintenance of normal partial pressure of arterial oxygen (Pa_{O_2}) and partial pressure of arterial carbon dioxide (CO_2) levels. Patients should also be well hydrated during the procedure with adequate crystalloid/colloid volume therapy, which may allow for less viscous pulmonary secretions following surgery.

Renal Disease. Five percent of the adult population may have pre-existing renal disease that could contribute to perioperative morbidity.[29] In addition, the risk of acute renal failure is increased by certain events or patient characteristics independent of pre-existing renal disease, such as hypovolemia and obstructive vascular disease. Ischemic tubular damage (i.e., acute tubular necrosis) is the most likely cause of acute renal failure in the perioperative period, reflecting events that cause an imbalance of O_2 supply to O_2 demand in the medullary ascending tubular cells.

Virtually all anesthetic drugs and techniques are associated with decreases in renal blood flow, the glomerular filtration rate, and urine output, reflecting multiple mechanisms such as decreased cardiac output, altered autonomic nervous system activity, neuroendocrine changes, and positive pressure ventilation. Renal blood flow (15%–25% of the cardiac output) far exceeds renal O_2 needs, but ensures optimal clearance of wastes and drugs. Prehydration and the depth of anesthesia may influence the renal response to anesthesia.

Management of anesthesia in patients with chronic renal disease requires attention to intraoperative fluid management and tight control of ventilation, as respiratory alkalosis will shift the oxyhemoglobin dissociation curve, and respiratory acidosis could raise serum potassium to dangerous levels. Because of decreased excretion by the kidney, doses of opioids and neuromuscular blocking agents must be attenuated.

Hepatobiliary Disease. Management of anesthesia for the patient with liver disease requires an understanding of the many physiologic functions of the liver: synthesis of albumin and coagulation factors, metabolism of drugs, glucose homeostasis, and the production of bilirubin. Data from the 1970s suggested that approximately 1 in every 700 adult patients who are scheduled for elective surgical procedures has unknown liver disease or is in the prodromal phase of viral hepatitis. Severe hepatic necrosis following surgery and anesthesia is most often due to decreased hepatic O_2 delivery rather than the anesthetic.

Regional anesthesia may be useful in patients with advanced liver disease, assuming coagulation status is acceptable. When general anesthesia is selected, administration of modest doses of volatile anesthetics with or without nitrous oxide or fentanyl often is recommended. Selection of nondepolarizing muscle relaxants should consider clearance mechanisms for these drugs. For example, patients with hepatic cirrhosis may be hypersensitive to mivacurium because of the lowered plasma cholinesterase activity. Perfusion to the liver is maintained by administering fluids (guided by filling pressures) and maintaining adequate systemic pressure and cardiac output.

The coexisting presence of liver disease may influence the selection of volatile anesthetics. Halothane is the anesthetic most studied regarding possible hepatotoxicity. Halothane hepatitis occurs rarely (approximately 1:25,000 patients) and may have an immune-mediated mechanism stimulated by repeated exposures to halothane.[30] Halothane, enflurane, isoflurane, and desflurane all yield a reactive oxidative trifluoroacetyl halide and may be cross-reactive, but the magnitude of metabolism of the volatile anesthetics is a probable factor in the ability to cause hepatitis.[31] Halothane is metabolized 20%, enflurane 2%, isoflurane 0.2%, and desflurane 0.02%; desflurane probably has the least potential for liver injury. Sevoflurane does not yield any trifluoroacetylated metabolites and is unlikely to cause hepatitis. An estimated 15 to 20 million adults in the United States have biliary tract disease. Treatment of gallbladder disease by open or laparoscopic cholecystectomy is most often performed with general anesthesia supplemented with muscle relaxants. Complete biliary tract obstruction could interfere with the clearance of some muscle relaxants dependent on liver metabolism, such as vecuronium and pancuronium. Anesthetic considerations for laparoscopic cholecystectomy are similar to those for other laparoscopic procedures. Insufflation of the abdominal cavity with CO_2 results in increased intra-abdominal pressure that may interfere with the ease of ventilation and venous return. During laparoscopic cholecystectomy, placement of the patient in the reverse Trendelenburg position favors movement of abdominal contents away from the operative site and may improve ventilation. However, this position may further interfere with venous return and reduce cardiac output, emphasizing the need to maintain intravascular fluid volume. Mechanical ventilation of the lungs is recommended to ensure adequate ventilation in the presence of increased intra-abdominal pressure and to offset the effects of systemic absorption of CO_2 used during insufflation of the abdominal cavity. High intra-abdominal pressure may increase the risk of passive reflux of gastric contents. Tracheal intubation with a cuffed tube is advised to minimize the risk of pulmonary aspiration.

Metabolic and Endocrine Disease. Metabolic and endocrine disorders encompass a wide range of diseases. These diseases may be the primary reason for surgery or can exist in patients requiring surgery for other unrelated disorders. Preoperative evaluation of endocrine function consists of relevant medical history, glucose or protein in the urine, vital signs, history of fluctuations in body weight, survey of sexual function, and concomitant medications. The three metabolic and endocrine conditions that are most prevalent in patients undergoing surgery are diabetes mellitus, hypothyroidism, and obesity. The prevalence of all three conditions, either alone or in combination, in the general population has been steadily rising throughout the world for the past 20 to 30 years.[12,32] The aging population and changes in the diagnostic criteria for diabetes mellitus are sure to continue this trend.[12,33]

Patients with diabetes are at an increased risk for perioperative myocardial ischemia, stroke, renal dysfunction or failure, and increased mortality.[34] Increased wound infections and impairment of wound healing also are associated with the preexistence of diabetes in patients undergoing surgery.[35]

The stress response to surgery is associated with hyperglycemia in nondiabetic patients due to increased secretion of catabolic hormones and a combination of reduced insulin secretion and increased insulin resistance.[36,37] Improved glycemic control in diabetic patients undergoing major surgery has been shown to improve perioperative morbidity and mortality; avoidance of hypoglycemia and hyperglycemic events is the standard of care in these patients.[33, 38-40]

Anesthetic techniques in the diabetic patient can modulate the secretion of catabolic hormones.[41] However, regional anesthesia may carry greater risks to the diabetic patient with autonomic neuropathy, and the hypotension associated with regional anesthesia may be deleterious to the diabetic patient with coexisting CAD.[33] There is no evidence that regional anesthesia or general anesthesia, either alone or in combination, offers any benefit to the diabetic surgical patient in terms of morbidity or mortality.[33]

Hypothyroidism is a deficiency in the secretion of the thyroid hormones, thyroxine and 3,5′,3-triiodothyronine, by the thyroid gland. More than 5 million Americans have this common medical condition, and as many as 10% of women may have some degree of thyroid hormone deficiency. Controlled clinical trials have not shown an increase in risk when patients with mild to moderate hypothyroidism undergo surgery.[42] Nevertheless, close monitoring of these patients for adverse effects of anesthesia, including delayed gastric emptying, adrenal insufficiency, and hypovolemia, is warranted.[43]

The prevalence of significant obesity continues to rise both in developed and developing countries and is associated with an increased incidence of a wide spectrum of medical and surgical pathologies[44] (Table 46-9). In the United States, one-third of people have a body weight more than 20% above their ideal weight.[45] Body mass index (BMI) is calculated by dividing the weight in kilograms by the square of the height in meters. In the United States, the prevalence of a BMI >25 kg/m^2 is 59.4% for men, 50.7% for women, and 54.9% for adults overall. Patients with a BMI >28 kg/m^2 have increased perioperative morbidity over the general population.

Anesthetic management of the obese patient is problematic, and tasks such as establishing IV access, applying monitoring equipment, managing the airway, and transporting the patient are more difficult. Ventilation may be a particular problem because of obstructive sleep apnea or because obesity itself imposes a restrictive ventilatory state with decreased expiratory reserve and vital capacity.[12] Induction of anesthesia is particularly challenging in the obese patient, as there is increased risk of pulmonary aspiration, and the increased mass of soft tissue about the head and neck makes establishing and maintaining a patent airway difficult.

Table 46-9

Disease conditions associated with obesity

CATEGORY	EXAMPLES
Cardiovascular disease	Sudden death, cardiomyopathy, hypertension, coronary artery disease, peripheral vascular disease
Respiratory disease	Restrictive lung disease, sleep apnea
Endocrine disease	Diabetes mellitus, hypothyroidism
GI disease	Hernia, gallstones
Malignancy	Breast, prostate, colorectal cancer
Musculoskeletal	Osteoarthritis, back pain

Source: Reproduced with permission from Adams JP, Murphy PG. Obesity in anaesthesia and intensive care. *Br J Anaesth.* 2000;85:91. By permission of Oxford University Press.

The impact of obesity on the pharmacokinetics of anesthetic drugs is variable. For example, blood volume is often increased in obese patients, which can decrease predicted concentrations of drugs, but adipose tissue has low blood flow, which could elevate blood concentrations of these agents. It is prudent to calculate the first dose of anesthetic based on ideal body weight and to base subsequent dosages on the patient's responsiveness.[12,46]

Central Nervous System Disease. Diseases of the CNS present unique situations for the anesthesiologist and require an understanding of the relationship between intracranial pressure (ICP), cerebral blood flow (CBF), and cerebral metabolic rate of O_2 consumption ($CMRO_2$). Preoperative assessment of ICP is difficult, as symptoms of headache, nausea, and vomiting are nonspecific, and signs of retinal changes do not occur acutely. A midline shift on computed tomography scanning or magnetic resonance imaging may indicate an expanding lesion in the brain.

Provision of anesthesia for intracranial procedures must balance hemodynamic factors such as fluid volume, mean arterial pressure, ICP, and CBF. For intracranial tumors, the mass effect of the tumor makes control of ICP and CBF critical. In intracranial aneurysm surgery, the goal of the anesthetic is to prevent sudden increases in systemic blood pressure that could rupture the aneurysm, especially during the stress of laryngoscopy and endotracheal intubation. The relationship between mean arterial pressure, ICP, and CBF is affected by pharmacologic agents. Inhalational agents in high concentrations (>0.6 MAC) cause dilation of the cerebral vasculature, decreasing cerebral vascular resistance. CBF is therefore increased in a dose-dependent fashion, despite decreases in $CMRO_2$.[12]

Propofol decreases CBF, ICP, and $CMRO_2$.[47] Propofol may also decrease systemic blood pressure, resulting in a decrease in cerebral perfusion pressure; however, propofol does not alter the autoregulation of CBF.[48] Etomidate is a potent cerebral vasoconstrictor that reduces CBF and ICP and should be used with caution in patients with epilepsy due to its excitatory effects seen on electroencephalograms.[49]

Opioids decrease CBF and may also decrease ICP under certain conditions. However, Sperry and associates have reported increases in ICP with the administration of fentanyl in head trauma patients.[50] Additionally, opioids have a depressant effect on consciousness and ventilation that may increase ICP if accompanied by an increase in partial pressure of arterial CO_2; opioids should be used with caution in head trauma patients.

Regardless of the drugs or technique selected, maintenance of stable hemodynamics is optimal. Recovery from anesthesia should be smooth, avoiding pain, coughing, and straining, all of which can increase blood pressure and ICP and cause bleeding at the surgical site.

Fluid therapy can increase cerebral edema and ICP when administered in large quantities, resulting in hypervolemia. Euvolemia should be the goal in head trauma patients, whereas hypervolemia may be beneficial for patients with intracranial aneurysms to reduce vasospasm.

INTRAOPERATIVE MANAGEMENT

Induction of Anesthesia

During induction of anesthesia, the patient becomes unconscious and rapidly apneic, myocardial function is usually depressed, and vascular tone abruptly changes. The induction of general anesthesia is the most critical component of practicing anesthesia, as the majority of catastrophic anesthetic complications occur during this phase. There are several different techniques used for the induction of general anesthesia, each with significant advantages and disadvantages (Fig. 46-3). Each patient must be carefully evaluated during the preoperative period to ensure that the most efficacious and safe technique is used.

IV induction, used primarily in adults, is smooth and is associated with a high level of patient satisfaction. The addition of opioids will blunt the response of laryngoscopy and intubation to avoid hypertension and tachycardia.

In a patient with a full stomach, the standard induction technique may result in vomiting and pulmonary aspiration of stomach contents. The goal of *rapid sequence induction* is to achieve secure protection of the airway with a cuffed endotracheal tube while preventing vomiting and aspiration.

Rapid sequence induction is performed as follows:

- Proceed only after evaluation of the airway predicts an uncomplicated intubation.
- Preoxygenate the patient.
- Rapidly introduce an IV induction agent (e.g., propofol).
- An assistant to the anesthesiologist presses firmly down on the cricoid cartilage to block any gastric contents from being regurgitated into the trachea, a muscle relaxant is injected, and the trachea is quickly intubated.
- The assistant is instructed not to release pressure on the cricoid cartilage until the cuff of the endotracheal tube is inflated and the position of the tube is confirmed.

Patients undergoing *inhalation induction* progress through three stages: (a) awake, (b) excitement, and (c) surgical level of anesthesia. Adult patients are not good candidates for this type of induction, as the smell of the inhalation agent is unpleasant and the excitement stage can last for several minutes, which may cause hypertension, tachycardia, laryngospasm, vomiting, and aspiration. Children, however, progress through stage 2 quickly and are highly motivated for inhalation induction as an alternative to the IV route. The benefit of postinduction IV cannulation is the avoidance of many presurgical anxieties, and inhalation induction is the most common technique for pediatric surgery.

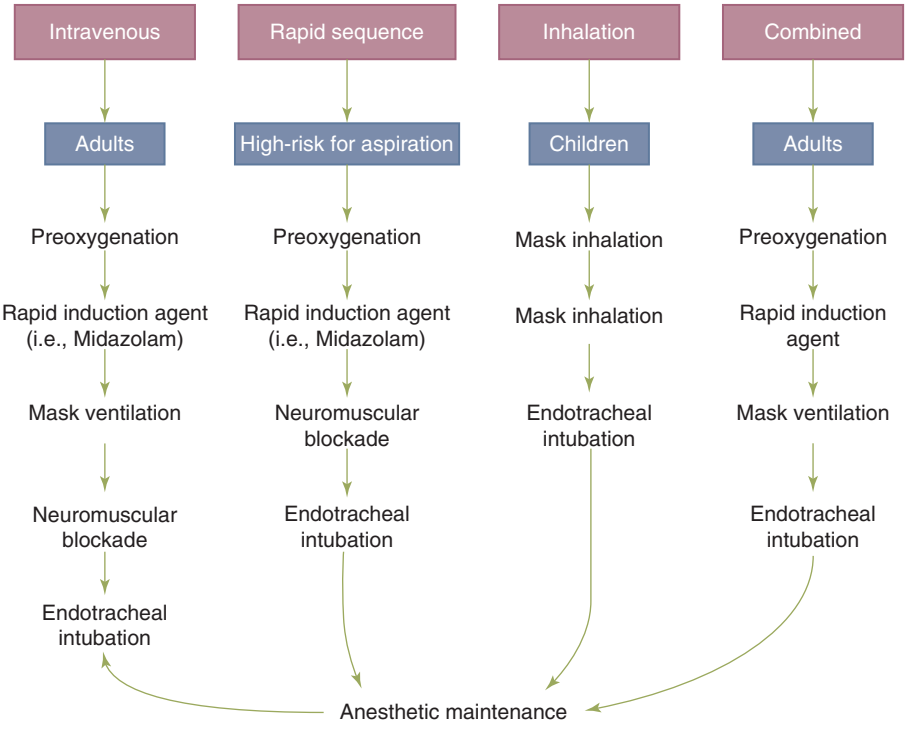

Figure 46-3. Techniques for the induction of general anesthesia.

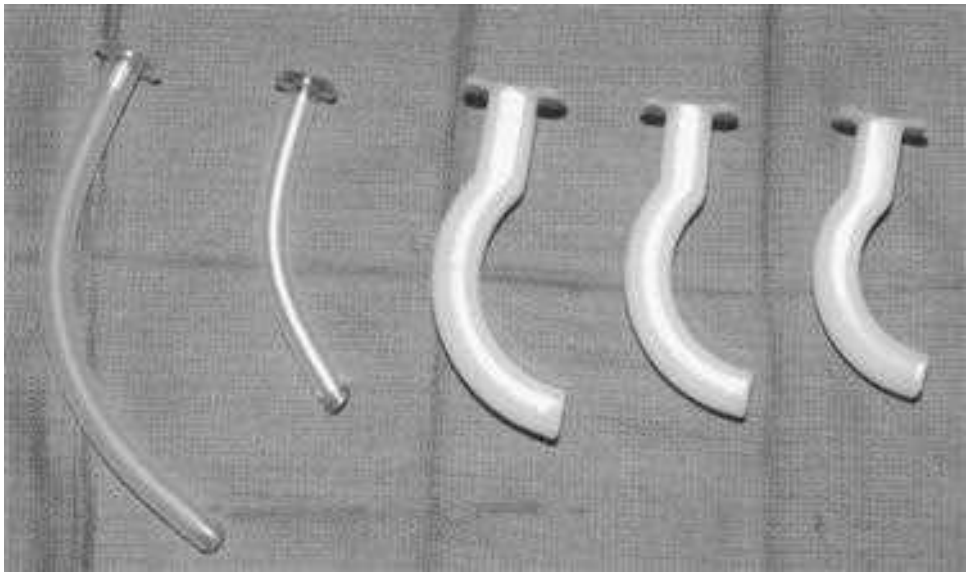

Figure 46-4. From left to right: two nasal airways and three oral airways.

Management of the Airway

After induction of anesthesia, the airway may be managed in several ways, including by face mask, with a laryngeal mask airway (LMA), or, most definitively, by endotracheal intubation with a cuffed endotracheal tube. Nasal and oral airways can help establish a patent airway in a patient being ventilated with a mask by creating an air passage behind the tongue (Fig. 46-4).

3▶

The LMA is a cuffed oral airway that sits in the oropharynx. It is passed blindly, and the cuff is inflated to push the soft tissues away from the laryngeal inlet. Because it does not pass through the vocal cords, it does not fully protect against aspiration. It should not be used in patients with a full stomach (Fig. 46-5; lower left). The accurate placement of an endotracheal tube requires skill and proper equipment and conditions. Usually, the patient is unconscious and immobile (including paralysis of the muscles of respiration). Intubation is typically performed under direct visualization by looking through the mouth with a laryngoscope directly at the vocal cords (direct laryngoscopy) and watching the endotracheal tube pass through the cords into the trachea. To obtain a direct line of sight, the patient is placed in the sniffing position. The neck is flexed at the lower cervical spine and extended at the atlanto-occipital joint. This flexion and extension are amplified during laryngoscopy. Laryngoscope handles contain batteries and can be fitted with curved (Macintosh) or straight (Miller) blades (see Fig. 46-5, top row).

Some patients have physical characteristics or a history suggesting difficulty in placing an endotracheal tube. A short neck, limited neck mobility, small interincisor distance, short thyromental distance, and Mallampati class IV may all represent a challenge to endotracheal intubation. Several devices have been developed to assist in management of the difficult airway. The Bullard rigid fiberoptic laryngoscope is a self-contained device that can be passed through a mouth with a narrow opening (Fig. 46-6). The head and neck also can be kept in a neutral position, as a direct line of sight needed with a standard laryngoscope is not necessary. Another new intubating device is the Glidescope, which allows visualization of the vocal cords on a screen (Fig. 46-7)

The intubating laryngeal mask airway (ILMA) is an advanced form of LMA designed to maintain a patent airway as well as facilitate tracheal intubation with an endotracheal tube. The ILMA can be placed in anticipated or unexpectedly difficult airways as an airway rescue device and as a guide for intubating the trachea. An endotracheal tube can be passed blindly through the ILMA into the larynx, or the ILMA can be used as a conduit for a flexible fiberoptic scope (Fig. 46-8).

The flexible fiberoptic intubation scope is the gold standard for difficult intubation. It is indicated in difficult or compromised airways where neck extension is not desirable or in cases with risk of dental damage. The scope is constructed of fiberoptic bundles and cables encased in a sheath. The cables

Figure 46-5. (*Top*) Laryngoscopes with curved straight blades. (*Bottom*) Laryngomask airway, intubating laryngomask airway, and Bullard rigid fiberoptic laryngoscope.

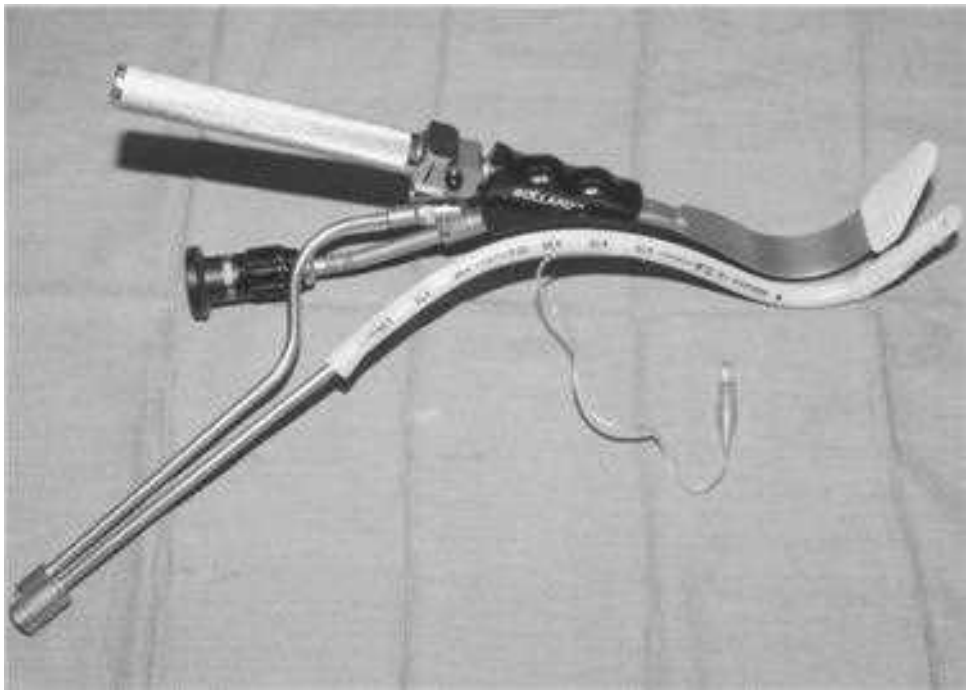

Figure 46-6. The Bullard rigid fiberoptic laryngoscope with endotracheal tube.

permit manipulation of the tip of the scope by adjustments made at the operating end of the device. There is a port for suction and/or insufflation of O_2. The scope gives excellent visualization of the airway with minimal hemodynamic stress when used properly. It can be used nasally or orally in an awake, spontaneously ventilating patient whose airway has been treated with topical anesthetic. It requires skill for proper use, is expensive, and requires careful maintenance (Fig. 46-9).

The ASA has developed algorithms for management of the difficult airway (Figs. 46-10 and 46-11).[51]

Fluid Therapy

Numerous preparations of IV fluid are available for the replacement of perioperative fluid losses in patients undergoing surgery. Different fluid preparations may influence clinical parameters (e.g., platelet function) and may also affect postoperative outcome.

Figure 46-7. Video laryngoscope showing view of vocal cords.

Traditionally, IV fluids have been classified according to whether they are crystalloid or colloid in nature. Crystalloid fluids comprise electrolyte solutions with or without a bicarbonate precursor such as acetate or lactate. The colloids contain a complex sugar or protein suspended in an electrolyte solution. A further distinction between IV fluid types may be based on the nature of the solution. Normal saline-based (0.9% sodium chloride) preparations (crystalloid or colloid) contain no electrolytes other than sodium and chloride. In contrast, balanced salt-based fluids such as lactated Ringer's solution contain other electrolytes, with or without a bicarbonate precursor.

Several types of colloids are available, but three are most commonly used—hydroxyethyl starch (HES), gelatin, and albumin. The HES preparations differ from one another according to their concentration, molecular weight, and extent of hydroxyethylation or substitution, with resultant varying physiochemical properties. HES solutions most often are described according to their weight-averaged mean molecular weight in kilodaltons (kDa): high molecular weight (450 kDa), middle molecular weight (200 kDa, 270 kDa), and low molecular weight (130 kDa, 70 kDa). HES 450 kDa solutions are available in a normal saline solution (HES 450/NS) and in a lactated, balanced salt solution (HES 450/BS). Although all of these colloids are used in Europe, gelatins are not available in the United States, and the only HES preparations approved by the U.S. Food and Drug Administration are the 6% high molecular weight (450 kDa) formulations.

The administration of a large volume of any type of IV fluid will cause dilution of platelets and coagulation factors and may lead to coagulopathy (i.e., dilutional coagulopathy). In addition, fluids can have a direct impact on blood clotting through effects on circulating components of the coagulation cascade or by altering platelet function.

Recent evidence suggests that the nature of the solution itself may influence coagulation and bleeding. HES 450/NS may be associated with more bleeding than other fluids. HES 450 in a balanced salt solution appears to be equivalent to 5% albumin

with respect to bleeding outcomes.[52-54] Waters and colleagues reported that patients undergoing abdominal aortic aneurysm repair who received lactated Ringer's solution received smaller volumes of platelets and had less blood product exposure than those treated with normal saline.[55]

It is possible that certain fluids may induce hypercoagulability that may be reflected not only by less bleeding, but also by an increased incidence of postoperative thrombotic complications (e.g., deep vein thrombosis and cerebrovascular accident). There are laboratory data[56] to suggest that IV fluid administration may induce a hypercoagulable state, but the clinical significance of this remains unclear. The type of fluid administered intraoperatively to a patient can have a significant impact on renal function. The administration of HES/NS or normal saline to critically ill patients or elderly patients undergoing major surgery was associated with the development of renal dysfunction.[57-59]

The administration of adequate IV fluids during the perioperative period results in a lower incidence of nausea, vomiting, and antiemetic use after minor or day case surgery.[60] In major noncardiac surgical patients, the administration of HES 450 (in a balanced salt or normal saline solution, or a combination of balanced crystalloid and colloid) has been associated with less postoperative nausea, vomiting, and antiemetic use and earlier return of postoperative bowel function, as reflected by first consumption of solid food, than the administration of 5% albumin, lactated Ringer's solution, or normal saline alone.[61] Studies of patients undergoing ambulatory surgery have shown that perioperative IV fluid administration decreases the incidence of dizziness, drowsiness, thirst, and headache.[62] In a randomized crossover study of healthy volunteers, subjective deterioration in mental status (lassitude and difficulty in abstract thinking) was reported only by individuals who received 0.9% sodium chloride and not by those who received lactated Ringer's solution.[63] The possible effect of different IV fluid preparations on CNS function has not yet been fully explored.

The relative impact of crystalloids and/or colloids on pulmonary function has been the subject of long-standing debate. No difference in postoperative pulmonary function was seen in cardiac surgery patients, orthopedic patients, or urologic surgery patients treated intraoperatively with different colloids.[57,64,65] In a number of studies in major surgical patients that compared crystalloid (lactated Ringer's solution) with colloid (HES 130/NS, HES 450/NS, 5% albumin/BS),[66-68] no difference was seen in the incidence or duration of mechanical ventilation or other indices of respiratory function. These findings suggest that the intraoperative administration of crystalloids does not have a detrimental effect on pulmonary function compared with the administration of colloids.

Transfusion of Red Blood Cells

ABO Blood Groups. There are four different ABO groups, which are determined by whether or not an individual's red blood cells (RBCs) carry the A antigen, the B antigen, both A and B antigens, or neither. From early in childhood, normal healthy individuals make antibodies against A or B antigens that are not expressed on their own cells. People who are group A have anti-B antibodies in their plasma, people who are group B have anti-A antibodies, people who are group O have anti-A and anti-B antibodies, and people who are group AB have neither of these antibodies. These naturally occurring antibodies are mainly immunoglobulin M that attack and rapidly destroy RBCs. Anti-A antibodies attack RBCs of group A (or AB), and anti-B antibodies attack RBCs of group B (or AB).

ABO-Incompatible Red Cell Transfusion. If RBCs of the wrong group are transfused, in particular if group A RBCs are infused into a recipient who is group O, the recipient's anti-A antibodies bind to the transfused cells. This activates the complement pathways, which damages the red cell membranes and lyses the RBCs. Hemoglobin released from the damaged RBCs is toxic to the kidneys, while the fragments of ruptured cell membranes activate the blood-clotting pathways. The patient suffers acute renal failure and disseminated intravascular coagulation.

Basics of Red Blood Cell Compatibility. Ensuring that the right blood group is transfused is imperative. It is essential to ensure that no ABO-incompatible RBC transfusion is ever given. This avoidable accident is likely to kill or harm the patient. Procedures in which compatibility is determined by establishing both transfusion recipient and donor blood ABO types via crossmatch analysis have evolved over years of clinical and laboratory experience to minimize the risk of this disastrous error. These procedures will continue to evolve as improved computerized systems are introduced to help staff avoid errors in blood administration.

Rhesus D Antigen and Antibody In a white population, about 15% will lack the Rhesus D (Rh D) antigen and are termed Rh D negative. Antibodies to Rh D antigen occur only in individuals who are Rh D negative and as a consequence of transfusion or pregnancy. Even small amounts of Rh D–positive cells entering the circulation of an Rh D–negative person can stimulate the production of antibodies to Rh D, usually immunoglobulin G.

Physiologic Response and Tolerance of Anemia. O_2 is carried in blood in two distinct forms: bound to hemoglobin (Hb) within the RBC and dissolved in the plasma. The actual oxygen content of arterial blood (Cao_2) is determined by the concentration of Hb in the blood, the arterial oxygen saturation of Hb (Sao_2), the O_2-binding capacity of Hb, the Pao_2, and the O_2 solubility of plasma. These variables are interrelated and can be expressed in the following equation:

$$Cao_2 = (Hb \times Sao_2 \times Hb\ O_2\ \text{binding capacity}) + (Pao_2 \times \text{plasma}\ O_2\ \text{solubility}).$$

Adult Hb consists of four protein chains, each carrying one heme group. One mole of Hb is able to bind to a maximum of 4 moles of O_2. O_2-binding capacity per gram of Hb is 1.39 g/mL. The relationship between Pao_2 and Hb O_2 saturation is shown in Fig. 46-12. The steep part of this curve (partial pressure of oxygen [Po_2] 20–40 mmHg) facilitates O_2 release from Hb. Tissue Po_2 values of different organs are also shown in Fig. 46-12 and lie on this steep part of the curve, facilitating O_2 release from Hb.

Hemodilution and Critical Hematocrit. The intentional dilution of blood volume often is referred to as acute normovolemic hemodilution (ANH) anemia. ANH is a technique in which whole blood is removed from a patient, while the circulating blood volume is maintained with acellular fluid. Blood is collected via central lines with simultaneous infusion of crystalloid or colloid solutions. Collected blood is reinfused after major blood loss has ceased, or sooner, if indicated. Blood units are reinfused in the reverse order of collection. Under conditions of ANH, the increased plasma compartment becomes an important source of O_2, which is delivered to the tissues.

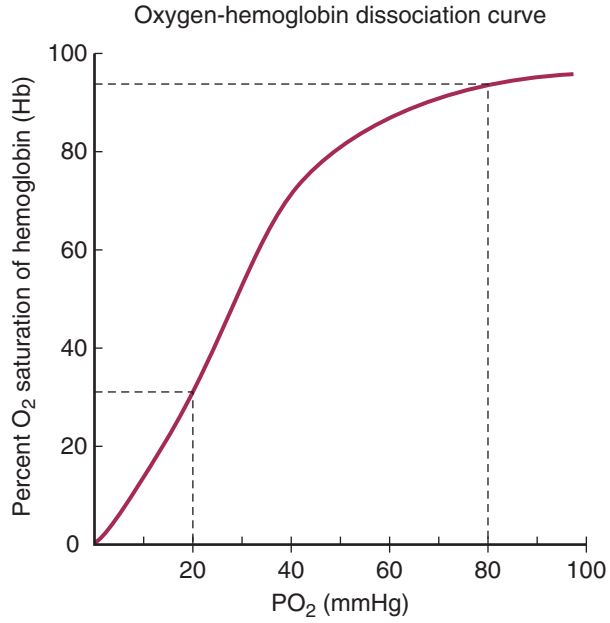

Figure 46-12. Oxygen hemoglobin dissociation curve. O_2 = oxygen; Po_2 = partial pressure of oxygen.

Oxygenation is maintained by increased cardiac output and increased O_2 extraction by the tissues, and when these compensatory mechanisms fail to match the O_2 needs of the tissues, the "critical hematocrit" is said to have been reached. The critical hematocrit has been a source of debate for many years. A theoretical model was developed that describes the relation between hematocrit, myocardial O_2 demand, and the required coronary blood flow during progressive hemodilution.[69] Using this model, the determinants of critical hematocrit and the limits of ANH can be calculated based on the limits of coronary reserve. Because the critical hematocrit varies with O_2 consumption and degree of CAD, a fixed critical hematocrit as a transfusion trigger is not appropriate in most patients. Rather, the indication for blood transfusions must individually take into account the specific circumstances of the patient, such as expected blood loss and required O_2 transport capacity reserves, hemodynamic stability, CAD, and systemic O_2 consumption.

RECOVERY FROM ANESTHESIA

Reversal of Neuromuscular Blockade

The elimination of neuromuscular blocking agents from the body and subsequent resumption of neuromuscular transmission takes a considerable amount of time, even with drugs such as vecuronium that have relatively short half-lives. Additionally, it is time consuming to wait for complete spontaneous recovery at the end of a surgical procedure. Therefore, it has become routine to antagonize the neuromuscular block pharmacologically with the use of reversal agents. Reversal agents raise the concentration of the neurotransmitter acetylcholine to a higher level than that of the neuromuscular blocking agent. This is accomplished by the use of anticholinesterase agents, which reduce the breakdown of acetylcholine. The most commonly used agents are neostigmine, pyridostigmine, and edrophonium.

The common side effects of these three anticholinesterase agents are bradycardia, bronchial and intestinal smooth muscle contractions, and excessive secretions from salivary and bronchial glands. These effects are primarily mediated by effects on muscarinic receptors, which are effectively blocked by the concomitant use of antimuscarinic drugs such as atropine or glycopyrrolate. To ensure adequate ventilation postoperatively, it is important that the neuromuscular blocking agents are fully reversed, as assessed by monitoring twitch strength with a nerve stimulator and clinically correlating this with signs such as grip strength or 5-second head lift.

The Postanesthesia Care Unit

It is of primary importance that all patients awakening from anesthesia are followed in a recovery room, as approximately 10% of all anesthetic accidents occur in the recovery period. As more serious surgeries are performed on older and sicker patients, the number of patients requiring postoperative ventilation and medications to support their circulation increases with age. The new trend for postoperative pain control with continuous epidural administration of local anesthetics and narcotics demands close observation, because respiratory depression can occur. In most hospitals, the number of intensive care beds is too small to accommodate the increasing number of these patients. What originally began as the recovery room now must function as an intensive care unit setting for short stays. The name "recovery room" has been changed to postanesthetic care unit (PACU). A variety of physiologic disorders that can affect different organ systems need to be diagnosed and treated in the PACU during emergence from anesthesia and surgery. Postoperative nausea and vomiting (PONV), airway support, and hypotension requiring pharmacologic support have been observed to be the most frequent complications in the PACU.[70] Abnormal bleeding, hypertension, dysrhythmia, myocardial infarction, and altered mental status are not uncommon.[70]

Postoperative Nausea and Vomiting

PONV typically occurs in 20% to 30% of surgical cases,[71] with considerable variation in frequency reported between studies (range, 8%–92%).[72] PONV is generally considered a transient, unpleasant event carrying little long-term morbidity; however, aspiration of emesis, gastric bleeding, and wound hematomas may occur with protracted or vigorous retching or vomiting. Troublesome PONV can prolong recovery room stay and hospitalization and is one of the most common causes of hospital admission following ambulatory surgery. Published evidence suggests that prophylactic administration of antiemetics is not cost-effective in the surgical setting.[73] Recent consensus guidelines using data from systematic reviews, randomized trials and studies, and logistic regression models have been published (Fig. 46-13).[73]

Agents usually administered for PONV are the serotonin receptor antagonists (e.g., ondansetron, dolasetron, granisetron, and tropisetron). The safety and efficacy of the compounds, when given at the end of surgery, are virtually identical.[73,74] Metoclopramide (not a true antiemetic), when used in the standard dose of 10 mg, is ineffective for PONV.[75] Although some studies have shown higher doses (20 mg) to have some effect on PONV, most evidence suggests that the serotonin receptor antagonists are the most efficacious choice.

Pain: The Fifth Vital Sign

Analgesic research methodology has been enhanced since the 1960s through the use of graduated and visual analog scales,

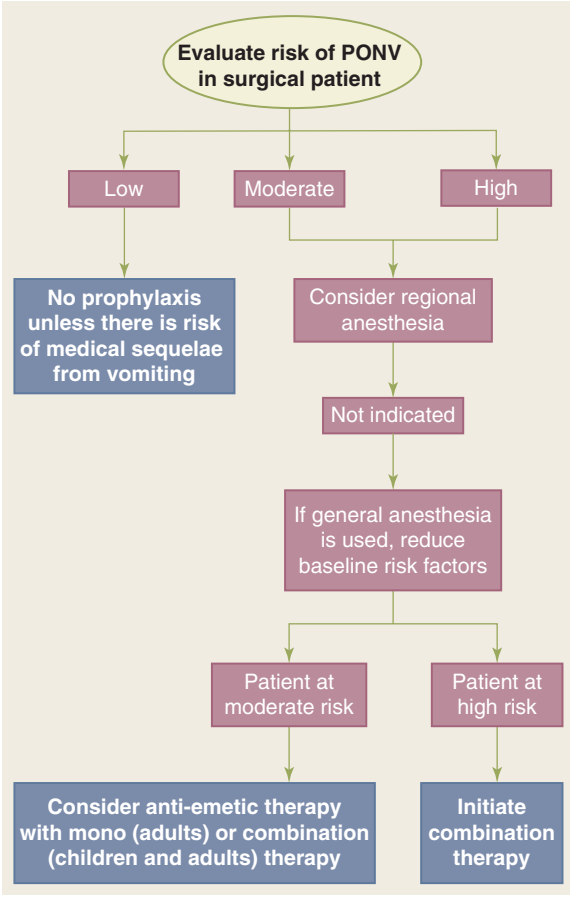

Figure 46-13. Algorithm for the management of postoperative nausea and vomiting (PONV). *(Reproduced with permission from Gan TJ, Meyer T, Apfel CC, et al: Consensus guidelines for managing postoperative nausea and vomiting.* Anesth Analg. *2003;97:62.)*

tools that permit the standardization of pain scores. One frequently used graduated scale is a four-point measure of pain intensity (0 = no pain, 1 = mild pain, 2 = moderate pain, and 3 = severe pain) and a five-point measure of relief (0 = no relief, 1 = a little relief, 2 = some relief, 3 = a lot of relief, and 4 = complete relief).

Acute postoperative pain and its treatment (or prophylaxis) are significant challenges for the healthcare professional. Despite the recent development of new nonnarcotic analgesics and a better understanding of the side effects associated with pain medication of all types, acute postoperative pain remains a significant concern for patients and represents an extremely negative experience for patients undergoing surgery. Many patients experience pain in the postoperative period despite the use of potent techniques such as patient-controlled analgesia, epidural analgesia, and regional anesthesia. The culture of acceptance of postoperative pain is changing. The American Pain Society has advocated the assessment of pain as the fifth vital sign, along with temperature, pulse, blood pressure, and respiratory rate. The four vital signs provide a quick snapshot of a patient's general condition, but pain management advocates claim the picture is not complete without including pain as the fifth vital sign.

This approach may improve the efficacy of pain treatment. Many departments of anesthesiology support an active pain service and provide consultation for postoperative pain relief, including the administration of nerve blocks.

Figure 46-14. Use of ultrasound to identify the popliteal nerve for analgesia of the ankle.

MULTIMODAL ANALGESIA

Opioids, long the staple of postoperative pain management, reduce pain by acting on the μ-receptor. Analgesia is accompanied by unwanted side effects also promulgated by the μ-receptor (e.g., sedation, nausea and vomiting, constipation, respiratory depression). Reducing opioid use and those side effects by the addition of nonopioid analgesics is called multimodal analgesia.[76] Analine derivatives (IV acetaminophen),[77] NSAIDs like celecoxib[78] and ketorolac,[79] steroids (dexamethasone),[80] and anticonvulsants (gabapentin and pregabalin)[81,82] have all been used as opioid-sparing methods to attenuate postoperative pain. The best mixture of drugs is yet to be found; continued work is necessary to find the idea combination.[83]

Regional analgesia, (i.e., nerve blocks) is an effective method for reducing postoperative pain while minimizing opioid consumption. Nerve blocks can be of the upper or lower extremities, truncal, epidural, or paravertebral (Fig. 46-14).

THE TRANSVERSUS ABDOMINIS PLANE BLOCK

The transversus abdominal plane (TAP) block is truncal regional analgesia that results in analgesia to the anterior abdominal wall and has rapidly gained popularity. Pain secondary to any transgression of the abdominal wall can be attenuated by a TAP block, including laparoscopic procedures[84]; vertical or Pfannenstiel incisions; inguinal,[85] incisional, or umbilical hernia repair; hysterectomy; cholecystectomy; and appendectomy (Figs. 46-15–46-18).[86-88]

Somatic nerves supplying the abdominal wall travel in the plane between the internal oblique muscle and the transversus abdominis muscle (Fig. 46-19). Injection of local anesthetic into this plane under ultrasound guidance results in pain relief for 8 to 12 hours (Figs. 46-20–46-22).

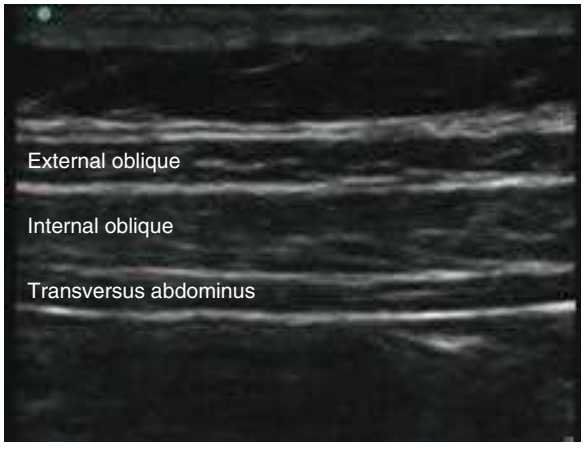

Figure 46-21. Ultrasound view of external oblique, internal oblique, and transversus abdominis muscles.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is a hereditary, life-threatening, hypermetabolic acute disorder, developing during or after receiving general anesthesia.[89] The clinical incidence of MH is about 1:12,000 in children and 1:40,000 in adults. A genetic predisposition and one or more triggering agents are necessary to evoke MH. Triggering agents include all volatile anesthetics (e.g., halothane, enflurane, isoflurane, sevoflurane, and desflurane) and the depolarizing muscle relaxant succinylcholine. Volatile anesthetics and/or succinylcholine cause a rise in the myoplasmic calcium concentration in susceptible patients, resulting in persistent muscle contraction.

MH is an autosomal dominant disorder associated with several gene loci, predominantly the ryanodine receptor gene *RYR1*. MH can be diagnosed with the caffeine-contracture halothane test (which requires muscle biopsy). Genetic testing is helpful after the fact; there is no simple reliable blood screening test yet available.

The classic MH crisis entails a hypermetabolic state, tachycardia, and the elevation of end-tidal CO_2 in the face of constant minute ventilation. Respiratory and metabolic acidosis and muscle rigidity follow, as well as rhabdomyolysis,

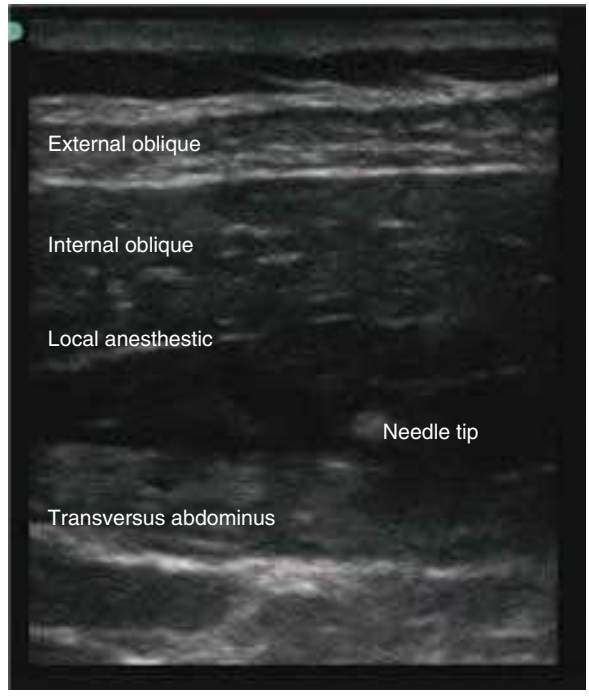

Figure 46-22. Ultrasound image of local anesthetic above the transversus abdominis.

arrhythmias, hyperkalemia, and sudden cardiac arrest. A rise in temperature is often a late sign of MH. Treatment must be aggressive and begin as soon as a case of MH is suspected:

- Call for help.
- Stop all volatile anesthetics and give 100% O_2.
- Hyperventilate the patient up to three times the calculated minute volume.
- Give bicarbonate to treat acidosis if dantrolene is ineffective.
- Treat hyperkalemia with insulin, glucose, and calcium.
- Avoid calcium channel blockers
- Begin infusion of dantrolene sodium, 2.5 mg/kg IV. Repeat as necessary, titrating to clinical signs of MH. Repeat dantrolene at 1 mg/kg every 6 to 8 hours at least twice, and monitor the patient in an intensive care unit setting for 24 hours or more for possible recrudescence.
- Call the MH hotline to report the case and get advice: 1-888-274-7899.

FUTURE DIRECTION OF ANESTHESIA

The general mantra of "gene therapy is the future of medicine" must be more specifically related to how those genes create, shape, and regulate proteins. The study of how proteins manifest their activity and/or concentration is called proteomics (from proteome—a fusion of "protein" and "genome").

As the technology advances to biologically identify individual proteins, studies of individual levels of proteomes will allow the study of disease processes on the molecular level, directly aiding diagnosis and therapeutics.[90]

5▶

Specifically to the field of anesthesiology, the technology of proteomics will be used to elucidate the actual mechanism of action of our anesthetic drugs and how these drugs have differing effects on different individuals. There will be a day when a

buccal swab in the preoperative clinic will become routine, with the results telling us which opioids carry the fewest side effects for that particular patient, for example, or which antiemetics are most effective, or which postoperative analgesics to use—a tailored anesthetic.

Recent studies in mice have examined the α5 subunit of the GABA receptor, which appears to regulate memory. The human genome is polymorphic for the α5 gene; because each variant may manifest in different amounts of memory/amnesia, proteomics may someday lead to tests that determine the propensity of a particular patient to experience awareness and allow us to tailor the anesthetic even further.[91]

Genetic testing for cytochrome P450 deficiencies is now commercially available.[92] As the number of enzymes able to be tested increases, we will be able to choose the most appropriate match between drug and patient.

chapter 47

Surgical Considerations in the Elderly

Rosemarie E. Hardin and Michael E. Zenilman

GENERAL CONSIDERATIONS

As our population ages, a dramatic increase is anticipated in the number of geriatric patients that will require various surgical interventions. The U.S. Census Bureau estimates that the number of people age 65 years and older will double between 2010 and 2050.[1] By 2030, people 65 years of age or older will account for 20% of the overall population. Furthermore, half of all Americans currently alive can expect to reach the ninth decade of life.[2] Geriatric patients represent a unique surgical challenge due to the complexity of comorbid conditions coupled with the physiologic changes that occur with aging. As a result of these considerations, and in response to research and specialized care protocols which are tailored for its age range, geriatric surgery has emerged as a subspecialty of surgery much as pediatric surgery developed decades ago.

Physiologic age is of greater importance in perioperative management of elderly surgical patients than chronologic age because it takes into account the burden of comorbid disease. It is, therefore, an accurate predictor of postoperative morbidity and mortality. The hallmark of physiologic aging or "senescence" is decreased functional reserve of critical organ systems, resulting in the decreased ability of these systems to respond to a challenge, with surgical stress being a prime example. The age of 70 years is typically accepted as the start of senescence because age-related organ dysfunction and the development of comorbid conditions sharply increases between ages 70 and 75 years.[3] This criterion for senescence is in contrast to clinical studies published just 50 years ago that categorized elderly patients as those over the age of 55 years. With improved technologies and expanded criteria for surgical interventions in extremely aged patients, increased awareness of the special needs of this population is required to ensure a comprehensive preoperative assessment, delivery of optimal surgical care, and minimization of postoperative complications. It is also critical that a multidisciplinary approach be developed, which involves the patient and their home caregivers, geriatric physicians, surgeons, and, at times, specialists in intensive care.

It is estimated that, by the year 2030, there will be 70 million people >65 years old in the United States, a stark increase over the 35 million in 2000.[4] This ever growing elderly population will increasingly require surgical care, and patients >65 years old already account for approximately 60% of the general surgeon's workload.[5] Patients >65 years old account for approximately 50% of all emergent operations and 75% of operative mortality.[4] These statistics challenge a surgeon to have an in-depth understanding of the careful perioperative evaluation required in elderly patients and the tailoring of surgical interventions based on the unique changes in physiologic reserve and comorbid conditions that make elderly patients more susceptible to postoperative complications. 1▶

The goal of this chapter is to highlight salient management strategies for aged surgical patients to achieve optimal care and reduce postoperative complications. Particular problems in the elderly population which impact on surgical care include the potential delay in surgical treatment due to a missed or delayed diagnosis secondary to an atypical presentation of disease, and the postponement of needed elective surgery because of the misconception that an elderly patient will suffer a poor outcome as a result of advanced age alone. For example, elective inguinal and umbilical hernia repairs are often postponed due to age bias; this can lead to potentially devastating consequences of bowel ischemia, gangrene, and perforation, to which elderly patients respond poorly. As a result, emergency hernia repairs are among the most common procedures performed in older patients; approximately 40% of hernia repairs are performed for incarceration or bowel obstruction in patients >65 years old.[5] Emergency repair of hernias is associated with an increased morbidity rate of approximately 50% and a mortality rate ranging between 8% to 14%; a significant increase from the 2% mortality rate following elective repair in age-matched patients.[5]

Another significant consideration with the geriatric population is the need to balance optimal health care delivery with rising health care costs. The goal of surgical therapy in the elderly is to provide needed interventions which result in maximum benefit to the patient without compromising quality of life or

Key Points

1. Frailty, dementia, and geriatric syndromes have recently been identified as major factors in the development of postoperative complications in the elderly.
2. Emergency surgery in the elderly carries a mortality rate that is 3 to 4 times that seen after elective surgery.
3. Impaired cardiac function is responsible for more than half of the postoperative deaths in elderly patients, so careful attention must be paid to intravascular volume status in the perioperative period.
4. In elderly patients with acute appendicitis or acute cholecystitis, one-third lack fever, one-third lack an elevated white blood cell count, and one-third lack physical findings of peritonitis.
5. Physiologic age, not chronologic age, is the consequence of diminished functional reserve due to comorbid conditions, and is the major predictor of perioperative morbidity and mortality in the elderly.
6. Laparoscopic approaches to surgical management, including the use of exploratory laparoscopy to rule out surgical disease, are associated with fewer complications and more rapid recovery in the elderly.
7. New tools exist to help assess perioperative risk in geriatric patients, in addition to medical comorbidities. They include identification of geriatric syndromes, frailty indicators.

unwanted adverse outcomes. For example, screening for breast or colorectal cancer should be performed if the patient has a reasonable expectation of quality and quantity of life. An extensive and/or invasive workup should not be performed if the patient would not tolerate the anticipated therapeutic intervention.

Finally, a fifth of elderly patients die in ICU settings and half of them require mechanical ventilation and a quarter undergo cardiopulmonary resuscitation in the days before their death.[6] Although Medicare expenditures in the last year of life are approximately five times higher than in nonterminal years, the actual quality of care at the end of life is often poor due to debilitating and persistent symptoms. Even more worrisome is the fact that some patients receive treatments which are inconsistent with their preferences for end of life measures. An additional component of geriatric surgery is therefore the provision of compassionate care that is more focused on symptomatic relief than on cure in patients who are near the end of life.

PHYSIOLOGY OF AGING

Elderly surgical patients are a heterogeneous cohort with various degrees of functional impairments and comorbid burdens. The "young old patient" may lead an active lifestyle with few, if any, comorbid conditions. But even for this seemingly healthy individual, it is crucial to remember that there are inherent physiologic changes that occur with aging and which affect every organ system. These physiologic changes may become more apparent and clinically consequential with the stress of major illness and operative interventions.

An important criterion in the geriatric surgery patient is the frailty score. Frailty is a syndrome associated with advanced age that results from decreased physiologic reserve and which makes patients less resistant to major stressors such as invasive surgical procedures. Frail patients are prone to poorer outcomes, due to falls, disability, impaired ability to perform activities of daily living (ADLs), prolonged hospitalizations and an increase in mortality.[1] Frail patients are more likely to require discharge to skilled nursing facilitiespostoperatively. Prior to surgery,frailpatients and their family members should be aware of this possibility. Therefore, the frailty score is a more accurate representation of the patient's physiologic age.

Chronologic age is rarely an accurate predictor of morbidity and mortality from surgical interventions. It is, however, an accurate marker for declining physiologic reserve and the likelihood of the presence of comorbid conditions. These place elderly patients at higher risk because of impaired cardiac, pulmonary, renal, and neurological reserves, which increase the morbidity and mortality risk of surgical interventions. Physiologic age, in addition to comorbid conditions, more accurately predicts surgical outcomes in the elderly than chronologic age. The physiologic changes of aging are summarized in Table 47-1.

The terms "frailty," "disability" and "comorbidity" have mistakenly been used interchangeably. These terms have very different connotations for the geriatric patient. Disability is defined as dependence on assistance with ADLs, and contributes to the risk of frailty. Comorbidity is defined as the presence of two or more existing diseases, and is quantified by the Charlson comorbidity index.[7] Geriatric assessment markers for frailty and disability include cognition, albumin level, history of falls, hematocrit level, and dependance on assistance with ADLs. These objective measures have been shown to predict six month postoperative mortality or the need for long term institutionalized care after surgery.[7] (Table 47-2)

SURGERY IN THE ELDERLY

It is critical in the assessment of any elderly patient to maintain a high index of suspicion for surgical pathology. Elderly patients often present with atypical symptoms and/or a misleadingly benign-appearing abdominal examination that may mask an intra-abdominal catastrophe. The effects of age-related impairments in immune function can be compounded by co-existent medical problems and altered mentation as a result of dementia, drugs, infection, or dehydration.

Acute appendicitis and acute cholecystitis are classic examples of common acute surgical pathologies in which elderly patients have a delay in diagnosis or misdiagnosis. This often leads to higher rates of perforation and complications that adversely affect morbidity and mortality.[8] Biliary tract disease, including acute cholecystitis, is the most common indication for surgical intervention in the elderly. This is likely related to age-related changes within the biliary system, such as increased lithogenicity of bile and an increased prevalence of cholelithiasis. Delayed diagnosis due to atypical or misleading symptoms may lead to complications such as ascending cholangitis, gallbladder perforation, or gallstone ileus.

Table 47-1

Physiologic limitations of aging, their clinical consequences, and "best practices" in the elderly surgical patient.

AGE-RELATED CHANGES	CLINICAL CONSEQUENCES	BEST PRACTICES
Body Composition		
• Significantly decreased muscle mass, accounting for much of decreased lean tissue mass • Increased fat mass	• Erosion of muscle mass during acute illness may result in strength rapidly falling below important clinical thresholds (e.g., impaired coughing, decreased mobility, increased risk of venous thrombosis) • Altered volumes of drug distribution	• Maintain physical function through effective pain relief, avoiding tubes, drains, and other "restraints," early mobilization, and assistance with mobilization. • Minimize fasting, provide early nutritional supplementation or support (both protein-calorie and micronutrient). • Adjust drug dosages for volume of distribution.
Respiratory		
• Decreased vital capacity • Increased closing volume • Decreased airway sensitivity and clearance • Decreased partial pressure of oxygen	• Less effective cough • Predisposition to aspiration • Increased closure of small airways during tidal respiration, especially postoperatively and when supine, leading to increased atelectasis and shunting • Predisposition to hypoxemia	• Provide early mobilization, assumption of upright rather than supine position. • Ensure effective pain relief to allow mobilization, deep breathing. • Provide routine supplemental oxygen in the immediate postoperative period, and then, as needed. • Minimize use of nasogastric tubes.
Cardiovascular		
• Decreased maximal heart rate, cardiac output, ejection fraction • Reliance on increased end-diastolic volume to increase cardiac output • Slowed ventricular filling, increased reliance on atrial contribution • Decreased baroreceptor sensitivity • Thermoregulation • Diminished sensitivity to ambient temperature and less efficient mechanisms of heat conservation, production, and dissipation • Febrile responses to infection may be blunted in frail or malnourished elderly and those at extreme old age.	• Greater reliance on ventricular filling and increases in stroke volume (rather than ejection fraction) to achieve increases in cardiac output • Intolerant of hypovolemia • Intolerant of tachycardia, dysrhythmias, including atrial fibrillation • Predisposition to hypothermia (e.g., decline in body temperature during surgery is more marked unless preventive measures are taken) • If there is hypothermia, shivering may result, associated with marked increases in oxygen consumption and cardiopulmonary demands. • Fever may be absent despite serious infection, especially in frail elderly.	• Use vigorous fluid resuscitation to achieve optimal ventricular filling. • Nonvasoconstricting inotropes and afterload reduction may be more effective, if pharmacologic support is required. • Use active measures to maintain normothermia during surgical procedures and to rewarm after trauma: warmed IV fluids, humidified gases, warm air. • Maintaining intraoperative normothermia reduces wound infections, adverse cardiac events, and length of hospital stay. • Be aware of hypothermia in trauma resuscitation.

(*Continued*)

Table 47-1

Physiologic limitations of aging, their clinical consequences, and "best practices" in the elderly surgical patient. (continued)

Renal function, fluid-electrolyte homeostasis		
• Decreased sensitivity to fluid, electrolyte perturbations • Decreased efficiency of solute, water conservation, and excretion • Decreased renal mass, renal blood flow, and glomerular filtration rate • Increased renal glucose threshold	• Predisposition to hypovolemia • Predisposition to electrolyte disorders, (e.g., hyponatremia) • Predisposition to hyperglycemia • Predisposition to hyperosmolar states	• Pay meticulous attention to fluid and electrolyte management. • Recognize that a "normal" serum creatinine value reflects decreased creatinine clearance because muscle mass (i.e., creatinine production) is decreased concurrently. • Select drugs carefully: Avoid those that may be nephrotoxic (e.g., aminoglycosides) or adversely affect renal blood flow (e.g., NSAIDs). • Adjust drug dosages as appropriate for altered pharmacokinetics.

Elderly patients with acute peritonitis may not present with typical symptoms of acute abdominal pain, fever, or leukocytosis, due to a depressed immune response. In older patients presenting with acute appendicitis, the initial diagnosis is correct in less than half of the patients.[8] A careful assessment and high index of suspicion are crucial to achieve timely operative intervention.

PREOPERATIVE ASSESSMENT

Surgical risk increases with advancing age as a consequence of physiologic decline and the development of comorbid conditions that make the elderly surgical patient more susceptible to postoperative complications. Geriatric patients may have masked vulnerabilities due to their unique physiologic state that requires a more detailed preoperative assessment. Comorbid illness serves as the basis for the American Society of Anesthesiologists' (ASA) physical status classification. This is a valuable tool for identifying elderly patients who are at high risk for postoperative complications because it is based on organ system dysfunction and severity of functional impairment. It helps to identify subgroups of patients in whom appropriate measures should be taken to reduce the risk of adverse outcomes.

Table 47-2

Frailty, disability, and comorbidities measures which are significant preoperative predictors of outcomes in the geriatric patient.[7]

MARKER	MEASURE
Frailty	Cognition (Mini-Cog test ≤3) Falls ≥ 1 in last six months Albumin ≤3.3 gm/dL Hematocrit ≤35%
Disability	DependanceDependence on ≥1 activity of daily living
Comorbidity	Charlson index ≥3

2▶ Importantly, it also quantifies the risks of morbidity and mortality for emergency surgery.A careful assessment of potential problems in the perioperative period combined with implementation of preventative measures can significantly reduce complications associated with general anesthesia in the elderly patient.[9] A useful algorithm for the preoperative assessment of an elderly surgical patient is provided in Fig. 47-1.

Cardiac complications are the leading cause of perioperative complications and death in surgical patients of all age groups, but particularly among the elderly. This is because patients often have co-existing cardiac dysfunction, combined with normal physiologic decline and poor functional reserve. The combined effect of depletion of intravascular volume, age-related impairment of response to catecholamines, and increased myocardial relaxation time adversely affects the cardiac function of an elderly patient under stress in the perioperative period.[10] Aging has been demonstrated to cause a decrease in cardiac output by approximately 1% per year. Older individuals fail to augment heart rate to the same extent as younger individuals. More importantly, the ability to increase cardiac output with aging is dependent on ventricular dilatation, which is determined by preload.[11] Therefore careful attention must be paid to volume status in the perioperative period. Dehydration or poor resuscitation may occur in elderly surgical patients for a variety of reasons, and both are poorly tolerated. Over one half of all postoperative deaths in elderly patients and 11% of postoperative complications are a result of impaired cardiac

3▶ function under physiologic stress. Incomplete emptying of the ventricle at end systole and subsequent reduction in ejection fraction is characteristic of the aging heart.[10] Reduced distensibility, in addition to acute stressors, leads to impaired coronary perfusion and cardiac ischemia.

As a result, the physiologic stress of general anesthesia and surgical interventions can unmask the limited cardiac reserve of the elderly patient. Poor reserve may become evident with increased myocardial oxygen demand resulting from tachycardia or loss of vascular tone from the vasodilatory effects of many general anesthetic agents. An important predictor of surgical

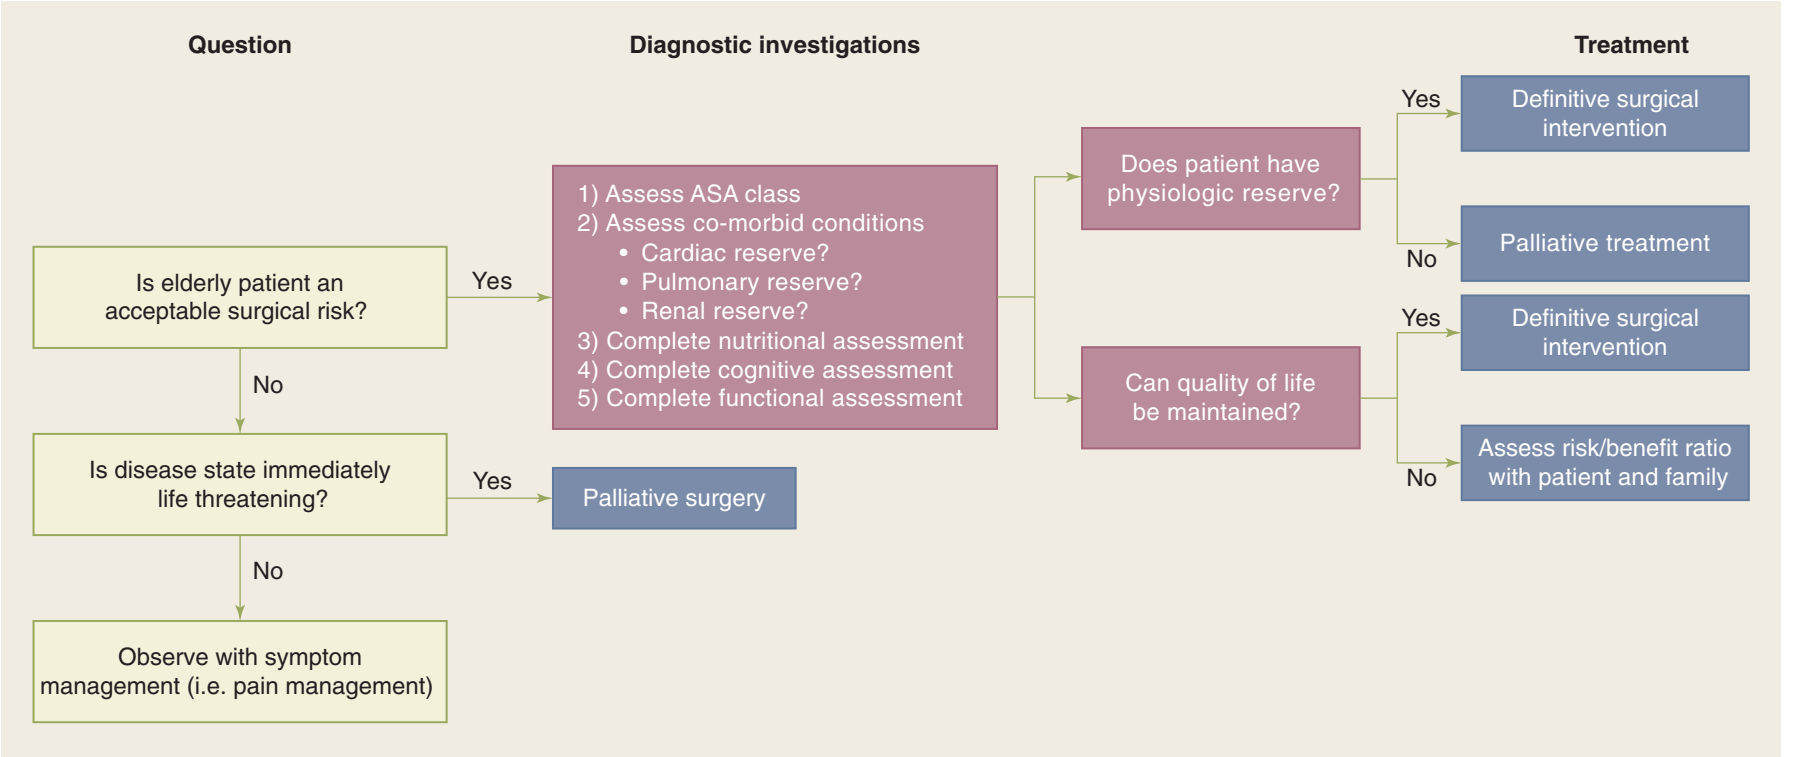

Figure 47-1. Useful preoperative algorithm to determine elderly patient's suitability for definitive surgical intervention balancing therapeutic goals, physiologic reserve, and quality of life with palliative treatment and surgery as viable options. ASA = American Society of Anesthesiologists.

outcomes and cardiac complications in the elderly is congestive heart failure (CHF). CHF is present in approximately 10% of patients older than 65 years and is the leading cause of postoperative morbidity and mortality.[12] This prevalence will likely increase as percutaneous interventions and medical therapy prolongs survival from myocardial ischemia and acute myocardial infarction. Therefore, identifying correctable and uncorrectable cardiovascular disease is critical before elective surgical interventions.

Pulmonary complications are a major source of morbidity and mortality in elderly surgical patients. The age-related changes that occur in the respiratory system limits the maximal breathing capacity by age 70 to 50% of the capacity present at age 30.[12] In addition, there is a decline in the forced expiratory volume in 1 second (FEV1) with advancing age. It is estimated that humans lose 35 mL of their FEV1 per year over the age of 35 years old. There is a slow decline between ages 35 and 65 years old followed by a much more progressive decline at approximately 75 years of age.[13] Pulmonary complications account for up to 50% of postoperative complications and 20% of preventable deaths.[14] Risk factors for pulmonary complications include a positive smoking history, presence of shortness of breath, or clinical evidence of chronic obstructive pulmonary disease. All elderly patients undergoing major surgical interventions should have a baseline chest radiograph. Screening spirometry can be performed to determine forced vital capacity and FEV1. A baseline arterial blood gas measurement also will help to identify hypoxemia and hypercapnia, both of which may increase postoperative complications. If abnormalities are found, perioperative use of bronchodilators and incentive spirometry may be invaluable. When possible, regional anesthetic techniques may provide excellent analgesia while helping to reduce the postoperative pulmonary complications associated with general anesthesia and endotracheal intubation.

Renal complications are also increased in elderly surgical patients in the perioperative period. Renal size and volume decrease with age, accompanied by intrarenal vascular changes. There is a decrease in the number of glomeruli and nephron mass, resulting in decreased filtration area. Serum creatinine concentration is an insensitive indicator of renal function in the elderly, however.[10] The physiologic age-related changes in renal function increase susceptibility to renal ischemia as well as to nephrotoxic agents. Age-related changes in renal function result from progressive glomerulosclerosis and reduction in renal mass resulting in decreased creatinine clearance and glomerular filtration rate. This is worsened by a decline in cardiac output with increasing age and subsequent decrease in renal blood flow. It has been shown that patients with impaired glomerular filtration rate are more susceptible to volume changes that occur in the perioperative period. Furthermore, decreased drug elimination can potentiate the effects of nephrotoxic drugs and prolong the sedative effects of anesthetics and narcotic used for postoperative pain management.[12] Acute renal failure is proven to dramatically increase morbidity and mortality in elderly patients. The mortality risk of perioperative renal failure in all patients is approximately 50% and may be even higher in elderly patients. Therefore, careful management of fluid and electrolyte status is prudent to avoid imbalances and limit exposure to nephrotoxic diagnostic studies and medications in the perioperative period. Patients >70 years old may be susceptible to the nephrotoxic effects of certain anesthetic agents, and thus should be protected by hydration and diuresis, as long as they can tolerate the fluid load.[10] Prompt recognition of renal compromise, marked by an elevation of blood urea nitrogen or creatinine levels or oliguria, requires aggressive correction of underlying causes. Furthermore, electrolyte imbalances can lead to potentially devastating cardiac conduction abnormalities and arrhythmias.[12] Although not routinely advocated in younger patients, elderly patients should have routine electrolyte panels and urinalysis before all surgical interventions to identify potential renal dysfunction.[15] Underlying causes of abnormalities found on screening should be corrected before surgery and may necessitate intravascular volume repletion to ensure adequate renal perfusion perioperatively.

A *functional evaluation* which includes an assessment of the cognitive level of functioning is an important part of the preoperative evaluation of elderly surgical candidates. This ensures that operative intervention will not significantly impair the quality of life of an elderly surgical candidate. The ability to withstand the stress of surgical interventions is dependent on functional reserve and the ability to build an appropriate response to peri-operative stress.[10] The ability to perform ADLs such as feeding, dressing, bathing, and toileting have been correlated with postoperative morbidity and mortality (Table 47-2). Preoperative functional assessment can be measured by hand grip strength, timed "up and go," and functional reach tests[7]. All of these tests independently predicted better recovery and shorter time to recover ADLs after major surgery. In addition, these tests provide an accurate assessment of a patient's muscle mass, nutritional status, coordination, gait speed, balance, and mobility.[5] Proper functional assessment will accurately predict rehabilitation needs, estimate biologic reserve, and indicate an enhanced risk of complications.[10]

The functional status of an elderly patient is directly and inversely correlated to pulmonary and cardiac complications that may ensue following surgical interventions. For example, functional impairment often leads to immobility, which can lead to increased risk of postoperative atelectasis, pneumonia, deep vein thrombosis (DVT), and pulmonary embolism. Furthermore, proper functional assessment has been shown to improve diagnostic and therapeutic outcomes as well as to lead to identification of previously undiagnosed conditions that may be treatable preoperatively or managed peri-operatively.[10]

Cognitive function often is overlooked in the preoperative assessment of patients, because patients are not typically formally evaluated before surgical intervention (i.e., mini-mental state examination). However, knowledge of baseline cognitive function provides invaluable information because subtle changes in cognition often herald postoperative complications, such as underlying infection. Cognitive impairment, including delirium and confusion commonly occur in the elderly patient during the early postoperative period and can result in increased morbidity, delayed functional recovery, and prolonged hospitalizations. The etiology of this postoperative cognitive dysfunction may be multifactorial. Advanced age, history of alcohol abuse, baseline cognitive disturbance, hypoxia, and hypotension have all been shown to be contributing factors.[16] It is crucial that careful attention be paid to adequate postoperative analgesia to improve recovery while avoiding compromise of cognitive function. Methods such as "Beer's Criteria" are useful tools to assess whether a particular drug is appropriate for the aged patient. Finally, dementia is a known predictor of poor long-term survival.

A *formal nutritional assessment* is invaluable in the perioperative assessment of elderly patients. Poor nutritional status in elderly patients is common and results from the interplay between physiologic, psychosocial, and economic changes that accompany the aging process. Elderly patients may have poor nutritional

status because of either poor intake due to the underlying illness or pre-existing comorbid conditions. In the outpatient setting, it is estimated that 9% to 15% of persons >65 years old are malnourished. This increases to 12% to 50% and 25% to 60% in the acute inpatient hospital setting and chronic institutional settings, respectively.[17] The cycle of frailty that occurs with chronic undernutrition or malnutrition can lead to progressive functional decline, loss of muscle mass, and decreased oxygen consumption and metabolic rate in this population.[17] Therefore, adequate assessment of nutritional status of these patients preoperatively and the prompt institution of nutritional support is of utmost importance. This is an integral component of the preoperative assessment, considering that nutritional status is a proven independent predictor of surgical outcomes. Deterioration of a patient's nutritional state in the perioperative period contributes to adverse outcomes. Poor nutrition can lead to increased nosocomial infections, multiorgan system dysfunction, poor wound healing, and impaired functional recovery. Therefore, nutritional assessment and support, if necessary, not only give patients additional reserve to minimize postoperative complications, but aid in appropriate wound healing, functional recovery, and rehabilitation.

Protein energy malnutrition (PEM) also can result from maintaining compromised surgical patients nil per os (NPO). PEM may occur quickly in the elderly, malnourished surgical patient in a hypermetabolic state induced by stress of illness and surgery. The physiologic consequences of PEM are multiple and include anorexia, hepatic dysfunction, decreased mucosal proliferation, and sarcopenia.[17] A good marker of PEM is hypoalbuminemia, also shown to be an extremely accurate predictor of surgical outcomes. The incidence of postoperative complications is increased in patients with serum albumin levels <3.5 g/L.[17] Current recommendations indicate that if patients demonstrate compromise of nutritional status as defined by >10% weight loss and serum albumin level <2.5 g/dL, they should be considered for a minimum of 7 to 10 days of nutritional repletion prior to surgery.[10]

The significant impact of nutritional status on surgical outcomes and functional recovery in the elderly population after surgical intervention underscores the importance of an accurate preoperative nutritional assessment. In busy surgical practices, the question arises as to whether this can be done in a simple, reproducible, and cost-effective manner while obtaining vital information. There are several methods of assessing nutritional status, including anthropomorphic measures (i.e., body mass index), biochemical laboratory values (i.e., transferrin, albumin, and prealbumin), and clinical assessments.[17]

The Mini Nutritional Assessment (MNA) is an established, validated nutritional assessment tool which can be useful for the preoperative assessment of the elderly surgical candidate. The MNA consists of a screening portion assessing the patient's current body mass index, food intake and weight loss, mobility, and presence of stressors, depression, or dementia, all of which can exacerbate undernutrition or malnutrition in the elderly patient. The goal is to identify patients at risk for malnutrition, and who need further evaluation involving a more complete psychosocial assessment and determination of mode of feedings. This tool helps to identify undernutrition and malnutrition in older individuals, >65 years old, and helps to direct timely interventions which result in improved functional recovery.

The combined effects of poor nutrition, decreased cognition, and immune impairments due to nutritional or pharmacologic factors create a treacherous circumstance for elderly patients with poorly defined symptoms or who present with more advanced disease. In acute abdominal conditions, such as acute appendicitis and acute cholecystitis, one third of elderly patients will lack an elevated white blood cell count, one third will lack fever, and one third will lack physical findings of localized peritonitis. These deficits contribute to a threefold higher rate of perforated appendicitis and of gangrene of the gallbladder in elderly patients compared to young patients. An "unimpressive" physical exam in an elderly patient with acute onset of abdominal symptoms should never be taken as a sign of the absence of surgical disease.

4▶

The value of the multifaceted geriatric preoperative assessment led to the formation of an expert geriatric surgery panel by the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) and the American Geriatric Society (AGS). The panel formulated best practice guidelines for surgery in the elderly that have been adopted as standards for training programs (see Fig. 47-2). This checklist may prove to be a useful tool in the preoperative identification of issues that may play an important role in the outcome of a surgical procedure. This not only highlights the importance of the factors described previously but also provides a tool that physicians can utilize in the nonurgent setting to institute preventative or corrective measures to help the geriatric patient maintain their quality of life. (Table 47-3)

Checklist for the Optimal Preoperative Assessment of the Geriatric Surgical Patient

In addition to conducting a complete history and physical examination of the patient, the following assessments are strongly recommended:

- ☐ Assesss the patient's cognitive ability and capacity to understand the anticipated surgery.
- ☐ Screen the patient for depression.
- ☐ Identify the patient's risk factors for developing postoperative delirium.
- ☐ Screen for alcohol and other substance abuse/dependence.
- ☐ Perform a preoperative cardiac evaluation according to the American College of Cardiology/American Heart Association algorithm for patients undergoing noncardiac surgery.
- ☐ Identify the patient's risk factors for postoperative pulmonary complications and implement appropriate strategies for prevention.
- ☐ Document functional status and history of falls.
- ☐ Determine baseline frailty score.
- ☐ Assess patient's nutritional status and consider preoperative interventions if the patient is at severe nutritional risk.
- ☐ Take an accurate and detailed medication history and consider appropriate perioperative adjustments. Monitor for polypharmacy.
- ☐ Determine the patient's treatment goals and expectations in the context of the possible treatment outcomes.
- ☐ Determine patient's family and social support system.
- ☐ Order appropriate preoperative diagnostic tests focused on elderly patients.

Table 47-3

Goals for ethical decision making in elderly surgical patient.

1. Acknowledge medical futility; physicians are not required to provide life-sustaining treatment that is deemed medically futile.
2. Clarify patients' wishes regarding life-sustaining therapies in accordance with Patient Self-Determination Act (i.e., advance directives, living wills, do not intubate/resuscitate orders).
3. Respect patient autonomy: right to accept and refuse treatment despite consequences of decision.
   - Ensure mental competency before establishing autonomy.
   - May appoint surrogate decision maker in case of incapacitation.

SPECIFIC CONSIDERATIONS

Cardiovascular

It is estimated that approximately 40% of the projected 25 million octogenarians comprising the U.S. population by the year 2025 will suffer cardiovascular symptoms, many of whom will require cardiovascular surgical treatment.[18] With advances in cardiopulmonary bypass technique, myocardial protection, and improved perioperative care, coronary artery bypass grafting (CABG) and valve replacement operations can be safely performed in elderly patients. Senile calcific aortic stenosis is common within this population, and referral for aortic valve replacement is increasing, encompassing many patients who are >75 years old. Interestingly, despite some degree of age bias in the referral of patients for major cardiac surgery, advanced age alone is not a predictor of poorer outcomes or increased mortality compared to younger patients. It has been demonstrated that emergency operations, preoperative New York Heart Association (NYHA) functional class 3 or greater, and chronic renal failure were the main predictors of increased operative mortality, but not patient age, per se.[18] In one study, preoperative renal dysfunction, cerebrovascular disease, valve surgery, and catastrophic state were independent predictors of increased mortality in elderly patients.[19] Elderly patients with nondialysis-dependent renal dysfunction had a 60% chance of death during a 5-year follow-up period compared to 25% in elderly patients without a history of renal dysfunction. Similarly, the presence of cerebrovascular disease resulted in a two-fold increase in mortality among elderly patients.[19] Even patients who were 80 years of age or more did not have any significant increase in surgical risk and within this population, the 4-year actuarial survival was 70.5% with an event-free survival of approximately 60.6%.[19]

There has been an increase in definitive operative intervention to elderly patients requiring CABG. Although older patients have higher morbidity and mortality rates after cardiac surgery than do younger patients, these rates are decreasing. The Society of Thoracic Surgeons reports that perioperative mortality rates range from 1.6% in patients 51 to 60 years of age to 7.7% in those 81 to 90 years of age.[20] This decline in morbidity and mortality rates likely reflects better preoperative assessment and patient selection. Furthermore, this decline has occurred despite the advancing age of cardiac patients at time of referral, advanced disease, and greater comorbid disease burden. Elderly patients are more likely to have significant triple-vessel disease accompanied by poor ejection fraction, left ventricular hypertrophy, significant valvular disease, and previous history of myocardial infarction than are younger patients.[20] Elderly patients also are more likely to be classified as NYHA functional class 3 or higher and are more likely to present on an emergent basis, in part because of reluctance to provide elective surgical intervention because of presumptive poorer outcome. Despite the increased risk of morbidity and mortality compared to younger patients, elderly patients, including those >80 years old, can undergo CABG with acceptable mortality risk. The overall mortality rate is approximately 7% to 12% for elderly patients, including those in whom CABG is performed under emergency conditions. The mortality rate decreases to approximately 2.8% when CABG is performed electively with careful preoperative evaluation.[21]

Valve Replacement

There also is an increasing percentage of the geriatric population who present with symptomatic valvular disease requiring intervention. The most common valvular abnormality present in elderly patients is calcific aortic stenosis, which can lead to angina and syncope.[22] The operative mortality from aortic valve replacement is estimated to be between 3% and 10%, with an average of approximately 7.7%.[20] If aortic stenosis is allowed to progress without operative intervention, CHF will ensue. The average survival of these patients is approximately 1.5 to 2 years. If a patient is a candidate for operative intervention, age should not be a deterrent, especially considering the potential to increase life expectancy. It has been recommended that the carefully selected, minimally symptomatic octogenarian with aortic stenosis should be considered a low-risk patient and be expected to experience an uneventful operative course and expedient recovery. More importantly, if elective procedures are delayed until symptoms or left ventricular dysfunction develop, patients may suffer from unnecessary increased operative risk and mortality.[18] Early intervention results in a demonstrable improvement in quality of life in these patients, with many improving their NYHA functional classification.

Elderly patients require surgery for mitral valve disease when ischemic regurgitation is present. Surgery for mitral valve disease carries a higher morbidity and mortality risk than for aortic intervention, with an estimated mortality rate as high as 20%.[20] Left ventricular function usually is compromised in patients requiring intervention, leading to a poorer outcome in these patients. The surgical outcome for mitral valve procedures depends on the extent of the disease, age of the patient, presence of pulmonary hypertension, and extent of coronary artery disease. The presence of comorbid conditions combined with the emergent nature of surgery in a large percentage of elderly patients further worsens the outcome. Therefore, a decision regarding management of mitral valve disease should be individualized to each patient with the previously mentioned below factors considered. Another concern regarding elderly patients who require surgery for valve disease is the additional requirement for coronary revascularization. This increases the morbidity and mortality from surgical intervention. An elderly patient with many comorbid conditions in need of a combined procedure should only have critically stenosed vessels bypassed.[22] Therefore, advanced age is not a contraindication to performing combined procedures; however, a higher mortality rate should be expected. Neurologic complications from valve surgery are particularly common in elderly patients. It has been estimated that approximately 30% of patients >70 years old who undergo valve procedures develop either transient or permanent

5▶

neurologic dysfunction.[22] This often is a result of embolism from debris dislodged from the valve during the procedure or from a formed thrombus in the right atrium.

An important consideration in valve replacement procedures in elderly patients is the type of prosthesis to be used. Elderly patients are at increased risk from bleeding-associated anticoagulation complications. This is especially significant in patients who have experienced falls and minor trauma that have resulted in intracranial hemorrhage. To avoid the lifelong requirement for anticoagulants, bioprosthetic valves should be used in place of mechanical valves whenever possible.[22] Although the bioprosthetic valves are not as durable as mechanical valves, studies demonstrate excellent structural integrity 10 years postprocedure, making it an appropriate choice in an elderly patient.

Cancer

The incidence of most cancers is age dependent, and the expanding aged population is rapidly increasing the number of elderly patients who require multimodal therapy for various oncologic diseases, including lung, breast, pancreas, esophagus, stomach, and colorectal malignancies. Approximately 50% of cancer diagnoses are currently made in patients aged 70 years or older.[10] It is predicted that the increase in the elderly population will account for up to a 50% increase in the number of patients undergoing oncologic procedures by the year 2020. The increased life expectancy of the geriatric patient coupled with the increasing incidence of cancer with advancing age will lead to an increased prevalence of malignant disease requiring surgical intervention. This is an area of great interest given that randomized clinical trials to determine the outcomes of elderly patients undergoing curative resections, as well as neoadjuvant and adjuvant therapy, are lacking. In addition, elderly patients are rarely included in clinical trials; therefore, treatment decisions are often based on individual surgeon experience and non-geriatric data, and may be flawed by inherent biases regarding the outcome of complete oncologic resections in elderly patients. Surgeons may also be reluctant to expose older patients to the toxic effects of chemotherapy and radiation without proven efficacy in this geriatric population. This highlights the need for research targeting the specific needs of elderly patients with malignancy to aid in the development of specific treatment guidelines for various cancers within this age cohort.

Currently, the geriatric population is undertreated for malignant diseases and does not receive curative resections or adjuvant therapies afforded to same-stage younger patients.[11] Potential reasons include poorer functional status compared to younger patients, patient and family preference, age bias, life expectancy, and concerns regarding quality of life after major operative interventions.[23] Surgeons will be challenged to decide whether major surgery is justified in elderly patients, especially those with limited life expectancy. Effectiveness of oncologic surgery in elderly patients depends on whether a cure can be achieved safely without compromise to functional status or quality of life. Postoperative life expectancy should be improved by surgery, or, at the very least, not diminished. A useful treatment algorithm is provided in Fig. 47-3. A study undertaken

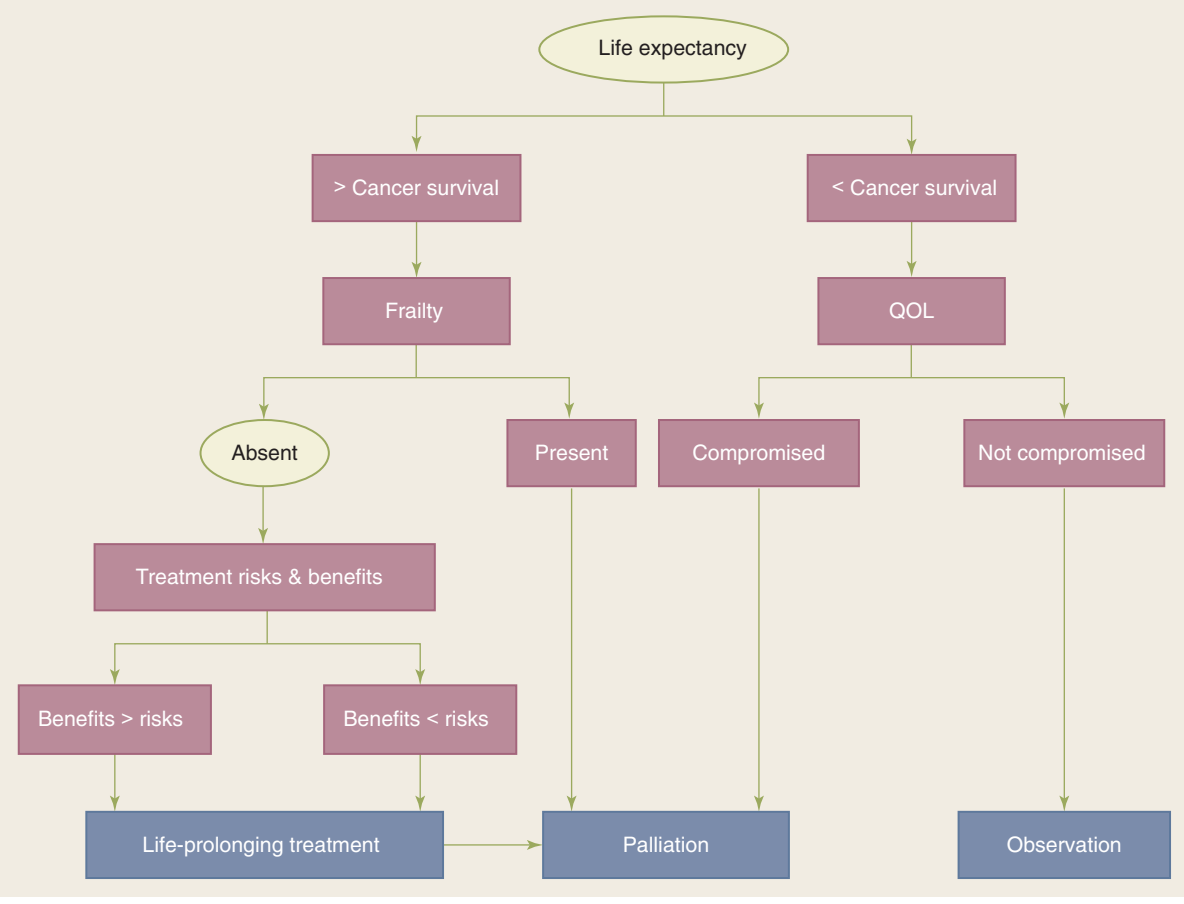

Figure 47-3. A useful treatment algorithm to illustrate the effectiveness of oncologic surgery depends on the balance between achieving cure and maintaining functional quality of life (QOL). *(Reproduced with permission from Balducci L, Beghe C. Cancer Control. Journal of the Moffitt Cancer Center. 1999; 6:466.)*

using the Surveillance, Epidemiology and End Results database assessing cancer-directed surgery (CDS) for localized disease for solid malignancies found that the rates of CDS declined with increasing age for all cancers, especially noted for the aged elderly >70 years old. In addition, CDS was less likely to occur with patients found to have lung, esophagus, stomach, liver, or pancreatic cancer. A careful assessment of the general and cancer-related condition of the patient is crucial to planning the best surgical intervention and postoperative adjuvant therapy.

Formulating a comprehensive, multimodal treatment plan for an elderly patient with a malignancy amendable to surgical intervention is based on careful consideration of the patient's expected life span, specifically if the life span is expected to exceed survival from the malignancy. Additionally, considerations include the patient's ability to tolerate the surgery and any complications that may ensue, as well as the likelihood that the patient would suffer a complication from the cancer which would adversely impact quality of life.[24] An ongoing international study that is titled "Preoperative Assessment of Cancer in the Elderly (PACE)" is designed to evaluate a scoring system that aids in assessing the oncogeriatric patient for surgical intervention. The PACE study incorporates several validated instruments that assess the functional and physiologic status of patients, including the Mini Mental State Examination, capacity to perform ADLs, Geriatric Depression Scale, and the ASA classification among other useful instruments. Interestingly, the PACE assessment also includes The Physiological and Operative Severity Score which has been shown to predict morbidity and postoperative mortality in general surgery and in patients with lung and colorectal malignancy. This score includes the age of the patient and gives consideration to operative factors, including the type of surgical procedure used, the presence and extent of malignancy, and the timing of the operation (i.e., planned elective procedure or an emergency intervention).[10] Palliative interventions are a part of the therapeutic armamentarium; however, a surgeon must weigh these variables carefully to determine which surgical intervention (i.e., palliative vs. curative) is appropriate.

Breast Cancer

It is projected that there will be a 72% increase in the number of elderly women diagnosed with breast cancer in the United States by 2025. Furthermore, 50% of breast cancers occur after the age of 65 years old and 25% after the age of 75 years old.[25] The estimated risk for development of new breast cancer is one in 14 women aged 60 to 79 years old compared to one in 24 in women aged 40 to 59 years old.[25] Mortality rates following breast cancer surgery in elderly women is <1%, and therefore, surgical interventions remain the cornerstone of therapy for breast cancer in elderly women. However, as expected, the presence of comorbid conditions affects clinical outcomes in elderly patients with breast cancer. A recent study demonstrated the presence of comorbid conditions in patients with breast cancer rose to as high as 55% in patients >80 years of age, with cardiovascular disease, diabetes, and previous cancer being most common.[26] As expected, the resulting 5-year survival rate was lower in patients with two or more comorbid conditions.

A recent study on risk factors for breast cancer in patients >75 years of age showed similarity to younger women and included obesity, nulliparity, family history, and advanced age at menopause.[27] Interestingly, although breast cancer presentation in elderly patients may be diagnosed at more advanced stages, both clinical and pathologic data demonstrate less aggressive disease in elderly women with more favorable biologic characteristics. Elderly breast cancer patients are more likely to have estrogen-positive tumors and increasing endocrine responsiveness.[27] Despite these relative advantages, a large number of elderly women are not offered conventional therapies for breast cancer. Moreover, elderly patients who are offered breast conservation surgery for breast cancer are less likely to have axillary dissection, postoperative radiation, and chemotherapy. This will undoubtedly influence surgical outcomes in elderly patients with breast cancer considering that local recurrence rates after conservative surgery without radiotherapy are reported as high as 47%. Advancing age has been demonstrated to be an independent predictor of nonconcordance with treatment guidelines for definitive surgical therapy and adjuvant chemotherapy, as well as hormonal therapy. One study demonstrated that the odds of receiving a recommendation for chemotherapy decreased by 22% for each year of advancing patient age.[23] The nonsurgical management of breast cancer in elderly patients is falling out of favor because there is currently no rationale for denying surgical therapy for elderly breast cancer patients. Surgery and hormonal therapy were the best options for overall survival, breast cancer–specific survival, and disease-free survival. A Cochrane Review concluded that treatment with tamoxifen alone is not an acceptable option because of higher local progression of disease; 81% compared to 38% with surgical intervention. Furthermore, the response rate only lasts for approximately 18 to 24 months.[23] The final conclusion is that surgery remains the standard of care for elderly patients with breast cancer. Alternative therapies should be reserved for patients who have multiple comorbid conditions leading to poor candidacy for operative intervention, those who are frail, or those who refuse surgery.

A timely study comparing the mortality after breast-conserving surgery (BCS) alone, BCS plus radiation therapy, mastectomy, and the receipt of adjuvant tamoxifen in elderly breast cancer patients confirmed that less than standard treatment for these patients resulted in increased mortality. Elderly women receiving BCS without radiotherapy have more than twice the rate of breast cancer mortality compared to women undergoing mastectomy. In addition, in older women with estrogen receptor and progesterone receptor positive tumors receiving tamoxifen, the rate of breast cancer death increased substantially with the decreasing duration of tamoxifen use.[28] The standard of treatment for elderly patients with breast cancer should be the same as younger patients; BCS plus radiotherapy when indicated. If patients decline postoperative radiotherapy or are medically unfit for radiotherapy, mastectomy should be performed. Furthermore, elderly patients with tumor size <2 to 3 cm and no clinical evidence of axillary involvement should be offered sentinel node biopsy.[29]

One of the most interesting controversies surrounding breast cancer in elderly women is the appropriate age limits of screening. A retrospective study demonstrated a decline in cancer-related mortality among women who underwent regular screening mammography up to 75 years of age.[27] Women who underwent at least two mammographic examinations between the ages of 70 and79 years experienced a two-and-one-half–fold reduction in breast cancer mortality compared to elderly women who did not undergo screening.[23] The screening benefits depend on life expectancy. In women with multiple comorbidities, the decision to perform screening should be based on estimated life expectancy. People with <5 years of life expectancy are unlikely to benefit from screening. The American Geriatric Society recommends that screening should be individualized rather than set by age-specific guidelines. The current recommendation is that

no upper age limit for screening be set as long as the estimated life expectancy is 4 or more years.

Colorectal Cancer

The incidence of colorectal cancer (CRC) increases with advancing age, similar to most other malignant conditions. Approximately 90% of cases of CRC are diagnosed in patients >55 years old.[33] Of concern is the increased postoperative morbidity and mortality following extensive surgical resections in elderly patients, with a significant increase in patients >70 years old. In fact, inhospital mortality for patients >85 years old undergoing surgery for colorectal malignancy is estimated to be nine-fold greater than for younger patients.[30] Furthermore, elderly patients often have decreased cancer-specific survival compared to younger patients. It has been proven that the 5-year cancer-specific survival for CRC is similar among the age cohorts. Therefore, age is not an independent factor accounting for the decreased survival among elderly patients. It is rather a consequence of comorbid conditions and impaired physical capacity necessary for recovery from perioperative physiological stress.[30] This leads to bias regarding poorer outcomes in elderly patients. For this reason, many elderly patients are receiving suboptimal cancer therapy and limited resections resulting in decreased survival rates and poorer outcomes. With the ever aging population, this must be addressed and clinical modifications implemented to improve outcomes of elderly patients undergoing surgical interventions for colorectal malignancies. Elderly patients should have continued, aggressive screening for colorectal malignancy and strict adherence to accepted surgical and adjuvant treatment guidelines.

One of the most important aspects to delivering appropriate care to elderly patients with CRC is to consider the patient's wishes as well as expectations from the surgical intervention. In this respect, functional outcomes and quality of life take precedence in treating elderly patients, especially the aged elderly. Of patients >75 years old who underwent elective surgery, few demonstrated protracted decline in ADLs and most experienced significant improvement in quality of life.[31] Approximately 10% of elderly patients >80 years old have protracted postoperative disability. Estimation of physical ability and surgical stress is useful for predicting decline in ADLs and postoperative disability. It has been shown that, in patients <80 years of age, a complete resection for cure is most important, whereas in patients >80 years old, avoidance of a stoma becomes paramount. These are important considerations for the geriatric surgeon.[30]

A prospective study was recently undertaken to specifically evaluate the epidemiology and risk of surgical intervention for CRC in elderly patients. A large cohort of 47,455 patients was divided based on age <75 years old and >75 years old.[30] It was determined that a significant portion of elderly CRC patients are female, with multiple comorbidities leading to advanced ASA levels of 3 and above. The study determined that elderly patients underwent surgical interventions less often than younger patients (81% vs. 88%, respectively, P <.001), more frequently required urgent or emergency operations, and were more likely to have operative procedures in which the primary cancer was not resected. Obstructive tumors are significantly more common in patients >70 years old, and elderly patients are still presenting far too commonly with surgical emergencies resulting from obstruction and perforation in up to 40% of the cases.[11] In addition, elderly patients had higher postoperative mortality than younger patients (10.6% vs. 3.8%, respectively). Right colectomies, Hartmann's procedures with colostomy, transanal endoscopic microsurgery, and transanal resection of tumors were more common in elderly patients, whereas formal resections, including low anterior and abdominoperineal resections, were more common in younger patients.[30] Elderly patients are less likely to undergo CDS; with each half a decade increase in age >70 years old, the odds of receiving cancer-directed surgery were reduced by 44%. Interestingly, many of these patients presented with lesions of lower-stage Duke's cancer classification. However, this was not secondary to earlier presentations as one might assume, but rather secondary to understaging from surgical treatment. Accurate staging may not be possible with local resections, limiting the number of lymph nodes available for proper staging.[32] Elderly patients also are less likely to undergo preoperative irradiation and neoadjuvant chemotherapy, reducing the likelihood of curative resection.[30]

Liver resection for CRC liver metastases in properly selected elderly patients 70 years of age or greater is feasible with older patients having similar operative survival to younger patients. Palliative surgery remains a viable option for elderly patients with disseminated CRC and should be aimed at the reduction of symptoms such as pain, obstruction, or hemorrhage. Bowel obstruction can be relieved with intestinal bypass or a diverting colostomy. The most common site of disseminated disease is the liver, and uncontrolled liver metastases are responsible for pain, abdominal distention, jaundice, and inferior vena caval obstruction. Elderly patients with metastatic disease who are not candidates for curative resection may be considered for ablation of the lesions by local destruction, cryotherapy, or radiofrequency ablation. More traditional means such as chemotherapy, which can be administered via the hepatic artery or radiation, also may be used.[33]

Similar to breast cancer, an upper age limit for CRC has not been clearly established. Screening for CRC may not lead to an observed survival benefit until 5 years or longer after screening had occurred. This would limit the benefit of screening in aged populations with limited life expectancy. An interesting way of looking at this controversy is from a recent study that determined that the number of screening colonoscopies needed to prevent one CRC-related death (the number necessary for survival or NNS) increased as with increasing age and comorbidities. For example, in healthy men and women aged 75 to 79 years old, the NNS was 50. The corresponding NNS in patients 90 years and older was 279 in women and 482 in men.[34] Consideration for continued screening in very elderly patients should take into account age and predicted life expectancy, comorbid burden, expected duration of the protective effect of screening, risk for cancer, results of previous screening colonoscopies, and patient preference.[34]

Lung Cancer

Lung cancer is the leading cause of cancer-related deaths in the United States for patients >70 years old. National Cancer Institute statistics show that the peak incidence of lung cancer is between 75 and 79 years of age. Elderly lung cancer patients also have a higher mortality rate, and therefore, the peak mortality rate is between ages 75 and 84 years.[35] Non–small cell lung cancer accounts for roughly 80% of all lung cancer cases, and >50% of these patients are >65 years of age. Interestingly, approximately 30% of these patients are 70 years or older at diagnosis.[36] Lung cancer is highly prevalent among elderly patients, so much so that a 2-cm, asymptomatic, solitary pulmonary nodule in a 70-year-old male smoker has a >70% chance of being an occult lung cancer. Squamous cell carcinomas are more common among elderly patients than among younger

patients, and these tumors are associated with a higher incidence of local disease, tend to have lower recurrence rates, and have longer survival times than nonsquamous cancers.[35] In cases of resectable primary lung cancer, surgery remains the treatment of choice independent of age.[11]

The estimated life expectancy of untreated lung cancer is approximately 9 months. This can increase to as high as 18 months with palliative chemotherapy and radiation. However, the life expectancy of an elderly patient who has undergone a successful operative resection is estimated to be as high as 31 months, making this the preferred option when feasible.[13] However, despite this and the fact that more elderly patients present with stage 1 disease, elderly patients are offered curative surgery less frequently than younger counterparts. The same holds true for chemotherapy and radiation.

Advanced age is an independent risk factor for death after thoracotomy, with significantly increased mortality after age 65. These reasons are multifactorial partly due to the physiologic debilitation that occurs with division of the intrathoracic muscles that aid in respiratory function and the loss of lung volume after resections.[13] One study demonstrated that patients 70 years of age or older who underwent thoracotomy for lung cancer had an operative mortality rate of 14%, which is directly related to the extent of the pulmonary resection. In one of the largest prospective, multi-institutional trials conducted, The Lung Cancer Study Group, increasing age led to a significant increase in 30-day mortality for patients undergoing thoracotomy and lung resection.[13] They found overall mortality to be approximately 3.5% in patients <65 years old, which rose to 7.3% for patients 70 years or older and as high as 8.1% for octogenarians. However, with improved surgical options, including minimally invasive video-assisted thoracic surgery (VATS) in the past decade, the mortality rate has ranged from 3% to 5% in carefully selected patients.[2] In a recent study conducted to determine if VATS resulted in lower morbidity in the elderly population in comparison to open, rib-spreading thoracotomy, the overall morbidity for minimally invasive surgery was 28%; this increased to 45% with traditional open procedures.[36] Furthermore, elderly patients undergoing VATS tended to have less severe complications compared to patients undergoing thoractomy.[36] Limited resections (segmentectomies) may be a consideration in elderly patients with limited life expectancy or poor cardiac and pulmonary reserve who may not tolerate a more extensive procedure. Some studies have shown that limited resections may provide a comparable survival rate to lobectomies in elderly patients as long as the resection includes all foci of tumors and provides a microscopically free margin. The most striking finding was that any survival difference between treatment modalities disappeared after 71 years of age. Interestingly, even smaller resections such as VATS and wedge resection may be a viable oncologic option in an elderly patient with resectable disease but limited life expectancy.[13] This is limited to very small tumors <7 mm in diameter and not yet proven to be clinically efficacious. Of particular interest is that VATS procedures may result in lower rates of postoperative confusion in elderly patients and this may be secondary to the decreased physiologic stress of minimally invasive procedures, faster recovery rates, and decreased narcotic requirement for pain control.[13] Careful preoperative selection and optimization combined with aggressive postoperative care and rehabilitation make surgical intervention for resectable disease feasible in aged populations.

Trauma

Patients >65 years of age currently account for approximately 23% of total hospital trauma admissions—many of which are multisystem and life threatening.[37] Geriatric trauma will continue to challenge surgeons in understanding the physical and physiologic impact of various mechanisms of injury, the need for careful assessment of comorbid conditions with particular attention to medication regimens, the rehabilitative capacity of an elderly trauma patient, and the knowledge of specific interventions that help to minimize morbidity and mortality in this population following traumatic injury.

The current geriatric population has fewer disabilities and is considerably more active than previous generations, which predisposes them to traumatic injuries. The most common type of trauma is blunt injury resulting from falls and motor vehicle collisions or pedestrian accidents. Falls currently account for 20% of severe injuries in elderly patients. Many underlying chronic and acute diseases common to elderly patients place them at increased risk for falls. These diseases include postural hypotension, leading to syncopal "drop attacks"; dysrhythmias from sick sinus syndrome; autonomic dysfunction; polypharmacy with improper dosage of antihypertensive and oral hypoglycemic agents resulting in hypotension; and hypoglycemia, respectively.[38]

Elderly patients also can fall victim to penetrating trauma, especially in elderly patients who may have underlying depression and suicidal ideations or are victims of elder abuse. It is estimated that approximately 40% of all trauma patients by 2050 will be >65 years old.[39] With the expanding elderly population, this will be an increasing source of morbidity and mortality; the risk of death after major trauma with multi-system and life-threatening injuries rises steeply after age 45 years old and doubles by age 75 years old. In contrast to what is observed for abdominal and thoracic surgery, even after controlling for injury severity and pre-existing medical conditions, patients aged 65 years and older sustaining traumatic injury were 4.6 times more likely to die than younger patients.[39] Of note, there are several interesting aspects of care of the acutely injured elderly patient that must be kept in mind. First, physiologic reserve can be challenged by trauma. For example, previously unknown disease such as cardiac impairment may be acutely unmasked. Secondly, medications common to elderly patients, such as beta blockers and anticoagulation, cannot only inhibit the physiologic response to stress but may even worsen injury. Finally, elderly patients with impaired functional status posttrauma are more likely to lose their ability to function independently without the support of a nursing home.

Elderly patients are particularly susceptible to trauma due to changes that occur with aging, specifically, gait instability, decreased hearing and visual acuity, presence of confusion or dementia, underlying comorbid conditions, and poor to tolerate the physiologic stress of traumatic injuries. Pre-existing medical conditions increase the risk of death after trauma significantly (up to three-fold).[37] This is worsened when combined with an elderly patient's decreased functional reserve for handling physiologic abnormalities accompanying major trauma, such as hypotension and hypoxia. It is important to consider a trauma patient's age, as patients aged 65 to 80 years old have a 6.6% overall mortality rate after traumatic injury, which rises to 10% in patients 80 years or older.[42]

Despite the increased risk of morbidity and mortality after traumatic injury, it is interesting to note that there is currently an undertriaging of elderly patients to level 1 trauma centers despite high injury severity scores.[39] In one study, elderly patients >65 years old were five times more likely to be

undertriaged to nondesignated trauma hospitals than younger counterparts.[39] However, a reduction in morbidity and mortality and posttraumatic complications as well as faster rehabilitation can result from better triaging practices. In one particular study involving acutely injured octogenarians with injury severity scores between 21 and 45, inhospital survival was as high as 56% in trauma centers, and this dramatically decreased to 8% in those treated at nontrauma hospitals.[39]

It is important to determine the medication regimen of elderly trauma patients. Medications such as beta blockers, calcium channel blockers, diuretics, and afterload reduction agents may impair critical augmentation of myocardial function in trauma patients, especially if they are hypovolemic. Approximately 20% of the elderly population with coronary artery disease and 10% of those with hypertension are currently on beta blocker therapy.[39] Therefore, tachycardia, one of the most valued signs of continued hypovolemia from either ongoing blood volume loss or underresuscitation, is lost in the elderly patient on beta blocker therapy. This makes interpretation of hemodynamic parameters in elderly patients inaccurate and, at times, misleading, which could lead to delays in appropriate interventions and resuscitation. However, it is important to keep in mind that, to date, evidence supporting early hemodynamic monitoring in elderly patients is lacking.

The other medication class that can be detrimental to an elderly, acutely injured patient is anticoagulation, ranging from aspirin and clopidogrel (Plavix) to warfarin, which may, at times, be supratherapeutic. Massive intracranial hemorrhages resulting from minor falls from standing in elderly patients are demonstrated in Fig. 47-4. Warfarin therapy may be used in patients with atrial fibrillation, DVT, and prosthetic heart valves. The mortality rate of elderly patients on warfarin with a traumatic intracranial hemorrhage was 48% compared with 10% in an age-matched cohort not on anticoagulation therapy; it is unknown for the newer factor Xa inhibitors.[39] One of the most important caveats to treating elderly patients on anticoagulation with blunt head injury is the potential for significant, life-threatening intracranial hemorrhage despite initial normal head (computed tomography) CT scans. In one study, >70% of patients with minor mechanisms and negative CT scan, admitted for observation subsequently, clinically deteriorated within 12 hours of admission with a Glasgow Coma Scale of <10 and were subsequently found to have significant intracranial hemorrhages.[39] Therefore, prompt reversal of anticoagulation, particularly if supratherapeutic, is warranted to reduce morbidity and mortality following blunt head injury. In addition to increased risk of mortality in elderly patients sustaining blunt head trauma, a significant portion fail to resume functional independence after traumatic injury. It is estimated that approximately 20% to 25% of elderly trauma patients require discharge to a skilled nursing facility for long-term care and rehabilitation.[37] Poor functional outcome has been attributed to several factors among which are age >75 years old, presence of shock on admission, severe head injury, and development of infectious complications.

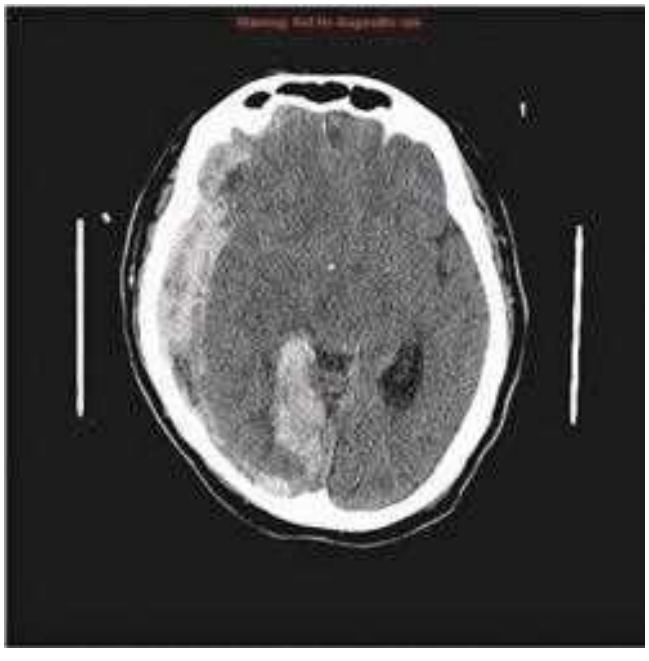

Figure 47-4. Massive intracranial hemorrhage resulting from seemingly minor trauma. An 86-year-old patient fell from a standing position and presented to the emergency room with six hours of injury with a Glascow Coma Scale of 5 and a blood pressure of 167/55. She was on aspirin and clopidogrel therapy for ischemic heart disease, along with 14 other medications for congestive heart failure, diabetes, and hypertension. She expired from her intracranial wounds. *(Photo used with permission of Dany Westerband, MD, Suburban Hospital, Bethesda, MD).*

MINIMALLY INVASIVE SURGERY

Laparoscopy

Open abdominal procedures may require more intensive postoperative care, longer hospital stays, and an increased need for postoperative rehabilitation and possible institutionalization for elderly patients with limited reserve. However, the increasing experience with laparoscopic techniques, combined with minimized pain, decreased length of hospital stay, and low morbidity and mortality rates, has led to the increased use of minimal access procedures among elderly patients. It has expanded from cholecystectomies to more complex procedures, including colon resections, gastrectomies, and cardiac surgery.

Minimally invasive laparoscopic surgery reduces common postoperative complications such as atelectasis, gastrointestinal ileus, and wound infections. In elderly surgical patients, these complications easily progress to pneumonia, DVT, and metabolic and electrolyte disturbances.[40] Decreased postoperative pain from smaller incisions leads to faster return to a preoperative level of functioning, including early ambulation, which decreases complications from prolonged bed rest, such as DVT and pneumonia from compromised pulmonary mechanics. The latter is especially important for elderly patients because deconditioning occurs with long hospital stays, which depresses their ability to return to preoperative functional status. Laparoscopic surgery also provides the added benefit of reduction of the inflammatory, hormonal, and metabolic stress induced by major open surgical operations. The net result is that patients who undergo laparoscopic procedures may do better; in colon surgery it has been shown to increase the chance that the patient returns home over an interim rehabilitation center.

6▶

However, these benefits must be balanced against the potential adverse effects of carbon dioxide (CO_2) insufflation and hemodynamic alterations induced by pneumoperitoneum and increased intra-abdominal pressure with concomitant decrease in venous return.[41] Therefore, decisions to perform minimal access procedures in the elderly must be individualized to the patient

with careful consideration of the impact of comorbid conditions and the potential for poor cardiopulmonary reserves. This helps to provide the optimal circumstance for intervention resulting in improved surgical outcomes.

It is important to consider using a reduced intra-abdominal insufflation pressure during a laparoscopic procedure in an elderly patient. Pressures up to 20 mmHg are associated with increased filling pressures and cardiac output. However, further increased elevations result in decreased central venous pressures and cardiac output, which can be life threatening in a patient with preexisting cardiac dysfunction and poor functional reserve.

Studies have demonstrated that both advanced age >70 years old and an ASA classification of 3 or 4 are associated with higher conversion rates for laparoscopic cholecystectomy to open cholecystectomy.[42] These additional challenges, however, are not a contraindication to attempting the less invasive approach because conversion to an open procedure does not adversely impact the overall morbidity and mortality of the patient.

A particularly useful application of minimally invasive techniques is to rule out a surgical abdomen in an elderly patient presenting with acute abdominal pain. Vague, poorly localized pain, further obscured by several underlying confounding comorbid conditions, as is the case with ischemic colitis and mesenteric ischemia, may subject an elderly patient with poor reserve to the risk of general anesthesia and a negative exploratory laparotomy (Fig. 47-5). Analysis of several studies directed at the application of laparoscopic techniques for the patient with acute abdominal pain demonstrated that approximately 41% had pathology necessitating open laparotomy, 10% had pathology amendable to laparoscopic intervention (i.e., acute cholecystitis), and 48% had nonsurgical disease that was subsequently managed nonoperatively, avoiding a negative exploration.[42] Therefore, laparoscopic evaluation of abdominal pain in the critically ill elderly patient may prove to be a valuable tool.

Figure 47-5. Diagnostic laparoscopy in an 80-year-old patient with abdominal pain, elevated white blood cell count and signs of bowel obstruction and sepsis. Comorbidities included severe aortic stenosis. Findings included a localized segment of bowel which was necrotic, associated with an adhesive band. The rest of the small intestine and colon were inspected, all of which were viable. A local resection was performed, and the patient recovered quickly.

Endovascular Surgery

Abdominal aortic aneurysm (AAA) is a disease that primarily affects the elderly male patient. With increasing use of screening abdominal CT scans and ultrasounds for evaluation of various abdominal complaints, AAAs are being identified with greater frequency, most of which are diagnosed in elderly patients, given the increased prevalence of AAA with increasing age. In fact, the percentage of AAA rises from about 1% at age 55 to 60 years to approximately 10% in patients 80 years of age or older.[43] Elderly patients, and octogenarians in particular, were deemed poor operative candidates for the traditional open repair given the frequent presence of comorbid conditions and limited cardiopulmonary reserve to tolerate a major operation or the many hours of required operative time and general anesthesia. Elderly patients had an increased perioperative morbidity and mortality following open aortic surgery in comparison to younger cohorts. However, the introduction of endovascular techniques for repair of AAA has shifted the risk-benefit ratio for operative intervention, allowing greater life expectancy for the elective repair of this potentially life-threatening condition with the benefits of minimally invasive techniques as previously described.

Studies have demonstrated that endovascular aortic repair (EVAR) is feasible and efficacious in elderly patients, including those previously considered unfit for open repair. EVAR is a minimally invasive technique in which a prosthetic graft is introduced into the aortic lumen via the common femoral artery to exclude the aortic aneurysm sac. EVAR significantly reduces operative and anesthesia times, blood loss, intensive care needs, length of stays, and major postoperative morbidity associated with open AAA repair. The most common complication following EVAR in elderly patients is renal impairment. Typically, patients are discharged 1 to 2 days following surgery and the graft is deployed via small bilateral groin incisions, obviating the need for a major laparotomy incision. Figure 47-6 demonstrates the endovascular repair of AAA and right iliac artery aneurysm via bilateral groin access in an 82-year-old man who was discharged from the hospital on postoperative Day 2. This procedure also can be done using epidural anesthesia for high-risk candidates who may tolerate general anesthesia poorly. Endovascular repair has even been described under local anesthesia in patients at extreme high risk of rupture and death or after rupture and hemodynamic instability, precluding the ability to tolerate general anesthesia.[44]

Careful consideration of the life expectancy and the risk of rupture dictate the necessity for intervention. EVAR remains a viable option in elderly patients. Nonoperative management is justified in frail elderly patients with multiple comorbidities and reduced life expectancy whose operative risks outweigh the risk of rupture and in those who are unlikely to survive long enough to benefit from the repair.

THYROID SURGERY

The prevalence of thyroid disease increases with advancing age. The etiologies, risk factors, and presentations of thyroid disease are similar across all ages, and therefore, are not discussed in detail. Of note, however, is that elderly patients more often present with cardiac manifestations of hyperthyroidism, such as atrial fibrillation, than do their younger counterparts. A common finding requiring evaluation in elderly patients is

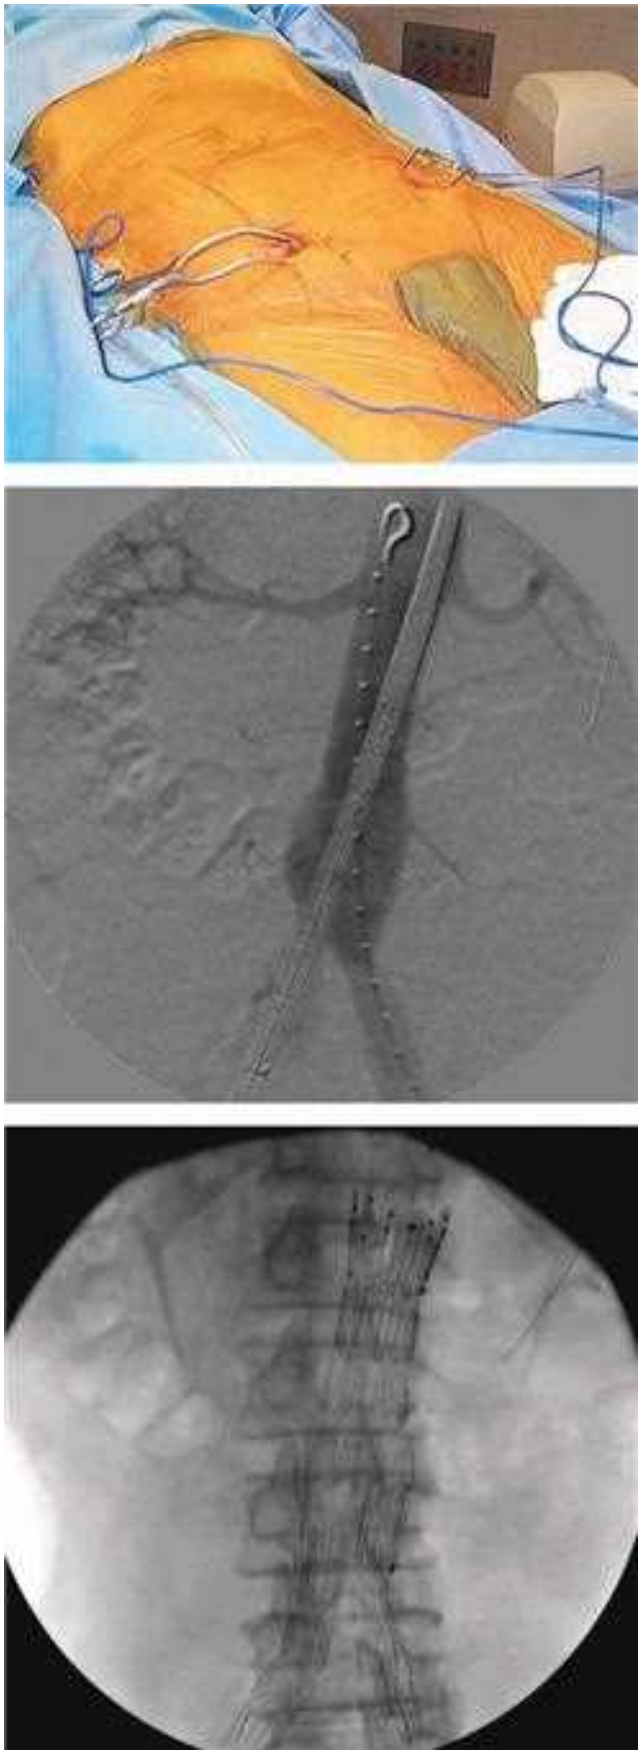

Figure 47-6. Endovascular repair of abdominal aortic aneurysms (AAAs) is gaining favor for suitable elderly patients to prevent rupture. Through minimal groin incisions, this 82-year-old patient underwent repair of an AAA and right iliac artery aneurysm and was discharged on postoperative day 2.

the presence of a thyroid nodule, usually detected by physical examination. These nodules usually are single and four times more common in women, making them a particular concern for postmenopausal elderly women. Papillary carcinoma in elderly patients tends to be sporadic with a bell-shaped distribution of age at presentation, occurring primarily in patients aged 30 to 59 years old. The incidence of papillary carcinoma decreases in patients >60 years of age.[45] However, patients >60 years of age have increased risk of local recurrence and for the development of distant metastases. Metastatic disease may be more common in this population secondary to delayed referral for surgical intervention because of the misconception that the surgeon will be unwilling to operate on an elderly patient with thyroid disease. Age is also a prognostic indicator for patients with follicular carcinoma. There is a 2.2 times increased risk of mortality from follicular carcinoma per 20 years of increasing age.[46] Therefore, prognosis for elderly patients with differentiated thyroid carcinomas is worse compared to younger counterparts. The higher prevalence of vascular invasion and extracapsular extension among older patients is, in part, responsible for the poorer prognosis in geriatric patients. Advancing age leads to increased mortality risk for patients with thyroid cancer and is demonstrated by the AMES (*a*ge, *m*etastases, *e*xtent of primary tumor, and *s*ize of tumor) classification system developed by the Lahey Clinic.

PARATHYROID SURGERY

Approximately 2% of the geriatric population, including 3% of women 75 years of age or older, will develop primary hyperparathyroidism.[47] Geriatric patients are usually referred to surgery only when advanced disease is present because of concerns regarding the risks of surgery, but low rates of morbidity and negligible mortality combined with high cure rates of approximately 95% to 98% make parathyroidectomy safe and effective. Convincing evidence of the benefit of surgery is the usual marked symptomatic improvement, which greatly improves the quality of life for most patients. The National Institutes of Health Consensus Development Statement recommends curative therapy after diagnosis of primary hyperthyroidism is established in a patient regardless of age. Specific indications for operative intervention regardless of age include a 30% decrease in creatinine clearance, 24-hour urinary calcium excretion >400 mg, and decreased bone density.[48]

Elderly patients are especially prone to developing mental manifestations of hyperparathyroidism that may be severe enough to produce a dementia-like state. There often is a significant improvement in mental status after parathyroidectomy. Another specific symptom of hyperparathyroidism that may easily be mistaken for osteoporosis and can be present in postmenopausal, elderly women is orthopedic disease; specifically back pain, and possibly, the occurrence of vertebral fractures. This pain can be of moderate intensity, leading to impaired mobility and severely affecting the quality of life of elderly patients. The decreased bone density observed in elderly patients with hyperparathyroidism tends to improve during the first 2 years after successful parathyroid surgery.

Limited parathyroidectomies with minimal dissection in geriatric patients are an effective alternative. This is a viable option in patients with multiple comorbid conditions in whom the increased risk of surgical intervention or general anesthesia remains a concern. One study demonstrated that preoperative

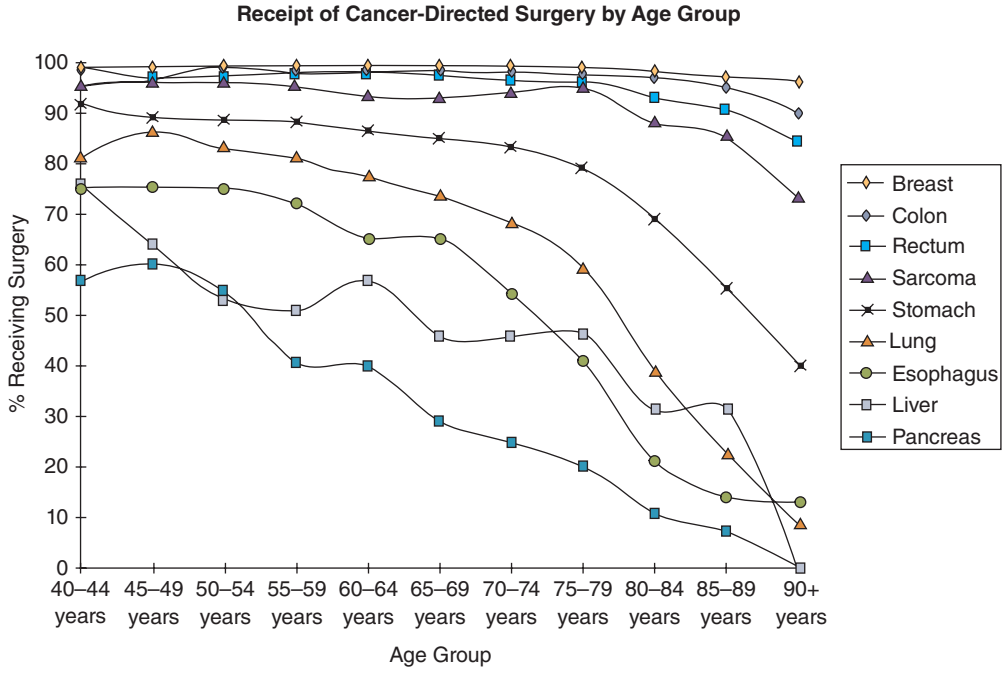

Figure 47-7. Decreased referrals of patients to oncologic surgery based on age. This graph includes potentially resectable lesions. The authors found that only 10% of patients over the age of 70 who had liver or pancreatic cancers were referred for cancer-directed surgery. localization of the hyperfunctioning gland with the aid of ^{99m}Tc-sestamibi nuclear scanning, as well as intraoperative parathyroid hormone (PTH) assays to rapidly confirm that all hypersecreting glands have been removed, allows limited parathyroidectomy to be performed with accuracy in elderly patients.[47] This procedure is described as "limited" because bilateral neck dissection for identification and biopsy of the remaining glands to determine if they are hypersecreting becomes unnecessary. The half-life of intact PTH is approximately 3 to 4 minutes. Therefore, a drop in the intraoperative PTH level at approximately 10 minutes after resection of the suspect hypersecreting gland suggests a 98% probability that the patient will return to normocalcemic levels postoperatively.[47]

PALLIATIVE SURGERY

Palliative surgery is defined as surgical intervention targeted to alleviate a patient's symptoms, thus improving the patient's quality of life despite minimal impact on the patient's survival.[54] With an increasing number of aging surgical patients who often present with advanced disease, surgeons must be familiar with the concept of palliation to control disease. This concept focuses on providing the maximal benefit to the patient using the least-invasive intervention. Ultimately, this leads to symptom relief and preservation of the quality of life in terminal disease states. The uses of palliative surgery can range from extensive debulking operations aimed at aiding in the effectiveness of chemotherapy and radiation, to less complex operations to alleviate symptoms such as intractable vomiting, severe pain, cachexia, and anorexia that are common to terminal disease states. The success of palliative surgery is a careful balance between achieving symptom relief while ensuring that the development of new symptoms from the palliative intervention itself does not occur.

THE ROLE OF THE SURGEON IN GERIATRIC PATIENTS IS NOT LIMITED TO THE OR

The need for surgical input in helping elderly patients make decisions has never been more important. Inherent biases to age exist, such that patients who can be cured or palliated by surgical procedures are in many cases not being helped. For example, O'Connell demonstrated a decrease in referrals to surgery in aged patients with potentially curable oncologic illnesses, including those of breast, gastrointestinal, and lung (Fig. 47-7).[50] Only a surgeon with knowledge of the current best practice approach for the aged patient can help a patient—and his or her referring physicians—understand the real risks and potential benefits of an intervention, be it curative or palliative.

The challenge for us is to improve perioperative care of the elderly surgical patient using new tools for careful patient selection, accurately assess risk factors to reduce postoperative morbidity and mortality, and deliver quality surgical interventions without compromising functional vitality.

Ethics, Palliative Care, and Care at the End of Life

Daniel E. Hall, Peter Angelos, Geoffrey P. Dunn, Daniel B. Hinshaw, and Timothy M. Pawlik

Dedicated to the advancement of surgery along its scientific and moral side.

June 10, 1926, dedication on the Murphy Auditorium, the first home of the American College of Surgeons

WHY ETHICS MATTER

Ethical concerns involve not only the interests of patients, but also the interests of surgeons and society. Surgeons choose among the options available to them because they have particular opinions regarding what would be good (or bad) for their patients. Aristotle described practical wisdom (Greek: *phronesis*) as the capacity to choose the best option from among several imperfect alternatives (Fig. 48-1).[1] Frequently, surgeons are confronted with clinical or interpersonal situations in which there is incomplete information, uncertain outcomes, and/or complex personal and familial relationships. The capacity to choose wisely in such circumstances is the challenge of surgical practice.

DEFINITIONS AND OVERVIEW

Biomedical ethics is the system of analysis and deliberation dedicated to guiding surgeons toward the "good" in the practice of surgery. One of the most influential ethical "systems" in the field of biomedical ethics is the principalist approach as articulated by Beauchamp and Childress.[2] In this approach to ethical issues, moral dilemmas are deliberated by using four guiding principles: autonomy, beneficence, nonmaleficence, and justice.[2]

The principle of autonomy respects the capacity of individuals to choose their own destiny, and it implies a right for individuals to make those choices. It also implies an obligation for physicians to permit patients to make autonomous choices about their medical care. Beneficence requires that proposed actions aim at and achieve something good whereas nonmaleficence aims at avoiding concrete harm: *primum non nocere**. Justice requires fairness where both the benefits and burdens of a particular action are distributed equitably.

The history of medical ethics has its origins in antiquity. The Hippocratic Oath along with other professional codes has guided the actions of physicians for thousands of years. However, the growing technical powers of modern medicine raise new questions that were inconceivable in previous generations. Life support, dialysis, and modern drugs, as well as organ and cellular transplantation, have engendered new moral and ethical questions. As such, the ethical challenges faced by the surgeon have become more complex and require greater attention.

The case-based paradigm for bioethics is used when the clinical team encounters a situation in which two or more values or principles come into apparent conflict. The first step is to clarify the relevant principles (e.g., autonomy, beneficence, nonmaleficence, and justice) and values at stake (e.g., self-determination, quality of life, etc.). After identifying the principles and values that are affecting the situation, a proposed course of action is considered given the circumstances.

Much of the discourse in bioethics adopts this "principlist" approach in which the relevant principles are identified, weighed and balanced, and then applied to formulate a course of action. This approach to bioethics is a powerful technique for thinking through moral problems because the four principles help identify what is at stake in any proposed course of action. However, the principles themselves do not resolve ethical dilemmas. Working together, patients and surgeons must use wise judgment to choose the best course of action for the specific case.

Choosing wisely requires the virtue of practical wisdom first described by Aristotle (Fig. 48-1). Along with the other cardinal virtues of courage, justice and temperance, practical wisdom is a central component of virtue ethics which complement principlist

*"First do no harm."

Key Points

1. The physician should document that the patient or surrogate has the capacity to make a medical decision.
2. The physician discloses to the patient details regarding the diagnosis and treatment options sufficient for the patient to make an informed consent.
3. Living wills are written to anticipate treatment options and choices in the event that a patient is rendered incompetent by a terminal illness.
4. The durable power of attorney for healthcare identifies surrogate decision makers and invests them with the authority to make healthcare decisions on the patient's behalf in the event that they are unable to speak for themselves.
5. Surgeons should encourage their patients to clearly identify their surrogates early in the course of treatment.
6. Earlier referral and wider use of palliative and hospice care may help more patients achieve their goals at the end of life.
7. Seven requirements for the ethical conduct of clinical trials have been articulated: value, scientific validity, fair subject selection, favorable risk-benefit ratio, independent review, informed consent, and respect for enrolled subjects.
8. Disclosure of error is consistent with recent ethical advances in medicine toward more openness with patients and the involvement of patients in their care.

ethics by guiding choices toward the best options for treatment. Practical wisdom cannot be learned from books and is developed only through experience. The apprenticeship model of surgical residency fosters the development of practical wisdom through experience. More than teaching merely technical mastery, surgical residency is also moral training. In fact, the sociologist Charles Bosk argues that the "postgraduate training of surgeons is above all things an ethical training."[3]

SPECIFIC ISSUES IN SURGICAL ETHICS

Informed Consent

Although a relatively recent development, the doctrine of informed consent is one of the most widely established tenets of modern biomedical ethics. During the nineteenth and early twentieth centuries, most physicians practiced a form of benign paternalism whereby patients were rarely involved in the decision-making process regarding their medical care, relying instead on the beneficence of the physician. Consensus among the wider public eventually changed such that surgeons are now expected to have an open discussion about diagnosis and treatment with the patient to obtain informed consent. In the United States, the legal doctrine of *simple* consent dates from the 1914 decision in *Schloendorff vs. The Society of New York Hospital* regarding a case in which a surgeon removed a diseased uterus after the patient had consented to an examination under anesthesia, but with the express stipulation that no operative excision should be performed. The physician argued that his decision was justified by the beneficent obligation to avoid the risks of a second anesthetic. However, Justice Benjamin Cardozo stated:

> *Every human being of adult years and sound mind has a right to determine what shall be done with his body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages . . . except in cases of emergency, where the patient is unconscious, and where it is necessary to operate before consent can be obtained.*[4]

Having established that patients have the right to determine what happens to their bodies, it took some time for the modern concept of *informed* consent to emerge from the initial doctrine of *simple* consent. The initial approach appealed to a *professional practice standard* whereby physicians were obligated to disclose to patients the kind of information that experienced surgeons customarily disclosed.[5] However, this disclosure was not always adequate for patient needs. In the 1972 landmark case, *Canterbury vs. Spence*, the court rejected the professional practice standard in favor of the *reasonable person standard* whereby physicians are obliged to disclose to patients all information regarding diagnosis, treatment options, and risks that a "reasonable patient" would want to know in a similar situation. Rather than relying on the practices or consensus of the medical community, the reasonable person standard empowers

the public (reasonable persons) to determine how much information should be disclosed by physicians to ensure that consent is truly informed. The court did recognize, however, that there are practical limits on the amount of information that can be communicated or assimilated.[5] Subsequent litigation has revolved around what reasonable people expect to be disclosed in the consent process to include the nature and frequency of potential complications, the prognostic life expectancy,[6] and the surgeon-specific success rates.[4] Despite the litigious environment of medical practice, it is difficult to prosecute a case of inadequate informed consent so long as the clinician has made a concerted and documented effort to involve the patient in the decision-making process.

Adequate informed consent entails at least four basic elements: (a) the physician documents that the patient or surrogate has the capacity to make a medical decision; (b) the surgeon discloses to the patient details regarding the diagnosis and treatment options sufficiently for the patient to make an informed choice; (c) the patient demonstrates understanding of the disclosed information before (d) authorizing freely a specific treatment plan without undue influence (Fig. 48-2). These goals are aimed at respecting each patient's prerogative for autonomous self-determination. To accomplish these goals, the surgeon needs to engage in a discussion about the causes and nature of the patient's disease, the risks and benefits of available treatment options, as well as details regarding what patients can expect after an operative intervention.[7–14]

Informed consent can be challenging in certain clinical settings. For example, obtaining consent for emergency surgery, where decisions are often made with incomplete information, can be difficult. Emergency consent requires the surgeon to consider if and how possible interventions might save a patient's life, and if successful, what kind of disability might be anticipated. Surgical emergencies are one of the few instances where the limits of patient autonomy are freely acknowledged, and surgeons are empowered by law and ethics to act promptly in the best interests of their patients according to the surgeon's judgment. Most applicable medical laws require physicians to provide the standard of care to incapacitated patients, even if it entails invasive procedures without the explicit consent of the patient or surrogate. If at all possible, surgeons should seek the permission of their patients to provide treatment, but when emergency medical conditions render patients unable to grant that permission, and when delay is likely to have grave consequences, surgeons are legally and ethically justified in providing whatever surgical treatment the surgeon judges necessary to preserve life and restore health.[4] This justification is based on the social consensus that most people would want their lives and health protected in this way, and this consensus is manifest in the medical profession's general orientation to preserve life. It may be that subsequent care may be withdrawn or withheld when the clinical prognosis is clearer, but in the context of initial resuscitation of injured patients, incomplete information makes clear judgments about the patient's ultimate prognosis or outcome impossible.

The process of consent can also be challenging in the pediatric population. For many reasons, children and adolescents cannot participate in the process of giving informed consent in the same way as adults. Depending on their age, children may lack the cognitive and emotional maturity to participate fully

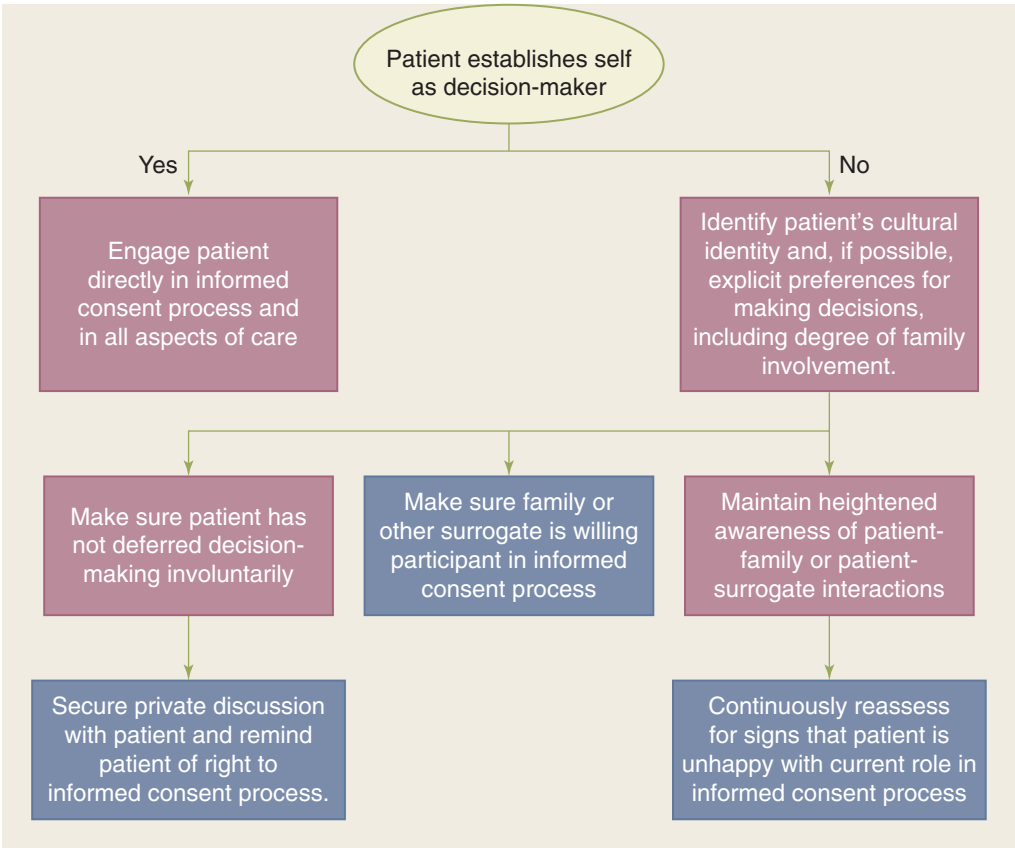

Figure 48-2. Algorithm for navigating the process of informed consent. (*From Childers R, Lipsett A, Pawlik T. Informed consent and the surgeon. J Am Coll Surg. E-pub Jan. 21, 2009. Copyright 2009, with permission from Elsevier.*)

in the process. In addition, depending on the child's age, their specific circumstances, as well as the local jurisdiction, children may not have legal standing to fully participate on their own independent of their parents. The use of parents or guardians as surrogate decision makers only partially addresses the ethical responsibility of the surgeon to involve the child in the informed consent process. The surgeon should strive to augment the role of the decision makers by involving the child in the process. Specifically, children should receive age-appropriate information about their clinical situation and therapeutic options so that the surgeon can solicit the child's "assent" for treatment. In this manner, while the parents or surrogate decision makers formally give the informed consent, the child remains an integral part of the process.

Certain religious practices can present difficulties in treating minor children in need of life-saving blood transfusions; however, case law has made clear the precedent that parents, regardless of their held beliefs, may not place their minor children at mortal risk. In such a circumstance, the physician should seek counsel from the hospital medicolegal team, as well as from the institutional ethics team. Legal precedent has, in general, established that the hospital or physician can proceed with providing all necessary care for the child.

Obtaining "consent" for organ donation deserves specific mention.[15] Historically, discussion of organ donation with families of potential donors was performed by transplant professionals, who were introduced to families by intensivists after brain death had been confirmed and the family had been informed of the fact of death. In other instances, consent might be obtained by intensivists caring for the donor, as they were assumed to know the patient's family and could facilitate the process. However, issues of moral "neutrality" as part of end-of-life care in the intensive care unit have caused a shift in how obtaining "consent" for organ donation is handled. Responsibility for obtaining consent from the donor family is now vested in trained "designated requestors" (or "organ procurement coordinators")[16] or by "independent" intensivists who do not have a therapeutic clinical relationship with the potential donor.[17] In this way, the donor family can be allowed to make the decision regarding donation in a "neutral" environment without erosion of the therapeutic relationship with the treating physician.

The process of informed consent also can be limited by the capacity of patients to assimilate information in the context of their illness. For example, despite the best efforts of surgeons, evidence suggests that patients rarely retain much of what is disclosed in the consent conversation, and they may not remember discussing details of the procedure that become relevant when postoperative complications arise.[18] It is important to recognize that the doctrine of informed consent places the most emphasis on the principle of autonomy precisely in those clinical situations when, because of their severe illness or impending death, patients are often divested of their autonomy.

The Boundaries of Autonomy: Advanced Directives and Powers of Attorney

Severe illness and impending death can often render patients incapable of exercising their autonomy regarding medical decisions. One approach to these difficult situations is to make decisions in the "best interests" of patients, but because such decisions require value judgments about which thoughtful people frequently disagree, ethicists, lawyers. and legislators have sought a more reliable solution. Advanced directives of various forms have been developed to carry forward into the future the autonomous choices of competent adults regarding health care decisions. Furthermore, the courts often accept "informal" advanced directives in the form of sworn testimony about statements the patient made at some time previous to their illness. When a formal document expressing the patient's advanced directives fails to exist, surgeons should consider the comments patients and families make when asked about their wishes in the setting of debilitating illness.

Living wills are written to anticipate treatment options and choices in the event that a patient is incapacitated by a terminal illness. In the living will, the patient indicates which treatments she wishes to permit or prohibit in the setting of terminal illness. The possible treatments addressed often include mechanical ventilation, cardiopulmonary resuscitation, artificial nutrition, dialysis, antibiotics, or transfusion of blood products. Unfortunately, living wills are often too vague to offer concrete guidance in complex clinical situations, and the language ("terminal illness," "artificial nutrition") can be interpreted in many ways. Furthermore, by limiting the directive only to "terminal" conditions, it does not provide guidance for common clinical scenarios like advanced dementia, delirium, or persistent vegetative states where the patient is unable to make decisions, but is not "terminally" ill. Perhaps even more problematic is the evidence that demonstrates that healthy patients cannot reliably predict their preferences when they are actually sick. This phenomenon is called "affective forecasting" and applies to many situations. For example, the general public estimates the health-related quality of life (HRQoL) score of patients on dialysis at 0.39, although dialysis patients themselves rate their HRQoL at 0.56.[19] Similarly, patients with colostomies rated their HRQoL at 0.92, compared to a score of 0.80 given by the general public for patients with colostomies.[19] For these and other reasons, living wills are often unable to provide the extent of assistance they promise.[20]

An alternative to living wills is the durable power of attorney for health care in which patients identify surrogate decision makers and invest them with the authority to make health care decisions on their behalf in the event that they are unable to speak for themselves. Proponents of this approach hope that the surrogate will be able to make decisions that reflect the choices that the patients themselves would make if they were able. Unfortunately, several studies demonstrate that surrogates are not much better than chance at predicting the choices patients make when the patient is able to state a preference. For example, a recent meta-analysis found that surrogates predicted patients' treatment preferences with only 68% accuracy.[21] These data reveal a flaw in the guiding principle of surrogate decision making: Surrogates do not necessarily have privileged insight into the autonomous preferences of patients. However, the durable power of attorney at least allows patients to choose the person who will eventually make prudential decisions on their behalf and in their best interests; therefore, respecting the judgment of the surrogate is a way of respecting the self-determination of the incapacitated patient.[22]

There is continuing enthusiasm for a wider use of advanced directives. In fact, the 1991 Patient Self Determination Act requires all U.S. health care facilities to (a) inform patients of their rights to have advanced directives, and (b) to document those advanced directives in the chart at the time any patient is admitted to the health care facility.[4] However, only a minority of patients in U.S. hospitals have advanced directives despite

concerted efforts to teach the public of their benefits. For example, the ambitious SUPPORT trial used specially trained nurses to promote communication between physicians, patients, and their surrogates to improve the care and decision making of critically ill patients. Despite this concerted effort, the intervention demonstrated "no significant change in the timing of do not resuscitate (DNR) orders, in physician-patient agreement about DNR orders, in the number of undesirable days (patients experiences), in the prevalence of pain, or in the resources consumed."[23]

Some of the reluctance around physician-patient agreement about DNR orders may reflect patient and family anxiety that DNR orders equate to "do not treat." Patients and families should be assured, when appropriate, that declarations of DNR/do not intubate will not necessarily result in a change in ongoing routine clinical care. The issue of temporarily rescinding DNR/do not intubate orders around the time of an operative procedure may also need to be addressed with the family.

Patients should be encouraged to clearly identify their surrogates, both formally and informally, early in the course of treatment, and before any major elective operation. Often, around the time of surgery or at the end of life, there are limits to patient autonomy in medical decision making. Seeking an advanced directive or surrogate decision maker requires time that is not always available when the clinical situation deteriorates. As such, these issues should be clarified as early as possible in the patient-physician relationship.

5▶

Withdrawing and Withholding Life-Sustaining Therapies

The implementation of various forms of life support technology raise a number of legal and ethical concerns about when it is permissible to withdraw or withhold available therapeutic technology. There is general consensus among ethicists that there are no philosophic differences between withdrawing (stopping) or withholding (not starting) treatments that are no longer beneficial.[24] However, the right to refuse, withdraw, and withhold beneficial treatments was not established before the landmark case of Karen Ann Quinlan. In 1975, Quinlan lapsed into a persistent vegetative state requiring ventilator support. After several months without clinical improvement, Quinlan's parents asked the hospital to withdraw ventilator support. The hospital refused, fearing prosecution for euthanasia. The case was appealed to the New Jersey Supreme Court where the justices ruled that it was permissible to withdraw ventilator support.[25] This case established a now commonly recognized right to withdraw "extraordinary" life-saving technology if it is no longer desired by the patient or the patient's surrogate.

The difference between "ordinary" and "extraordinary" care, and whether there is an ethical difference in withholding or withdrawing "ordinary" vs. "extraordinary" care, has been an area of much contention. The 1983 Nancy Cruzan case highlighted this issue. In this case, Cruzan had suffered severe injuries in an automobile crash that rendered her in a persistent vegetative state. Cruzan's family asked that her tube feeds be withheld, but the hospital refused. The case was appealed to the U.S. Supreme Court, which ruled that the tube feeding could be withheld if her parents demonstrated "clear and convincing evidence" that the incapacitated patient would have rejected the treatment.[26] In this ruling, the court essentially ruled that there was no legal distinction between "ordinary" vs. "extraordinary" life-sustaining therapies.[27] In allowing the feeding tube to be removed, the court accepted the principle that a competent person (even through a surrogate decision maker) has the right to decline treatment under the Fourteenth Amendment of the U.S. Constitution. The court noted, however, that there has to be clear and convincing evidence of the patient's wishes (principle of autonomy) and that the burdens of the medical intervention should outweigh its benefits (consistent with the principles of beneficence and nonmaleficence).

In deliberating the issue of withdrawing vs. withholding life-sustaining therapies, the principle of "double effect" is often mentioned. According to the principle of "double effect," a treatment (e.g., opioid administration in the terminally ill) that is intended to help and not harm the patient (i.e., relieve pain) is ethically acceptable even if an unintended consequence (side effect) of its administration is to shorten the life of the patient (e.g., by respiratory depression). Under the principle of double effect, a physician may withhold or withdraw a life-sustaining therapy if the surgeon's *intent* is to relieve suffering, not to hasten death. The classic formulation of double effect has four elements (Fig. 48-3).

Withholding or withdrawing of life-sustaining therapy is ethically justified under the principle of double effect if the physician's intent is to relieve suffering, not to kill the patient. Thus, in managing the distress of the dying, there is a fundamental ethical difference between titrating medications rapidly to achieve relief of distress and administering a very large bolus with the intent of causing apnea. It is important to note, however, that although the use of opioids for pain relief in advanced illness is frequently cited as the classic example of the double effect rule, opioids can be used safely without significant risk. In fact, if administered appropriately, in the vast majority of instances the

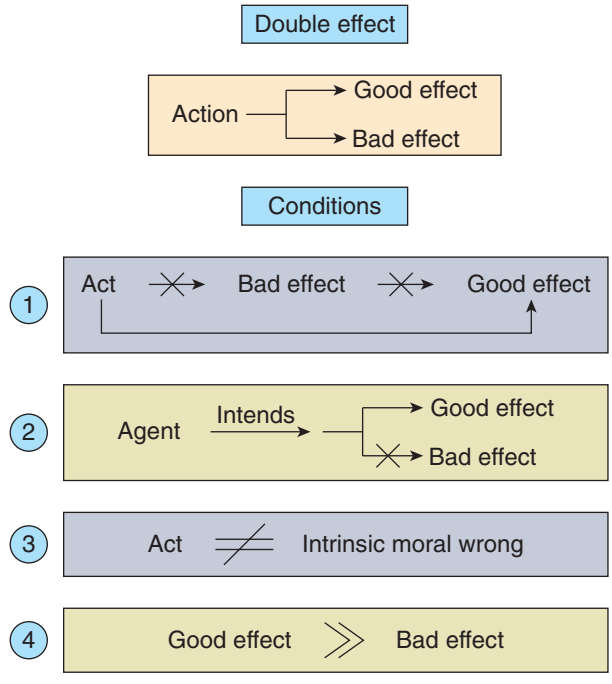

Figure 48-3. The four elements of the double effect principle: a) The good effect is produced directly by the action and not by the bad effect. b) The person must intend only the good effect, even though the bad effect may be foreseen. c) The act itself must not be intrinsically wrong, or needs to be at least neutral. d) The good effect is sufficiently desirable to compensate for allowing the bad effect.

rule of double effect need not be invoked when administering opioids for symptom relief in advanced illness.[28]

In accepting the ethical equivalence of withholding and withdrawing of life-sustaining therapy, surgeons can make difficult treatment decisions in the face of prognostic uncertainty.[24] In light of this, some important principles to consider when considering withdrawal of life-sustaining therapy include: (a) Any and all treatments can be withdrawn. If circumstances justify withdrawal of one therapy (e.g., IV pressors, antibiotics), they may also justify withdrawal of others; (b) Be aware of the symbolic value of continuing some therapies (e.g., nutrition, hydration) even though their role in palliation is questionable; (c) Before withdrawing life-sustaining therapy, ask the patient and family if a spiritual advisor (e.g., pastor, imam, rabbi, or priest) should be called; and (d) Consider requesting an ethics consult.

Although the clinical setting may seem limited, a range of options usually exists with respect to withdrawing or withholding treatment, allowing for an incremental approach, for example (a) continuing the current regimen without adding new interventions or tests; (b) continuing the current regimen but withdrawing elements when they are no longer beneficial; and (c) withdrawing and withholding all treatments that are not targeted to relieve symptoms and maximize patient comfort.[29]

The surgeon might consider discussing the clinical situation with the patient or proxy decision maker, identify the various therapeutic options, and delineate the reasons why withholding or withdrawing life-sustaining therapy would be in the patient's best interest. If the patient (or designated proxy decision maker) does not agree with withholding or withdrawing life-sustaining therapy, the surgeon should consider or recommend a second medical opinion. If the second opinion corroborates that life-sustaining therapy should be withheld or withdrawn but the patient/family continues to disagree, the surgeon should consider assistance from institutional resources such as the ethics committee and hospital administration. Although the surgeon is not ethically obligated to provide treatment that he or she believes is futile, the surgeon is responsible for continued care of the patient, which may involve transferring the patient to a surgeon who is willing to provide the requested intervention.[24]

PALLIATIVE CARE

General Principles of Palliative Care

Palliative care is a coordinated, interdisciplinary effort that aims to relieve suffering and improve quality of life for patients and their families in the context of serious illness.[34] It is offered simultaneously with all other appropriate medical treatment, and its indication is not limited to situations associated with a poor prognosis for survival. Palliative care strives to achieve more than symptom control, but it should not be confused with noncurative treatment.

The World Health Organization defines palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual."[29] Palliative care is both a philosophy of care and an organized, highly structured system for delivering care.

Palliative care includes the entire spectrum of intervention for the relief of symptoms and the promotion of quality of life. No specific therapy, including surgical intervention, is excluded from consideration. Therefore, surgeons have valuable contributions to make to palliative care. In fact, the term *palliative care* was coined in 1975 by Canadian surgeon, Balfour Mount. Furthermore, *surgical palliative care* can be defined as the treatment of suffering and the promotion of quality of life for seriously or terminally ill patients under the care of surgeons.[31] The standard of palliative treatment lies in the agreement between patient and physician that the expected outcome is relief from distressing symptoms, lessening of pain, and improvement of quality of life. The decision to intervene is based on the treatment's ability to meet the stated goals, rather than its impact on the underlying disease.

The fundamental elements of palliative care consist of pain and nonpain symptom management, communication among patients, their families, and care providers, and continuity of care across health systems and through the trajectory of illness. Additional features of system-based palliative care are team-based planning that includes patient and family; close attention to spiritual matters; and psychosocial support for patients, their families, and care providers, including bereavement support.

Indications for palliative care consultation in surgical practice include: (a) patients with conditions that are progressive and life-limiting, especially if characterized by burdensome symptoms, functional decline, and progressive cognitive deficits; (b) assistance in clarification or reorientation of patient/family goals of care; (c) assistance in resolution of ethical dilemmas; (d) situations in which a patient/surrogate declines further invasive or curative treatments with stated preference for comfort measures only; (e) patients who are expected to die imminently or shortly after hospital discharge; and (f) provision of bereavement support for patient care staff, particularly after loss of a colleague under care[31] (Table 48-1). Although all patients, regardless of prognosis, may benefit from the services of a palliative care physician, hospice care is a specific form of palliative care intended for patients who have an estimated prognosis of 6 months or less to live. Hospice care is covered under Medicare Part A, and benefits may be continued beyond the original 6 months of estimated survival if physicians certify that life expectancy remains limited to 6 months or less.

6▶ Although most Americans indicate a preference to die at home, nearly 75% die in an institutional setting. Earlier referral and wider use of the hospice benefit may help more patients achieve their goal of dying at home.

Table 48-1

Indications for palliative care consultation

Patients with conditions that are progressive and life-limiting, especially if characterized by burdensome symptoms, functional decline, and progressive cognitive deficits
Assistance in clarification or reorientation of patient/family goals of care
Assistance in resolution of ethical dilemmas
Situations in which patient/surrogate declines further invasive or curative treatments with stated preference for comfort measures only
Patients who are expected to die imminently or shortly after hospital discharge
Provision of bereavement support for patient care staff, particularly after loss of a colleague under care

Concepts of Suffering, Pain, Health, and Healing

Palliative care addresses specifically the individual patient's experience of suffering due to illness. Indeed, the philosophical origins of palliative care began with attention to suffering and the existential questions suffering engenders. More than mere technologic evolution in the management of symptoms, the early proponents of palliative care sought a revolution in the moral foundations of medicine that challenged the assumptions that so often seemed to result in futile invasive intervention, and identified many of the problems that were subsequently taken up by medical ethicists. This reorientation of the goals of medical care from a focus on disease and its management to the patient's experience of illness focuses attention on the purpose of medicine and the meaning of health and healing.

Over the past half century, several concepts and theories about the nature of pain, suffering, and health have been proposed in service of the evolving conceptual framework of palliative care. For example, while considering the differences between disease-oriented and illness-oriented approaches to the care of seriously ill patients, psychiatrist Arthur Kleinman wrote, "There is a moral core to healing in all societies. [Healing] is the central purpose of medicine . . . the purpose of medicine is both control of disease processes and care for the illness experience. Nowhere is this clearer than in the relationship of the chronically ill to their medical system: For them, the control of disease is by definition limited; care for the life problems created by the disorder is the chief issue."[34]

The relief of pain has been the clinical foundation for hospice and palliative care. It has been defined by the International Association for the Study of Pain as "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[35] For purposes of interdisciplinary palliative care, Saunders's concept of "Total Pain"[31] is a more useful definition and is frequently used as the basis for palliative assessments. Total Pain is the sum total of four principal domains of pain: physical, psychologic, social or socioeconomic, and spiritual. Each of these contributes to, but is not synonymous with, suffering.

Effective Communication and Negotiating the Goals of Care

Changing the goals of care from cure to palliation near the end of life is both emotionally and clinically challenging, and it depends on a clear prognosis and effective communication. Unfortunately, prognostication can be notoriously difficult and inaccurate in advanced illness, and Christakis has argued that, to a large degree, physicians have abdicated their traditional responsibility to provide clear prognosis regarding incurable disease and approaching death.[37] However, there are validated tools for prognosis in critical illness (APACHE, MODS, etc.), and with most advanced diseases, functional status is the most powerful predictor of survival. For example, patients with advanced metastatic cancer who are resting/sleeping for 50% or more of normal waking hours and require some assistance with activities of daily living (ADL) have a projected survival of weeks, and patients who are essentially bedfast and dependent for ADL have a projected survival of days to a week or two at best. Table 48-2 shows a simple prognostic tool to aid clinicians in recognizing patients nearing the end of life.

Alternatively, the Karnofsky Performance Scale is a scale of functional status ranging from 100 (high level of function) to 0 (death). It is commonly used in palliative care to roughly assess patient anticipated needs as well as prognosis. The Palliative Performance Scale[38] is a validated[39] expansion of the Karnofsky Performance Scale that includes five palliative-focused domains, including ambulation, activity level, self-care, intake, and level of consciousness, in addition to evidence of disease. The Missoula-Vitas Quality of Life Index is a 25-question scale specifically for palliative care and hospice patients that scores symptoms, function, interpersonal relationships, well-being, and spirituality. Updates and Spanish versions are available.[36]

Table 48-2

Simple prognostication tool in advanced illness (especially cancer)

FUNCTIONAL LEVEL	PERFORMANCE STATUS (ECOG)	PROGNOSIS
Able to perform all basic ADLs independently and some IADLs	2	Months
Resting/sleeping up to 50% or more of waking hours and requiring some assistance with basic ADLs	3	Weeks to a few months
Dependent for basic ADLs and bed-to-chair existence	4	Days to a few weeks at most

These observations apply to patients with advanced, progressive, incurable illnesses (e.g., metastatic cancer refractory to treatment). Basic ADL = activities of daily living (e.g., transferring, toileting, bathing, dressing, and feeding oneself); IADL = instrumental activities of daily living (e.g., more complex activities such as meal preparation, performing household chores, balancing a checkbook, shopping, etc.); ECOG = Eastern Cooperative Oncology Group functional (performance) status.

Regardless of the prognostic tool used, the prognosis should be conveyed to the patient and family. If done well, communication and negotiation with patients and families about advanced terminal illnesses can potentially avoid great psychologic harm and help make a difficult transition easier. To communicate effectively and compassionately, it is helpful to pursue an organized process similar to the structured history and physical central to the evaluation of any patient. One such structured approach to delivering unfavorable news proposes six steps that can be easily learned by clinicians: (a) getting started by selection of the appropriate setting, introductions, and seating; (b) determining what the patient or family knows; (c) determining what the patient or family wants to know; (d) giving the information; (e) expressing empathy; and (f) establishing expectations, planning, and aftercare (Table 48-3).[40] Success with this approach to breaking bad news is critically dependent upon the clinician's ability to empathically respond to the patient's (and family's) reaction to the news.[41] The empathic response does not require the surgeon to share the same emotions of the patient, but it does require the surgeon to identify the patient's emotion and accurately reflect that awareness back to the patient. Patient assessment in these conversations should give the highest priority to identifying and responding to the most immediate source of distress. Relieving a pressing symptom is prerequisite for a more thorough search for other potential sources of

Table 48-3

Communicating unfavorable news: Important principles

- Setting: Find a quiet, private place to meet. Sit down close to the patient.
- Listen: Clarify the patient's and/or the family's understanding of the situation.
- "Warning shot": Prepare patient and family and obtain their permission to communicate bad news (e.g., "I'm afraid I have bad news.").
- Silence: Pause after giving bad news. Allow patient/family to absorb/react to the news.
- Encourage: Convey hope that is realistic and appropriate to the circumstances (e.g., patient will not be abandoned; symptoms will be controlled).

suffering, and the assessment process, itself, can be therapeutic if conducted in a respectful and gentle manner.

CARE AT THE END OF LIFE

The process of dying and the care of a patient at the time of death is a distinct clinical entity that demands specific skills from physicians. The issues specific to dying and the available tools for compassionate care at the end of life are addressed in this section.

The Syndrome of Imminent Demise[29,42]

In a patient who has progressed to the terminal stage of an advanced illness (e.g., cancer), a number of signs provide evidence of imminent death. As terminally ill patients progress toward death, they become increasingly bedbound, requiring assistance for all basic ADL. There is a steady decrease in desire and requests for food and fluids. More distressing to the dying patient is a progressively dry mouth that may be confused by the treating team as thirst. It is often exacerbated by anticholinergic medications, mouth breathing, and supplemental oxygen (O_2) administered without humidification.

With progressive debility, fatigue, and weight loss, it is common for terminally ill patients to experience increasing difficulty swallowing. This may result in aspiration episodes and an inability to swallow tablets, requiring alternative routes for medication administration (e.g., IV, SC, PR, sublingual, buccal, or transdermal). In addition to the increased risk of aspiration, patients near death develop great difficulty clearing oropharyngeal and upper airway secretions, leading to noisy breathing or the so-called "death rattle." As death approaches, the respiratory pattern may change to increasingly frequent periods of apnea often following a Cheyne-Stokes pattern of rapid, progressively longer breaths leading up to an apneic period. As circulatory instability develops near death, patients may exhibit cool and mottled extremities. Periods of confusion are often accompanied by decreasing urine output and episodes of fecal and urinary incontinence.

A number of cognitive changes occur as death approaches. Patients who are in the last days of life may demonstrate some signs of confusion or delirium. Agitated delirium is a prominent feature of a difficult death. Other cognitive changes that may be seen include a decreased interest in social interactions, increased somnolence, reduced attention span, disorientation to time (often with altered sleep-wake cycles), and an altered dream life, including vivid "waking dreams" or visual hallucinations. Reduced hearing and visual acuity may be an issue for some patients; however, patients who appear comatose may still be aware of their surroundings. Severely cachectic patients may lose the ability to keep their eyes closed during sleep because of loss of the retro-orbital fat pad.

Common Symptoms at the End of Life and Their Management[29,42,43]

The three most common, major symptoms that threaten the comfort of dying patients in their last days are respiratory distress, pain, and cognitive failure. General principles that are applicable to symptom management in the last days of life include: (a) anticipating symptoms before they develop; (b) minimizing technologic interventions (usually manage symptoms with medications); and (c) planning alternative routes for medications in case the oral route fails. It may be possible to cautiously reduce the dose of opioids and other medications as renal clearance decreases near the end of life, but it is important to remember that increased somnolence and decreasing respirations are prominent features of the dying process independent of medication side effects. Sudden cessation of opioid analgesics near the end of life could precipitate withdrawal symptoms, and therefore, medications should not be stopped for increasing somnolence or slowed respirations.

The principles of pharmacotherapy for pain and non-pain symptoms in the palliative care setting are outlined in Table 48-4. The World Health Organization,[30] the United States Agency for Health Care Policy and Research,[44] the Academy of Hospice and Palliative Medicine,[45] and many other agencies have endorsed a "step ladder" approach to cancer pain management that can predictably result in satisfactory pain control in most patients (Table 48-5). More refractory pain problems require additional expertise, and occasionally, more invasive approaches (Tables 48-6 and 48-7).

The primary treatment of dyspnea (air hunger) in the dying is opioids, which should be cautiously titrated to increase comfort and reduce tachypnea to a range of 15 to 20 breaths/min. Air movement across the face generated by a fan can sometimes be quite helpful. If this is not effective, empirical use of supplemental O_2 by nasal cannula (2–3 L/min) may bring some subjective relief, independent of observable changes in pulse oximetry. Supplemental O_2 should be humidified to avoid exacerbation of dry mouth. Typical starting doses of an immediate release opioid for breathlessness should be one-half to two-thirds of a starting dose of the same agent for cancer pain. For patients already on opioids for pain, a 25% to 50% increment in the dose of the current immediate release agent for breakthrough pain often will be effective in relieving breathlessness in addition to breakthrough pain.

The availability and variety of drugs should not prevent consideration of nonpharmacologic therapy. Massage therapy, music therapy, art therapy, guided imagery, hypnosis, physical therapy, pet therapy, and others play a constructive role not only for the relief of symptoms, but for promoting a sense of hope through improving function, aesthetic pleasure, and social connectedness. Talents and capacities neglected during the treatment and progression of disease can be recovered even in the most advanced stages of illness.

Pain is often less of a problem in the last days of life because the reduced activity level is associated with lower incident pain. This, combined with lower renal clearance of opioids,

Table 48-4

Principles of pharmacotherapy in palliative care

- Believe patient report of symptoms.
- Modify pathologic process when possible and appropriate.
- In terminally ill, avoid medications not directly linked to symptom control.
- Use a multidisciplinary approach.
- Consider nonpharmacologic approaches whenever possible.
- Engage participation of clinical pharmacist in treatment plan.
- Select drugs that can multitask (i.e., use haloperidol for agitated delirium and nausea).
- For pain, use adjuvant medications when possible (see Table 48-7).
- When using opioids, spare when possible (adjuvant medication, local or regional anesthetics, surgical interventions, etc.).
- Avoid fixed combination drugs.
- Avoid excessive cost.
- Select agents with minimum side effects.
- Anticipate and prophylax against side effects.
- For the elderly, the hypoproteinemic, theazotemic: "Start low and go slow."
- Oral route whenever possible and practical.
- No IM injections.
- Scheduled dosing, not prn, for persistent symptoms.
- Stepwise approach. (See the World Health Organization Analgesic Ladder for pain. See Table 48-5.)
- Reassess continuously and titrate to effect.
- Use equianalgesic doses when changing opioids (see Table 48-5).
- Assess patient/family's comprehension of management plan.

may result in greater potency of the prescribed agents. Severe pain crises are fortunately rare, but when they are inadequately addressed, can cause great and lasting distress (complicated grief) for loved ones who witness the final hours or days of agony. Such situations may require continuous administration of parenteral opioids. As death approaches and patients become less verbal, it is important to assess pain frequently, including the use of close observation for nonverbal signs of distress (e.g., grimacing, increased respiratory rate). Adequate dosing of opioid analgesics may require alternate route(s) of administration as patients become more somnolent or develop swallowing difficulties. Opioids should not be stopped abruptly, even if the patient becomes nonresponsive because sudden withdrawal can cause severe distress.[46,47]

Table 48-5

The World Health Organization three-step ladder for control of cancer pain[30]

Step:1 mild pain (visual analogue scale, 1–3)
Nonopioid ± adjuvant medication
Step 2: moderate pain (visual analogue scale, 4–6)
Opioid for mild to moderate pain and nonopioid ± an adjuvant
Step 3: severe pain (visual analogue scale, 7–10)
Opioid for moderate to severe pain ± nonopioid ± an adjuvant

Cognitive failure at the end of life is manifested in most patients by increasing somnolence and delirium. Gradually increasing somnolence can be accompanied by periods of disorientation and mild confusion, and it may respond to the reassuring presence of loved ones and caregivers with minimal need for medications. A more distressing form of delirium also can develop, manifested by increasing agitation that may require the use of neuroleptic medications. Increasing amounts of opioids and/or benzodiazepines may exacerbate the delirium (especially in the elderly).

Pronouncing Death[48]

If the body is hypothermic or has been hypothermic, such as a drowning victim pulled from the water in the winter, the physician should not declare death until warming attempts have been made. In the hospital, hospice, or home setting, the declaration of death becomes part of the medical or legal record of the event. There are a number of physical signs of death a physician should look for in confirming the patient's demise: complete lack of responsiveness to verbal or tactile stimuli, absence of heart beat and respirations, fixed pupils, skin color change to a waxen hue as blood settles, gradual poikilothermia, and sphincter relaxation with loss of urine and feces. For deaths in the home with patients who have been enrolled in hospice, the hospice nurse on call should be contacted immediately. In some states, deaths at home may require a brief police investigation and report. For deaths in the hospital, the family must be notified (in person, if possible). A coroner or medical examiner may need to be contacted under specific circumstances (e.g., deaths in the operating room), but most deaths do not require their services. However, the pronouncing physician will need to complete a death certificate according to local regulations. Survivors may also be approached, if appropriate, regarding potential autopsy and organ donation. Finally, it is important to accommodate religious rituals that may be important to the dying patient or the family. *Bereavement* is the experience of loss by death of a person to whom one is attached. *Mourning* is the process of adapting to such a loss in the thoughts, feelings, and behaviors that one experiences after the loss.[49] Although grief and mourning are accentuated in the immediate period around death, it is important to note that patients and families may begin the process of bereavement well before the time of death as patients and families grieve incremental losses of independence, vitality, and control. In addition to the surviving loved ones, it is important to acknowledge that caregivers also experience grief for the loss of their patients.[50,51]

PROFESSIONAL ETHICS: CONFLICT OF INTEREST, RESEARCH, AND CLINICAL ETHICS

Conflict of Interest

Conflicts of interest for surgeons can arise in many situations in which the potential benefits or gains to be realized by the surgeon are, or are perceived to be, in conflict with the responsibility to put the patient's interests before the surgeon's own. Conflicts of interest for the surgeon can involve actual or perceived situations in which the individual stands to gain monetarily by his or her role as a physician or investigator. In the academic community, monetary gain may not be the primary factor. Instead,

Table 48-6

Analgesics for persistent pain

DRUG	INITIAL DOSING (ADULT, >60 kg)	COMMENTS
Mild persistent pain, visual analogue scale (VAS) 1–3		
Acetaminophen (Tylenol)	325–650 mg PO qid Maximum = 3200 mg/24 h	Use <2400 mg if other potentially hepatotoxic drugs taken. Acetaminophen contained in concurrent nonprescription medications can easily exceed maximum daily allowable dose.
Aspirin	600–1500 mg PO qid	Gastric bleeding, platelet dysfunction
Choline magnesium trisalicylate (Trilisate)	750–1500 mg PO bid	Useful for avoiding platelet dysfunction
Ibuprofen (Advil, Motrin)	200–400 mg PO qid Maximum = 3200 mg/24 h	Gastropathy, nephropathy, decreased platelet aggregation
Naproxen (Naprosyn)	250 mg PO bid Maximum = 1300 mg/24 h	Available as a transcutaneous gel
Moderate persistent pain, VAS 4–6		
Hydrocodone (Vicodin, Lortab)	5–7.5 mg PO q4h	Most prescribed drug in the United States Acetaminophen in compounded drug limits use to moderate pain.
Oxycodone	5 mg PO q4h	Sold as single agent or compounded with aspirin or acetaminophen. Slow release form available (Oxycontin)
Severe persistent pain, VAS 7–10		
Morphine	10 mg PO q2–4h 2–4 mg IV, SC q1–2h	Standard drug for comparison to alternative opioids. Avoid or caution when giving to the elderly, patients with diminished glomerular filtration rate, or liver disease. Slow release PO form available (MS Contin).
Hydromorphone	1–3 mg PO, PR q4h 1 mg IV, SC q1–2h	Suppository form available Oral dose forms limited to 4 mg maximum
Fentanyl, transdermal	12 μg/h patch q72h	Not for acute pain management. Do not use on opioid-naive patients. Absorption unpredictable in cachectic patients.
Methadone	**Consultation with pain management, clinical pharmacists, or palliative care/hospice services skilled in methadone use is recommended for those inexperienced in prescribing methadone.**	Not a first-line agent, although very effective, especially for pain with a neuropathic component Very inexpensive Can be given PO, IV, SC, PR, sublingually, and vaginally Its long half-life makes dosing more difficult than alternative opioids and close monitoring is required when initiating Numerous medications, alcohol, and cigarette smoking can alter its serum levels **Physicians who write methadone prescriptions for pain should specify this indication.** Methadone use for drug withdrawal treatment requires special licensure.

Risk factors for NSAID-induced nephropathy include: advanced age, decreased glomerular filtration rate, congestive heart failure, hypovolemia, pressors, hepatic dysfunction, concomitant nephrotoxic agents. Dose reduction and hydration reduce risk.

Opioids compounded with aspirin or acetaminophen are limited to treatment of moderate persistent pain because of dose-limiting toxicities of acetaminophen and aspirin.

Slow-release preparations of morphine and oxycodone may be given rectally.

Timed-release tablets or patches should never be crushed or cut.

Opioid analgesics are the agents of choice for severe cancer-related pain. Sedation is a common side effect when initiating opioid therapy. Tolerance to this usually develops within a few days. If sedation persists beyond a few days, a stimulant (methylphenidate 2.5–5 mg PO bid) can be given.

Initiate bowel stimulant prophylaxis for constipation when prescribing opioids unless contraindicated.

Adjuvant or coanalgesic agents are drugs that enhance analgesic efficacy of opioids, treat concurrent symptoms that exacerbate pain, or provide independent analgesia for specific types of pain (e.g., a tricyclic antidepressant for treatment of neuropathic pain). Coanalgesics can be initiated for persistent pain at any visual analogue scale level. Gabapentin is commonly used as an initial agent for neuropathic pain.

No place for meperidine (Demerol), propoxyphene (Darvon, Darvocet, or mixed agonist-antagonist agents [Stadol, Talwin]) in management of persistent pain.

Always consider alternative approaches (axial analgesia, operative approaches, etc.) when managing severe persistent pain.

Note: These are not recommendations for specific patients. The inter- and intraindividual variability to opioids requires individualizing dosing and titration to effect.

Table 48-7

Examples of adjuvant medications for treatment of neuropathic, visceral, and bone pain[a]

DRUG CLASS	INITIAL DOSING (ADULT, >60 kg)	COMMENTS
Tricyclic antidepressants Best for continuous burning or tingling pain and allodynia Efficacy for pain not due to antidepressant effect Dose generally less than that required for antidepressant effect Dose titrated up every few days until effect. Pain may respond to alternative antidepressants if no response to initial agent.	Amitriptyline 10–25 mg PO qhs Nortriptyline 10–25 mg PO qd Doxepin 10–25 mg PO qhs Imipramine 10–25 mg PO qd	Sedating properties may be useful for relief of other concurrent symptoms. Side effects may precede benefit. Avoid in the elderly due to anticholinergic side effects. Less anticholinergic effect
Anticonvulsants For shooting, stabbing pain	Gabapentin 100–300 mg PO qd. Titrate up rapidly as needed. Max: 1800 mg qd Carbamazepine 200 mg PO q12h Valproic acid 250 mg PO tid	Commonly used first-line agent. Generally well tolerated. Does not require blood level monitoring. Effective. Well studied. Requires blood monitoring.
Local anesthetics Systemic use requires monitoring. Nebulized local anesthetics (lidocaine, bupivacaine) can be used for severe, refractory cough.	Lidocaine transdermal patch 5%. Apply to painful areas. Max: 3 simultaneous patches over 12 h (each patch contains 700 mg lidocaine). Lidocaine/prilocaine topical. Apply to painful areas.	Systemic toxicity can result from applying more than recommended number per unit time and in patients with liver failure. Effective for postherpetic neuralgia.
Miscellaneous	Bisphosphonates (pamidronate, zoledronic acid) Calcitonin nasal spray Dexamethasone Radionuclides (Sr-89) Octreotide	For bone pain and reduced incidence of skeletal complications secondary to malignancy—best results in myeloma and breast cancer. Contraindicated in renal failure. Refractory bone pain For bone pain, acute nerve compression, visceral pain secondary to tumor infiltration or luminal obstruction by reducing inflammatory component of tumor For malignant bone pain secondary to osteoclastic activity. 4–6 wk delay in benefit. Requires adequate bone marrow reserve. For prognosis of more than 3 mo. Reduces GI secretions that contribute to visceral pain

[a]Recommendations are based on experience of practitioners of hospice and palliative medicine and in some instances do not reflect current clinical trials.

motivators such as power, tenure, or authorship on a publication may serve as potential sources of conflict of interest. For example, the accrual of subjects in research studies or patients in surgical series may ensure surgeons better authorship or more financial gains. The dual-role of the surgeon-scientist therefore needs to be considered because the duty as surgeon can conflict with the role of scientist or clinical researcher.

Research Ethics

Over the last three decades in the United States, the ethical requirements for the conduct of human subject research have been formalized and widely accepted. Although detailed informed consent is a necessary condition for the conduct of ethically good human subject research, other factors also determine whether research is designed and conducted ethically. Emanuel and colleagues[52] described seven requirements for all clinical research studies to be ethically sound: (a) value—enhancement(s) of health or knowledge must be derived from the research; (b) scientific validity—the research must be methodologically rigorous; (c) fair subject selection—scientific objectives, not vulnerability or privilege, and the potential for and distribution of risks and benefits, should determine communities selected as study sites and the inclusion criteria for individual subjects; (d) favorable risk-benefit ratio—within the context of standard clinical practice and the research protocol, risks must be minimized, potential benefits enhanced, and the potential benefits to individuals and knowledge gained for society must outweigh the risks; (e) independent review—unaffiliated individuals must review the research and approve, amend, or terminate it; (f) informed consent—individuals should be informed about the research and provide their voluntary consent; and (g) respect for enrolled subjects—subjects should have their privacy protected, the opportunity to withdraw, and their well-being monitored.[52]

7▶

Special Concerns in Surgical Research

A significant issue for clinical surgical research is that it is often analyzed in a retrospective manner and not commonly undertaken in a prospective double-blind, randomized fashion. For a randomized trial to be undertaken, the researchers should be in a state of equipoise—that is, there must be a state of genuine uncertainty on the part of the clinical investigator or the expert medical community regarding the comparative therapeutic merits of each arm in a trial.[53] To randomize subjects to receive two different treatments, a researcher must believe that the existing data are not sufficient to conclude that one treatment strategy is better than another. In designing surgical trials, surgeons usually have biases that one treatment is better than another and often have difficulty maintaining the state of equipoise. As such, it is frequently difficult to demonstrate that a randomized trial is necessary or feasible, and treatment options that question the validity of clinical tenets are difficult to accept. Meakins has suggested that a slightly different hierarchy of evidence applies to evidence-based surgery.[54]

A second major issue for surgical trials is whether it is ethically acceptable to have a placebo-controlled surgical trial. Some commentators have argued that sham surgery is always wrong because, unlike a placebo medication that is harmless, every surgical procedure carries some risk.[55] Others have argued that sham operations are essential to the design of a valid randomized clinical trial because, without a sham operation, it is not possible to know if the surgical intervention is the cause of improvement in patient symptoms or whether the improvement is due to the effect of having surgery.[56,57] Most surgeons readily agree that designing an appropriately low-risk sham surgical procedure would create problems for the surgeon-patient relationship in that the surgeon would need to keep the sham a secret.[58] In this sense, a sham surgical arm of a trial is very different from a placebo medication in that there cannot be blinding of the surgeon as to which procedure was undertaken. As a result, to have a sham surgery arm in a clinical trial, the interactions between the surgeon and the subject must be limited and the surgeon performing the procedure should not be the researcher who follows the subject during the trial. Despite difficulties with designing a surgical trial in which the surgeon could ethically perform a sham operation, there are specific circumstances that allow for placebo operations to be conducted, so long as certain criteria are met and are analyzed on a case by case basis.[59,60]

Surgical Innovation and Surgical Research

An important issue is whether surgical innovation should be treated as research or as standard of care. Many of the advances in surgical technique and surgical technology have resulted from the innovations that individual surgeons have discovered or created during the course of challenging operations. As every patient is different and the surgeon is always trying to determine the best way to complete an operation, innovations have developed that have often moved the field of surgery forward.[61] In the Korean and Vietnam wars, the military guidelines for the treatment of vascular injuries recommended ligation and amputation rather than interposition grafting of vascular injuries. Individual surgeons chose to ignore those guidelines and subsequently demonstrated the value of reconstructive techniques that ultimately became the standard of care. It is debated whether modifications in an accepted surgical technique based on the circumstances of an individual patient and the skill and judgment of an individual surgeon should require the same type of prior approval that enrollment in a clinical trial would warrant.[62] However, if a surgeon decides to use a new technique on several occasions and to study the outcomes, Institutional Review Board approval and all other ethical requirements for research are necessary. These situations require strict oversight as well as explicit consent by the patient.[63] In particular, when developing new and innovative techniques, the surgeon should work in close consultation with his or her senior colleagues, including the chairperson of the department. Frequently, more senior individuals can provide sage ethical advice regarding what constitutes minor innovative changes in a technique vs. true novel research.

Compared to the formalized process for new drug approval by the Food and Drug Administration, the process for a surgeon developing an innovative operation is relatively unregulated and unsupervised.

Clinical Ethics: Disclosure of Errors

Disclosure of error—either in medical or research matters—is important, but often difficult (see Chap. 12). Errors of judgment, errors in technique, and system errors are responsible for most errors that result in complications and deaths. Hospitals are evaluated based on the number of complications and deaths that occur in surgical patients, and surgeons traditionally review their complications and deaths in a formal exercise known as

the *mortality and morbidity conference*, or *M&M*. The exercise places importance on the attending surgeon's responsibility for errors made, whether he or she made them themselves, and the value of the exercise is related to the effect of "peer pressure"—the entire department knows about the case—on reducing repeated occurrences of such an error. Although a time-honored ritual in surgery, the M&M conference is nonetheless a poor method for analyzing causes of error and for developing methods to prevent them. Moreover, the proceedings of the M&M conference are protected from disclosure by the privilege of "peer review," and the details are rarely shared with patients or those outside the department.

A report from the United States Institute of Medicine titled "To Err Is Human" highlighted the large number of medical errors that occur and encouraged efforts to prevent patient harm.[64] Medical errors are generally considered to be "preventable adverse medical events."[65] Given that medical errors clearly occur with some frequency, the question becomes what and how should patients be told of medical errors and what is the surgeon's ethical responsibility for this disclosure.[66]

Disclosure of error is consistent with the ethical tenets of openness with patients and the involvement of patients in their care. In contrast, failing to disclose errors to patients undermines public trust in medicine and potentially compromises the treatment of the consequences of errors. In addition, failure to self-disclose medical errors can be construed as a breach of professional ethics, as it is a failure to act solely for the patient's best interests. Patients require information regarding medical errors so that additional harm can be avoided. In addition, information regarding a medical error may be needed so that patients can make independent and well-informed decisions about future aspects of their care. The principles of autonomy and justice dictate that surgeons need to respect individuals by being fair in providing accurate information about all aspects of their care—even the medical errors.

Disclosing one's own errors is therefore part of the ethical standard of honesty and putting the patient's interests above one's own. Disclosing the errors of others is more complicated and may require careful consideration and consultation. Surgeons sometimes discover that a prior operation has included an apparent error; an injured bile duct or a stenotic anastomosis may lead to the condition for which the surgeon is now treating the patient. Declaring a finding as an "error" may be inaccurate, however, and a nonjudgmental assessment of the situation is usually advisable. When clear evidence of a mistake is at hand, the surgeon's responsibility is defined by his or her obligation to act as the patient's agent.

chapter 49

Global Surgery

Raymond R. Price and Catherine R. deVries

INTRODUCTION

Modern surgery can save lives, help expand economies, and offer hope to individuals and communities. Prior to the acceptance and availability of aseptic technique to prevent or decrease infections, and improved anesthesia for controlling pain, surgery as a specialty was held in very low esteem. Over the last 100 years, surgery has developed into an elite discipline that not only provides opportunities for curing certain diseases, but fulfills a special role in preventing and mitigating disability.

Yet, surgery is currently unavailable to most people worldwide. The vast majority—90%—of the world's population receives only 10% of the surgical care delivered. Said another way, 90% of the world's surgical resources are consumed by the most privileged 10% of the world's population. More than 2 billion people lack access to even basic surgical care.[1] Very few surgical procedures occur in countries spending less than US $100/ person on health care per year compared to countries spending greater than U.S. $1000/ person (Fig. 49-1).[2]

Examples of disparities abound. In many countries, including the wealthiest, deep pockets of poverty coexist within cities replete with material resources. Tertiary level hospitals operate within eyesight of slums whose inhabitants have no access to even basic care. Most of the people without access—people in rural areas and in countries with poor infrastructure—are the very people most at risk for death or disability due to lack of surgical care. Often the poor accept and endure many painful and potentially correctable fatal conditions as a fact of life.[3-6] Care for trauma and obstetrical emergencies are considered basic surgical needs but are absent in many rural regions. Other chronic conditions—often equally debilitating—progress to death or serious disability due to lack of available, safe surgery and anesthesia.

Many factors contribute to the disparity in access to surgical care. Poverty, a primary risk factor for all types of diseases, is a major obstacle hindering access to surgery. Healthcare professionals, including surgeons, migrate from areas of need due to a lack of infrastructure (hospitals, roadways, and stable electrical sources), limited supplies and equipment, lack of human resources, few opportunities for professional development, and concerns for personal safety. Finally, the lack of information about the burden of surgical disease and surgery's impact on communities has led to misconceptions of policy makers that quality surgical care is cost prohibitive and too complex to be seriously considered a viable conduit for improving global health.[7,8]

1▶ Disparities in care and outcomes are multidimensional, and no simple solution exists to improve access to appropriate and affordable surgical care. Yet, five major forces are reshaping priorities and strategies leading the charge for the globalization of surgical care:

1. *The epidemiologic transition of diseases* from primarily infectious to more chronic conditions;
2. *The mobile nature of the world's populations* allows more convenient travel opportunities for people to move freely between more isolated areas of the world leading to a more integrated global community;
3. *Ubiquitous information access* exponentially enabling universal participation in understanding and designing innovative opportunities for high-quality surgical care;
4. *A revolution for equity and human rights* where the world's poor are demanding benefits to surgical care similar to those found in developed countries;
5. *Recognition of the cost-effectiveness of surgical care,* and its potential to build economies, demonstrating the potential value of, including surgery in global health strategies.[9,10]

The potential benefits of surgical care for economic productivity are astounding. Considering that the annual economic loss from road traffic injuries alone exceeds U.S. $500 billion globally, a panel of expert economists at the Copenhagen Consensus of 2012, including four Nobel prize laureates, understandably prioritized strengthening surgical capacity as the eighth most cost-effective investment for addressing the world's current most pressing problems.[8,11] Good health, which fosters productive economies and political stability, must include access to the full spectrum of health care, including surgical care to

Key Points

1. There are five major forces reshaping priorities and strategies for the globalization of surgical care:
   a. The epidemiologic transition of diseases
   b. The mobile nature of the world's populations
   c. Ubiquitous information access
   d. A revolution for equity and human rights
   e. Recognition of the cost-effectiveness of surgical care
2. Understanding and addressing the necessary communication, energy and transportation technologies along with the underlying cultural context represent the foundation critical to implementing sustainable infrastructure necessary for appropriate surgical care.
3. The key components of the global surgery ecosystem include technology, education, community, healthcare, business, and multidisciplinary engagement between a variety of disciplines.
4. There has been a significant shift from communicable, maternal, neonatal, and nutritional causes to noncommunicable causes, many of which require surgical care.
5. Patients and their communities in low-middle income countries (LMICs) bear a much greater share of the burden of cancer than high-income countries.
6. Globally, trauma has become a leading cause of death and disability; 90% of trauma deaths occur in LMICs.
7. The burden of disease is greatest in areas where human resources—physicians, nurses, pharmacists, and other healthcare workers—are the least.
8. Surgery is gaining an increasingly recognized role for improving public health.
9. Surgery has a role in prevention as well as treatment.
10. The cost-effectiveness of various aspects of surgical care has allowed surgical initiatives to be included when prioritizing public health initiatives.
11. Developing advanced surgical capabilities in resource-poor countries has the potential to decrease overall cost and actually develop the infrastructure necessary to entice physicians and other healthcare workers to remain in their own countries.
12. Academic involvement in global surgery provides training for the next generation of surgical leaders.
13. Surgical innovations that consider cost as well as quality and design for challenging energy environments will foster equity in surgical care for LMICs.

"advance the quality of life for billions of citizens around the world."[8]

This chapter examines the need for expanding surgical care globally, explores some of the seemingly insurmountable challenges, and presents potential guiding concepts along with examples of successful strategies for sustainable surgical development.

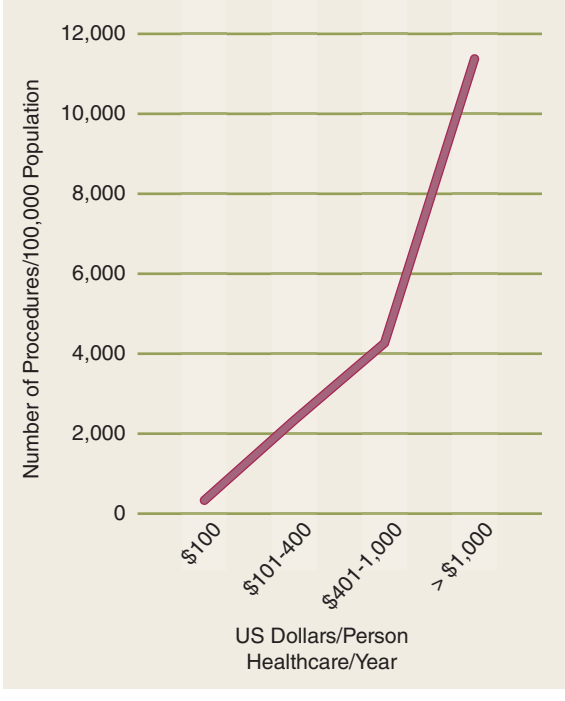

Figure 49-1. Worldwide distribution of surgical procedures. (*Data from Weiser TG, Regenbogen SE, Thompson KD, et al. An estimation of the global volume of surgery: a modeling strategy based on available data. Lancet. 2008;372(9633):139-144. Illustration reproduced with permission from Intermountain Healthcare.*)

DEFINING GLOBAL SURGERY

Global Surgery Ecosystem

To understand how surgery fits into healthcare systems and to understand its unique needs, it is helpful to consider global surgery as an ecosystem. The emerging field of global surgery considers surgical care to be a fundamental component of global health. As a system with both local and international scope, global surgery encompasses not just the medical and technical aspects of surgical care but also the societal and environmental context in which surgery is performed. Surgery as an ecosystem considers the diverse but interrelated systems that must be functional for quality surgical care to be delivered. Only part of these systems falls within the traditional training of surgeons. Yet, modern surgical care requires these systems to work in a coordinated fashion to support three priorities critical for expanding surgery globally—accessibility, affordability, and innovation (Fig. 49-2). Global surgery is a way to consider a "systems-based practice" beyond a single hospital or community for the benefit of people worldwide. Many of the interrelated components of this surgical ecosystem originate outside the hospital.

2. Disparities in surgical care have geographical, socioeconomic, and cultural components. Most people who live in major cities in northern and western hemisphere countries take for granted a functioning energy grid. The development of energy beyond major cities has enabled many wealthier communities to imagine, and indeed, to expect healthcare to be available at all times and to be affordable. Yet, a lack of reliable energy sources is a major limiting factor. Communication and transportation technologies, for example, the mobile phone and air and ground travel, have dramatically progressed

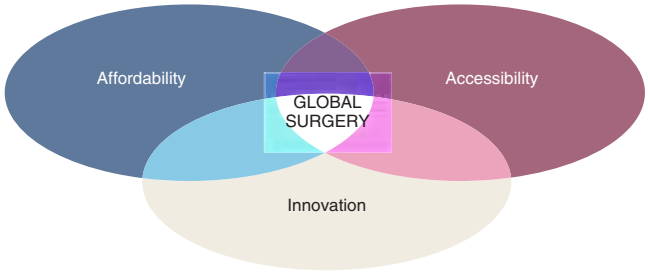

Figure 49-2. Global surgery priorities. (*Reproduced with permission from University of Utah Center for Global Surgery and Intermountain Healthcare.*)

in high- and middle-income countries but are still rudimentary in poor countries. Many of the current disparities in health care, particularly surgical care, are due to the lack of penetration of these technologies. Understanding and addressing the necessary communication, energy and transportation deficits as well as the underlying cultural nuances are necessary to support the sustainable development of surgical care (Fig. 49-3).

Electricity is necessary for all modern surgery. Anesthesia monitoring, OR lighting, cautery, suction, and patient warming devices all require sources of electricity that are stable, without huge electrical surges. Only in the last 50 years or so could stable electricity be expected in most wealthy cities. However, in rural areas of even wealthy countries, electricity remains unpredictable (Fig. 49-4).

In poorer countries, the cost and availability of electricity is frequently the limiting factor for more advanced diagnostic and therapeutic technology—from laboratories that require refrigeration to radiology in all of its various branches. Modern design for surgical devices has, for the most part, not taken into account the wide range of energy environments where surgery is practiced. Fragile instruments and monitors that cannot survive the rigors of the real working environment limit the types of surgery that can be provided.

Components of the Global Surgery Ecosystem. 3▶ Improvements in energy, transportation, and communication are critical to support the growth of six key components of surgical care (Fig. 49-5).[9] While building capacity within each component is important, it is the interaction between the components that creates a functioning, sustainable system.

When surgeons think of surgery, they usually think in terms of science and hands-on technical expertise. However, global surgery requires a broader understanding of systems in other disciplines. Surgeons must work collaboratively with engineers and business leaders to develop technology that can function in lower resource environments. These innovations can provide a source of economic growth for the community, which in turn supports better health care.

Figure 49-3. Foundation for creating surgical infrastructure. (*Reproduced with permission from Catherine R. deVries,* M.D., *University of Utah, and Intermountain Healthcare.*)

No sustainable surgical system in the modern age can function without specialists in bioengineering, sterile process, supply chain, hospital safety and waste management. These often unappreciated colleagues make possible the daily practice of surgery. Similarly, specialists in anesthesia, nursing, and the diagnostic specialties of radiology, pathology, and laboratory services are fundamental to a fully functional surgical service.

Burden of Surgical Disease

Epidemiologic Transition of Disease. The population on Earth currently stands at more than 7 billion.While the rate of growth has slowed in recent years, projections estimate that the population will continue to grow to 9 billion by 2050.[12] When thinking about global surgery, it is helpful to step back from the individual and consider families, communities, and nations. Each entity has its unique cultural and economic history and geographic advantages or disadvantages. Each has its own system for addressing surgical care but operates within a larger ecosystem, including energy availability, telecommunications and social networks, an interdependent global economy, and local material resources.

Population characteristics are changing rapidly. According to United Nations estimates, the human population of the entire world is aging, even in low-income countries, and by 2050, 2 billion people will be over the age of 60. Currently, Asia is home to 55% of the world's population over the age of 60.[13] Until recently, infectious diseases dominated public health strategy. Now with major scourges like polio isolated to relatively small regions of the world and HIV and malaria decreasing in their relative impact worldwide, chronic diseases and their complications, as well as the effects of aging, are gaining dominance in health care needs. Many of these chronic diseases are best approached by surgery.

4▶ The lack of metrics and paucity of data identifying the unmet burden of surgical need in many countries have been obstacles facing global surgery initiatives. The 2010 Global Burden of Disease Study was the first worldwide comprehensive burden of disease evaluation since the initial 1990 epidemiologic study. Using the disability-adjusted life years (DALY), a metric initially proposed for the 1990 study that captures both premature mortality and the prevalence and severity of illnesses, disease burdens were calculated for 291 causes in 21 regions of the world (including 187 countries) for 1990, 2005, and 2010 to enable identification of significant trends over time.[14] While the global DALYs remained stable from 1990 to 2010, the study identified a significant shift from communicable, maternal, neonatal, and nutritional causes to noncommunicable causes (Fig. 49-6).[15]

In the 2006 *Disease Control Priorities* 2nd *edition*, the global burden of premature death and disability from surgically treatable conditions was estimated at 11% of the total global burden of disease.[10] Recently, country-wide population surveys using the Surgeons OverSeas Assessment of Surgical Need (SOSAS) methodology identified a large unmet burden of surgical disease. In Sierra Leone, 25% of deaths of household members during the previous year might have been averted

Figure 49-4. Map of world electrification. (*NASA, Visible Earth, http://visibleearth.nasa.gov/view.php?id=79765*)

by timely surgical care; 25% of respondents also reported a current condition needing surgical attention.[16]. In Rwanda, in 2011, the SOSAS survey found 41.2% of the population had at least one operative condition during their life time; 6.4% of the population was found to have a current surgically treatable condition.[17] Using the percentage of the population currently needing surgical care from Rwanda and Sierra Leone combined with the 2012 population in Sub-Saharan Africa of almost 900 million, there are between 56 million and 218 million people just in Sub-Saharan Africa needing surgical attention today! Untreated acute and chronic surgical conditions represent a significant unmet burden of disease that have major impact on the economies of these nations.[18]

Cancer. 5▶ Patients and their communities in low- and middle-income countries(LMICs) bear a much greater share of the burden of cancer than high-income countries. The dramatic increase in the proportion of reported cancer cases in LMICs is a result of population growth, aging populations, and the decreased mortality from infectious diseases. In 1970, only 15% of newly reported cancer cases worldwide were from the developing world; by 2008, this proportion rose dramatically to 58% and is expected to grow to 70% by 2030.[19] Previously thought to be a disease almost exclusive to high-income countries, nearly two-thirds of the 7.6 million cancer deaths worldwide occur in LMICs. Mortality from cancer correlates inversely with a country's economy for certain treatable cancers, including breast, testicular, and cervical cancer—LMICs have higher case fatality rates than high-income countries (Fig. 49-7).[19,20]

For example, breast cancer case fatality rates illustrate the great disparity in outcomes between regions. Case fatality rates in East Africa reach an unacceptable 59% compared to 19% in the United States.[20] In LMICs, patients have very limited access to screening. They present for care with much later stages of cancer. In Haiti, after the great earthquake, in 2010, and after the initial onslaught of orthopedic injuries, many aid organizations found themselves faced with the unmet underlying burden of disease, including late stage breast cancer and other tumors (Fig. 49-8).

Trauma. 6▶ Trauma has become a leading cause of death and disability around the world; 90% of trauma deaths occur in LMICs.[21] Approximately 32% more people die

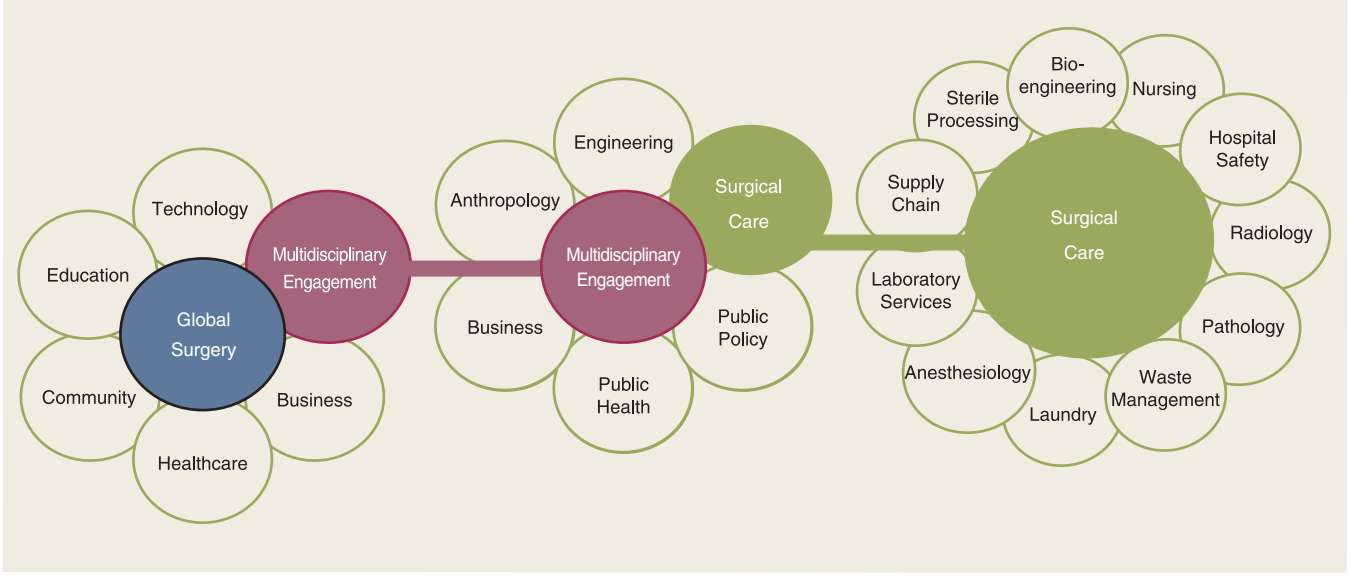

Figure 49-5. Key components of the global surgery ecosystem. (*Reproduced with permission from Intermountain Healthcare.*)

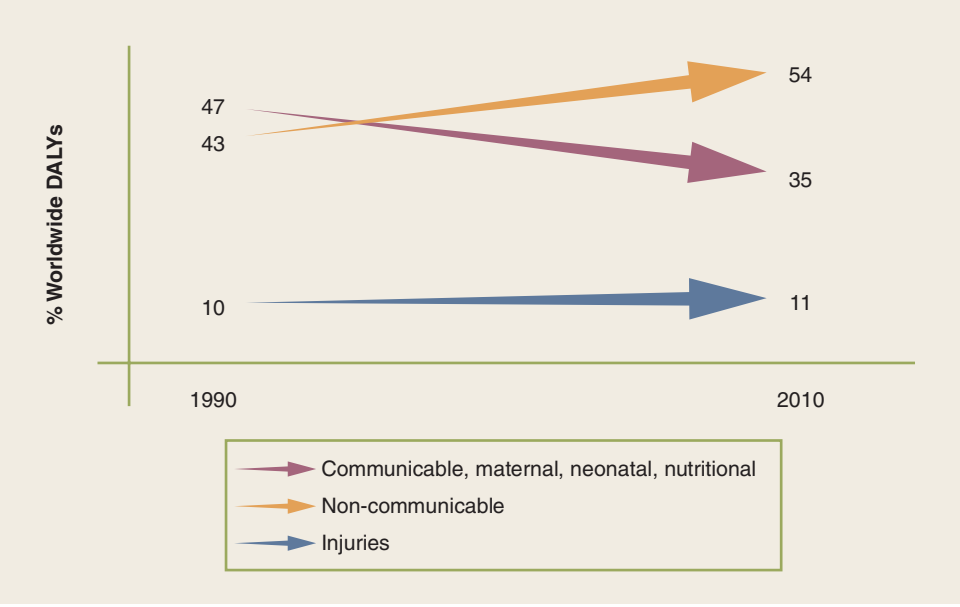

Figure 49-6. Shift in disease burden 1990–2010. (*Data from Murray CJ, Vos T, Lozano R, et al. Disability-adjusted life years (DALYs) for 291 diseases and injuries in 21 regions, 1990-2010: a systematic analysis for the Global Burden of Disease Study 2010.* Lancet. *2012;380(9859):2197-2223. Figure 49-8. Underlying unmet cancer burden in Haiti (2010).(*Photos reproduced with permission from R. Dirk Noyes, MD; layout reproduced with permission from Intermountain Healthcare.*)

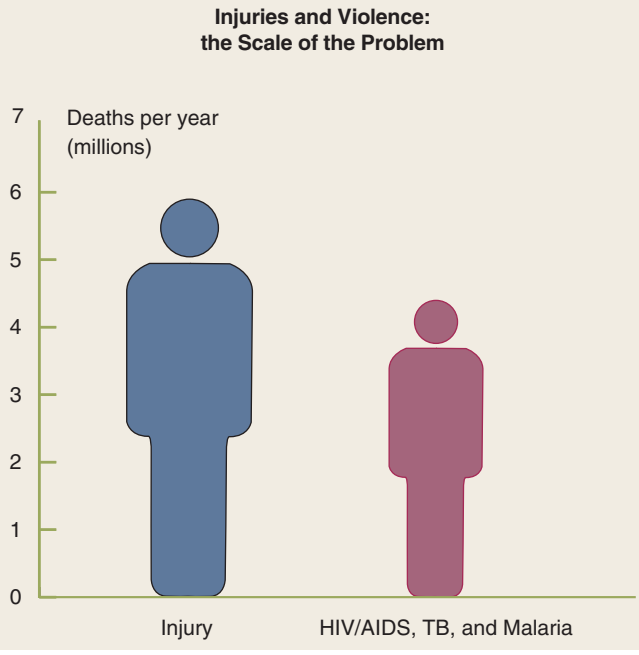

Figure 49-9. Injuries and violence: the scale of the problem. (*Injuries and violence: the facts*. Geneva, World Health Organization, 2010, *http://www.who.int/violence_injury_prevention/key_facts/VIP_key_fact_1.pdf*)

as a result from injuries than from malaria, tuberculosis, and HIV/AIDS combined representing 10% of the world's deaths (Fig. 49-9).[22,23] In the United States, a patient presenting with an injury in a rural community has a higher mortality than those from an urban setting.[24] This disparity is much more pronounced in economically disadvantaged societies where seriously injured patients from road traffic accidents are twice as likely to die compared to similarly injured patients in a high-income setting (Fig. 49-10).[22,25] Additionally, death is much more likely to occur in the pre-hospital settings for injured patients from low-income countries. The lack of integrated communication and emergency transportation systems contribute to the pre-hospital risk, while the lack of infrastructure, supplies, and personnel contribute to in-hospital mortality.

Burns. Almost 11 million people worldwide sought medical or surgical care related to burns in 2004. However, the vast majority of burned people never present for medical care. Burns represent a significant cause of death as well as disability globally.[26] The vast majority of deaths from fires (95%) occur in LMICs. Burns result in nearly 200,000 deaths each year from fires while other forms of burns, including scalds and electrical burns, represent another significant source of death and disability. Women and children in LMICs are most likely to be burned in domestic kitchens; men are more likely to be burned in the workplace. The economic and social impact from long hospitalizations and from the resulting disfigurement provides a significant negative stigma causing ostracism and rejection.

Of all the forms of trauma worldwide, burns are the only type that predominantly afflicts women and children. Southeast Asia accounts for 27% of the burn-related deaths worldwide; 70% of people dying from burns in the region are women.[27] Cooking on wood, charcoal, or low kerosene stoves also puts children at risk, particularly from scalding (Fig. 49-11). Small children in the WHO African region have triple the number of burn deaths as children worldwide. Contrast this with the United States, where more burns and burn deaths affect men.

People living in rural areas suffer disproportionately because there are fewer facilities capable of managing the acute and chronic aspects of burn management and because the population is generally poorer. Surgical grafting and management of contractures is often best done in specialized burn centers, but these are rare in LMICs. Telemedicine has been shown to be effective in managing burns and preventing complications.[28]

Human Resources

7▶ The greatest burden of disease occurs in areas where human resources—physicians, nurses, pharmacists, and other healthcare workers—are scarce (Fig. 49-12).[29] The proportion of physicians is low both in high population areas and in areas

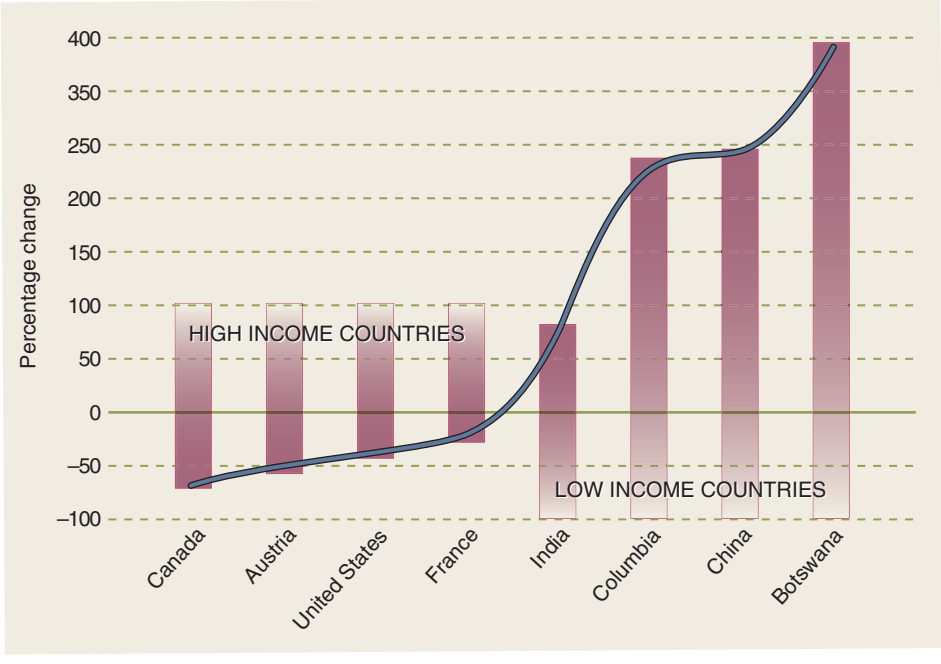

Figure 49-10. Change in traffic fatality risk (deaths/10,000 persons), 1975-1998). (*Data from Kopits E, Cropper M. Traffic fatalities and economic growth.* Accid Anal Prev. *2005;37(1):169-178. Illustration reproduced with permission from Intermountain Healthcare.*)

Figure 49-11. Domestic kitchen: risk factor for burns in women and children in LMICs. (*Reproduced with permission from James H. Kenney, Jr.*)

where the population is growing most rapidly (Fig. 49-13).[30,31] Fully trained surgeons and anesthesiologists comprise only a small proportion of the total number of the Human Resources in Health (HRH). In the Eastern Mediterranean, Southeast Asia, and Africa, HRH per 1000 people falls below the WHO minimum threshold (Fig. 49-14).[29] Many countries in Africa—for example Tanzania and Ethiopia—have only 0.6 surgeons per 100,000 population while the United States and Canada have 51 and 26 surgeons per 100,000 population, respectively.[32] To provide the same concentration of surgeons in East Africa that currently exists in Canada would require training an estimated additional 42,000 surgeons.[33]

Primary care physicians, nurses, midwives, or advanced care practitioners (ACPs) provide much of the basic surgical and anesthetic care in LMICs. Where regulations allow, "task shifting," or training ACPs to deliver surgery and anesthesia services previously allowed only under the purview of fully trained specialists, can provide expanded access to care.[34-36] Non-M.D. practitioners, variously known as *assistant medical officers* (AMOs) or "*tecnicos de cirurgia*" in Mozambique, often have extensive operative experience, including obstetrical care and are the primary providers of surgical care in a region.[37-38] Task shifting to ACPs also occurs in the United States and other countries where they fill a need otherwise unmet by specialists

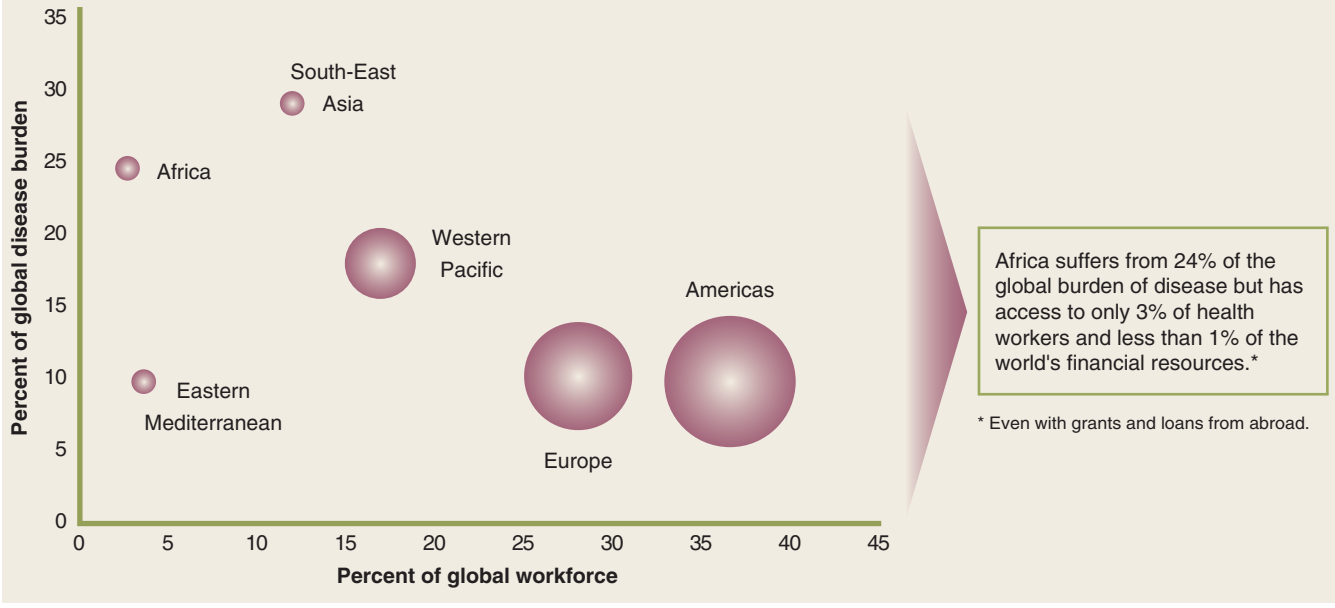

Figure 49-12. Distribution of healthcare workers by burden of disease in WHO regions. (*Redrawn from Fig 5.1, The Business of Health in Africa (29) by permission. Reproduced with permission from Intermountain Healthcare.*)

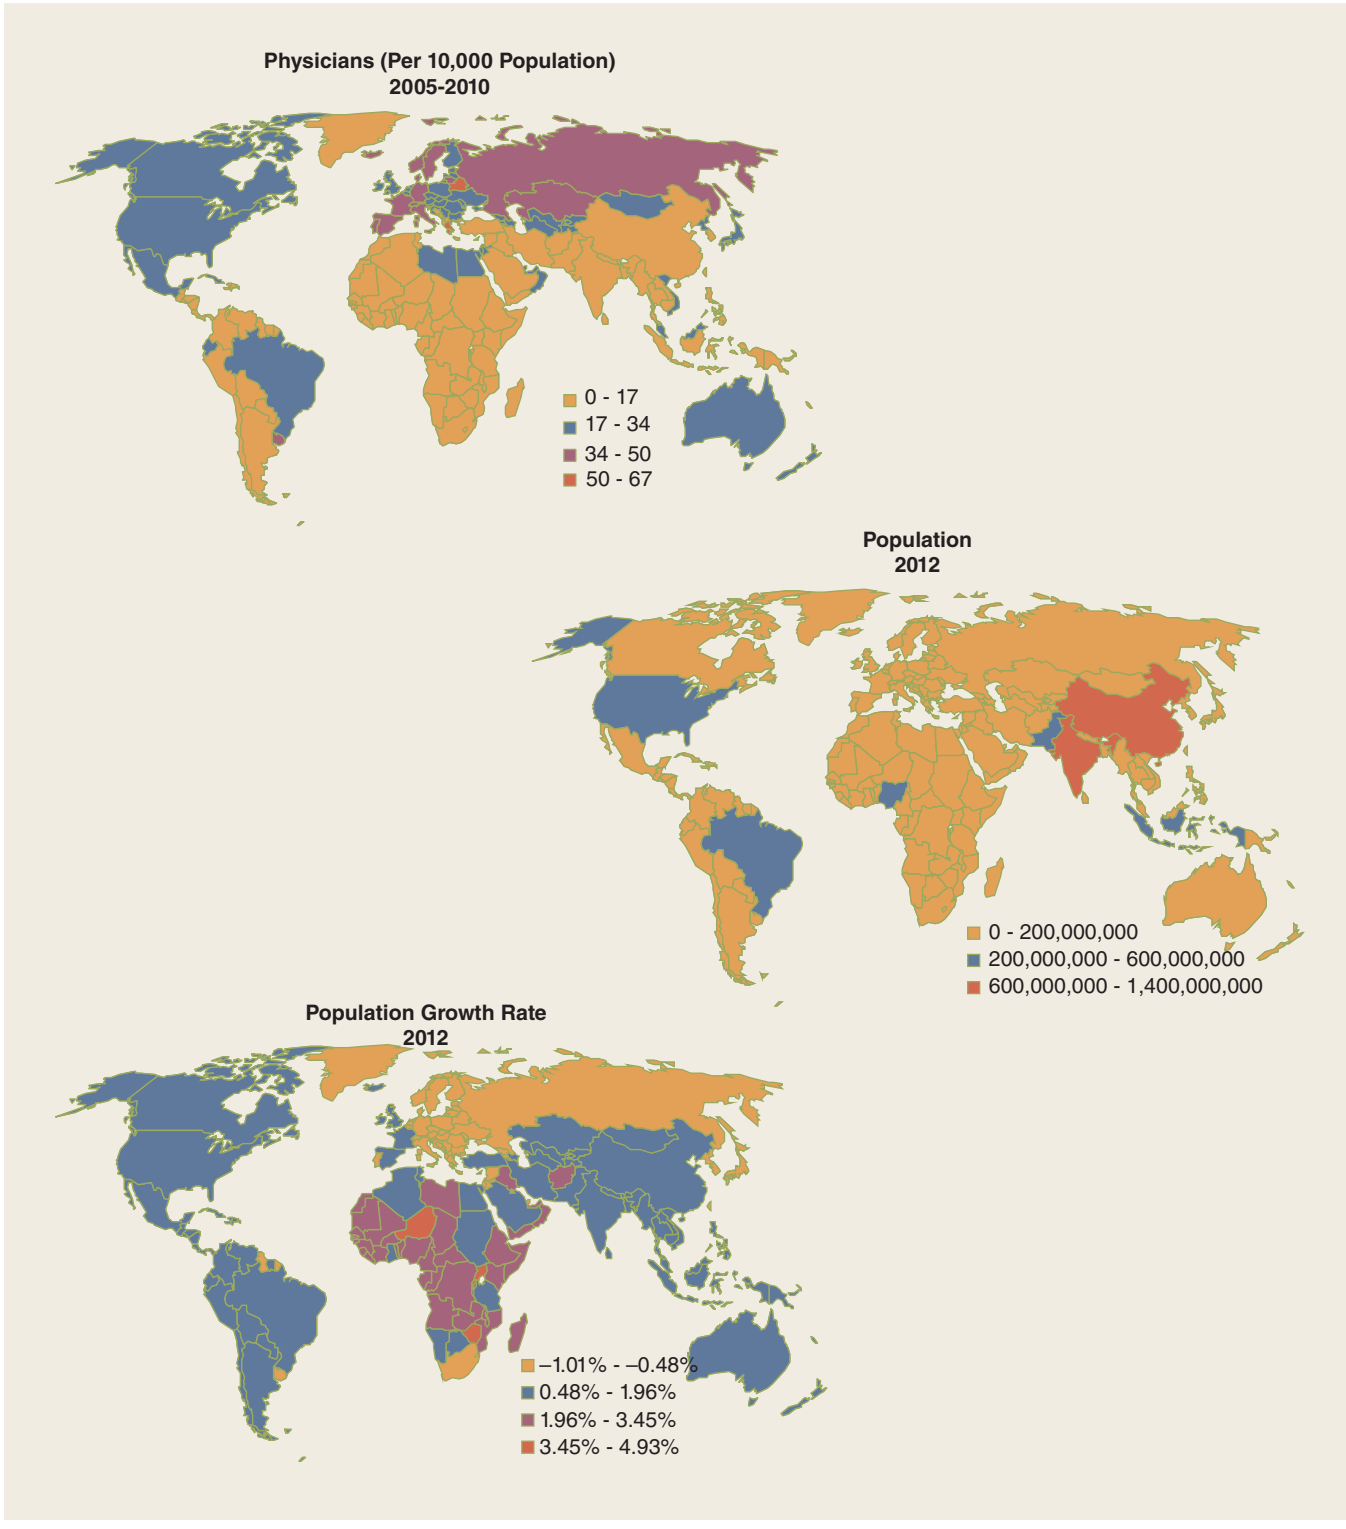

Figure 49-13. Number of physicians, world populations, and world population growth rates. (*Figure Created from Data: Number of physicians per 10,000 population, 2005-2010,WHO, World Health Statistics 2012, available at: http://www.who.int/gho/publications/world_health_statistics/2012/en/index.html. See also, WHO, Global Health Observatory, available at: http://www.who.int/gho/database/en/; Population 2012,* Sources:*CIA, The World Factbook, available at: https://www.cia.gov/library/publications/the-world-factbook/.*)

even in major tertiary care centers.[39] However, concerns about the quality of care, lack of adequate supervision, and the effect on prestige and professional development for specialists and ACPs, continue to be topics for debate.[40]

Migration of practitioners to economically and culturally favorable locales is universal and not restricted to low-resource countries.[41] However, the net impact on poor countries is greater. In a 2004 study, more than 23% of U.S. physicians received their medical training from other countries; of these 64% were from low-income countries.[42] Investments in training greater numbers of doctors in these countries, including surgical specialists, have been only partially successful in meeting the demand in poor countries. Until economic conditions improve or opportunities for professional development increase,

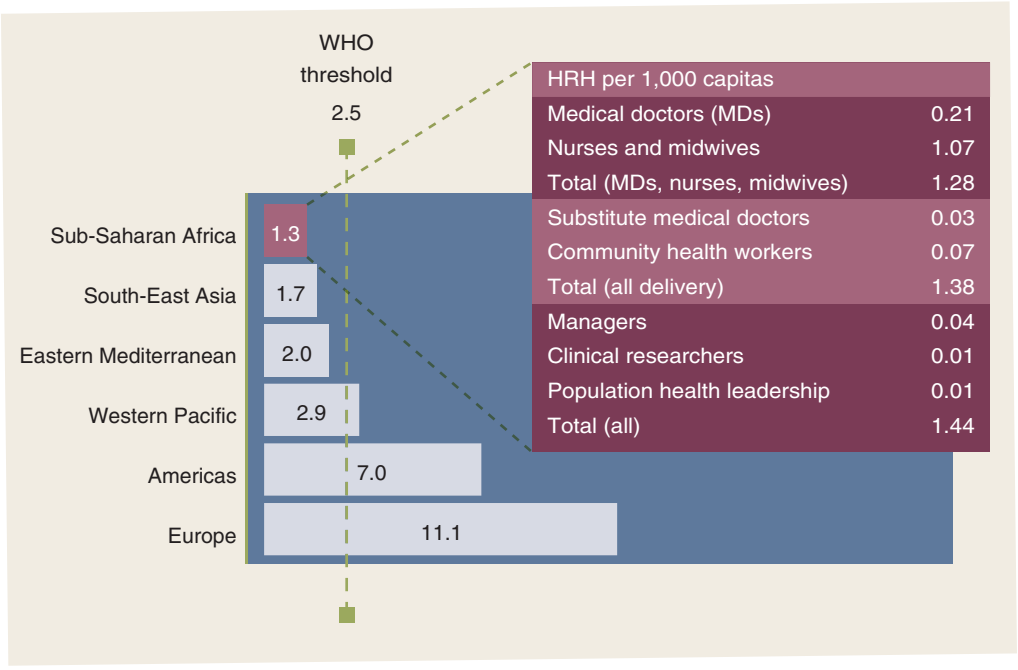

Figure 49-14. Human resources for health (HRH) by WHO region, 2006. (*Redrawn from Fig 5.2, The Business of Health in Africa (29) by permission. Reproduced with permission from Intermountain Healthcare.*)

and incentives enticing migration of health care workers to high-income countries abate, it is unlikely that the most skilled practitioners will remain in resource-poor areas beyond their immediate obligations.[43-47]

STRATEGIES FOR DEVELOPMENT

Initiatives for Outreach and Engagement

Many models for outreach and engagement have had a positive impact on the accessibility of surgery. Organizations participating in outreach are guided by a wide range of motivations and resources (Fig. 49-15). Some organizations are purely humanitarian and service oriented; others are primarily educational. Some even use the promise of healthcare to advance political, religious, or personal agendas.

Responding to the challenges of disparities, new generations of students, faculty, philanthropists, private industry leaders and policy makers have demonstrated a growing passion to address global surgery as part of global health. Prior to 1984 only 0.32% of physicians and 0.12% of nurses were involved in international health (either paid or volunteer).[48] Recently, interest in global health has exploded among medical students in the United States. A 2009 survey indicated that 25% of U.S. medical students have traveled to LMICs for clinical and research electives. At some medical schools the number has risen to over 50%.[49,50] In 2004, 40% of medical students in the United Kingdom spent their 6 to 12 week elective rotation in developing countries.[51] A structured questionnaire was administered anonymously to all American College of Surgeons resident members. Approximately 94% of the respondents were general surgery residents, and 92% were interested in an international elective with many planning to volunteer in the future.[52]

Many patients have benefited from the multitude of service-oriented volunteer "missions" providing much needed surgical care that would otherwise have been unavailable. While volunteerism and medical missions are laudable activities, they are not a sustainable solution to long-term manpower shortages for health.[53] Comprehensive initiatives are also necessary to engage local healthcare professionals and organizations, governments, and academic institutions to build capacity at home.[54]

International Organizations

United Nations (UN). Committed to maintaining international peace, developing friendly relations between nations, and promoting better standards of living (conquering hunger, disease, and illiteracy) and human rights, representatives from 51 nations in 1945 signed the United Nations Charter at the United Nations Conference on International Organization held in San Francisco, California.[55] There are now 193 member states.[56] The UN promotes a social justice agenda advocating for worldwide health, engagement of philanthropies and civil society in global health initiatives, and supports the Millennium Development Goals (MDGs).

Millennium Development Goals (MDGs). Leaders from 189 countries gathered at the UN headquarters in September 2000 and agreed on eight specific "Millennium Development Goals" (Table 49-1).[57] Some have argued that strengthening basic surgical care at district level hospitals is critical to reaching MDGs 4, 5, and 6 (reducing child and maternal mortality and halting and reversing the spread of AIDS).[6,58] In poor countries, the enormous shortfalls in infrastructure, and human and material resources severely limits the capabilities to provide access to life-saving and life-changing services such as timely Cesarean-section, control of peri-partum hemorrhage, appropriate care for pediatric trauma, and treatment for a multitude of congenital diseases.[3,59-64] While the evolution of public policy has been slow to accept surgical care as integral to poverty reduction and public healthcare, surgeons are actively campaigning for and joining the process of negotiating for inclusion of surgical care development into the new post-2015 to 2030 MDGs.[65]

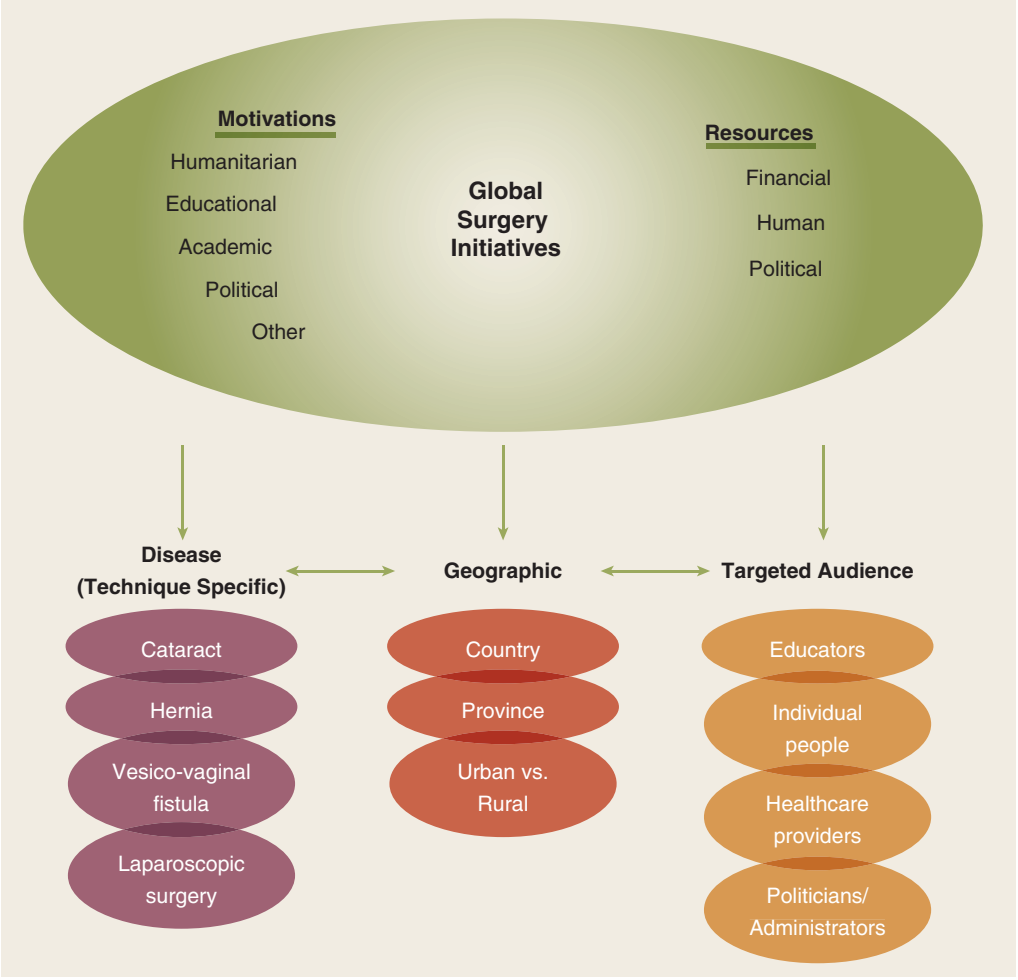

Figure 49-15. Global surgery initiatives. (*Illustration reproduced with permission from Intermountain Healthcare.*)

World Health Organization (WHO). The initial UN Conference in 1945 voted to establish a new international health organization. The Constitution of the World Health Organization (WHO) was approved and ratified in 1948.[55] The first World Assembly in 1948 established malaria, tuberculosis, venereal diseases, maternal and child health, sanitary engineering, and nutrition as WHO priorities. One of the WHO's greatest public health stories is the worldwide eradication of smallpox that began with the USSR proposal for the WHO-led program in 1958 culminating in the last identified case in Somalia in 1977.

Table 49-1

Millennium development goals 2000–2015

1. Reduce by half the number of people who suffer from hunger and whose income is < $ 1/ day
2. Provide universal primary education
3. Promote gender equality
4. Reduce mortality rate for children < 5 years by two-thirds
5. Reduce maternal mortality rate by three quarters
6. Halt and reverse the spread of AIDS, malaria, tuberculosis, and other major diseases
7. Improve the environment
8. Strengthen the global partnership for development.

Data adapted from Millennium Development Goals. http://www.undp.org/content/undp/en/home/mdgoverview/

While the disease burden from communicable diseases has abated in large part from these successful international cooperative interventions, little has been done to address the growing global burden of surgical disease. Despite the laudable 1978 Declaration of Alma Alta that expressed the need for urgent action for the world community to protect and promote the health for all people, the declaration did so by crowning primary health care as the key to achieving the goal of health for all—which was then accepted by the member countries in the World Health Organization.[66] Although the Alma-Ata slogan "Health for all by 2000" did not materialize, it did galvanize efforts for global partnerships for healthcare improvements and poverty reduction.

The Violence and Injury Prevention Program (VIP) and the Global Initiative for Emergency and Essentials Surgical Care (GIEESC) are two programs related to surgery within the WHO that began before 2008. But, as a response to a growing recognition of the significant unmet surgical need, in 2008, the WHO for the first time included basic surgery as a component for community primary health care(Fig. 49-16).[67]

The Global Initiative for Emergency and Essential Surgical Care (GIEESC). The Clinical Procedures (CPR) team in the WHO Department of Essential Health Technologies (EHT) convened a multidisciplinary group of experts from various surgical disciplines, professionals and civic leaders from national and international organizations, and representative from various WHO departments in December 2005 in Geneva, Switzerland, to formally organize the GIEESC.[68] GIEESC's main aim was

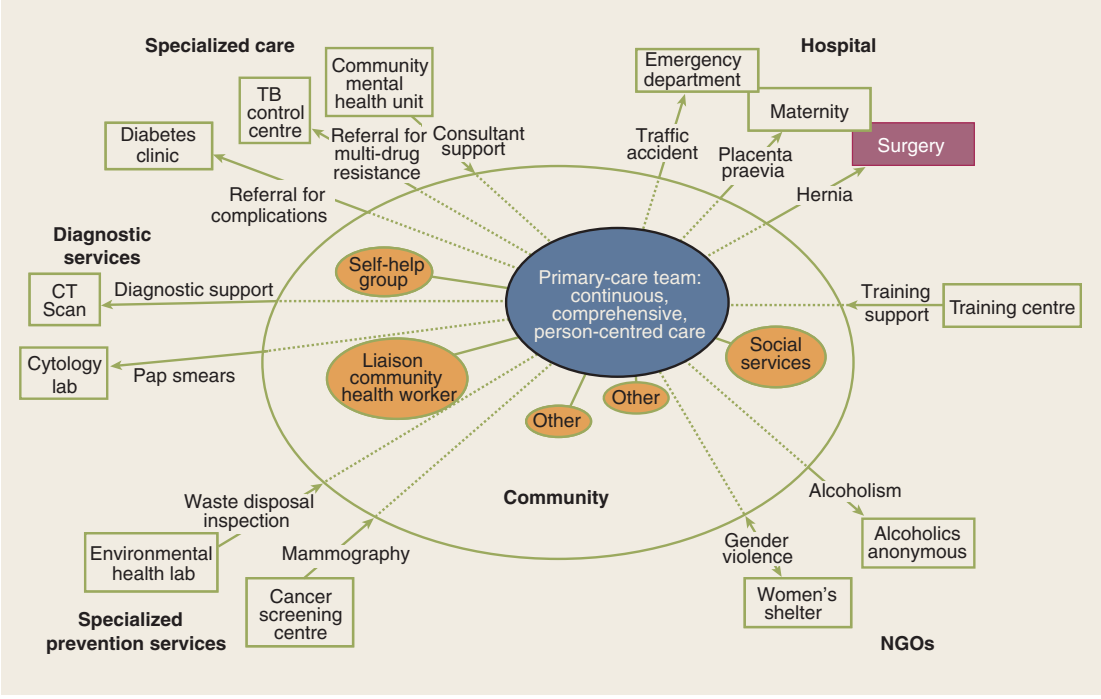

Figure 49-16. Emergency and essential surgery: an integral component of primary care. (*The World Health Report 2008, Primary Health Care Report, Now More Than Ever, p. 55, Figure 3.5. http://www.who.int/whr/2008/en/*)

to assist member states with capacity strengthening in the safe and appropriate use of emergency and essential surgical care (procedures, equipment) at resource-limited healthcare facilities through training and education programs. The training program was built around the WHO "Integrated Management of Emergency and Essential Surgical Care (IMEESC)" tool kit.[69] The tool kit included best practice protocols, guidelines on policies, training curriculum, emergency equipment, teaching slides, and monitoring and evaluation instructions. Additionally, low-cost editions of the manual *Surgical Care at the District Hospital* have been made available in local languages. A Mongolian edition facilitated early expansion of GIEESC throughout the country. Mongolia has improved basic infrastructure, human resources and capabilities; and the use of the tool kit system has led to its incorporation into the countrywide healthcare plan.[70] (**Box:** Mongolia GIEESC)

Mongolia GIEESC

The WHO situational analysis tool developed in 2007 to assess the availability of emergency and essential surgical care (EESC) at individual health facilities has been utilized in 35 different countries documenting the limited infrastructure, human resources, procedures, equipment and supplies available for even basic EESC.[69] For example, there were no trained surgeons or anesthetists at 44 first referral hospitals in Mongolia.[3] Only 66% of the facilities had electricity and 45% had running water (Fig. 49-17).

Most facilities lacked any policy for EESC, disaster preparedness, basic equipment to provide EESC, or any access to training for EESC. Adopting a health systems strengthening approach to rectify these glaring deficiencies, Mongolia implemented a nationwide EESC program involving 14 of the 21 provinces (Aimags) from 2004 to 2010 (Fig. 49-18).[70] In six years, dramatic improvements in short-term process measures were identified using the WHO Monitoring and Process form: 57.1% increase in availability of emergency rooms; 59.1% increase in the supply of emergency tool kits; and a 73.6% increase in the recording of emergency cases (Figs. 49-19 and 49-20).[70] More important, countrywide morbidity and mortality dropped significantly (Fig. 49-21). [71]

Violence and Injury Prevention (VIP). The Violence and Injury Prevention (VIP) program promotes numerous activities to assist countries to prevent and mitigate the consequences of violence and injury.[72] While injury prevention is paramount, VIP provides guidance for strengthening trauma systems in countries of all economic levels to improve emergency care and rehabilitation. VIP also encourages development of systematic data collection and analysis to better guide appropriate interventions. Prevention programs include the WHO Helmet initiative while the Essential Trauma Care Project (ESTC) creates standards for the care of injured patients and promotes systematic capacity building.

WHO Safe Surgery Saves Lives Initiative. Surgeons have always sought ways to prevent peri-operative complications. Aseptic technique, one of the greatest forms of prevention in surgical care, requires vigilant reinforcement to prevent serious wound infections. In resource-limited areas inadequate pre-, intra-, and post-operative monitoring, lack of critical medications, and poor documentation can be severely lacking placing patients at increased risk for serious complications. The WHO Safe Surgery Saves Lives Initiative is a worldwide attempt to prevent peri-operative complications.[73]

Deaths from surgery occur at 0.4% to 0.8% globally; however, they may exceed 5% to 10% in developing countries. There are about 1 million deaths and 7 million disabling complications related to surgery worldwide, 50% of which are estimated to be preventable. The WHO Safe Surgery Saves Lives initiative targets preventable surgical injuries.[73] The initiative identified 10 basic and essential objectives that can help prevent peri-operative injuries (Table 49-2).[74] A three-stage simple checklist (initiated as the patient entered the operating room, just before the procedure, and just prior to the patient leaving the room) implemented in 8 countries from high-, middle-, and low-income countries found a 50% reduction in the failure to meet basic safety standards resulting in a 50 % decrease in mortality (Fig. 49-22).[75]

Table 49-2

Ten basic and essential objectives for safe surgery (WHO*)

1. Operate on the correct patient at the correct site
2. Use method known to prevent harm from anesthetic administration, while protecting the patient from pain
3. Recognize and effectively prepare for life-threatening loss of airway or respiratory function
4. Recognize and effectively prepare for risk of high blood loss
5. Avoid inducing any allergic or adverse drug reaction known to be a significant risk for the patient
6. Consistently use method known to minimize risk of surgical site infection
7. Prevent inadvertent retention of instruments or sponges in surgical wounds
8. Secure and accurately identify all surgical specimens
9. Effectively communicate and exchange critical patient information for the safe conduct of the operation
10. Establish routine surveillance of surgical capacity, volume, and results

Global Surgery and Public Health

8▶ Surgical care is increasingly recognized as an integral component of public health. Traditional public health teaching portrays surgery as the antithesis of public health: treating the individual instead of the community, reactionary instead of preventative, and too expensive especially for countries with developing economies. Yet in reality, surgery and public health priorities overlap in many areas (Fig. 49-23). For example, providing *access* to obstetrical care or birth attendants for every delivery could *prevent* the majority of vescio-vaginal fistulas and markedly decrease the most common cause of maternal death—hemorrhage—for entire communities.

Even after Learmonth presented his landmark lecture in 1949 "The Contributions of Surgery to Preventive Medicine" at the University of London's Health Clark Lecture series, surgery has been neglected as a component of public health.[7,76] The World Bank, in the 2006 *Disease Priorities, 2nd edition*, included its first chapter on surgery. An entire volume dedicated to surgical care is planned for the 3rd edition. There are three significant developments helping to accelerate the integration of surgery and public health:

1. Improved understanding of the burden of surgical disease and its significant component of the overall burden of global disease;
2. Recognition that surgery has a primary, secondary, and tertiary preventative role; and
3. Documentation that surgical care can be cost-effective for community-based healthcare.

Assigning Disease Priorities. Global surgery interventions can be prioritized to identify those conditions in which clinicians and public health professionals should collaborate most closely—targeting those diseases that impose the largest burden on a society and have a highly successful surgical outcome (Table 49-3).[69,77] Levels defining public health burden, success, and feasibility have not been precisely defined. However, four broad, high-priority areas where surgery has an important role for public health interventions include: trauma care; obstetrical emergencies; acute-surgical emergencies; and nonacute surgical conditions that significantly affect the quality of life (Table 49-4).[10]

Trauma Care. The Essential Trauma Care Project (EsTC) begun in 2001 is a collaboration effort between the International Association for Trauma Surgery and Intensive Care, an integrated society within the International Society of Surgery-Societe-Internationale Chirurgie (ISS-SIC) and the World Health Organization (WHO), specifically the Violence and Injury Prevention unit. The project culminated in a document that identified 11 core Essential Trauma Care services (identified as the "rights of the injured patient") that should be available at all levels of healthcare facilities (Table 49-5).[78] In addition, the document delineated 260 human and physical resources that should be available based on the type of facility (Table 49-6).

The EsTC recommendations provide a cost-effective framework for LMICs to improve their trauma care. These recommendations have been used as a planning guide and as an advocacy statement. To catalyze strengthening trauma and

Surgical Safety Checklist

Before induction of anaesthesia (with at least nurse and anaesthetist)	Before skin incision (with nurse, anaesthetist and surgeon)	Before patient leaves operating room (with nurse, anaesthetist and surgeon)
Has the patient confirmed his/her identity, site, procedure, and consent? ☐ Yes	☐ **Confirm all team members have introduced themselves by name and role.**	**Nurse Verbally Confirms:** ☐ The name of the procedure
Is the site marked? ☐ Yes ☐ Not applicable	☐ **Confirm the patient's name, procedure, and where the incision will be made.**	☐ Completion of instrument, sponge and needle counts
Is the anaesthesia machine and medication check complete? ☐ Yes	**Has antibiotic prophylaxis been given within the last 60 minutes?** ☐ Yes ☐ Not applicable	☐ Specimen labeling (read specimen labels aloud, including patient name)
Is the pulse oximeter on the patient and functioning? ☐ Yes	**Anticipated Critical Events** **To Surgeon:** ☐ What are the critical or non-routine steps? ☐ How long will the case take? ☐ What is the anticipated blood loss?	☐ Whether there are any equipment problems to be addressed
Does the patient have a: **Known allergy?** ☐ No ☐ Yes **Difficult airway or aspiration risk?** ☐ No ☐ Yes, and equipment/assistance available **Risk of >500ml blood loss (7ml/kg in children)?** ☐ No ☐ Yes, and two IVs/central access and fluids planned	**To Anaesthetist:** ☐ Are there any patient-specific concerns? **To Nursing Team:** ☐ Has sterility (including indicator results) been confirmed? ☐ Are there equipment issues or any concerns? **Is essential imaging displayed?** ☐ Yes ☐ Not applicable	**To Surgeon, Anaesthetist and Nurse:** ☐ What are the key concerns for recovery and management of this patient?

This checklist is not intended to be comprehensive. Additions and modifications to fit local practice are encouraged.

Based on the WHO Surgical Safety Checklist
http://whqlibdoc.who.int/publications/2009/9789241598590_eng_Checklist.pdf

Figure 49-22. Surgical safety checklist. (*WHO surgical safety checklist. 2009, http://whqlibdoc.who.int/publications/2009/9789241598590_eng_Checklist.pdf.* © World Health Organization 2009 All rights reserved.)

emergency care in low-and middle-income countries, in 2007, the World Health Assembly (WHA) adopted a resolution on Emergency Care Systems (Resolution WHA 60.22).[79,80] This first-ever WHA resolution dedicated specifically to trauma care highlights the importance accorded by world governments in caring for their injured.

Obstetrical and Other Acute Surgical Emergencies. Reduction of maternal deaths and long term disability are high priorities for the international community.[81] Despite the 47% reduction in maternal deaths from 1990 to 2010, many women—mostly in LMICs—still die daily from preventable causes related to pregnancy and childbirth.[82] The global maternal mortality ratio (the number of maternal deaths per 100,000 live births) declined by only 3.1% per year which is significantly less than the 5.5% reduction necessary to achieve MDG 5—to decrease maternal mortality by 75% by 2015.[82] For every maternal death, 30 women are incapacitated by chronic problems that reduce their quality of life and ability to care for their families. High priority surgical procedures to improve maternal health include Cesarean-section, hysterectomy for postpartum bleeding and uterine rupture, management of ectopic pregnancy, and dilatation and curettage.[77]

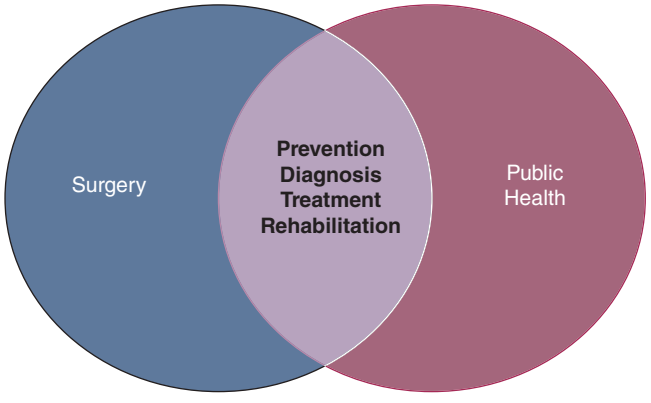

Figure 49-23. Overlapping priorities of surgery and public health. (*Illustration reproduced with permission from Intermountain Healthcare.*)

About 90% of other acute surgical emergencies could be addressed by developing the capability to care for the 10 most common acute surgical conditions in any local region. While a few types of disease processes vary by geographical location, there are many that are universal, including appendicitis, strangulated hernia, small bowel obstruction, perforated peptic ulcer, fractures, lacerations, and wounds.

Nonacute Surgical Conditions. Even common nonacute conditions can have significant impact on the quality of life. Hernias can prevent otherwise healthy individuals from working, especially in societies where the economy relies heavily on manual labor. Cleft lip and cleft palate deformities interfere with the ability to speak or eat properly and predispose affected individuals to chronic ear infections leading to hearing loss. Many live in isolation because social ostracism prevents them from attending school, marrying, or holding jobs.[83] Plastic surgeons who pioneered global outreach for reconstructive procedures for

Table 49-3

Prioritization of surgical conditions

PRIORITY*	PUBLIC HEALTH BURDEN	SURGICAL PROCEDURE SUCCESSFUL	COST-EFFECTIVE AND FEASIBLE TO PROMOTE GLOBALLY
1	High	Highly	Highly
2	Moderate	Moderately	Moderately
3	Low	Neither highly or moderately	Low

*Priority one implies that all three conditions must be met. The priority should be shifted to 2 or 3 if any of the conditions are moderate or low.
Data adapted from: *Mock C, et al.* Developing priorities for addressing surgical conditions globally: furthering the link between surgery and public health policy. *World J Surg.* 2010;34(3): 381–385.

cleft lip and palate opened the door for subsequent outreach by other specialties, including ophthalmology, orthopedics, general surgery, urology, and dentistry.[84-86]

The most common form of blindness is caused by cataracts. Cataracts decrease the quality of life and the socioeconomic status for both the blind person and his family. The fact that 90% of blind people no longer work, places extra burdens on the family members who care for them.[87] The Himalayan Cataract Project (HCP) is a highly successful initiative focusing on cataracts in Asia and Africa. HCP priorities and measurable outcomes illustrates how combining key public health concepts with a comprehensive approach to surgical care creates a model for curing disease, building economies, and delivering hope in resource-poor areas.[9] (**Box**: The Himalayan Cataract Project: A Sustainable Public Health Approach for Curing Blindness)

Cancer Initiatives

Surgery for cancer in public health plays a role not only for curative surgery, but also for early diagnosis, prevention, and palliation.[19,91-93] Solid tumors, in their early stages, presents insidiously as a nonacute surgical problem. Due to cancer's recent recognition as a leading cause of death, cancer has been identified as a health priority in LMICs. Most solid tumors are incurable without surgery and at a minimum require surgical excision of the primary lesion.[91]

It is often not appreciated that surgeons provide a significant amount of primary care and are the principle providers involved in endoscopic screening and treatment of gastrointestinal tumors in LMICs. In countries without specialized services, low-cost and effective treatment options combining early prevention and treatment with off-patent drug use have led to coverage of cancer treatment in several middle-income countries' national health insurance plans.[19] Cancer care provides significant opportunity for including surgery in community-wide public health programs as a high priority according to the prioritization model; cancer has a high public health burden, is treated with highly successful procedures, and can be cost-effective and feasible globally. In 2009, a coalition of leaders in cancer care and public health organized the Global Task Force on Expanded Access to Cancer Care and Control in Developing Countries (GTFCCC).[94] GTFCCC's mission is to expand access

Table 49-4

The role of surgery for public health strategies

Trauma care	Prevention of death and chronic disability by the provision of timely, expert, and complete surgical care
Obstetrical emergencies	Timely surgical intervention in obstructed labor, in pre- and post-partum hemorrhage, and other obstetrical complications
Acute surgical emergencies	Provision of competent surgery to treat a wide range of emergency abdominal and nonabdominal conditions
Nonacute surgical conditions	Surgical care for several elective conditions that have a significant effect on the quality of life such as cataract, otitis media, clubfoot, and hernias

Data adapted from Debas, HT, et al, *Surgery, in Disease Control Priorities in Developing Countries*. 2nd ed. Jamison DT, Breman JG, Measham AR et al (eds.) New York: Oxford University Press for The World Bank, 2006, p. 1245–59.

Table 49-5

Essential trauma care services

1. Obstructed airway appropriately maintained
2. Impaired breathing supported
3. Pneumothorax and hemothorax promptly diagnosed and treated
4. Bleeding promptly stopped (internal or external)
5. Shock recognized and treated appropriately (I.V. fluids)
6. Timely decompression of space occupying lesions to prevent secondary brain injury
7. Abdominal injuries diagnosed and promptly repaired (intestinal injuries and others)
8. Disabling extremity injuries corrected
9. Potentially unstable spine injuries identified and managed (early immobilization)
10. Minimize consequences of injuries by appropriate rehabilitative services
11. Medication to provide above services and relieve pain readily available

Data adapted from Mock C, Joshipura M, Goosen J, Maier R. Overview of the Essential Trauma Care Project. *World J Surg*. 2006;30(6): 919–929.

Table 49-6

Airway management recommendations for physical and human resources based on type of facility(sample from EsTC*)

	FACILITY LEVEL			
KNOWLEDGE AND SKILLS	BASIC	GENERAL PRACTITIONER	SPECIALIST	TERTIARY
Assessment of airway compromise	E	E	E	E
Manual maneuvers (chin lift, jaw thrust)	E	E	E	E
Insertion of oral or nasal airway	D	E	E	E
Endotracheal Intubation	D	D	E	E
Equipment and supplies				
Oral or nasal airway	D	E	E	E
Laryngoscope	D	D	E	E

The Himalayan Cataract Project (HCP): A Sustainable Public Health Approach for Curing Blindness

According to the WHO criteria, 180 million people worldwide are visually disabled. Of that population, 45 million are classified as bilaterally blind; 90% live in the developing world where poor water quality, lack of sanitation, malnutrition, and inadequate services cause a higher incidence of eye disease.[87] The most common cause of avoidable blindness in LMICs is cataract (50%). Nepal has one of the highest incidences of cataracts due to increased exposure to ultraviolet sunlight encountered at its higher elevations; 70% of curable blindness in Nepal is due to cataracts.[88]

In 1995, Sanduk Ruit joined forces with Geoffrey Tabin to establish the Himalayan Cataract Project (HCP). In the early 1990's, difficult geography and lack of transportation, the cost of the intraocular lens, and lack of trained ophthalmologists, assistants, and nurses limited access to cataract surgery for the poor.

HCP developed and defined six priorities each with an associated public health principle and outcome measurements that provided the basis for assessing success and for implementing change (Fig. 49-24). HCP's care model targeted the entire population of blind people with cataracts regardless of the ability to pay. Since most of the potential patients lived in remote areas, HCP found it imperative to take cataract surgery to the local communities. The Tilganga Institute of Ophthalmology (TIO) in Katmandu, Nepal, has served as a base from which over 100 doctors and100 ophthalmic assistants and nurses have been trained.[89] Through the TIO and its outreach programs, over 2,573,000 people have been screened and more than 172,000 eye surgeries have been performed since 1994 (Fig. 49-25).[89]

The TIO developed an ophthalmology residency training program implementing standards set forth by the American Academy of Ophthalmology. In addition to the formal residency program for ophthalmologists, HCP established training programs for community eye care workers in a three-year Ophthalmic Assistant Training Program.

Ruit developed an innovative suture-less technique for cataract surgery yielding equivalent results to those in developed countries but also reproducible in resource-constrained areas. By redesigning the intraocular lens and mass producing it locally in Nepal for U.S. $4.00, Ruit and Tabin provided a low cost alternative to the higher-priced lens produced in developed countries. A local business—the Fred Hollows Intraocular Lens Factory—mass produces the lenses and helps support the local economy by introducing a new sustainable business locally.[90]

HCP also designed a socially acceptable method for cost-recovery that involves a sliding scale for payment: 45% of patients pay U.S. $120.00; 20% pay a smaller amount based on their economic situation; and 35% receive cataract surgery for free.

HCP Priorities	Public Health Principles	Implementation
Humanitarian	Accessible	Entire Population Care at Local Level
High Quality	Appropriate	Care Comparable to Western Standards Disease with High Incidence/Prevalence
Innovation	Disruptive Technology	Designed $4 lens Local Business
Direct Impact	Sustainable Growth	Skills Transfer Building Infrastructure
Affordability	Affordable	Delivery Model $20 Cost/Cataract
Replication	Sustainability	Meet Needs of Current Population Culturally and Economically Acceptable

Figure 49-24. Himalayan cataract project priorities, public health principles, and outcome measurements. (*Redrawn from Himalayan Cataract Project and Tilganga Eye Center, (Cureblindness.org) (82-84) by permission. Illustration reproduced with permission from Intermountain Healthcare.*)

to cancer prevention, detection, and care in LMICs. Successful partnerships have already been entered into Haiti, Rwanda, Mexico, Malawi, and Jordan.

The Preventive Role of Surgery. Surgery plays a significant role at all levels of prevention of disease (Table 49-7). Trying to disassociate treatment from prevention presents challenges. Treatments can also be a form of prevention. For example, one of the root causes for the development of a vesico-vaginal fistula is lack of access to appropriate peri-partum care. Expeditiously performing a Cesarean-section (a form of secondary prevention) for obstructed labor primarily prevents the development of vesico-vaginal fistulas (primarily preventing the development of a different disease).

9▶

The surgeon's role for disease prevention in the developing world is in its infancy of realization. Diseases commonly present in very late stages in LMICs and in disadvantaged populations in developed countries. Many morbid conditions could have been cured while localized in their earlier stages and likely eradicated by a local surgical procedure. Early recognition and treatment of surgically correctable diseases is a critical preventive role for surgery. Many surgical procedures are not only a form of tertiary prevention, but are also forms of primary prevention (Table 49-8).[91]

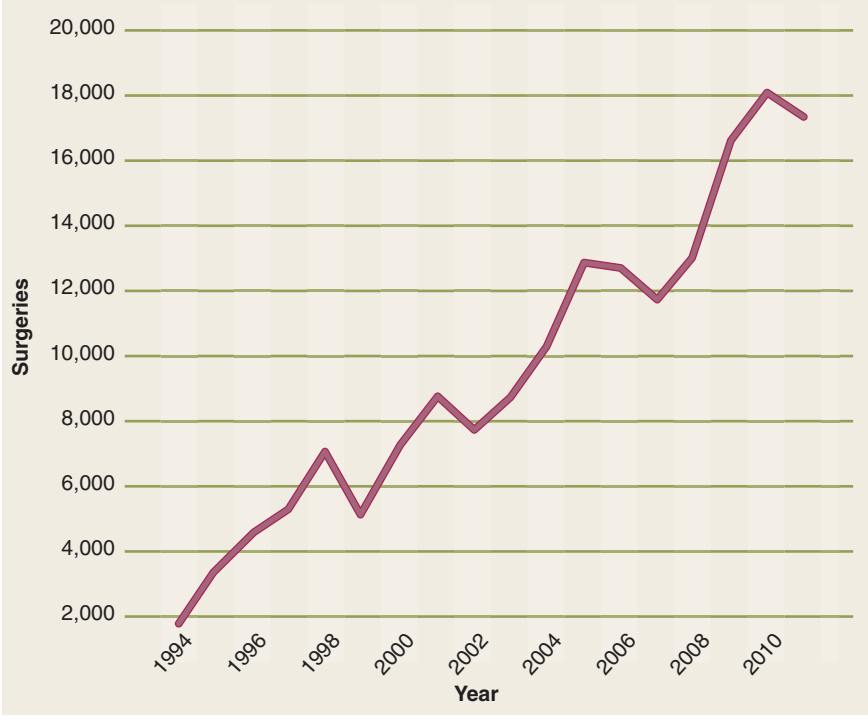

Figure 49-25. Eye surgeries Tilganga eye center and outreach. (*Redrawn from Himalayan Cataract Project and Tilganga Eye Center, (Cureblindness.org) (82-84) by permission. Illustration reproduced with permission from Intermountain Healthcare.*)

Table 49-7

Prevention strategies

PREVENTION STRATEGY	TARGET	GOAL
1. Primary	Root causes of disease	Eliminate or reduce risk of developing illness
2. Secondary	Illness or disease at earliest stages	Limit progression of disease
3. Tertiary	Disease at later stages	Cure or limit the effect of existing disease

Cost-effectiveness of Surgical Care. Funders in healthcare look for measurable return on their investments. While comparison of outcomes and objective measures would be ideal, reality demonstrates that healthcare budgets more commonly are dictated by politics rather than actual need. Nevertheless, in a world of limited resources and tightening budgets for healthcare, cost-effective analysis of various options for intervention are critical for policy makers. Comparing various options that have different outcomes is an approach called cost-utility analysis (CUA). Surgical interventions can be evaluated by specific diseases or conditions, or by systems or services required to support the delivery of surgical care. In 1990, the World Bank defined the Disability Adjusted Life Year (DALY) as the sum of Years of Life Lost (YLL) due to premature mortality in the population and the Years Lost due to Disability (YLD) for people living with the health condition or its consequences. (DALY = YLL + YLD). Evaluating the cost per DALY averted is one approach for comparing the cost-utility between medical and surgical interventions. Recent surgical cost/DALY studies identifying the cost-effectiveness of various types of surgical care have allowed surgical initiatives to be considered when prioritizing public health initiatives.

10▸

The World Bank arbitrarily defined U.S. $100/DALY averted per day in low-income countries as highly cost-effective. Compared to other public health initiatives, developing basic and emergency surgical care at the district level hospital is as cost-effective as or more so than typical public health programs such as retroviral treatments for HIV/AIDS or immunization for measles (Table 49-9).[95-99]

Using the WHO's cost-effectiveness standards, investing in emergency obstetrical systems, including timely Caesarean delivery can also be considered "highly cost-effective" for 48 of 49 countries in which there are currently inadequate numbers of Cesarean deliveries[100,101]. The median cost per DALY averted by Cesarean-section was $304. In addition, the cost-benefit ratio in 46 of 49 countries was >1, suggesting that investment in Caesarean delivery is a viable economic proposition.

Table 49-9

Cost effectiveness of public health measures

PUBLIC HEALTH INTERVENTION	COST-EFFECTIVENESS (U.S. $/DALY* AVERTED)
Rapid impact package for neglected tropical diseases	2–9[a]
Measles vaccination	5[a]
Basic surgical services district hospital	11–33[a]
Antiviral therapy for HIV	300–500[a]
Lichtenstein hernia repair with mosquito net mesh Western Ghana	12[b]
Lichtenstein hernia repair with polypropylene or mosquito net Ecuador	78[c]
Emergency systems for Caesarean delivery	304[d]
Cataract surgery	57[e]

*DALY: Disability Adjusted Life Year

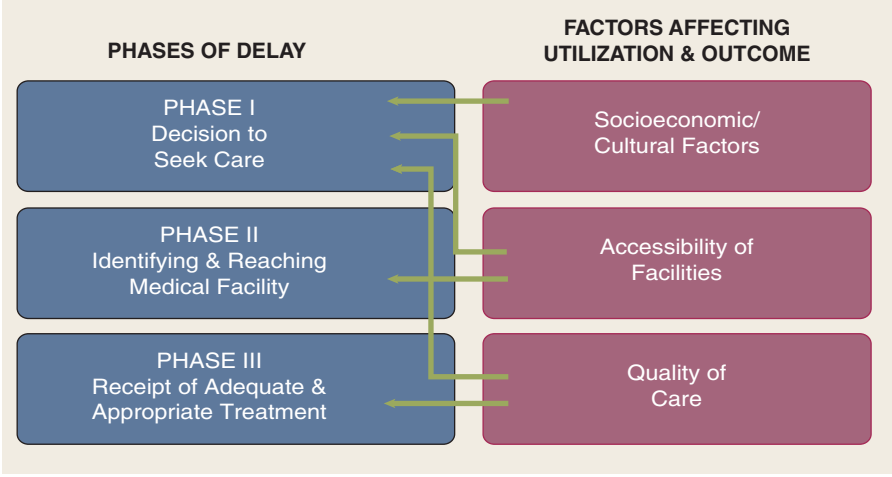

Figure 49-26. Factors affecting utilization and outcome of surgical care. (*Adapted from UNFPA United Nations Population Fund (UNFPA); Providing emergency obstetric and newborn care to all in need. [cited 2013 February 27]; Available from: http://www.unfpa.org/public/mothers/pid/4385. Illustration reproduced with permission from Intermountain Healthcare.*)

Inguinal hernia repair is one of the most common operations performed worldwide. Tension-free inguinal hernia repairs performed with mosquito netting or polypropylene mesh was cost-effective in Western Ecuador and Western Ghana ($78.18/ DALY and $12.88/ DALY averted, respectively).[96,102] Using mosquito netting in India was 3700 times cheaper than using traditional polypropylene mesh.[103]

Factors Affecting Utilization and Outcome for Surgical Care. There are three major factors that severely limit utilization of surgical services:

1. socioeconomic and cultural
2. accessibility of facilities and
3. quality of care (Fig. 49-26)[104]

The decision to seek timely care is affected by the costs associated with time off from work and inability to support the family during the absence, transportation and lodging, and the surgical services themselves. Cultural and religious traditions may define acceptability of various treatment options. For example, many people in Mongolia refuse to have surgery on Tuesdays as this is viewed as a "bad luck" day. Understanding local customs and cultural concerns can improve utilization of surgical services.

Austere environments, difficult terrain, and long distances from health care facilities significantly delay or prevent access to surgical care. Triage and transfer guidelines along with telemedicine have the potential to mitigate the limitations of geography. However, without adequately trained care providers and support staff, the risk for poor outcomes is increased.

Recognizing these three important factors for increasing utilization and outcomes, Mongolia initiated a public health approach for the management of gallbladder disease incorporating minimally invasive surgery. (**Box:** The Public Health Approach to Management of Gallbladder Disease in Mongolia)

The Public Health Approach to Management of Gallbladder Disease in Mongolia

Mongolia, the most sparsely populated country in the world, covers a large geographic area nestled between China and Siberia.[105] The austere environment with extremes of weather, dry deserts, and high mountains present significant obstacles for road building limiting transportation for patients in the vast rural areas (Fig. 49-27). Significant deficiencies in infrastructure, supplies, equipment, and human resources at primary healthcare facilities exist: sporadic electricity, no fully qualified surgeons or anesthesiologists, and less than half the facilities with running water.[3]In 2006, Healthcare expenditures reached only U.S. $23.2 per capita.[106,107]

The second most common cause of inpatient morbidity in Mongolia has transitioned to gastrointestinal diseases with liver disease, appendicitis, and gallbladder disease the top three causes.[108] While laparoscopic cholecystectomy was introduced in Mongolia in 1994, by 2005 only 2% of gallbladders were removed laparoscopically, and then, only in the capital city.[109] A cohort study in 2005 comparing open with laparoscopic cholecystectomy by Dr. Sergelen, the chief of surgery at the Health Sciences University of Mongolia (HSUM), found the wound infection rate to be significantly lower, hospital stays shorter, and hospital expenditures 50% less with laparoscopy compared to open cholecystectomy.[110] Dr. Sergelen formulated a plan to expand access to laparoscopic surgery throughout Mongolia. This plan targeted the three main areas affecting utilization and outcome.

a) **Quality of Care** Develop a laparoscopic training didactic and practical course to train surgical teams.
b) **Accessibility of Quality Care** Begin training surgical teams in the capital city, but then expand them to four carefully selected regional diagnostic treatment and referral centers (RDTRCs) in all four quadrants of the country.
c) **Quality of Care** Improve the surgical infrastructure for each facility.
d) **Socioeconomic/Cultural Factors** Educate the public on the increased benefits of laparoscopic surgery so they would initiate lobbying efforts demanding the government increase funding for these services.
e) **Socioeconomic/Cultural Factors** Educate government leaders about the need and benefit of laparoscopic cholecystectomy for the Mongolian people.
f) **Quality of Care** Expand the surgical residency to include laparoscopic training.
g) **Accessibility and Quality** Invite industry to offer cost-affordable supplies and replacement parts to sustain the laparoscopic equipment in Mongolia.

Figure 49-27. Rural Ger. (*Photo reproduced with permission from Michelle K. Price.*)

Laparoscopic cholecystectomy has been expanded within the capital city and established in the initial 4 key Regional Diagnostic and Treatment Referral Centers (RDTRCs) and an additional fifth regional hospital creating countrywide access to high-quality modern surgery for a regionally prevalent disease through a multinational partnership directed by the chief of surgery at HSUM (Fig. 49-28).[105,111]

As people began to see their neighbors return to functional ability faster with the laparoscopic approach, the Mongolian people developed increased trust in their healthcare providers and the quality of care they could receive. This led to not only an increase in laparoscopic cholecystectomy but an increase in open cholecystectomy and many other procedures (Fig. 49-29).[105]

The Mongolian surgical residency has been expanded to incorporate laparoscopic training. The MOH has committed to increase funding for laparoscopic cholecystectomy and change existing laws making it easier for hospitals to purchase their needed supplies.

Advanced Surgical Care for Resource-Poor Areas

Limited financial, physical, and human resources, political and social conflicts, and austere environments cause many to believe that advanced surgical care is inappropriate in resource poor countries.[77,112-114] Misconception of the needs and abilities of people in LMICs cause some policy makers to discount the desire of people worldwide for advanced surgical care.[105] Developing these capabilities in resource-poor countries has the potential to decrease overall cost and actually develop the infrastructure necessary to entice physicians and other healthcare workers to remain in their own countries. Establishing advanced surgical care requires expertise and services that symbiotically support and improve general medical care. Therefore, many developing countries are actively building capacity and capability to provide the full spectrum of modern surgical care locally.[115]

As economies improve and the benefits of laparoscopic surgery for resource-poor areas become better delineated, patients and doctors, surgical societies, ministries of health, and industries are demanding the benefits of minimally invasive surgery for patients and communities.[111,116-122] The economic impact of laparoscopy may be even greater in LMICs than in developed countries.[123] Worldwide surgeons have identified laparoscopic training as one of their greatest needs. In a recent survey, developing laparoscopic and endoscopic skills were identified as the most important skills desired by surgeons from the West Africa College of Surgeons (WACS) (Fig. 49-30).[124]

Transplantation is another area of great interest to people in poor countries partly because of the high prevalence of kidney failure and because chronic dialysis facilities are limited. Hepatoma and liver failure are very common in countries with a strong prevalence of hepatitis B and C. Transplantation has become the treatment of choice for end-stage kidney disease in developed countries as it dramatically improves the quality of life and increases survival rates compared to medical management.[125] Yet, transplantation eludes most of the developing world. Initial attempts to transport critically ill patients from LMICs to developed countries for kidney transplantation were

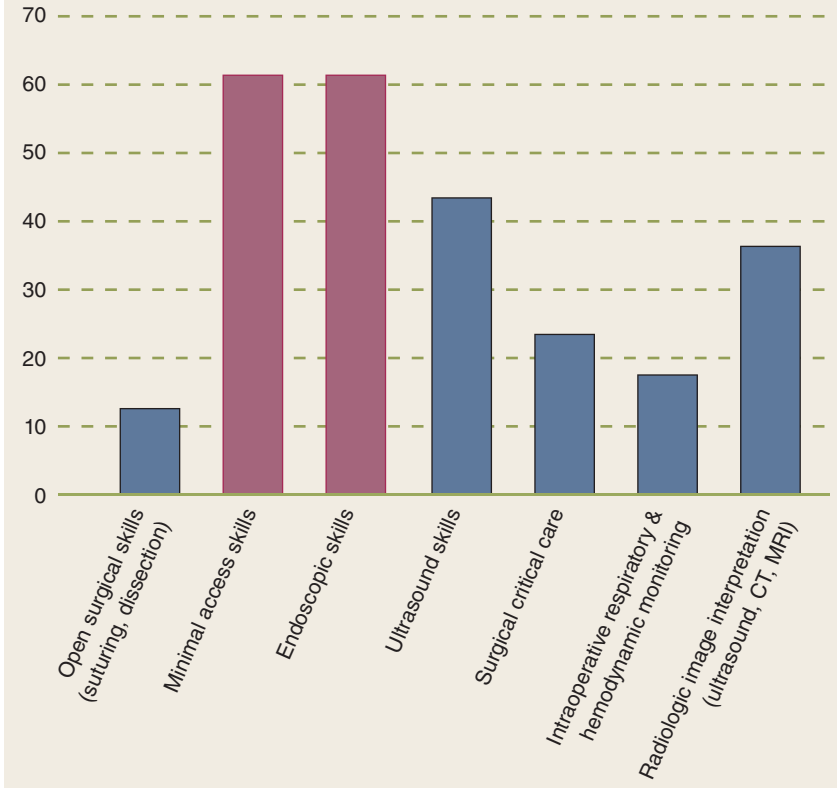

Figure 49-30. West African College of Surgeons: most desired skills. (*Adapted from Trigen Survey WACS: Akporiaye L. (2010). Trigen Survey: West African College of Surgeon. Port-Harcourt: Unpublished data. Illustration reproduced with permission from Intermountain Healthcare.*)

cost-prohibitive.[126] With the alarming increase in the rate at which young people have been presenting with kidney disease in developing countries, the increased utilization placed on the few dialysis machines has been overwhelming.[127] Dialysis units which previously were utilized three times a week, now operate 24 hours a day, 7 days a week, and cannot begin to provide the needed services to the multitudes needing treatment. Even programs to develop peritoneal dialysis cannot fully ease the demand.

The majority of kidney transplants in developing countries are from living related donation. Laparoscopic living related donation has the potential to increase the voluntary donor pool as patients have less postoperative pain, return to work and activities quicker, and have much better cosmesis than open surgery.[128] Adapting to the limited resources, surgeons have described various cost-saving techniques to facilitate the laparoscopic approach in resource poor areas such as using endoclips instead of staplers for vascular control, modifications to the surgical approach, and suprapubic extraction of the kidney rather than endocatch removal.[128-130]

Academic Partnerships

Academic institutions have historically pioneered discovery in disease causation and treatment. As globalization expands, academic surgical programs are beginning to respond by broadening their vision for an interdisciplinary and collaborative approach to research, education, development, and advocacy.[131-132]

12▶ Academic involvement in global surgery provides training for the next generation of surgical leaders. Leaders for the 21st century will need to know how to provide outstanding cost-effective clinical care for all environments. With a more global view, the significant advances in scientific knowledge and clinical practice realized through basic and clinical research will potentially provide solutions for access to surgical care for all patients worldwide. Partnering academic programs with NGOs provides another opportunity for collaboration. (**Box:** Academic Global Surgery Partnerships)

Ethics

The ethics involved in working outside one's own home country are complex. While a practitioner's scope of practice is usually constrained by regulation in America and Europe, in many countries the limits of what one can do are neither regulated nor enforced. Guidelines for what should be done—where, and under what circumstances are beyond the expertise of some ministries of health. Some problems are so episodic that they are not anticipated, and few guidelines exist. For example, in natural disasters and emergencies, should any willing provider from any country be granted permission to provide care? Should specific disaster-related training be encouraged or required?[134,135] In the

Academic Global Surgery Partnerships

A. Global Health Equity Residency

"In 2012, Brigham and Women's Hospital (BWH) Center for Surgery and Public Health (CSPH) launched the Global Health Equity in Surgery (GHE-S) residency program. Related to its sister program in Internal Medicine at BWH, the GHE-S program seeks to create future leaders in academic global surgery through structured education, field work, research, and mentoring throughout the length of their surgical residency at BWH. During the research years, GHE residents engage in collaborative field-based programs and research that link and support many of BWH global surgery activities. Projects to date include: Understanding Trauma Epidemiology in Rwanda, Understanding Surgical Epidemiology of Burera District, Cost-Effectiveness analysis of the Team Heart global cardiac surgery program, and Breast cancer epidemiology of Rwanda.[133]" —Robert Riviello MD

B. Rwanda Human Resources for Health (HRH) Program

"The Rwanda HRH program is an ambitious 7-year long, U.S. federally funded, collaborative program of the Rwanda Ministry of Health (MOH) and 13 U.S. academic medical centers and universities. HRH seeks to greatly expand and improve Rwanda's health care workforce by strengthening national training programs of specialized physicians, nurses, oral health providers, and hospital managers by recruiting U.S. faculty educators to join the National University of Rwanda (NUR) training faculty. In year one of the program (August 2012–July 2103), BWH contributed the largest number of physician educators to the program, recruiting 40% of the U.S. HRH physician faculty, including 6 surgeons. These surgeons have worked closely with their Rwandan faculty counterparts to restructure and organize the NUR surgery residency program, including development of curriculum, organizing didactic and clinical teaching, and greatly strengthening resident supervision and mentorship[133]." —Robert Riviello MD

C. Coordinating Non-Governmental Organizations (NGO) and Academic Organizations: IVUmed

Nonprofit organizations (NGO) have filled a niche in establishing surgical care in countries where training centers and healthcare systems are historically non-existent or understaffed. More recently, professional organizations have developed a focus on specific diseases or patient groups and have become a resource for education and training in poor countries.

For more than 20 years, the IVUmed NGO has focused on urological education and hands-on training in Africa, Asia, and Latin America. IVUmed evolved from a need identified by plastic surgeons that had seen many children with hypospadias and other urological anomalies such as exstrophy, when providing care for children with cleft lip and palate. Adult surgeons were not trained in the delicate reconstruction of pediatric genitourinary anomalies, and pediatric surgeons were not trained in endoscopic or reconstructive urological surgery. The program has expanded to support training in all aspects of urological care, including adult reconstruction, oncology, and endoscopic management of stones and prostatic disease.

As a nonprofit organization, IVUmed is a partnership between surgeons, anesthesiologists and nurses, academic medical centers, urological professional associations, industry and the public with urologic surgery training in more than 20 countries. It also provides North American trainees scholarships to travel to low-resource countries to learn and to share knowledge gained in their own programs. Many former scholars become mentors for other residents when they complete their training. The sites with the longest collaborations have developed their own educational programs in general urology or subspecialty areas and are now providing advanced training and care locally (Fig. 49-31).

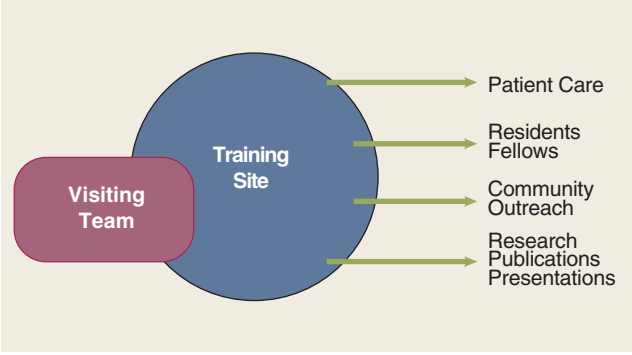

Figure 49-31. Training outcomes from NGO/academic partnership. (*Reproduced with permission from IVUmed and Intermountain Healthcare.*)

non-acute setting, should practitioners not licensed or credentialed in their home environments be allowed to perform volunteer surgery in other countries? What entity should oversee the flow of volunteer practitioners? Can a standard set of guidelines meet the needs of most countries? Currently, there is little cross national agreement between state entities, like ministries of health and independent organizations and individuals. While many countries require at least temporary licensure, some do not. In many cases enforcement is inconsistent.

With respect to research, the poor historically have not received benefit from research performed on them. In international studies, even local collaborators have been left out of study design and publication.[136] As Internet communications have improved, these lapses no longer are tolerated.[137] Informed consent for surgical procedures, given in the appropriate language and respectful of local customs, are becoming more the norm. Few hospitals outside academic medical centers have institutional review boards (IRBs) to oversee the implementation and review of clinical research. In recent years, peer reviewed journals have become more mindful of attribution of credit, and authors are strongly encouraged to design and report studies with local input at all levels.

With regard to transplantation, many countries have laws against cadaveric transplants because of the very real concern for illegal marketing of organs. Even living-donor transplantation has seen effects of coercion in some regions and for some populations such as prisoners. Nevertheless, the need and popular desire for transplantation is accelerating acquisition of skills and technology to make transplantation available worldwide.[138]

Finally, what is considered ethical in one country or one community might be considered highly unethical in another. Consent for surgery may in one setting rest with the patient, but in another, with the community or family. And values about privacy vary markedly from region to region. Health information in many cultures is considered to be a community concern and not the personal property of an individual patient.

Innovation in Global Surgery

The pressing need for surgical care at all levels and the shortage of fully trained surgeons, anesthesiologists and support personnel, equipment and supplies means that opportunities abound for innovation. Innovations in education, including simulation, can potentially shorten the time necessary for learning technical skills. Gaming technology can potentially teach algorithms for decision making and interpretation of X-rays and ultrasounds. Telemedicine/telehealth has the potential to transform education through combinations of clinical case-based learning and massively open online courses (MOOC). The potential for education innovation in surgery beyond the apprenticeship system championed by Halsted in 1904 is vast.

13▶

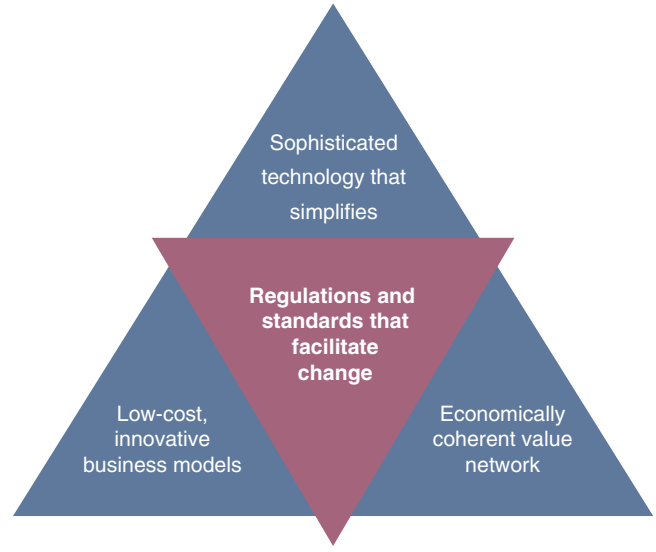

Figure 49-32. Elements of disruptive innovation. (*Redrawn with permission from Christensen CM, Grossman JH, Hwang J.* The Innovator's Prescription. *New York: McGraw-Hill, 2009. Copyright © The McGraw-Hill Companies, Inc. Illustration reproduced with permission from Intermountain Healthcare.*)

Innovation that radically changes the way we do things, that changes a paradigm of a service or system is called "disruptive"; it abruptly changes an older and more expensive system in favor of a less expensive, more widely available technology or process. The ability for disruptive innovations to transform products and services into affordable realities requires three main factors (Fig. 49-32).[139]

Regulations and standards that vary between countries and locales can facilitate or impede disruptive change. While disruptions often are not qualitatively superior to the status quo, they make the process both less expensive and more accessible, and through multiple iterations, ultimately improve quality as they cycle through the transformative process.

De-centralizing education, laboratory testing, and medical records have been made possible through Free and Open Source Software, apps, and devices such as smart phones, tablets, and laptop computers. Monitoring devices, laparoscopic instruments, and imaging devices designed for low resource environments have the potential to not only improve accessibility in poor countries, but also to radically reduce surgical costs in wealthy ones.

THE FUTURE FOR GLOBAL SURGERY

Surgeons of the future will need to educate themselves in areas that have not historically been taught in surgical curricula. Beyond the business of surgical practice, there is a complex ecosystem that supports surgical care. Surgeons must become more aware of the complexities of cost in order to be able to shape the

environment in which they work. They must understand better what patients are seeking from the surgical experience rather than focusing primarily on a narrow view of what surgery might have to offer. Surgeons must engage in policy development and advocate for affordable and accessible surgical care without sacrificing quality. Thoughtful technology design can focus on improving quality and on decreasing cost, both in poor and wealthy countries. As our colleagues in public health and the World Bank, Paul Farmer and Jim Kim have challenged us, "We need our surgical colleagues to speak fluently about rebuilding infrastructure, training, personnel, and delivering high-quality care to the very poorest."[7]
