Peyer's patches are macroscopic aggregates of B-cell follicles and intervening T-cell areas found in the lamina propria of the small intestine, primarily the distal ileum. Overlying Peyer's patches are a specialized epithelium containing microfold (M) cells. These cells possess an apical membrane with microfolds rather than microvilli, which is characteristic of most intestinal epithelial cells. Using transepithelial vesicular transport, M cells transfer microbes to underlying professional antigen-presenting cells (APCs), such as dendritic cells. Dendritic cells, in addition, may sample luminal antigens directly through their dendrite-like processes that extend through epithelial tight junctions. APCs interact with and prime naïve lymphocytes, which then exit through the draining lymphatics to enter the mesenteric lymph nodes where they undergo differentiation. These lymphocytes then migrate into the systemic circulation via the thoracic duct and ultimately accumulate in the intestinal mucosa at effector sites. Alternative induction mechanisms, such as antigen presentation within mesenteric lymph nodes, are also likely to exist.

Effector lymphocytes are distributed into distinct compartments. IgA-producing plasma cells are derived from B cells and are located in the lamina propria. $CD4^+$ T cells are also located in the lamina propria. $CD8^+$ T cells migrate preferentially to the epithelium, but are also found in the lamina propria. These T cells are central to immune regulation; in addition, the $CD8^+$ T cells have potent cytotoxic (CTL) activity. IgA is transported through the intestinal epithelial cells into the lumen, where it exists in the form of a dimer complexed with a secretory component. This configuration renders IgA resistant to proteolysis by digestive enzymes. IgA is believed to both help prevent the entry of microbes through the epithelium and to promote excretion of antigens or microbes that have already penetrated into the lamina propria.

It has been increasingly recognized that the gastrointestinal tract is colonized with many bacteria that are essential for health. Communication between the microbiota and the host defense allows for protective immune responses against pathogens while preventing adverse inflammatory responses to harmless commensal microbes, which could lead to chronic inflammatory disorders such as celiac disease and Crohn's disease.[11]

Motility

Myocytes of the intestinal muscle layers are electrically and mechanically coordinated in the form of syncytia. Contractions of the muscularis propria are responsible for small-intestinal peristalsis. Contraction of the outer longitudinal muscle layer results in bowel shortening; contraction of the inner circular layer results in luminal narrowing. Contractions of the muscularis mucosa contribute to mucosal or villus motility, but not to peristalsis.

Several distinctive patterns of muscularis propria activity have been observed to occur in the small intestine. These patterns include *ascending excitation and descending inhibition* in which muscular contraction occurs proximal to a stimulus, such as the presence of a bolus of ingested food, and muscular relaxation occurs distal to the stimulus (Fig. 28-11). These two

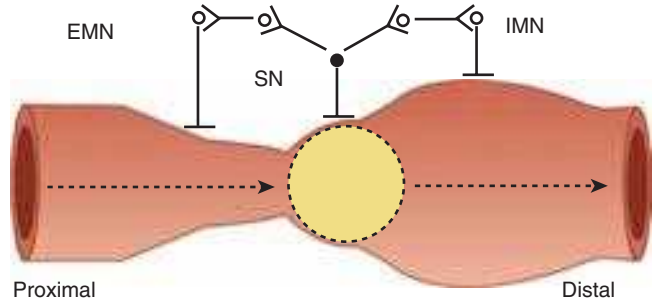

Figure 28-11. Ascending excitation and descending inhibition. The presence of a food bolus within the intestinal lumen is sensed by a sensory neuron (SN) that relays signals to (a) excitatory motor neurons (EMN) that have projections to intestinal muscle cells located proximal to the food bolus and (b) inhibitory motor neurons (IMN) that have projections to intestinal muscle cells located distal to the food bolus. This stereotypical motor reflex is controlled by the enteric nervous system and occurs in the absence of extraintestinal innervations. It contributes to peristalsis.

reflexes are present even in the absence of any extrinsic innervation to the small intestine and contribute to peristalsis when they are propagated in a coordinated fashion along the length of the intestine. The *fed or postprandial pattern* begins within 10 to 20 minutes of meal ingestion and abates 4 to 6 hours afterward. *Rhythmic segmentations* or pressure waves traveling only short distances also are observed. This segmenting pattern is hypothesized to assist in mixing intraluminal contents and in facilitating their contact with the absorptive mucosal surface. The *fasting pattern or interdigestive motor cycle (IDMC*) consists of three phases. Phase I is characterized by motor quiescence, phase II by seemingly disorganized pressure waves occurring at submaximal rates, and phase III by sustained pressure waves occurring at maximal rates. This pattern is hypothesized to expel residual debris and bacteria from the small intestine. The median duration of the IDMC ranges from 90 to 120 minutes. At any given time, different portions of the small intestine can be in different phases of the IDMC.

The regulatory mechanisms driving small-intestinal motility consist of both pacemakers intrinsic to the small intestine and external neurohumoral modulatory signals. The interstitial cells of Cajal are pleomorphic mesenchymal cells located within the muscularis propria of the intestine that generate the electrical slow wave (basic electrical rhythm or pacesetter potential) that plays a pacemaker role in setting the fundamental rhythmicity of small-intestinal contractions. The frequency of the slow wave varies along the longitudinal axis of the intestine: it ranges from 12 waves per minute in the duodenum to 7 waves per minute in the distal ileum. Smooth muscle contraction occurs only when an electrical action potential (spike burst) is superimposed on the slow wave. Thus, the slow wave determines the maximum frequency of contractions; however, not every slow wave is associated with a contraction.

This intrinsic contractile mechanism is subject to neural and hormonal regulation. The enteric nervous system (ENS) provides both inhibitory and excitatory stimuli. The predominant excitatory transmitters are acetylcholine and substance P, and the inhibitory transmitters include nitric oxide, vasoactive intestinal peptide, and adenosine triphosphate. In general, the sympathetic motor supply is inhibitory to the ENS; therefore, increased sympathetic input into the intestine leads to decreased intestinal smooth muscle activity. The parasympathetic motor supply is more complex, with projections to both inhibitory and excitatory ENS motor neurons. Correspondingly, the effects of parasympathetic inputs into intestinal motility are more difficult to predict.

Endocrine Function

Endocrinology as a discipline was born with the discovery of secretin, an intestinal regulatory peptide that was the first hormone to be identified. Our improving understanding of the physiology of the small intestine has lead to identification of many additional intestinal-derived hormones that make this the largest hormone-producing organ in the body. Over 30 peptide hormone genes have been identified as being expressed in the gastrointestinal tract. Because of differential posttranscriptional and posttranslational processing, over 100 distinct regulatory peptides are produced. In addition, monoamines, such as histamine and dopamine, and eicosanoids with hormone-like activities are produced in the intestine.

"Gut hormones" were previously conceptualized as peptides produced by the enteroendocrine cells of the intestinal mucosa that are released into the systemic circulation to reach receptors in target sites in the gastrointestinal tract. Now it is clear that "gut hormone" genes are widely expressed throughout the body, not only in endocrine cells, but also in central and peripheral neurons. The products of these genes are general intercellular messengers that can act as endocrine, paracrine, autocrine, or neurocrine mediators. Thus, they may act as true blood-borne hormones as well as through local effects.

There are notable homology patterns among individual regulatory peptides found in the gastrointestinal tract. Based on these homologies, approximately one half of the known regulatory peptides can be classified into families.[12] For example, the secretin family includes secretin, glucagon, and glucagon-like peptides, glucose-dependent insulinotropic peptide, vasoactive intestinal polypeptide, peptide histidine isoleucine, growth hormone–releasing hormone, and pituitary adenylyl cyclase–activating peptide. Other peptide families include those named for insulin, epidermal growth factor, gastrin, pancreatic polypeptide, tachykinin, and somatostatin.

Receptor subtype multiplicity and cell-specific expression patterns for these receptor subtypes that are characteristic of these regulatory mediators make definition of their actions complex. Detailed description of these actions is beyond the scope of this chapter; however, examples of regulatory peptides produced by enteroendocrine cells of the small-intestinal epithelium and their most commonly ascribed functions are summarized in Table 28-2. Some of these peptides, or their analogues, are used in routine clinical practice. For example, therapeutic applications of octreotide, a long-acting analogue of somatostatin, include the amelioration of symptoms associated with neuroendocrine tumors (e.g., carcinoid syndrome), postgastrectomy dumping syndrome, enterocutaneous fistulas, and the initial treatment of acute hemorrhage due to esophageal varices. The gastrin secretory response to secretin administration forms the basis for the standard test used to establish the diagnosis of Zollinger-Ellison syndrome. Cholecystokinin is used in evaluations of gallbladder ejection fraction, a parameter that may have utility in patients who have symptoms of biliary colic but are not found to have gallstones. Of the peptides listed in Table 28-2, glucagon-like peptide-2 (GLP-2) has been identified as a specific and potent intestinotrophic hormone and is currently under clinical evaluation as an intestinotrophic agent in patients suffering from the short bowel syndrome, as discussed in the later Short Bowel Syndrome section.

Intestinal Adaptation

The small intestine has the capacity to adapt in response to varying demands imposed by physiologic and pathologic conditions. Of particular relevance to many of the diseases discussed in this chapter is the adaptation that occurs in the remnant intestine following surgical resection of a large portion of the small intestine (massive small bowel resection). Postresection intestinal adaptation has been studied extensively using animal models. Within a few hours after bowel resection, the remnant small intestine displays evidence of epithelial cellular hyperplasia. With additional time, villi lengthen, intestinal absorptive surface area increases, and digestive and absorptive functions improve. Postresection intestinal adaptation in human patients is less well studied, but seems to follow similar steps as those seen in experimental models, and takes 1 to 2 years to complete.[13]

The mechanisms responsible for inducing postresection intestinal adaptation are under active investigation.

Table 28-2

Representative regulatory peptides produced in the small intestine

HORMONE	SOURCE[a]	ACTIONS
Somatostatin	D cell	Inhibits gastrointestinal secretion, motility, and splanchnic perfusion
Secretin	S cell	Stimulates exocrine pancreatic secretion, stimulates intestinal secretion
Cholecystokinin	I cell	Simulates pancreatic exocrine secretion, simulates gallbladder emptying, inhibits sphincter of Oddi contraction
Motilin	M cell	Simulates intestinal motility
Peptide YY	L cell	Inhibits intestinal motility and secretion
Glucagon-like peptide 2	L cell	Stimulates intestinal epithelial proliferation
Neurotensin	N cell	Stimulates pancreatic and biliary secretion, inhibits small bowel motility, stimulates intestinal mucosal growth

[a]This table indicates which enteroendocrine cell types located in the intestinal epithelium produce these peptides. These peptides are also widely expressed in nonintestinal tissues.

Several classes of effectors that stimulate intestinal growth include specific nutrients, peptide hormones and growth factors, pancreatic secretions, and some cytokines. Nutritional components with intestinal growth-stimulating effects include fiber, fatty acids, triglycerides, glutamine, polyamines, and lectins.

Postresection adaptation serves to compensate for the function of intestine that has been resected. Jejunal resection is generally better tolerated, as ileum shows better capacity to compensate. However, the magnitude of this response is limited. If enough small intestine is resected, a devastating condition known as the short bowel syndrome results. This condition is discussed in the Short Bowel Syndrome section at the end of this chapter.

SMALL BOWEL OBSTRUCTION

Epidemiology

Mechanical small bowel obstruction is the most frequently encountered surgical disorder of the small intestine. 2▶ Although a wide range of etiologies for this condition exists, the obstructing lesion can be conceptualized according to its anatomic relationship to the intestinal wall as:

1. *Intraluminal* (e.g., foreign bodies, gallstones, or meconium)
2. *Intramural* (e.g., tumors, Crohn's disease–associated inflammatory strictures)
3. *Extrinsic* (e.g., adhesions, hernias, or carcinomatosis)

Intra-abdominal adhesions related to prior abdominal surgery account for up to 75% of cases of small bowel obstruction. 3▶ Over 300,000 patients are estimated to undergo surgery to treat adhesion-induced small bowel obstruction in the United States annually. A 20-year trend analysis between 1988 and 2007 has documented no decrease in this rate during this time period, highlighting the ongoing problem with this "old" disease.[14]

Less prevalent etiologies for small bowel obstruction include hernias, malignant bowel obstruction, and Crohn's disease. The frequency with which obstruction related to these conditions is encountered varies according to the patient population and practice setting. Cancer-related small bowel obstructions are commonly due to extrinsic compression or invasion by advanced malignancies arising in organs other than the small bowel; few are due to primary small bowel tumors. The most commonly encountered etiologies of small bowel obstruction are summarized in Table 28-3. Although 4▶ congenital abnormalities capable of causing small bowel obstruction usually become evident during childhood, they sometimes elude detection and are diagnosed for the first time in adult patients presenting with abdominal symptoms. For example, intestinal malrotation and mid-gut volvulus should not be forgotten when considering the differential

Table 28-3

Small bowel obstruction: common etiologies

- Adhesions
- Neoplasms
  - Primary small bowel neoplasms
  - Secondary small bowel cancer (e.g., melanoma-derived metastasis)
  - Local invasion by intra-abdominal malignancy (e.g., desmoid tumors)
  - Carcinomatosis
- Hernias
  - External (e.g., inguinal and femoral)
  - Internal (e.g., following Roux-en-Y gastric bypass surgery)
- Crohn's disease
- Volvulus
- Intussusception
- Radiation-induced stricture
- Postischemic stricture
- Foreign body
- Gallstone ileus
- Diverticulitis
- Meckel's diverticulum
- Hematoma
- Congenital abnormalities (e.g., webs, duplications, and malrotation)

diagnosis of adult patients with acute or chronic symptoms of small bowel obstruction, especially those without a history of prior abdominal surgery. A rare etiology of obstruction is the superior mesenteric artery syndrome, characterized by compression of the third portion of the duodenum by the superior mesenteric artery as it crosses over this portion of the duodenum. This condition should be considered in young asthenic individuals who have chronic symptoms suggestive of proximal small bowel obstruction.

Pathophysiology

With onset of obstruction, gas and fluid accumulate within the intestinal lumen proximal to the site of obstruction. The intestinal activity increases in an effort to overcome the obstruction, accounting for the colicky pain and the diarrhea that some experience even in the presence of complete bowel obstruction. Most of the gas that accumulates originates from swallowed air, although some is produced within the intestine. The fluid consists of swallowed liquids and gastrointestinal secretions (obstruction stimulates intestinal epithelial water secretion). With ongoing gas and fluid accumulation, the bowel distends and intraluminal and intramural pressures rise. The intestinal motility is eventually reduced with fewer contractions. With obstruction, the luminal flora of the small bowel, which is usually sterile, changes, and a variety of organisms have been cultured from the contents. Translocation of these bacteria to regional lymph nodes has been demonstrated, although the significance of this process is not well understood. If the intramural pressure becomes high enough, intestinal microvascular perfusion is impaired, leading to intestinal ischemia and, ultimately, necrosis. This condition is termed *strangulated bowel obstruction*.

With *partial small bowel obstruction*, only a portion of the intestinal lumen is occluded, allowing passage of some gas and fluid. The progression of pathophysiologic events described earlier tends to occur more slowly than with *complete small bowel obstruction*, and development of strangulation is less likely.

A particularly dangerous form of bowel obstruction is *closed-loop obstruction* in which a segment of intestine is obstructed both proximally and distally (e.g., with volvulus). In such cases, the accumulating gas and fluid cannot escape either proximally or distally from the obstructed segment, leading to a rapid rise in luminal pressure and a rapid progression to strangulation.

Clinical Presentation

The symptoms of small bowel obstruction are colicky abdominal pain, nausea, vomiting, and obstipation. Vomiting is a more prominent symptom with proximal obstructions than distal. The character of vomitus is important because with bacterial overgrowth, the vomitus is more feculent, suggesting a more established obstruction. Continued passage of flatus and/or stool beyond 6 to 12 hours after onset of symptoms is characteristic of partial rather than complete obstruction. The signs of small bowel obstruction include abdominal distention, which is most pronounced if the site of obstruction is in the distal ileum and may be absent if the site of obstruction is in the proximal small intestine. Bowel sounds may be hyperactive initially, but in late stages of bowel obstruction, minimal bowel sounds may be heard. Laboratory findings reflect intravascular volume depletion and consist of hemoconcentration and electrolyte abnormalities. Mild leukocytosis is common.

Features of strangulated obstruction include abdominal pain often disproportionate to the degree of abdominal findings, suggestive of intestinal ischemia. Patients often have tachycardia, localized abdominal tenderness, fever, marked leukocytosis, and acidosis. Any of these findings should alert the clinician to the possibility of strangulation and need for early surgical intervention.

Diagnosis

The diagnostic evaluation should focus on the following goals: (a) distinguish mechanical obstruction from ileus, (b) determine the etiology of the obstruction, (c) discriminate partial from complete obstruction, and (d) discriminate simple from strangulating obstruction.

Important elements to obtain on history include prior abdominal operations (suggesting the presence of adhesions) and the presence of abdominal disorders (e.g., intra-abdominal cancer or inflammatory bowel disease) that may provide insights into the etiology of obstruction. Upon examination, a meticulous search for hernias (particularly in the inguinal and femoral regions) should be conducted.

The diagnosis of small bowel obstruction is usually confirmed with radiographic examination. The *abdominal series* consists of (a) a radiograph of the abdomen with the patient in a supine position, (b) a radiograph of the abdomen with the patient in an upright position, and (c) a radiograph of the chest with the patient in an upright position. The finding most specific for small bowel obstruction is the triad of dilated small bowel loops (>3 cm in diameter), air-fluid levels seen on upright films, and a paucity of air in the colon. The sensitivity of abdominal radiographs in the detection of small bowel obstruction ranges 70% to 80%.[15] Specificity is low, because ileus and colonic obstruction can be associated with findings that mimic those observed with small bowel obstruction. False-negative findings on radiographs can result when the site of obstruction is located in the proximal small bowel and when the bowel lumen is filled with fluid but no gas, thereby preventing visualization of air-fluid levels or bowel distention. The latter situation is associated with closed-loop obstruction. Despite these limitations, abdominal radiographs remain an important study in patients with suspected small bowel obstruction because of their widespread availability and low cost (Fig. 28-12).

Computed tomography (CT) scanning is 80% to 90% sensitive and 70% to 90% specific in the detection of small bowel obstruction.[15] The findings of small bowel obstruction include a discrete transition zone with dilation of bowel proximally, decompression of bowel distally, intraluminal contrast that does not pass beyond the transition zone, and a colon containing little gas or fluid (Figs. 28-13 and 28-14). CT scanning may also provide evidence for the presence of closed-loop obstruction and strangulation. Closed-loop obstruction is suggested by the presence of a U-shaped or C-shaped dilated bowel loop associated with a radial distribution of mesenteric vessels converging toward a torsion point. Strangulation is suggested by thickening of the bowel wall, pneumatosis intestinalis (air in the bowel wall), portal venous gas, mesenteric haziness, and poor uptake of intravenous contrast into the wall of the affected bowel (Fig. 28-15). CT scanning also offers a global evaluation of the abdomen and may therefore reveal the etiology of obstruction. This feature is important in the acute setting when intestinal obstruction represents only one of many diagnoses in patients presenting with acute abdominal conditions.

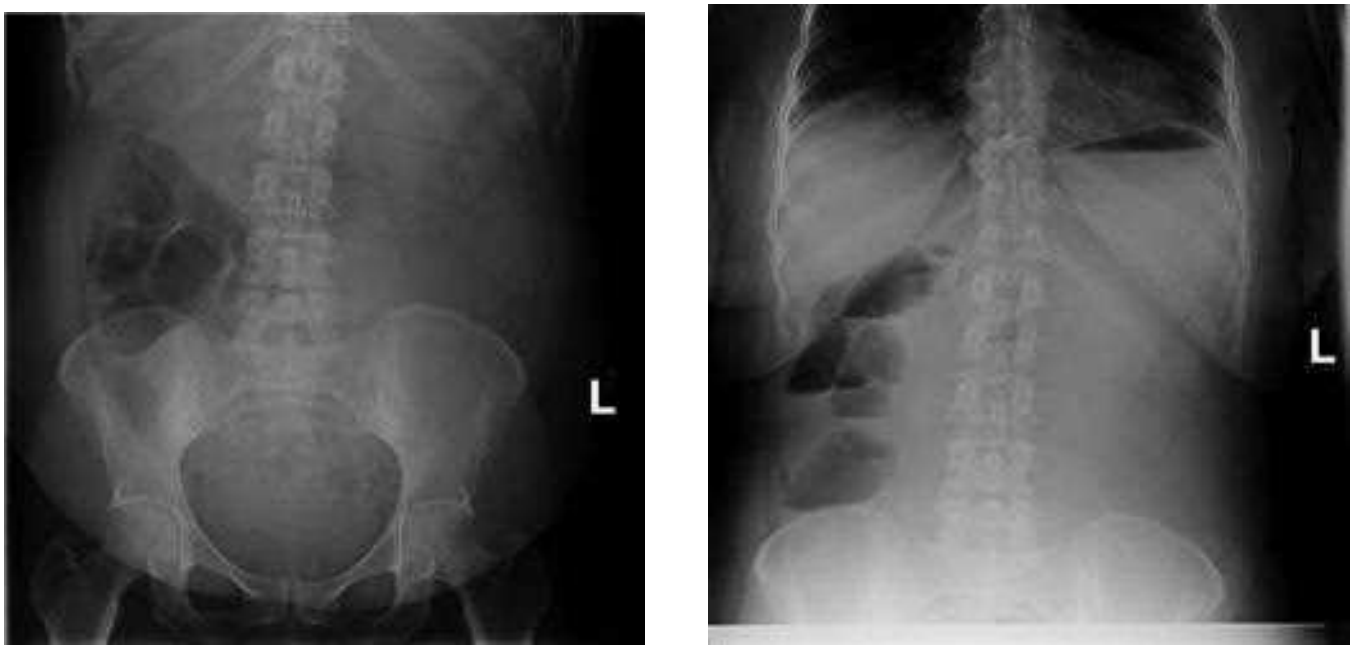

Figure 28-12. Small bowel obstruction. Plain radiographs (**A**) supine, which show dilated loops of small bowel in the right upper quadrant, and (**B**) erect, which confirm the presence of air-fluid level in the loops of small bowel as well as the stomach, consistent with small bowel obstruction.

The CT scan is usually performed after administration of oral water-soluble contrast or diluted barium. The water-soluble contrast has been shown to have prognostic and therapeutic value too. Several studies and a subsequent meta-analysis have shown that appearance of the contrast in the colon within 24 hours is predictive of nonsurgical resolution of bowel obstruction.[16] Although use of oral contrast did not alter the rate of surgical intervention, it did reduce the overall length of hospital stay in those presenting with small bowel obstruction.

A limitation of CT scanning is its low sensitivity (<50%) in the detection of low-grade or partial small bowel obstruction. A subtle transition zone may be difficult to identify in the axial images obtained during CT scanning. In such cases, contrast examinations of the small bowel, either *small bowel series* (small bowel follow-through) or *enteroclysis*, can be helpful. For standard small bowel series, contrast is swallowed or instilled into the stomach through a nasogastric tube. Abdominal radiographs are then taken serially as the contrast travels distally in the intestine. Although barium can be used, water-soluble contrast agents, such as Gastrografin, should be used if the possibility of intestinal perforation exists. These examinations are more labor-intensive and less rapidly performed than

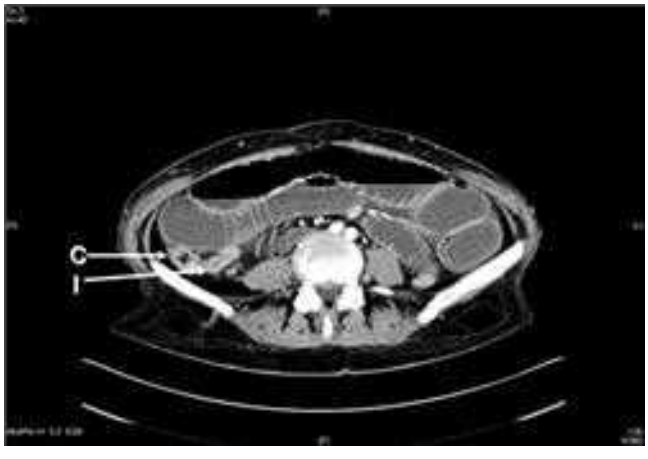

Figure 28-13. Small bowel obstruction. A computed tomography scan of a patient presenting with signs and symptoms of bowel obstruction. Image shows grossly dilated loops of small bowel, with decompressed terminal ileum (I) and ascending colon (C), suggesting a complete distal small bowel obstruction. At laparotomy, adhesive bands from a previous surgery were identified and divided.

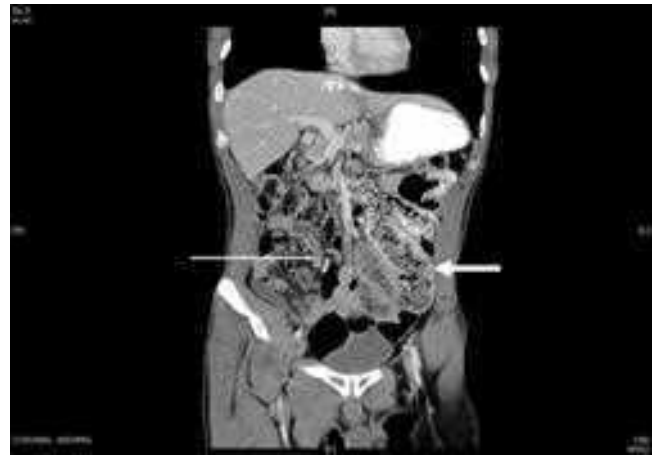

Figure 28-14. Chronic partial small bowel obstruction. This patient presented with a several-month history of chronic abdominal pain and intermittent vomiting. The coronal computed tomography image shows grossly dilated loops of proximal small bowel on the left side (*wide arrow*), with decompressed loops of small bowel on the right side (*narrow arrow*). The dilated segment shows evidence of feculization of bowel contents, consistent with the chronic nature of the obstruction. Patient's vomitus had characteristic feculent smell and quality. At exploratory laparotomy, adhesive band were identified and divided.

Figure 28-15. Intestinal pneumatosis. This computed tomography scan shows intestinal pneumatosis (*arrow*). The cause of this radiologic finding was intestinal ischemia. Patient was taken emergently to the operating room and underwent resection of an infarcted segment of small bowel.

CT scanning but may offer greater sensitivity in the detection of luminal and mural etiologies of obstruction, such as primary intestinal tumors. For enteroclysis, 200 to 250 mL of barium followed by 1 to 2 L of a solution of methylcellulose in water are instilled into the proximal jejunum via a long nasoenteric catheter. The double-contrast technique used in enteroclysis permits a better assessment of mucosal surface and detection of relatively small lesions, even through overlapping small bowel loops. Enteroclysis is rarely performed in the acute setting but offers greater sensitivity than small bowel series in the detection of lesions that may be causing partial small bowel obstruction. Recently, CT enteroclysis has been used and reported to be superior to plain x-ray small bowel contrast studies.

Therapy

Small bowel obstruction is usually associated with a marked depletion of intravascular volume due to decreased oral intake, vomiting, and sequestration of fluid in bowel lumen and wall. Therefore, fluid resuscitation is integral to treatment. Isotonic fluid should be given intravenously, and an indwelling bladder catheter may be placed to monitor urine output. Central venous or pulmonary artery catheter monitoring may be necessary to assist with fluid management in patients with underlying cardiac disease and severe dehydration. Broad-spectrum antibiotics are given by some because of concerns that bacterial translocation may occur in the setting of small bowel obstruction; however, there are no data to support this approach.

The stomach should be continuously evacuated of air and fluid using a nasogastric (NG) tube. Effective gastric decompression decreases nausea, distention, and the risk of vomiting and aspiration. Longer nasoenteric tubes, with tips placed into the jejunum or ileum, were favored in the past but are rarely used today, as they are associated with higher complication rates than NG tubes, with no proven greater efficacy in several studies.

The standard therapy for *complete* small bowel obstruction has generally been expeditious surgery, with the dictum that "the sun should never rise and set on a complete bowel obstruction." Recently, however, some have advocated nonoperative approaches in management of these patients, provided closed-loop obstruction is ruled out and there is no evidence of intestinal ischemia. Such patients need to be observed closely and undergo serial exams. The rationale for those favoring early surgical intervention is to minimize the risk for bowel strangulation, which is associated with an increased risk for morbidity and mortality. Clinical signs and currently available laboratory tests and imaging studies do not reliably permit the distinction between patients with simple obstruction and those with strangulated obstruction prior to the onset of irreversible ischemia. Therefore, the goal is to operate before the onset of irreversible ischemia. Others note, however, that a period of observation and nasogastric decompression, provided no tachycardia, tenderness, or an increase in white cell count is noted, are appropriate (see Fig. 28-16 for a proposed management algorithm).

However, conservative therapy, in the form of NG decompression and fluid resuscitation, is commonly recommended in the initial recommendation for:

1. Partial small bowel obstruction
2. Obstruction occurring in the early postoperative period
3. Intestinal obstruction due to Crohn's disease
4. Carcinomatosis

In *partial obstruction*, progression to strangulation is unlikely to occur, and an attempt at nonoperative resolution is warranted. Nonoperative management has been documented to be successful in 65% to 81% of patients with partial small bowel obstruction. Of those successfully treated nonoperatively, only 5% to 15% have been reported to have symptoms that were not substantially improved within 48 hours after initiation of therapy.[17] Therefore, most patients with partial small bowel obstruction whose symptoms do not improve within 48 hours after initiation of nonoperative therapy should undergo surgery. In a recent study, using the National Inpatient Sample, this principle was further highlighted. The authors concluded that a 2-day limit of watchful waiting before surgery is not associated with an increase in mortality or postoperative morbidity, although inpatient costs were higher.[18]

Patients undergoing nonoperative therapy should be closely monitored for signs suggestive of peritonitis, the development of which would mandate urgent surgery. As stated before, the administration of hypertonic water-soluble contrast agents, such as Gastrografin used in upper gastrointestinal (GI) and small bowel follow-through examinations, causes a shift of fluid into the intestinal lumen, thereby increasing the pressure gradient across the site of obstruction. This effect may accelerate resolution of partial small bowel obstruction; however, there is less evidence that administration of water-soluble contrast agents increases the probability that an episode of bowel obstruction will be successfully managed nonoperatively.[16]

Obstruction presenting in the *early postoperative period* has been reported to occur in 0.7% patients undergoing laparotomy.[19] Patients undergoing pelvic surgery, especially colorectal procedures, have the greatest risk for developing early postoperative small bowel obstruction. The presence of obstruction should be considered if symptoms of intestinal obstruction occur after the initial return of bowel function or if bowel function fails to return within the expected 3 to 5 days after abdominal surgery. Plain radiographs may demonstrate dilated loops of small intestine with air-fluid levels but are interpreted as normal

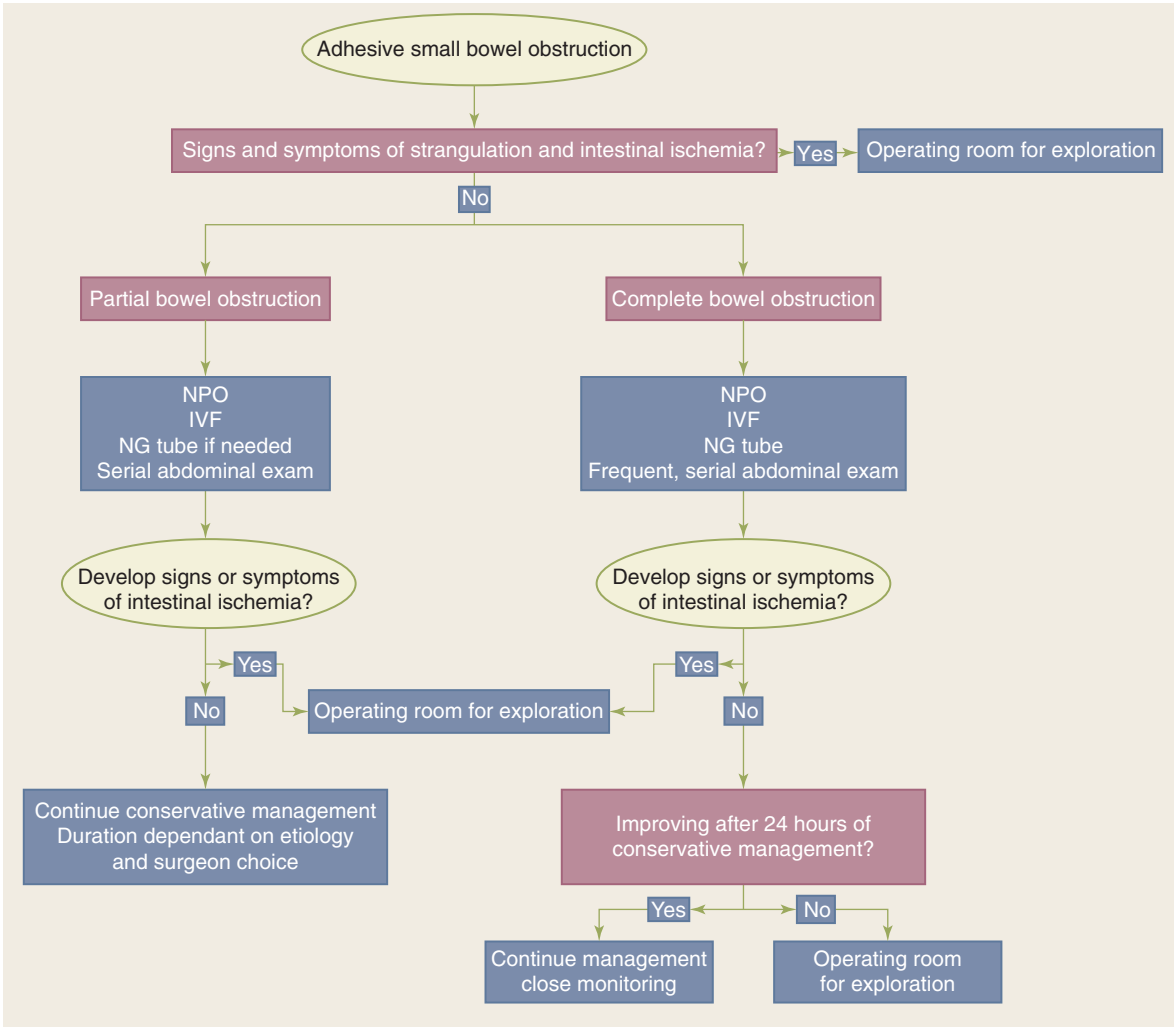

Figure 28-16. Management algorithm of small bowel obstruction. IVF = intravenous fluid; NG = nasogastric; NPO = nothing by mouth.

or nonspecific in up to a third of patients with early postoperative obstruction. CT scanning or a small bowel series is often required to make the diagnosis. Obstruction that occurs in the early postoperative period is usually partial and only rarely is associated with strangulation. Therefore, a period of extended nonoperative therapy (2–3 weeks) consisting of bowel rest, hydration, and total parental nutrition (TPN) administration is usually warranted. However, if complete obstruction is demonstrated or if signs suggestive of peritonitis are detected, expeditious reoperation should be undertaken without delay.

Crohn's disease as a cause of small bowel obstruction is discussed in more detail later in the Crohn's Disease section.

Twenty-five to thirty-three percent of patients with a history of cancer who present with small bowel obstruction have adhesions as the etiology of their obstruction and therefore should not be denied appropriate therapy.[20] Even in cases in which the obstruction is related to recurrent malignancy, palliative resection or bypass can be performed. Patients with obvious carcinomatosis pose a difficult challenge, given their limited prognosis. Management must be tailored to an individual patient's prognosis and desires, and relief of the obstruction may be best achieved by a bypass procedure, avoiding a potentially difficult bowel resection.

The operative procedure performed for small bowel obstruction varies according to the etiology of the obstruction. For example, adhesions are lysed, tumors are resected, and hernias are reduced and repaired. Regardless of the etiology, the affected intestine should be examined, and nonviable bowel resected. Criteria suggesting viability are normal color, peristalsis, and marginal arterial pulsations. Usually, visual inspection alone is adequate in judging viability. In borderline cases, a Doppler probe may be used to check for pulsatile flow to the bowel, and arterial perfusion can be verified by visualizing intravenously administered fluorescein dye in the bowel wall under ultraviolet illumination. However, neither technique has been found to be superior to clinical judgment. In general, if the patient is hemodynamically stable, short lengths of bowel of questionable viability should be resected and primary anastomosis of the remaining intestine performed. However, if the viability of a large proportion of the intestine is in question, a concerted effort to preserve intestinal tissue should be made. In such situations, the bowel of uncertain viability should be left intact and the patient re-explored in 24 to 48 hours in a "second-look" operation. At that time, definitive resection of nonviable bowel is completed.

Successful laparoscopic surgery for bowel obstruction is being reported with greater frequency.[22,23] Those who undergo successful laparoscopic procedure have a quicker recovery, less complications, and lower costs. Since distended loops of bowel can interfere with adequate visualization, early cases of proximal small bowel obstruction that are likely due to a single

adhesive band are best suited for this approach. Presence of bowel distention and multiple adhesions can cause these procedures to be difficult and potentially hazardous. Conversion rate to open surgery is between 17% and 33%.[21-23]

Outcomes

Prognosis is related to the etiology of obstruction. The majority of patients who are treated conservatively for adhesive small bowel obstruction do not require future readmissions; less than 20% of such patients will have a readmission over the subsequent 5 years with another episode of bowel obstruction.[23]

The perioperative mortality rate associated with surgery for nonstrangulating small bowel obstruction is less than 5%, with most deaths occurring in elderly patients with significant comorbidities. Mortality rates associated with surgery for strangulating obstruction range from 8% to 25%.

Considering the frequency of small bowel obstruction and the varied degree of clinical severity and presentation, there is often no consistency as to whether the patient is admitted to the medical or surgical service, and further variability in whether and when surgery is consulted. Recent studies have shown that a standard hospital-wide policy can help improve care of patients with bowel obstruction, reducing their time to surgery and shortening their length of hospital stay.[24]

Prevention

With adhesive small bowel obstruction representing a large therapeutic burden, prevention of postoperative adhesions has become an area of great interest. Good surgical technique, careful handling of tissue, and minimal use and exposure of peritoneum to foreign bodies form the cornerstone of adhesion prevention. These measures alone are often inadequate. In patients undergoing colorectal or pelvic surgery, hospital readmission rates of greater than 30% over the subsequent 10 years have been reported for adhesive small bowel obstruction.[25]

Use of laparoscopic surgery, when possible, has been strongly promoted. A recent study using the Swedish Inpatient Register has shown that, compared to laparoscopy, open surgery is associated with a four-fold increase in risk of small bowel obstruction within 5 years of the index procedure even after accounting for other risk factors such as age, comorbidity, and previous abdominal surgery.[26]

In those undergoing open surgery, several strategies for adhesion prevention have been tried; however, the only therapy that has shown some success has been the use of hyaluronan-based agents, such as Seprafilm. The use of this barrier has been clearly shown to reduce the incidence of postoperative bowel adhesions; however, its effect in actually reducing the incidence of small bowel obstruction remains less well defined.[27] The use of these products is often left to the discretion of the surgeon and the clinical context. Wrapping of an intestinal anastomosis with the material may be associated with increased leak rates and is generally discouraged.[28]

ILEUS AND OTHER DISORDERS OF INTESTINAL MOTILITY

Ileus and intestinal pseudo-obstruction designate clinical syndromes caused by impaired intestinal motility and are characterized by symptoms and signs of intestinal obstruction in the absence of a lesion-causing mechanical obstruction. Ileus is a major cause of morbidity in hospitalized patients. Postoperative ileus is the most frequently implicated cause of delayed discharge following abdominal operations; its economic impact has been estimated to be between $750 million and $1 billion annually in the United States.[29]

Ileus is a temporary motility disorder that is reversed with time as the inciting factor is corrected. In contrast, chronic intestinal pseudo-obstruction comprises a spectrum of specific disorders associated with irreversible intestinal dysmotility.

Pathophysiology

Numerous factors capable of impairing intestinal motility, and thus inciting ileus, have been described (Table 28-4). The most frequently encountered factors are abdominal operations, infection and inflammation, electrolyte abnormalities, and drugs.

Following most abdominal operations or injuries, the motility of the GI tract is transiently impaired. Among the proposed mechanisms responsible for this dysmotility are surgical stress-induced sympathetic reflexes, inflammatory response mediator release, and anesthetic/analgesic side effects, each of which can inhibit intestinal motility.[30] The return of normal motility generally follows a characteristic temporal sequence, with small-intestinal motility returning to normal within the first 24 hours after laparotomy and gastric and colonic motility returning to normal by 48 hours and 3 to 5 days, respectively. Because small bowel motility is returned before colonic and gastric motility, listening for bowel sounds is not a reliable indicator that ileus has fully resolved. Functional evidence of coordinated GI motility in the form of passing flatus or a bowel movement is a more useful indicator. Resolution of ileus may be delayed in the presence of other factors capable of inciting ileus such as the presence of intra-abdominal abscesses or electrolyte abnormalities.

Chronic intestinal pseudo-obstruction can be caused by a large number of specific abnormalities affecting intestinal

smooth muscle, the myenteric plexus, or the extraintestinal nervous system (Table 28-5). Visceral myopathies constitute a group of diseases characterized by degeneration and fibrosis of the intestinal muscularis propria. Visceral neuropathies encompass a variety of degenerative disorders of the myenteric and submucosal plexuses. Both sporadic and familial forms of visceral myopathies and neuropathies exist. Systemic disorders involving the smooth muscle, such as progressive systemic sclerosis and progressive muscular dystrophy, and neurologic diseases, such as Parkinson's disease, can also be complicated by chronic intestinal pseudo-obstruction. In addition, viral infections, such as those associated with cytomegalovirus and Epstein-Barr virus, can cause intestinal pseudo-obstruction.

Clinical Presentation

The clinical presentation of ileus resembles that of small bowel obstruction. Inability to tolerate liquids and solids by mouth, nausea, and lack of flatus or bowel movements are the most common symptoms. Vomiting and abdominal distension may occur. Bowel sounds are characteristically diminished or absent, in contrast to the hyperactive bowel sounds that usually accompany mechanical small bowel obstruction. The clinical manifestations of chronic intestinal pseudo-obstruction include variable degrees of nausea and vomiting and abdominal pain and distention.

Diagnosis

Routine postoperative ileus should be expected and requires no diagnostic evaluation. If ileus persists beyond 3 to 5 days postoperatively or occurs in the absence of abdominal surgery, diagnostic evaluation to detect specific underlying factors capable of inciting ileus and to rule out the presence of mechanical obstruction is warranted.

Patient medication lists should be reviewed for the presence of drugs, especially opiates, known to be associated with impaired intestinal motility. Measurement of serum electrolytes may demonstrate electrolyte abnormalities commonly associated with ileus. Abdominal radiographs are often obtained, but the distinction between ileus and mechanical obstruction may be difficult based on this test alone. In the postoperative setting, CT scanning is the test of choice because it can demonstrate the presence of an intra-abdominal abscess or other evidence of peritoneal sepsis that may be causing ileus and can exclude the presence of complete mechanical obstruction. Distinction of postoperative ileus from early postoperative obstruction can be difficult but is helpful in developing the appropriate management plan.

The diagnosis of chronic pseudo-obstruction is suggested by clinical features and confirmed by radiographic and manometric studies. Diagnostic laparotomy or laparoscopy with full-thickness biopsy of the small intestine may be required to establish the specific underlying cause.

Therapy

The management of ileus consists of limiting oral intake and correcting the underlying inciting factor. If vomiting or abdominal distention is prominent, the stomach should be decompressed using a nasogastric tube. Fluid and electrolytes should be administered intravenously until ileus resolves. If the duration of ileus is prolonged, TPN may be required.

Given the frequency of postoperative ileus and its financial impact, a large number of investigations have been conducted to define strategies to reduce its duration. Although often recommended, the use of early ambulation and routine nasogastric intubation has not been demonstrated to be associated with earlier resolution of postoperative ileus. There is some evidence that early postoperative feeding protocols and are generally well tolerated, reduce postoperative ileus, and can result in a shorter hospital stay.[31] The administration of nonsteroidal anti-inflammatory drugs such as ketorolac and concomitant reductions in opioid dosing have been shown to reduce the duration of ileus in most studies. Similarly, the use of perioperative thoracic epidural anesthesia/analgesia with regimens containing local anesthetics combined with limitation or elimination of systemically administered opioids has been shown to reduce duration of postoperative ileus, although they have not reduced the overall length of hospital stay.[32] Interestingly, recent data have suggested that limiting intra- and postoperative fluid administration can also result in reduction of postoperative ileus and shortened hospital stay.[33] Table 28-6 summarizes some of the measures used to minimize postoperative ileus.

Most other pharmacologic agents, including prokinetic agents, are associated with efficacy-toxicity profiles that are

Table 28-6

Measures to reduce postoperative ileus

- Intraoperative measures
  - Minimize handling of the bowel
  - Laparoscopic approach, if possible
  - Avoid excessive intraoperative fluid administration
- Postoperative measures
  - Early enteral feeding
  - Epidural anesthesia, if indicated
  - Avoid excessive intravenous fluid administration
  - Correct electrolyte abnormalities
  - Consider mu-opioid antagonists

too unfavorable to warrant routine use. Recently, administration of alvimopan, a novel peripherally active mu-opioid receptor antagonist with limited oral absorption, has been shown to reduce duration of postoperative ileus, hospital stay, and rate of readmissions in several prospective, randomized, placebo-controlled trials and a subsequent meta-analysis.[34] However, any cost savings associated with the use of this drug outside of a clinical trial have been debated.[35]

Surgical interest in minimizing postoperative ileus has led to exploration of other potential avenues. Experiments in rodents have shown reduced postoperative ileus with enteral administration of lipid-rich nutrition, which is believed to work through a CCK-dependent vagovagal reflex.[36]

Therapy of patients with chronic intestinal pseudo-obstruction focuses on palliation of symptoms as well as fluid, electrolyte, and nutritional management. Surgery should be avoided if at all possible. No standard therapies are curative or delay the natural history of any of the specific disorders causing intestinal pseudo-obstruction. Prokinetic agents, such as metoclopramide and erythromycin, are associated with poor efficacy. Cisapride has been associated with palliation of symptoms; however, because of cardiac toxicity and reported deaths, this agent is restricted to compassionate use in the United States.

Patients with refractory disease may require strict limitation of oral intake and long-term TPN administration. Despite these measures, some patients will continue to have severe abdominal pain or such copious intestinal secretions that vomiting and fluid and electrolyte losses remain substantial. These patients may require a decompressive gastrostomy or an extended small bowel resection to remove abnormal intestine. Small-intestinal transplantation has been applied in these patients with increasing frequency; the ultimate role of this modality remains to be defined.

CROHN'S DISEASE

Crohn's disease is a chronic, idiopathic transmural inflammatory disease with a propensity to affect the distal ileum, although any part of the alimentary tract can be involved. Estimates of the incidence of Crohn's disease in the United States have ranged from 3.6 to 8.8 per 100,000, with recent studies suggesting a prevalence of about 200 cases per 100,000.[37] A dramatic increase in incidence in the United States was observed to occur from the mid-1950s though the early 1970s. Incidence rates have been stable since the 1980s. Substantial regional variations in incidence have been observed, with the highest incidences reported to exist in northern latitudes. The incidence of Crohn's disease varies among ethnic groups within the same geographic region. For example, members of Eastern European Ashkenazi Jewish population are at two- to four-fold higher risk of developing Crohn's disease than members of other populations living in the same location. In countries such as China, the prevalence of Crohn's disease is estimated at 1.38 cases per 100,000, substantially below that seen in the West, but the rates have been on a rapid increase recently.[38]

Most studies suggest that Crohn's disease is slightly more prevalent in females than in males. The mean age at which patients are diagnosed with Crohn's disease falls in the third decade of life years, with a second smaller peak in the sixth decade of life, giving it a bimodal distribution. However, the age at diagnosis can range from early childhood through the entire lifespan.

Both genetic and environmental factors appear to influence the risk for developing Crohn's disease. The relative risk among first-degree relatives of patients with Crohn's disease is 14 to 15 times higher than that of the general population. Approximately one in five patients with Crohn's disease will report having at least one affected relative. The concordance rate among monozygotic twins is as high as 67%; however, Crohn's disease is not associated with simple Mendelian inheritance patterns. Although there is a tendency within families for either ulcerative colitis or Crohn's disease to be present exclusively, mixed kindreds also occur, suggesting the presence of some shared genetic traits as a basis for both diseases.

Higher socioeconomic status is associated with an increased risk of Crohn's disease. Most studies have found breastfeeding to be protective against the development of Crohn's disease. Crohn's disease is more prevalent among smokers. Furthermore, smoking is associated with the increased risk for both the need for surgery and the risk of relapse after surgery for Crohn's disease.

Pathophysiology

Crohn's disease is characterized by sustained inflammation. Whether this inflammation represents an appropriate response to a yet unrecognized pathogen or an inappropriate response to a normally innocuous stimulus is unknown. Various hypotheses on the roles of environmental and genetic factors in the pathogenesis of Crohn's disease have been proposed. Many infectious agents have been suggested to be the causative organism of Crohn's disease. Candidate organisms have included chlamydia, *Listeria monocytogenes*, *Pseudomonas* species, reovirus, *Mycobacterium paratuberculosis*, and many others. There is no conclusive evidence that any of these organisms is the causative agent. Studies using animal models suggest that in a genetically susceptible host, nonpathogenic, commensal enteric flora are sufficient to induce a chronic inflammatory response resembling that associated with Crohn's disease. In these models, the sustained intestinal inflammation is the result of either abnormal epithelial barrier function or immune dysregulation. Poor barrier function is hypothesized to permit inappropriate exposure of lamina propria lymphocytes to antigenic stimuli derived from the intestinal lumen. In addition, a variety of defects in immune regulatory mechanisms (e.g., overresponsiveness of mucosal T cells to enteric flora-derived antigens) can lead to defective immune tolerance and sustained inflammation.

Specific genetic defects associated with Crohn's disease in human patients are beginning to be defined. For example, the presence of a locus on chromosome 16 (the so-called IBD1 locus) has been linked to Crohn's disease. The IBD1 locus has been identified as the *NOD2* gene. Persons with allelic variants on both chromosomes have a 40-fold relative risk of Crohn's disease compared to those without variant *NOD2* genes. The relevance of this gene to the pathogenesis of Crohn's disease is biologically plausible, as the protein product of the *NOD2* gene mediates the innate immune response to microbial pathogens. Other putative IBD loci have been identified on other chromosomes (IBD2 on chromosome 12q and IBD3 on chromosome 6) and are under investigation.

Although the pathologic hallmark of Crohn's disease is focal, transmural inflammation of the intestine, a spectrum of pathologic lesions can be present. The earliest lesion characteristic of Crohn's disease is the aphthous ulcer. These superficial ulcers are up to 3 mm in diameter and are surrounded by a halo

of erythema. In the small intestine, aphthous ulcers typically arise over lymphoid aggregates. Granulomas are highly characteristic of Crohn's disease and are reported to be present in up to 70% of intestinal specimens obtained during surgical resection. These granulomas are noncaseating and can be found in both areas of active disease and apparently normal intestine, in any layer of the bowel wall, and in mesenteric lymph nodes.

As disease progresses, aphthae coalesce into larger, stellate-shaped ulcers. Linear or serpiginous ulcers may form when multiple ulcers fuse in a direction parallel to the longitudinal axis of the intestine. With transverse coalescence of ulcers, a cobblestoned appearance of the mucosa may arise.

With advanced disease, inflammation can be transmural. Serosal involvement results in adhesion of the inflamed bowel to other loops of bowel or other adjacent organs. Transmural inflammation can also result in fibrosis with stricture formation, intra-abdominal abscesses, fistulas, and, rarely, free perforation. Inflammation in Crohn's disease can affect discontinuous portions of intestine—so-called "skip lesions" that are separated by intervening normal-appearing intestine.

A feature of Crohn's disease that is grossly evident and helpful in identifying affected segments of intestine during surgery is the presence of *fat wrapping*, which represents encroachment of mesenteric fat onto the serosal surface of the bowel (Fig. 28-17). This finding is virtually pathognomonic of Crohn's disease. The presence of fat wrapping correlates well with the presence of underlying acute and chronic inflammation.

Features that allow for differentiation between Crohn's disease of the colon and ulcerative colitis include the layers of the bowel wall affected (inflammation in ulcerative colitis is limited to the mucosa and submucosa but may involve the full thickness of the bowel wall in Crohn's disease) and the longitudinal extent of inflammation (inflammation is continuous and characteristically affects the rectum in ulcerative colitis but may be discontinuous and spare the rectum in Crohn's disease). In the absence of full expression of features of advanced disease, Crohn's colitis can sometimes be difficult to distinguish from ulcerative colitis. It is also important to remember that although ulcerative colitis is a disease of the colon, it can be associated with inflammatory changes in the distal ileum (backwash ileitis).

Figure 28-17. Crohn's disease. This intraoperative photograph demonstrates encroachment of mesenteric fat onto the serosal surface of the intestine ("fat wrapping") that is characteristic of intestinal segments affected by active Crohn's' disease.

Clinical Presentation

The most common symptoms of Crohn's disease are abdominal pain, diarrhea, and weight loss. However, the clinical features are highly variable among individual patients and depend on which segment(s) of the GI tract is (are) predominantly affected, the intensity of inflammation, and the presence or absence of specific complications. Patients with Crohn's disease can be classified by their predominant clinical manifestation as having primarily (a) fibrostenotic disease, (b) fistulizing disease, or (c) aggressive inflammatory disease. There is substantial overlap among these disease patterns in individual patients, however. The onset of symptoms is insidious, and once present, their severity follows a waxing and waning course. Constitutional symptoms, particularly weight loss and fever, or growth retardation in children, may also be prominent and are occasionally the sole presenting features of Crohn's disease.

The disease affects the small bowel in 80% of cases and the colon alone in 20%. In those with small bowel disease, the majority have ileocecal disease. The small bowel alone is affected in 15% to 30% of patients. Isolated perineal and anorectal disease occurs in 5% to 10% of affected patients. Uncommon sites of involvement include the esophagus, stomach, and duodenum.

An estimated one fourth of all patients with Crohn's disease will have an extraintestinal manifestation of their disease. One fourth of those affected will have more than one manifestation. Many of these complications are common to both Crohn's disease and ulcerative colitis, although as a whole, they are more prevalent among patients with Crohn's disease than those with ulcerative colitis. The most common extraintestinal manifestations are listed in Table 28-7. The clinical severity of some of these manifestations, such as erythema nodosum and peripheral arthritis, are correlated with the severity of intestinal inflammation. The severity of other manifestations, such as pyoderma gangrenosum and ankylosing spondylitis, bear no apparent relationship to the severity of intestinal inflammation.

Diagnosis

The diagnosis is usually established with endoscopic findings in a patient with a compatible clinical history. The diagnosis should be considered in those presenting with acute or chronic abdominal pain, especially when localized to the right lower quadrant, chronic diarrhea, evidence of intestinal inflammation on radiography or endoscopy, the discovery of a bowel stricture or fistula arising from the bowel, and evidence of inflammation or granulomas on intestinal histology. Disorders associated with clinical presentations that resemble those of Crohn's disease include ulcerative colitis, functional bowel disorders such as irritable bowel syndrome, mesenteric ischemia, collagen vascular diseases, carcinoma and lymphoma, diverticular disease, and infectious enteritides. These infectious enteritides are most frequently diagnosed in immunocompromised patients but can also occur in patients with normal immune function. Acute ileitis caused by *Campylobacter* and *Yersinia* species can be difficult to distinguish from that caused by an acute presentation of Crohn's disease. Typhoid enteritis caused by *Salmonella typhosa* can lead to overt intestinal bleeding and perforation, most often affecting the terminal ileum. The distal ileum and cecum are the most common sites of intestinal involvement by infection due to *Mycobacterium tuberculosis*. This condition can result in intestinal inflammation, strictures, and fistula formation, similar to those seen in Crohn's disease.

Table 28-7

Extraintestinal manifestations of Crohn's disease

Interstitial lung disease
Amyloidosis
Pancreatitis

Cytomegalovirus (CMV) can cause intestinal ulcers, bleeding, and perforation.

No single symptom, sign, or diagnostic test establishes the diagnosis of Crohn's disease. Instead, the diagnosis is based on a complete assessment of the clinical presentation with confirmatory findings derived from radiographic, endoscopic, and in most cases pathologic tests. Colonoscopy with intubation of terminal ileum is the main diagnostic tool and can reveal focal ulcerations adjacent to areas of normal-appearing mucosa along with polypoid mucosal changes that give a "cobblestone appearance." Skip areas of involvement are typical, with segments of normal-appearing bowel interrupted by large areas of obvious disease; this pattern is different from the continuous involvement in ulcerative colitis. Pseudopolyps, as seen in ulcerative colitis, are also often present. Contrast examinations of the small bowel and colon may reveal strictures or networks of ulcers and fissures. CT scanning may reveal intra-abdominal abscesses and is useful in acute presentations to rule out the presence of other intra-abdominal disorders. Esophagogastroduodenoscopy (EGD) is done for disease of the proximal alimentary tract. Because Crohn's disease often affects the small bowel, which is difficult to image, capsule endoscopy has been increasingly used to make this diagnosis (Fig. 28-18).[39]

Several antibodies have also been identified in patients with inflammatory bowel disease, which may have diagnostic value. The most commonly tested antibodies are antineutrophil cytoplasmic antibody (pANCA) and anti-*Saccharomyces cerevisiae* antibody (ASCA). ASCA +/pANCA– is associated with a diagnosis of Crohn's disease, while ASCA–/pANCA+ correlates with ulcerative colitis. Although these antibody tests

Figure 28-18. Crohn's disease. This image was captured by a wireless capsule endoscope as it was traveling through the small intestine. It demonstrates a superficial ulceration in the small bowel consistent with Crohn's disease. *(Used with permission from Dr. Anne C. Travis, Division of Gastroenterology, Brigham and Women's Hospital, Boston, MA.)*

are commercially available, their widespread use has been hampered by low test sensitivities.

Because of the insidious, and often nonspecific, presentation, the diagnosis of Crohn's disease is typically made only after symptoms have been present for several years. However, in acute presentations, the diagnosis is sometimes made intraoperatively or during surgical evaluation. The initial manifestation of Crohn's disease can consist of right lower quadrant abdominal mimicking the presentation of acute appendicitis. In patients with this presentation, Crohn's disease can be discovered for the first time during laparotomy or laparoscopy performed for presumed appendicitis. In some patients, the initial manifestation of Crohn's disease is an acute abdomen related to small bowel obstruction, intra-abdominal abscess, or free intestinal perforation. In other patients, perianal abscesses and fistulas requiring surgical therapy may be the first manifestation of Crohn's disease.

Therapy

Because no curative therapies are available for Crohn's disease, the goal of treatment is to palliate symptoms rather than to achieve cure. Medical therapy is used to induce and maintain disease remission. Surgery is reserved for specific indications described later. In addition nutritional support in the form of aggressive enteral regimens or, if necessary, parenteral nutrition is used to manage the malnutrition that is common in patients with Crohn's disease.

Medical Therapy. Pharmacologic agents used to treat Crohn's disease include antibiotics, aminosalicylates, corticosteroids, and immunomodulators. Antibiotics have an adjunctive role in the treatment of infectious complications associated with Crohn's disease. They are also used to treat patients with perianal disease, enterocutaneous fistulas, and active colonic disease.

Most studies have shown oral 5-aminosalicylic acid (5-ASA) drugs (e.g., mesalamine) to be superior to placebo in inducing disease remission. Their efficacy in the maintenance of remission is less clear. Aminosalicylates are associated with minimal toxicity and are available in a variety of formulations that allow for their delivery to specific regions of the alimentary tract. In Crohn's disease, sulfasalazine, the parent compound of 5-ASA and widely used in ulcerative colitis, has been shown to be less effective than 5-ASA.

Orally administered glucocorticoids are used to treat patients with mildly to moderately severe disease that does not respond to aminosalicylates. Patients with severe active disease usually require intravenous administration of glucocorticoids. Although glucocorticoids are effective in inducing remission, they are ineffective in preventing relapse, and their adverse effect profile makes long-term use hazardous. Therefore, they should be tapered once remission is achieved. Some patients are unable to undergo glucocorticoid tapering without suffering recurrence of symptoms. Such patients are said to have steroid dependence. In these patients, along with those who do not respond to steroids at all (steroid resistant), use of immune modulators should be considered.

The thiopurine antimetabolites azathioprine and its active metabolite, 6-mercaptopurine, have demonstrated efficacy in inducing remission, in maintaining remission, and in allowing for glucocorticoid tapering in glucocorticoid-dependent patients. A response to these medications is usually observed in 3 to 6 months. There is also some evidence that they decrease the risk of relapse after intestinal resection for Crohn's disease. These agents are relatively safe but can induce bone marrow suppression and promote infectious complications. For patients who do not respond to the thiopurines, methotrexate is an alternative that is usually given intramuscularly before switching to an oral form after achieving symptomatic control. There is little role for cyclosporine in Crohn's disease; its efficacy/toxicity profile in this disease is poor.

The successful introduction of infliximab (Remicade), an anti–tumor necrosis factor-α (TNF-α) antibody, heralded the era of biologic therapies for inflammatory bowel disease. Infliximab is a chimeric monoclonal anti-TNFα antibody that has been shown to have efficacy in inducing remission and in promoting closure of enterocutaneous fistulae. It is generally used for patients resistant to standard therapy, in order to help taper steroid dosage. Infliximab is generally well tolerated but should not be used in patients with ongoing septic processes, such as undrained intra-abdominal abscesses. Whereas infliximab is a mouse-human chimeric antibody, the newer drugs in this group include adalimumab (Humira), which is a fully human antibody. Antibodies against other targets in this inflammatory pathway have also been developed and are in various stages of clinical evaluation. Recent studies have shown that these biologic therapies can be used safely after surgery for Crohn's disease. In a randomized study of 24 patients, those receiving infliximab starting 4 weeks after ileal resection had improved endoscopic and histologic scores at 1-year follow-up compared to those receiving placebo.[40]

For patients with perianal disease, antibiotic therapy with metronidazole or ciprofloxacin is the primary step. Two to 4 weeks of therapy is needed before improvements are seen, and often long-term therapy is required to prevent relapse. In cases of relapse, azathioprine can be considered. In patients with fistulas, infliximab and azathioprine are drugs of choice.

Surgical Therapy. Fifty to seventy percent of patients with Crohn's disease will ultimately require at least one surgical intervention for their disease.[41,42] Surgery is generally reserved for patients whose disease is unresponsive to aggressive medical therapy or who develop complications of their disease (Table 28-8). Failure of medical management may be the indication for surgery if symptoms persist despite aggressive therapy for several months or if symptoms recur whenever aggressive therapy is tapered. Surgery should be considered if medication-induced complications arise, specifically corticosteroid-related complications, such as cushingoid features, cataracts, glaucoma, systemic hypertension, compression fractures, or aseptic necrosis of the femoral head. Growth retardation constitutes an indication for surgery in 30% of children with Crohn's disease.

One of the most common indications for surgical intervention is intestinal obstruction. Abscesses and fistulas are frequently encountered during operations performed for intestinal obstruction in these patients, but are rarely the only indication for surgery. Most abscesses are amenable to percutaneous drainage, and fistulas, unless associated with symptoms or metabolic derangements, do not require surgical intervention. Less common complications that require surgical intervention are acute GI hemorrhage, perforations, and development of cancer.

Although most commonly, surgery for Crohn's disease is planned, an uncommon, but not rare, scenario is the intraoperative discovery of inflammation limited to the terminal ileum during operations performed for presumed appendicitis. This scenario can result from an acute presentation of Crohn's disease or from acute ileitis caused by bacteria such as *Yersinia* or *Campylobacter*. Both conditions should be treated medically; ileal resection is not generally indicated. However, the appendix, even if normal appearing, should be removed (unless the cecum is inflamed, increasing the potential morbidity of this procedure) in order to eliminate appendicitis from the differential diagnosis of abdominal pain in these patients, particularly those with Crohn's disease who may be destined to have recurring symptoms.

When the diagnosis of Crohn's disease is known and surgery planned, thorough examination of the entire intestine should be performed. The presence of active disease is suggested by thickening of the bowel wall, narrowing of the lumen, serosal inflammation and coverage by creeping fat, and thickening of the mesentery. Skip lesions are present in approximately

Table 28-8

Indications for surgical intervention in Crohn's disease

Acute onset of severe disease:
Crohn's colitis +/- toxic megacolon (rare)
Failure of medical therapy:
Persistent symptoms despite long-term steroid use
Recurrence of symptoms when high-dose steroids are tapered
Drug-induced complications (Cushing's disease, hypertension)
Development of disease complications:
Obstruction
Perforation
Complicated fistulas
Hemorrhage
Malignancy risk

20% of cases and should be sought. The length of uninvolved small intestine should be noted.

Segmental intestinal resection of grossly evident disease followed by primary anastomosis is the usual procedure of choice. Microscopic evidence of Crohn's disease at the resection margins does not compromise a safe anastomosis, and frozen-section analysis of resection margins is unnecessary. In a randomized prospective trial, the effects of achieving 2-cm resection margins beyond grossly evident disease were compared with achieving 12-cm resection margins.[43] There were no evident differences with respect to clinical recurrence rates or anastomotic recurrences. Recurrence rates were similar whether margins were histologically free of or involved with Crohn's disease. An area of controversy in surgical management of Crohn's disease has been the ideal anastomotic technique for the bowel after intestinal resection. This issue was addressed in a randomized study of 139 patients undergoing an ileocolic resection for Crohn's disease, with a mean follow-up of 11.9 months. There were no differences in endoscopic or symptomatic disease recurrence between the groups reconstructed using end-to-end sutured (2-0 PDS) anastomosis vs. those with side-to-side staples anastomosis.[44]

An alternative to segmental resection for obstructing lesions is stricturoplasty (Fig. 28-19). This technique allows for preservation of intestinal surface area and is especially well suited to patients with extensive disease and fibrotic strictures who may have undergone previous resection and are at risk for developing short bowel syndrome. In this technique, the bowel is opened longitudinally to expose the lumen. Any intraluminal ulcerations should be biopsied to rule out the presence of neoplasia. Depending on the length of the stricture, the reconstruction can be fashioned in a manner similar to the Heinecke-Mickulicz pyloroplasty (for strictures <12 cm in length) or the Finney pyloroplasty (for longer strictures as much as 25 cm in length). For longer strictures, variations on the standard stricturoplasty, namely the side-to-side isoperistaltic enteroenterostomy, have been advocated and used for strictures with mean lengths of 50 cm.[45] Stricturoplasty sites should be marked with metallic clips to facilitate their identification on radiographs and during subsequent operations. Stricturoplasty is associated with recurrence rates that are no different from those associated with segmental resection. Because the affected bowel is left in situ rather than resected, there is the potential for cancer developing at the stricturoplasty site. However, as data on this complication are limited to anecdotes, this risk remains a theoretical one. Stricturoplasty is contraindicated in patients with intra-abdominal abscesses or intestinal fistulas. The presence of a solitary stricture relatively close to a segment for which resection is planned is a relative contraindication. In general, stricturoplasty is performed in cases where single or multiple strictures are identified in diffusely involved segments of bowel or where previous resections have been performed and maintenance of intestinal length is of great importance.

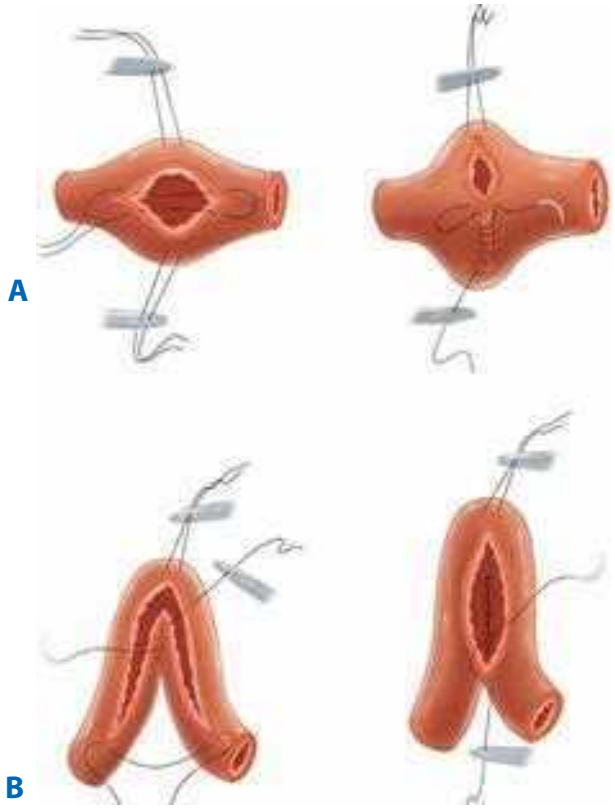

Figure 28-19. Stricturoplasty. The wall of the strictured bowel is incised longitudinally. Reconstruction is performed by closing the defect transversely in a manner similar to the Heinecke-Mickulicz pyloroplasty for short strictures (**A**), or the Finney pyloroplasty for longer strictures (**B**).

Intestinal bypass procedures are sometimes required in the presence of intramesenteric abscesses or if the diseased bowel is coalesced in the form of a dense inflammatory mass, making its mobilization unsafe. Bypass procedures (gastrojejunostomy) are also used in the presence of duodenal strictures, for which stricturoplasty and segmental resection can be technically difficult.

Since the 1990s, laparoscopic surgical techniques have been applied to patients with Crohn's disease. The inflammatory changes associated with Crohn's disease such as thickened and foreshortened mesentery, obliterated tissue planes, and friable tissues with engorged vasculature can make the laparoscopic approach challenging. Randomized studies and a meta-analysis have confirmed that laparoscopic surgery for Crohn's disease is associated with less postoperative pain, shorter duration of ileus, and a shorter hospital stay. The rates of disease recurrence were similar between the two groups.[46]

Outcomes

Overall complication rates following surgery for Crohn's disease range from 15% to 30%. Wound infections, postoperative intra-abdominal abscesses, and anastomotic leaks account for most of these complications.

Most patients whose disease is resected eventually develop recurrence. If recurrence is defined endoscopically, 70% recur within 1 year of a bowel resection and 85% by 3 years.[47] Clinical recurrence, defined as the return of symptoms confirmed as being due to Crohn's disease, affects 60% of patients by 5 years and 94% by 15 years after intestinal resection. Reoperation becomes necessary in approximately one third of patients by 5 years after the initial operation, with a median time to reoperation of 7 to 10 years.[48]

INTESTINAL FISTULAS

A *fistula* is defined as an abnormal communication between two epithelialized surfaces. The communication occurs between two parts of the GI tract or adjacent organs in an *internal fistula* (e.g., enterocolonic fistula or colovesicular fistula). An *external*

fistula (e.g., enterocutaneous fistula or rectovaginal fistula) involves the skin or another external surface epithelium. Enterocutaneous fistulas that drain less than 200 mL of fluid per day are known as *low-output fistulas*, whereas those that drain more than 500 mL of fluid per day are known as *high-output fistulas*.

Over 80% of enterocutaneous fistulas represent iatrogenic complications that occur as the result of enterotomies or intestinal anastomotic dehiscences. Fistulas that arise spontaneously without antecedent iatrogenic injury are usually manifestations of progression of underlying Crohn's disease or cancer.

Pathophysiology

The manifestations of fistulas depend on which structures are involved. Low-resistance enteroenteric fistulas, which allow luminal contents to bypass a significant proportion of the small intestine, may result in clinically significant malabsorption. Enterovesicular fistulas often cause recurrent urinary tract infections. The drainage emanating from enterocutaneous fistulas are irritating to the skin and cause excoriation. The loss of enteric luminal contents, particularly from high-output fistulas originating from the proximal small intestine, results in dehydration, electrolyte abnormalities, and malnutrition.

Fistulas have the potential to close spontaneously. Factors inhibiting spontaneous closure, however, include malnutrition, sepsis, inflammatory bowel disease, cancer, radiation, obstruction of the intestine distal to the origin of the fistula, foreign bodies, high output, short fistulous tract (<2 cm) and epithelialization of the fistula tract (Table 28-9).

Clinical Presentation

Iatrogenic enterocutaneous fistulas usually become clinically evident between the fifth and tenth postoperative days. Fever, leukocytosis, prolonged ileus, abdominal tenderness, and wound infection are the initial signs. The diagnosis becomes obvious when drainage of enteric material through the abdominal wound or through existing drains occurs. These fistulas are often associated with intra-abdominal abscesses.

Diagnosis

CT scanning following the administration of enteral contrast is the most useful initial test. Leakage of contrast material from the intestinal lumen can be observed. Intra-abdominal abscesses should be sought and drained percutaneously. If the anatomy of the fistula is not clear on CT scanning, a small bowel series or enteroclysis examination can be obtained to demonstrate the fistula's site of origin in the bowel. This study is also useful to rule out the presence of intestinal obstruction distal to the site of origin. Occasionally, contrast administered into the intestine does not demonstrate the fistula tract. A *fistulogram*, in which contrast is injected under pressure through a catheter placed percutaneously into the fistula tract, may offer greater sensitivity in localizing the fistula origin.

Table 28-9

Factors negatively impacting enteric fistula closure

Local factors
Persistence of local inflammation and sepsis
Presence of a foreign body (e.g., meshes or sutures)
Epithelialization of fistula tract
Fistula tract <2 cm
Distal obstruction to the fistula site

Therapy

The treatment of enterocutaneous fistulas should proceed through an orderly sequence of steps.[49]

1. *Stabilization*. Fluid and electrolyte resuscitation is begun. Nutrition is provided, usually through the parenteral route initially. Sepsis is controlled with antibiotics and drainage of abscesses. The skin is protected from the fistula effluent with ostomy appliances or fistula drains.
2. *Investigation.* The anatomy of the fistula is defined using the studies described earlier.
3. *Decision.* The available treatment options are considered, and a timeline for conservative measures is determined.
4. *Definitive management*. This entails the surgical procedure and requires appropriate preoperative planning and surgical experience.
5. *Rehabilitation.*

The overall objective is to increase the probability of spontaneous closure. Nutrition and time are the key components of this approach. Most patients will require TPN; however, a trial of oral or enteral nutrition should be attempted in patients with low-output fistulas originating from the distal intestine. The somatostatin analogue octreotide is a useful adjunct, particularly in patients with high-output fistulas; its administration reduces the volume of fistula output, thereby facilitating fluid and electrolyte management. Further, octreotide may accelerate the rate at which fistulas close; however, its administration has not clearly been demonstrated to increase the probability of spontaneous closure.

Timing of Surgical Intervention. Most surgeons would pursue 2 to 3 months of conservative therapy before considering surgical intervention. This approach is based on evidence that 90% of fistulas that are going to close do so within 5 weeks and also that surgical intervention after this time period is associated with better outcomes and lower morbidity.[50]

If the fistula fails to resolve during this period, surgery may be required during which the fistula tract, together with the segment of intestine from which it originates, should be resected. Simple closure of the opening in the intestine from which the fistula originates is associated with high recurrence rates. Patients with intestinal fistulas typically have extensive and dense intra-abdominal adhesions. As a result, operations performed for nonhealing fistulas can present formidable challenges. Successful applications of alternative therapies to close intestinal fistulas such as the use of biologic sealants have been reported. The indications for their use remain to be defined.

Outcomes

Over 50% of intestinal fistulas close spontaneously. A useful mnemonic designates factors that inhibit spontaneous closure of

Table 28-10

Features of small-intestinal malignancies

TUMOR TYPE	CELL OF ORIGIN	FREQUENCY[a]	PREDOMINANT SITE
Adenocarcinoma	Epithelial cell	35%–50%	Duodenum
Carcinoid	Enterochromaffin cell	20%–40%	Ileum
Lymphoma	Lymphocyte	10%–15%	Ileum
GIST	?Interstitial cell of Cajal	10%–15%	—

intestinal fistulas: "FRIEND" (Foreign body within the fistula tract, Radiation enteritis, Infection/Inflammation at the fistula origin, Epithelialization of the fistula tract, Neoplasm at the fistula origin, Distal obstruction of the intestine) (Table 28-10).

In a recent 23-year old retrospective review of 153 cases of enterocutaneous fistulas that were treated surgically, the majority of fistulas were found to originate from the small bowel and be iatrogenic in nature, with patients having undergone five or more previous abdominal surgeries. Operative repair was associated with a 30-day mortality of approximately 4% and a 1-year mortality of 15%. Morbidity was over 80%. First attempt at surgical repair was successful in 70% of cases, with an overall closure rate of 84% and some patients requiring up to three attempts at surgical repair. The authors identified closure of the abdominal fascia as an important factor in reducing rates of refistulization and postoperative mortality.[51] In another similar study, fistula recurrence rates of 30% were again documented and were independently associated with high-output fistulas and the type of surgical treatment: operations not involving resection of the fistula had a much higher rate of recurrence.[52]

SMALL BOWEL NEOPLASMS

Adenomas are the most common benign neoplasm of the small intestine. Other benign tumors include fibromas, lipomas, hemangiomas, lymphangiomas, and neurofibromas. The prevalence of small bowel tumors identified at autopsy is 0.2% to 0.3%, which is significantly higher than the rate of operation for small bowel tumors. This suggests that the majority of small bowel tumors are asymptomatic. These lesions are most frequently encountered in the duodenum as incidental findings during esophagogastroduodenoscopic (EGD) examinations (Fig. 28-20). The reported prevalence of duodenal polyps, as detected during EGD performed for other reasons, ranges from 0.3% to 4.6%.[53]

Benign neoplasms account for 30% to 50% of small bowel tumors and include adenomas, lipomas, hamartomas, and hemangiomas. Primary small bowel cancers are rare, with an estimated incidence of 5300 cases per year in the United States.[54] Among small bowel cancers, adenocarcinomas comprise 35% to 50% of all cases, carcinoid tumors comprise 20% to 40%, and lymphomas comprise approximately 10% to 15%. In a retrospective review of a large U.S. database (Surveillance, Epidemiology, and End Results) between 1992 and 2006, of a total of 10,945 small intestine cancers, 4315 were neuroendocrine in origin, 3412 were carcinomas, 2023 were lymphomas, and 1084 were sarcomas.[55] GI stromal tumors (GISTs) are the most common mesenchymal tumors arising in the small intestine and comprise the vast majority of tumors that were formerly classified as leiomyomas, leiomyosarcomas, and smooth muscle tumors of the intestine. The small intestine is frequently affected by metastases from or local invasion by cancers originating at other sites. Melanoma, in particular, is associated with a propensity for metastasis to the small intestine.

Figure 28-20. Duodenal polyp. This polyp was incidentally encountered during esophagogastroduodenoscopy. It was biopsied and found to be an adenoma.

Most patients with small-intestinal cancers are in their fifth or sixth decade of life. Reported risk factors for developing small-intestinal cancers include consumption of red meat, ingestion of smoked or cured foods, Crohn's disease, celiac sprue, hereditary nonpolyposis colorectal cancer (HNPCC), familial adenomatous polyposis (FAP), and Peutz-Jeghers syndrome.

Pathophysiology

The small intestine contains over 90% of the mucosal surface area of the GI tract, but only 1.1% to 2.4% of all GI malignancies. Proposed explanations for the low frequency of small-intestinal neoplasms include (a) dilution of environmental carcinogens in the liquid chyme present in the small-intestinal lumen, (b) rapid transit of chyme, limiting the contact time between carcinogens and the intestinal mucosa, (c) a relatively

low concentration of bacteria in small-intestinal chyme and, therefore, a relatively low concentration of carcinogenic products of bacterial metabolism, (d) mucosal protection by secretory IgA and hydrolases such as benzpyrene hydroxylase that may render carcinogens less active, and (e) efficient epithelial cellular apoptotic mechanisms that serve to eliminate clones harboring genetic mutations.

Recent advances have begun to clarify the molecular pathogenesis of small-intestinal adenocarcinomas and GISTs; there has been less progress with respect to the pathogenesis of the other small-intestinal malignancies (see Table 28-10). Small-intestinal adenocarcinomas are believed to arise from pre-existing adenomas through a sequential accumulation of genetic abnormalities in a model similar to that described for the pathogenesis of colorectal cancer. Adenomas are histologically classified as tubular, villous, and tubulovillous. Tubular adenomas have the least aggressive features. Villous adenomas have the most aggressive features and tend to be large, sessile, and located in the second portion of the duodenum. Malignant degeneration has been reported to be present in up to 45% of villous adenomas by the time of diagnosis. Patients with FAP have a nearly 100% cumulative lifetime risk of developing duodenal adenomas that have the potential to undergo malignant transformation. The risk of duodenal cancer in these patients is over 100-fold that in the general population. Indeed, duodenal cancer is the leading cause of cancer-related death among patients with FAP who have undergone colectomy. Patients with Peutz-Jeghers syndrome develop hamartomatous polyps; however, these polyps can contain adenomatous foci that can undergo malignant transformation (Fig. 28-21).

A defining feature of GISTs is their gain-of-function mutation of proto-oncogene KIT, a receptor tyrosine kinase. Pathologic KIT signal transduction is believed to be a central event in GIST pathogenesis. The majority of GISTs have activating mutations in the c-*kit* protooncogene, which cause KIT to become constitutively activated, presumably leading to persistence of cellular growth or survival signals. Because the interstitial cells of Cajal normally express KIT, these cells have been implicated as the cell of origin for GISTs. KIT expression is assessed by staining the tissues for CD117 antigen, which is part of the KIT receptor, and present in 95% of GISTs.

Figure 28-21. Small bowel polyp in Peutz-Jeghers syndrome. This image was captured by a wireless capsule endoscope as it was traveling through the small intestine. *(Used with permission from Dr. Anne C. Travis, Division of Gastroenterology, Brigham and Women's Hospital, Boston, MA.)*

Clinical Presentation

Most small-intestinal neoplasms are asymptomatic until they become large. Partial small bowel obstruction, with associated symptoms of crampy abdominal pain and distention, nausea, and vomiting, is the most common mode of presentation. Obstruction can be the result of either luminal narrowing by the tumor itself or intussusception, with the tumor serving as the lead point. Hemorrhage, usually indolent, is the second most common mode of presentation.

Physical examination may be unrevealing. Up to 25% of patients with small-intestinal malignancies are reported to have a palpable abdominal mass. Findings of intestinal obstruction are reported to be present in 25% of patients. Fecal occult blood test may be positive. Jaundice secondary to biliary obstruction or hepatic metastasis may be present. Cachexia, hepatomegaly, and ascites may be present with advanced disease.

Although the clinical presentation is usually not specific for tumor type, some general comments are appropriate. Adenocarcinomas, as well as adenomas (from which most are believed to arise), are most commonly found in the duodenum, except in patients with Crohn's disease, in whom most are found in the ileum. Lesions in the periampullary location can cause obstructive jaundice or pancreatitis. Adenocarcinomas located in the duodenum tend to be diagnosed earlier in their progression than those located in the jejunum or ileum, which are rarely diagnosed prior to the onset of locally advanced or metastatic disease.

Carcinoid tumors of the small intestine are also usually diagnosed after the development of metastatic disease. These tumors are associated with a more aggressive behavior than the more common appendiceal carcinoid tumors. Approximately 25% to 50% of patients with carcinoid tumor–derived liver metastases will develop manifestations of the carcinoid syndrome. These manifestations include diarrhea, flushing, hypotension, tachycardia, and fibrosis of the endocardium and valves of the right heart. Candidate tumor-derived mediators of the carcinoid syndrome such as serotonin, bradykinin, and substance P undergo nearly complete metabolism during first passage through the liver. As a result, symptoms of carcinoid syndrome are rare in the absence of liver metastases.

Lymphoma may involve the small intestine primarily or as a manifestation of disseminated systemic disease. Primary small-intestinal lymphomas are most commonly located in the ileum, which contains the highest concentration of lymphoid tissue in the intestine. Although partial small bowel obstruction is the most common mode of presentation, 10% of patients with small-intestinal lymphoma present with bowel perforation.

Sixty to seventy percent of GISTs are located in the stomach. The small intestine is the second most common site, containing 25% to 35% of GISTs. There appears to be no regional variation in the prevalence of GISTs within the small intestine. GISTs have a greater propensity to be associated with overt hemorrhage than the other small-intestinal malignancies (Fig. 28-22).

Metastatic tumors involving the small intestine can induce intestinal obstruction and bleeding.

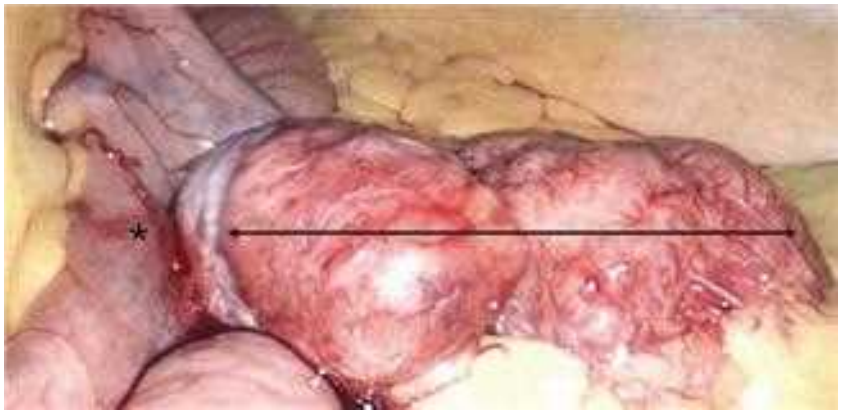

Figure 28-22. Jejunal gastrointestinal (GI) stromal tumor (GIST). This patient presented with overt obscure GI bleeding and was found to have a 7-cm jejunal GIST. The picture represents the laparoscopic view of the mass (*black arrow*), arising from the antimesenteric side of the small bowel (*). He underwent a successful laparoscopic resection.

Diagnosis

Because of the absent or nonspecific symptoms associated with most small-intestinal neoplasms, these lesions are rarely diagnosed preoperatively. Laboratory tests are nonspecific, with the exception of elevated serum 5-hydroxyindole acetic acid (5-HIAA) levels in patients with the carcinoid syndrome. Elevated carcinoembryonic antigen (CEA) levels are associated with small-intestinal adenocarcinomas, but only in the presence of liver metastases.

Contrast radiography of the small intestine may demonstrate benign and malignant lesions. Enteroclysis is reported to have a sensitivity of over 90% in the detection of small bowel tumors and is the test of choice, particularly for tumors located in the distal small bowel. Upper GI with small bowel follow-through examinations have reported sensitivities ranging from only 30% to 44%.[55] CT scanning has low sensitivity for detecting mucosal or intramural lesions but can demonstrate large tumors and is useful in the staging of intestinal malignancies. Tumors associated with significant bleeding can be localized with angiography or radioisotope-tagged red blood cell (RBC) scans.

Tumors located in the duodenum can be visualized and biopsied on EGD. In addition, endoscopic ultrasonography (EUS) can offer additional information such as the layers of the intestinal wall involved by the lesion. Occasionally, the distal ileum can be successfully visualized during colonoscopy. Intraoperative enteroscopy can be used to directly visualize small-intestinal tumors beyond the reach of standard endoscopic techniques. Recently, capsule endoscopy and double-balloon endoscopy have been used to evaluate small bowel.

Therapy

Benign neoplasms of the small intestine that are symptomatic should be surgically resected or removed endoscopically, if feasible. Tumors located in the duodenum, including asymptomatic lesions incidentally found during EGD, can pose the greatest therapeutic challenges. These lesions should be biopsied; symptomatic tumors and adenomas, because of their malignant potential, should be removed. In general, duodenal tumors less than 1 cm in diameter are amenable to endoscopic polypectomy. Lesions greater than 2 cm in diameter are technically difficult to remove endoscopically and may need to be removed surgically. Surgical options include transduodenal polypectomy and segmental duodenal resection. Tumors located in the second portion of the duodenum near the ampulla of Vater may require pancreaticoduodenectomy. EUS may offer utility for duodenal tumors ranging in size between 1 and 2 cm in diameter, with those limited to the mucosa being amenable to endoscopic polypectomy. Recent studies have shown that endoscopic resection of biopsy-proven benign duodenal periampullary adenomas leads to equivalent efficacy to surgery but with lower morbidity. Adenomas can recur; therefore, surveillance endoscopy is required after these procedures.[56]

Duodenal adenomas occurring in the setting of FAP require an especially aggressive approach to management. Patients with FAP should undergo screening EGD starting sometime during their second or third decade of life. Adenomas detected should be removed endoscopically, if possible, followed by surveillance endoscopy in 6 months and yearly thereafter, in the absence of recurrence. If surgery is required, pancreaticoduodenectomy is generally necessary because adenomas in patients with FAP tend to be multiple and sessile, with a predilection for the periampullary region. Further, localized resections are complicated by high recurrence rates. Given the potential for recurrences in the duodenal remnant following pylorus-preserving pancreaticoduodenectomy, there is rationale for recommending the application of standard pancreaticoduodenectomy in these patients. However, recurrences have been reported even following this procedure; therefore, continuing surveillance is necessary. For most adenocarcinomas of the duodenum, except those in the third or fourth portion of the duodenum where a local resection could be considered, pancreaticoduodenectomy is required.

The surgical therapy of jejunal and ileal malignancies usually consists of wide local resection of the intestine harboring the lesion. For adenocarcinomas, a wide excision of corresponding mesentery is done to achieve regional lymphadenectomy, as is done for adenocarcinomas of the colon. In the presence of locally advanced or metastatic disease, palliative intestinal resection or bypass is performed. Chemotherapy has no proven efficacy in the adjuvant or palliative treatment of small-intestinal adenocarcinomas.

The goal of surgical therapy for carcinoids is resection of all visible disease. Localized small-intestinal carcinoid tumors should be treated with segmental intestinal resection and regional lymphadenectomy. Nodal metastases are unusual with tumors less than 1 cm in diameter but are present with 75% to 90% of tumors larger than 3 cm in diameter. In approximately 30% of cases, multiple small-intestinal carcinoid tumors are present. Therefore, the entire small intestine should be examined before planning extent of resection. In the presence of metastatic disease, tumor debulking should be conducted as it can be associated with long-term survival and amelioration of symptoms of the carcinoid syndrome. Response rates of 30% to 50% have been reported with chemotherapy regimens based on

agents such as doxorubicin, 5-fluorouracil, and streptozocin. However, none of these regimens is associated with a clearly demonstrable impact on the natural history of disease. Octreotide is the most effective pharmacologic agent for management of symptoms of carcinoid syndrome.

Localized small-intestinal lymphoma should be treated with segmental resection of the involved intestine and adjacent mesentery. If the small intestine is diffusely affected by lymphoma, chemotherapy rather than surgical resection should be the primary therapy. The value to adjuvant chemotherapy after resection of localized lymphoma is controversial.

Small-intestinal GISTs should be treated with segmental intestinal resection. If the diagnosis is known prior to resection, wide lymphadenectomy can be avoided as GISTs are rarely associated with lymph node metastases. GISTs are resistant to conventional chemotherapy agents. Imatinib (Gleevec) is a tyrosine kinase inhibitor with potent activity against the tyrosine kinase KIT and is used in those with metastatic disease. Clinical trials have shown that 80% of patients with unresectable or metastatic GISTs derive clinical benefit from the administration of imatinib, with 50% to 60% having objective evidence of reduction in tumor volume.[57] Imatinib has shown great promise as a neoadjuvant and adjuvant therapy of GISTs. Studies have emphasized the potential for development of tumor resistance to this agent. In this setting, an alternative tyrosine kinas inhibitor, sunitinib, has been used with good results.[57]

Metastatic cancers affecting the small intestine that are symptomatic should be treated with palliative resection or bypass except in the most advanced cases. Systemic therapy may be offered if effective chemotherapy exists for the primary cancer.

Outcomes

Complete resection of duodenal adenocarcinomas is associated with postoperative 5-year survival rates ranging from 50% to 60%. Complete resection of adenocarcinomas located in the jejunum or ileum is associated with 5-year survival rates of 20% to 30%.[58] Five-year survival rates of 75% to 95% following resection of localized small-intestinal carcinoid tumors have been reported. In the presence of carcinoid tumor–derived liver metastases, 5-year survival rates of 19% to 54% have been reported. The overall 5-year survival rate for patients diagnosed with intestinal lymphoma ranges from 20% to 40%. For patients with localized lymphoma amenable to surgical resection, the 5-year survival rate is 60%.

The recurrence rate after resection of GISTs averages 35%. The 5-year survival rate after surgical resection has been reported to range from 35% to 60%. Both tumor size and mitotic index are independently correlated with prognosis. Low-grade tumors (mitotic index <10 per high-power field) measuring less than 5 cm in diameter are associated with excellent prognosis.

RADIATION ENTERITIS

Radiation therapy is a component of multimodality therapy for many intra-abdominal and pelvic cancers such as those of the cervix, endometrium, ovary, bladder, prostate, and rectum. An undesired side effect of radiation therapy is radiation-induced injury to the small intestine, which can present clinically as two distinct syndromes: acute and chronic radiation enteritis. Acute radiation enteritis is a transient condition that occurs in approximately 75% of patients undergoing radiation therapy for abdominal and pelvic cancers. Chronic radiation is enteritis is inexorable and develops in approximately 5% to15% of these patients.

Pathophysiology

Radiation induces cellular injury directly and through the generation of free radicals. The principal mechanism of radiation-induced cell death is believed to be apoptosis resulting from free radical–induced breaks in double-stranded DNA. Because radiation has its greatest impact on rapidly proliferating cells, the small-intestinal epithelium is acutely susceptible to radiation-induced injury. Pathologic correlates of this acute injury include villus blunting and a dense infiltrate of leukocytes and plasma cells within the crypts. With severe cases, mucosal sloughing, ulceration, and hemorrhage are observed. The intensity of injury is related to the dose of radiation administered, with most cases occurring in patients who have received *at least 4500 cGy*. Risk factors for acute radiation enteritis include conditions that may limit splanchnic perfusion such as hypertension, diabetes mellitus, coronary artery disease, and restricted mobility of the small intestine due to adhesions. Injury is potentiated by concomitant administration of chemotherapeutic agents such as doxorubicin, 5-fluorouracil, dactinomycin, and methotrexate that act as radiation sensitizers. Because of the intestinal epithelium's capacity for regeneration, the mucosal injury that is characteristic of acute radiation enteritis resolves after the cessation of radiation therapy.

In contrast, chronic radiation enteritis is characterized by a progressive occlusive vasculitis that leads to chronic ischemia and fibrosis that affects all layers of the intestinal wall, rather than the mucosa alone. These changes can lead to strictures, abscesses, and fistulas, which are responsible for the clinical manifestations of chronic radiation enteritis.

Clinical Presentation

The most common manifestations of acute radiation enteritis are nausea, vomiting, diarrhea, and crampy abdominal pain. Symptoms are generally transient and subside after the discontinuation of radiation therapy. Because the diagnosis is usually obvious, given the clinical context, no specific diagnostic tests are required. However, if patients develop signs suggestive of peritonitis, CT scanning should be performed to rule out the presence of other conditions capable of causing acute abdominal syndromes.

The clinical manifestations of chronic radiation enteritis usually become evident within 2 years of radiation administration, although they can begin as early as several months or as late as decades afterward. The most common clinical presentation is one of partial small bowel obstruction, with nausea, vomiting, intermittent abdominal distention, crampy abdominal pain, and weight loss being the most common symptoms. The terminal ileum is the most frequently affected segment. Other manifestations of chronic radiation enteritis include complete bowel obstruction, acute or chronic intestinal hemorrhage, and abscess or fistula formation.

Diagnosis

Evaluation of patients suspected of having chronic radiation enteritis should include review of the records of their radiation treatments for information on total radiation dose administered, fractionation, and volume of treatment. Areas that received high doses should be noted, as lesions subsequently found in imaging studies usually localize to areas that had received high

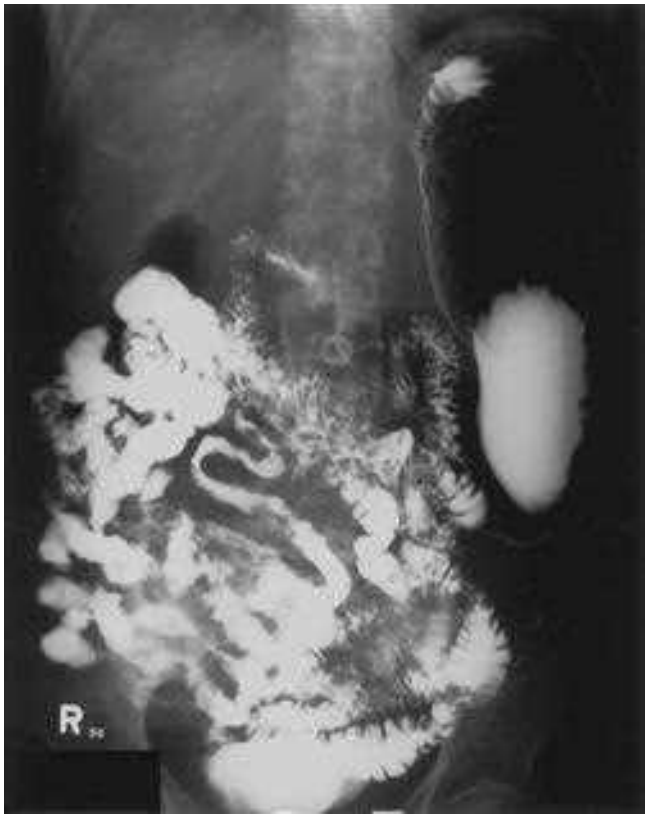

Figure 28-23. Radiation enteritis. This contrast radiograph reveals widely separated loops of small bowel with luminal narrowing, loss of mucosal folds, and ulceration. This patient had received radiation therapy for a pelvic malignancy 8 years before this examination.

radiation doses. Enteroclysis is the most accurate imaging test for diagnosing chronic radiation enteritis, with reported sensitivities and specificities of over 90% (Fig. 28-23). CT scan findings are neither very sensitive nor specific for chronic radiation enteritis. However, CT scanning should be obtained to rule out the presence of recurrent cancer since its clinical manifestations may overlap with those of chronic radiation enteritis.

Therapy

Most cases of acute radiation enteritis are self-limited. Supportive therapy, including the administration of antiemetics, is usually sufficient. Patients with diarrhea-induced dehydration may require hospital admission and parenteral fluid administration. Rarely are symptoms severe enough to necessitate reduction in or cessation of radiation therapy.

In contrast, the treatment of chronic radiation enteritis represents a formidable challenge. Surgery for this condition is difficult, is associated with high morbidity rates, and should be avoided in the absence of specific indications such as high-grade obstruction, perforation, hemorrhage, intra-abdominal abscesses, and fistulas. The goal of surgery is limited resection of diseased intestine with primary anastomosis between healthy bowel segments. However, the characteristically diffuse nature of fibrosis and dense adhesions among bowel segments can make limited resection difficult to achieve. Further, it is difficult to distinguish between normal and irradiated intestine intraoperatively by either gross inspection or even frozen section analysis. This distinction is important as anastomoses between irradiated segments of intestine have been associated with leak rates as high as 50%.[59] If limited resection is not achievable, an intestinal bypass procedure may be an option, except in cases for which hemorrhage is the surgical indication. There remain cases in which resections extensive enough to cause short bowel syndrome are unavoidable. This condition is discussed in detail later in the Short Bowel Syndrome section.

Outcomes

Acute radiation injury to the intestine is self-limited; its severity is not correlated with the probability of chronic radiation enteritis developing. Surgery for chronic radiation enteritis is associated with high morbidity rates and reported mortality rates averaging 10%.

Prevention

In view of significant morbidity associated with radiation enteritis, groups have studied possible measures to reduce or prevent such side effects. Keeping radiation exposure to below 5000 cGy is associated with minimal long-term side effects and recommended where clinically possible.

Multi-beam radiation techniques to minimize the area of maximal radiation exposure and tilt tables to move the bowel out of the pelvis during radiation are increasingly used. Few small studies have suggested that oral sulfasalazine may help reduce the incidence of acute radiation-induced enteritis.[60]

In patients undergoing pelvic surgery who are likely to require postoperative radiation therapy, surgical techniques that keep the small bowel out of the pelvis have been recommended. These measures include use of absorbable mesh sling to separate the pelvis from the true abdominal cavity and prevent the small bowel from being exposed to pelvic radiation.[61]

MECKEL'S DIVERTICULUM

Meckel's diverticulum is the most prevalent congenital anomaly of the GI tract, affecting approximately 2% of the general population. Meckel's diverticula are designated *true diverticula* because their walls contain all of the layers found in normal small intestine. Their location varies among individual patients, but they are usually found in the ileum within 100 cm of the ileocecal valve (Fig. 28-24). Approximately 60% of Meckel's diverticula contain heterotopic mucosa, of which over 60% consist of

Figure 28-24. Meckel's diverticulum. This intraoperative photograph shows Meckel's diverticulum in ileum that has been eviscerated.

gastric mucosa. Pancreatic acini are the next most common; others include Brunner's glands, pancreatic islets, colonic mucosa, endometriosis, and hepatobiliary tissues. A useful, although crude, mnemonic describing Meckel's diverticula is the "rule of two's": 2% prevalence, 2:1 male predominance, location 2 feet proximal to the ileocecal valve in adults, and half of those who are symptomatic are under 2 years of age.

Pathophysiology

During the eighth week of gestation, the omphalomesenteric (vitelline) duct normally undergoes obliteration. Failure or incomplete vitelline duct obliteration results in a spectrum of abnormalities, the most common of which is Meckel's diverticulum. Other abnormalities include omphalomesenteric fistula, enterocyst, and a fibrous band connecting the intestine to the umbilicus. A remnant of the left vitelline artery can persist to form a mesodiverticular band tethering a Meckel's diverticulum to the ileal mesentery.

Bleeding associated with Meckel's diverticulum is usually the result of ileal mucosal ulceration that occurs adjacent to acid-producing, heterotopic gastric mucosa located within the diverticulum. Intestinal obstruction associated with Meckel's diverticulum can result from several mechanisms:

1. Volvulus of the intestine around the fibrous band attaching the diverticulum to the umbilicus
2. Entrapment of intestine by a mesodiverticular band (Fig. 28-25)
3. Intussusception with the diverticulum acting as a lead point
4. Stricture secondary to chronic diverticulitis

Meckel's diverticula can be found in inguinal or femoral hernia sacs (known as Littre's hernia). These hernias, when incarcerated, can cause intestinal obstruction.

Clinical Presentation

Meckel's diverticula are asymptomatic unless associated complications arise. The lifetime incidence rate of complications arising in patients with Meckel's diverticula has been estimated to be approximately 4% to 6%.[62,63] Although initial data had suggested that the risk of developing a complication related to Meckel's diverticulum decreases with age, this has been now been questioned. In a population-based review at Olmsted County, MN, Cullen and colleagues showed that the risk of developing Meckel's-related complications does not change with age.[63]

The most common presentations associated with symptomatic Meckel's diverticula are bleeding, intestinal obstruction, and diverticulitis. Bleeding is the most common presentation in children with Meckel's diverticula, representing over 50% of Meckel's diverticulum–related complications among patients less than 18 years of age. Bleeding associated with Meckel's diverticula is rare among patients older than 30 years of age.

Intestinal obstruction is the most common presentation in adults with Meckel's diverticula. Diverticulitis, present in 20% of patients with symptomatic Meckel's diverticula, is associated with a clinical syndrome that is indistinguishable from acute appendicitis. Neoplasms, most commonly carcinoid tumors, are present in 0.5% to 3.2% of symptomatic Meckel's diverticula that are resected.[56]

Diagnosis

Most Meckel's diverticula are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. In the absence of bleeding, Meckel's diverticula rarely are diagnosed prior to the time of surgical intervention. For those presenting with symptoms suggestive of a Meckel's diverticulum, confirmatory imaging can be challenging. The sensitivity of CT scanning for the detection of Meckel's diverticula is too low to be clinically useful. Enteroclysis is associated with an accuracy of 75% but is usually not applicable during acute presentations of complications related to Meckel's diverticula. Radionuclide scans (^{99m}Tc-pertechnetate) can be helpful in the diagnosis of Meckel's diverticulum; however, this test is positive only when the diverticulum contains associated ectopic gastric mucosa that is capable of uptake of the tracer (Fig. 28-26). The accuracy of radionuclide scanning is reported to be 90% in pediatric patients but less than 50% in adults. Angiography can localize the site of bleeding during acute hemorrhage related to Meckel's diverticula.

Therapy

The surgical treatment of symptomatic Meckel's diverticula should consist of diverticulectomy with removal of associated bands connecting the diverticulum to the abdominal wall or intestinal mesentery. If the indication for diverticulectomy is bleeding, segmental resection of ileum that includes both the diverticulum and the adjacent ileal peptic ulcer should be performed. Segmental ileal resection may also be necessary if the diverticulum contains a tumor or if the base of the diverticulum is inflamed or perforated.

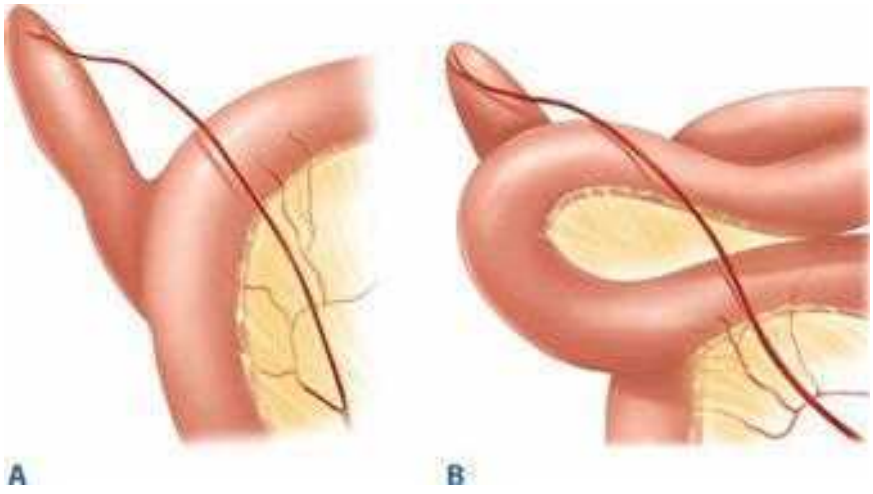

Figure 28-25. **A.** Meckel's diverticulum with mesodiverticular band. **B.** One mechanism by which Meckel's diverticula can cause small bowel obstruction is entrapment of the intestine by a mesodiverticular band.

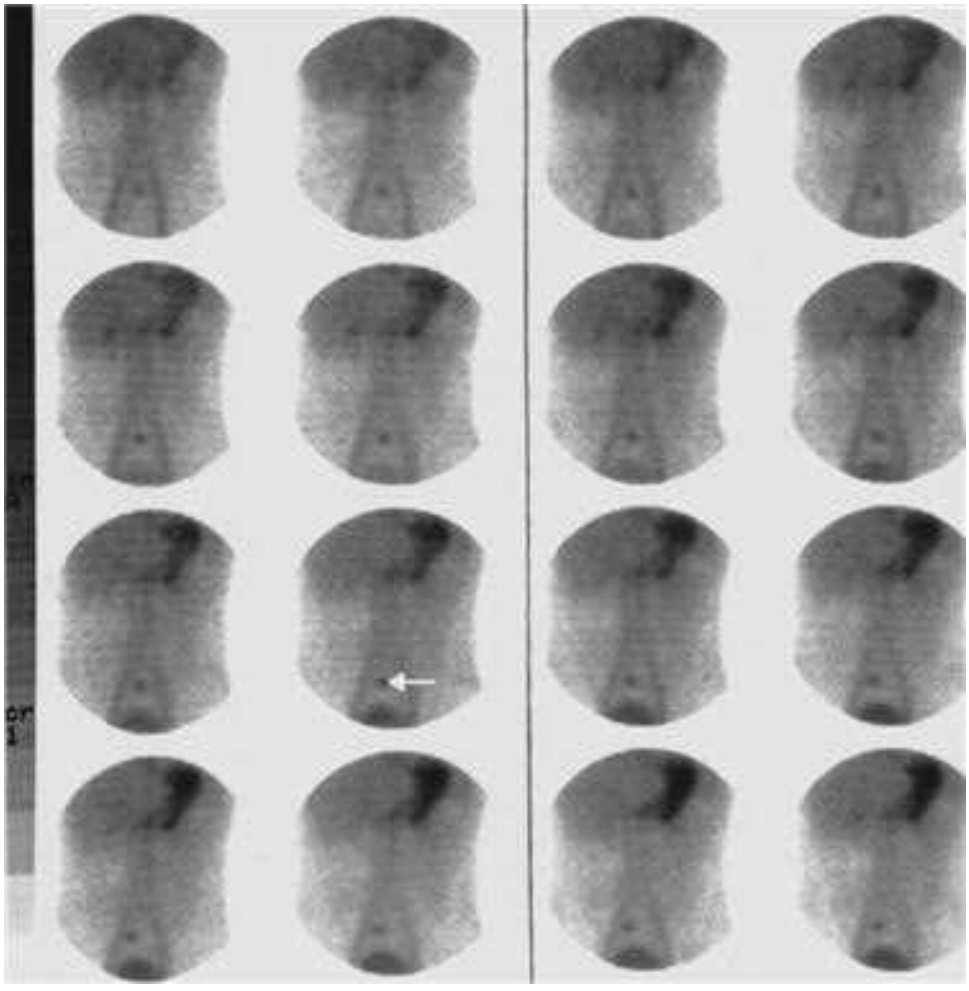

Figure 28-26. Meckel's diverticulum with ectopic gastric tissue. The diagnosis was made in this patient using ^{99m}Tc-pertechnetate scintigraphy. The study revealed an abnormal focus of radiotracer accumulation in the right lower quadrant (*arrow*).

The management of incidentally found (asymptomatic) Meckel's diverticula is controversial. Until recently, most authors recommended against prophylactic removal of asymptomatic Meckel's diverticula, given the low lifetime incidence of complications. More recently, greater enthusiasm for prophylactic diverticulectomy has appeared in the literature.[63] Proponents of this approach cite the minimal morbidity associated with removing Meckel's diverticula and the possibility that previous estimates of the lifetime incidence of complications related to Meckel's diverticula may be erroneously low. Other authors have advocated a selective approach, with a recommendation to remove diverticula attached by bands and those with narrow bases, on the assumption that these diverticula are more likely to develop complications. No controlled data supporting or refuting these recommendations exist.

ACQUIRED DIVERTICULA

Acquired diverticula are designated *false diverticula* because their walls consist of mucosa and submucosa but lack a complete muscularis. Acquired diverticula are more common in the duodenum and tend to be located near the ampulla; such diverticula are known as *periampullary*, *juxtapapillary*, or *perivaterian diverticula*. Approximately 75% of juxtapapillary diverticula arise on the medial wall of the duodenum. Acquired diverticula in the jejunum or ileum are known as *jejunoileal diverticula*. Eighty percent of jejunoileal diverticula are localized to the jejunum, 15% to the ileum, and 5% to both jejunum and ileum. Diverticula in the jejunum tend to be large and accompanied by multiple other diverticula, whereas those in the ileum tend to be small and solitary.

The prevalence of duodenal diverticula, as detected on upper GI examinations (Fig. 28-27), has been reported to range from 0.16% to 6%.[64] Their prevalence, as detected during endoscopic retrograde cholangiography (ERCP) examinations, has been reported to range from 5% to 27%. A 23% prevalence rate has been reported in an autopsy series. The prevalence of duodenal diverticula increases with age; they are rare in patients under the age of 40 years. The mean age of diagnosis ranges from 56 to 76 years.

The prevalence of jejunoileal diverticula (Fig. 28-28) has been estimated to range from 1% to 5%.[65] Their prevalence increases with age; most patients diagnosed with these diverticula are in the sixth and seventh decades of life.

Pathophysiology

The pathogenesis of acquired diverticula is hypothesized to be related to acquired abnormalities of intestinal smooth muscle or dysregulated motility, leading to herniation of mucosa and submucosa through weakened areas of muscularis.

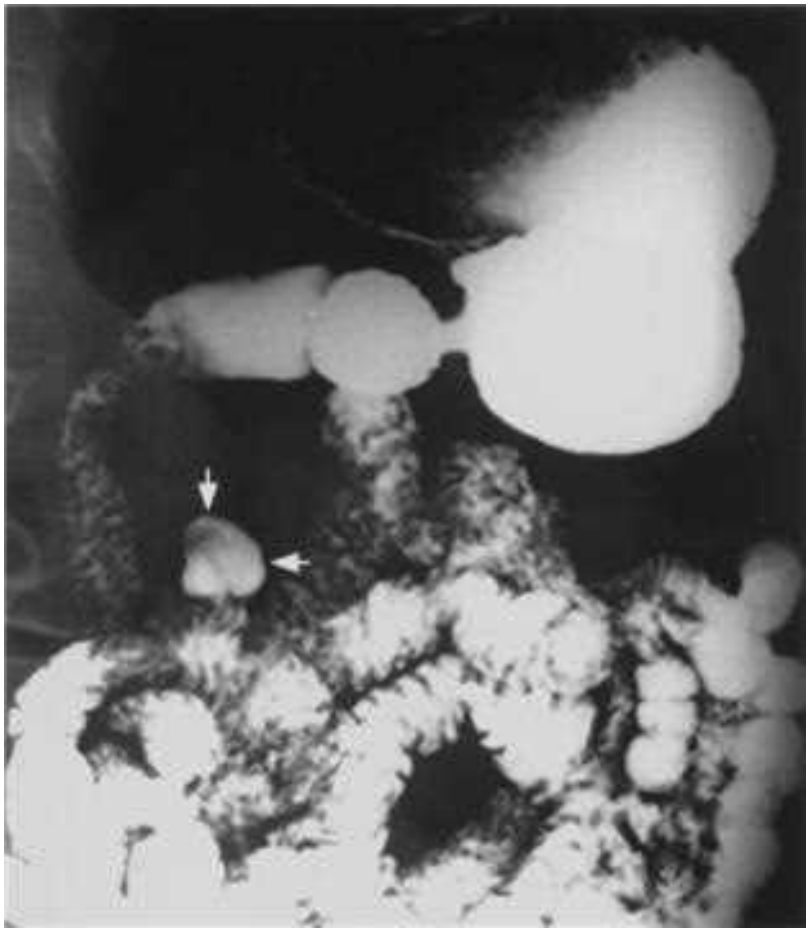

Figure 28-27. Duodenal diverticulum. This contrast radiograph demonstrates a duodenal diverticulum (*arrows*) that extends medially into the substance of the head of the pancreas.

Acquired diverticula can be associated with bacterial overgrowth, leading to vitamin B_{12} deficiency, megaloblastic anemia, malabsorption, and steatorrhea. Periampullary duodenal diverticula have been described to become distended with intraluminal debris and to compress the common bile duct or pancreatic duct, thus causing obstructive jaundice or pancreatitis, respectively. Jejunoileal diverticula can also cause intestinal obstruction through intussusception or compression of adjacent bowel.

Clinical Presentation

Acquired diverticula are asymptomatic unless associated complications arise. Such complications are estimated to occur in 6% to 10% of patients with acquired diverticula and include intestinal obstruction, diverticulitis, hemorrhage, perforation, and malabsorption. Periampullary duodenal diverticula may be associated with choledocholithiasis, cholangitis, recurrent pancreatitis, and sphincter of Oddi dysfunction. However, a clear link between the presence of the diverticula and the development of these

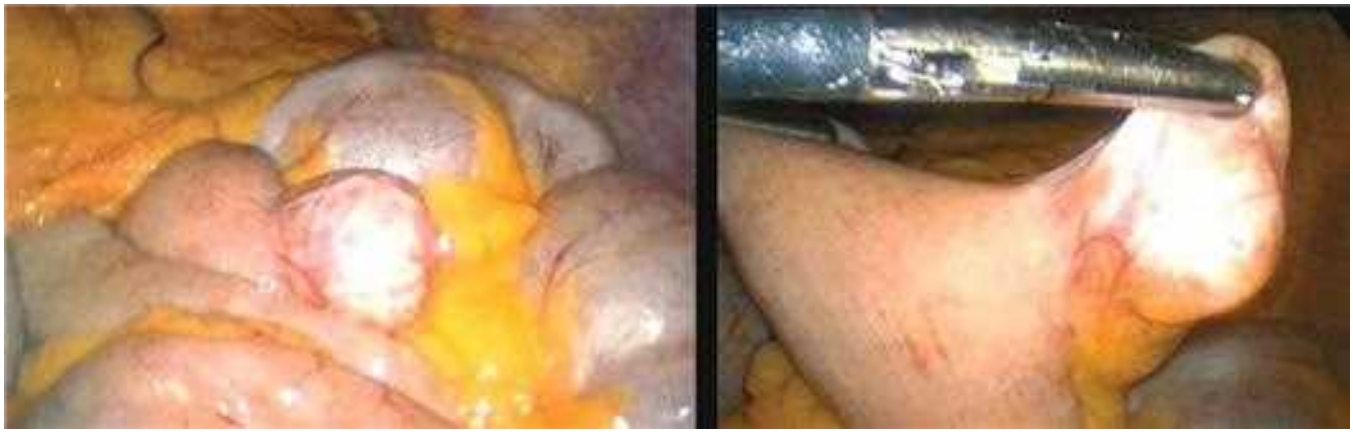

Figure 28-28. Jejunoileal diverticula. This picture demonstrates incidental jejunal diverticula identified during a laparoscopic cholecystectomy. The diverticula are typically located on the mesenteric aspect of the jejunum. Resection was not indicated because the diverticula were asymptomatic.

conditions has not been demonstrated. Symptoms such as intermittent abdominal pain, flatulence, diarrhea, and constipation are reported to be present in 10% to 30% of patients with jejunoileal diverticula. The relationship between these symptoms and the presence of diverticula is similarly unclear.

Diagnosis

Most acquired diverticula are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. On ultrasound and CT scanning, duodenal diverticula may be mistaken for pancreatic pseudocysts and fluid collections, biliary cysts, and periampullary neoplasms. These lesions can be missed on endoscopy, particularly with forward-viewing endoscopes, and are best diagnosed on upper GI radiographs. Enteroclysis is the most sensitive test for detecting jejunoileal diverticula.

Therapy

Asymptomatic acquired diverticula should be left alone. Bacterial overgrowth associated with acquired diverticula is treated with antibiotics. Other complications, such as bleeding and diverticulitis, are treated with segmental intestinal resection for diverticula located in the jejunum or ileum.

Bleeding and obstruction related to lateral duodenal diverticula are generally treated with diverticulectomy alone. These procedures can be technically difficult for medial duodenal diverticula that penetrate into the substance of the pancreas. Complications related to these medial duodenal diverticula should be managed nonoperatively, if possible, using endoscopy. In emergent situations, bleeding related to medial duodenal diverticula can be controlled using a lateral duodenotomy and oversewing of the bleeding vessel. Similarly, perforation can be managed with wide drainage rather than complex surgery. Whether diverticulectomy should be done in patients with biliary or pancreatic symptoms is controversial and is not routinely recommended.[58]

MESENTERIC ISCHEMIA

Mesenteric ischemia can present as one of two distinct clinical syndromes: acute mesenteric ischemia and chronic mesenteric ischemia.

Four distinct pathophysiologic mechanisms can lead to *acute mesenteric ischemia*:

1. Arterial embolus
2. Arterial thrombosis
3. Vasospasm (also known as nonocclusive mesenteric ischemia [NOMI])
4. Venous thrombosis

Embolus is the most common cause of acute mesenteric ischemia and is responsible for over 50% of cases. The embolic source is usually in the heart, most often the left atrial or ventricular thrombi or valvular lesions. Indeed, up to 95% of patients with acute mesenteric ischemia due to emboli will have a documented history of cardiac disease. Embolism to the superior mesenteric artery accounts for 50% of cases; most of these emboli become wedged and cause occlusion at branch points in the mid to distal superior mesenteric artery, usually distal to the origin of the middle colic artery. In contrast, acute occlusions due to thrombosis tend to occur in the proximal mesenteric arteries, near their origins. Acute thrombosis is usually superimposed on pre-existing atherosclerotic lesions at these sites. NOMI is the result of vasospasm and is usually diagnosed in critically ill patients receiving vasopressor agents.

Mesenteric venous thrombosis accounts for 5% to 15% of cases of acute mesenteric ischemia and involves the superior mesenteric vein in 95% of cases.[66] The inferior mesenteric vein is only rarely involved. Mesenteric venous thrombosis is classified as primary if no etiologic factor is identifiable or as secondary if an etiologic factor, such as heritable or acquired coagulation disorders, is identified.

Regardless of the pathophysiologic mechanism, acute mesenteric ischemia can lead to intestinal mucosal sloughing within 3 hours of onset and full-thickness intestinal infarction by 6 hours.

In contrast, *chronic mesenteric ischemia* develops insidiously, allowing for development of collateral circulation, and, therefore, rarely leads to intestinal infarction. Chronic mesenteric arterial ischemia results from atherosclerotic lesions in the main splanchnic arteries (celiac, superior mesenteric, and inferior mesenteric arteries). In most patients with symptoms attributable to chronic mesenteric ischemia, at least two of these arteries are either occluded or severely stenosed. A chronic form of mesenteric venous thrombosis can involve the portal or splenic veins and may lead to portal hypertension, with resulting esophagogastric varices, splenomegaly, and hypersplenism.

Severe abdominal pain, out of proportion to the degree of tenderness on examination, is the hallmark of acute mesenteric ischemia, regardless of the pathophysiologic mechanism. The pain is typically perceived to be colicky and most severe in the midabdomen. Associated symptoms can include nausea, vomiting, and diarrhea. Physical findings are characteristically absent early in the course of ischemia. With the onset of bowel infarction, abdominal distension, peritonitis, and passage of bloody stools occur.

Chronic mesenteric ischemia presents insidiously. Postprandial abdominal pain is the most prevalent symptom, producing a characteristic aversion to food ("food fear") and weight loss. These patients are often thought to have a malignancy and suffer a prolonged period of symptoms before the correct diagnosis is made.

Most patients with chronic mesenteric venous thrombosis are asymptomatic because of the presence of extensive collateral venous drainage routes; this condition is usually discovered as an incidental finding on imaging studies. However, some patients with chronic mesenteric venous thrombosis present with bleeding from esophagogastric varices.

The diagnosis and management of these disorders, which are of primary vascular origin, are discussed in the section on mesenteric artery occlusive disease in the chapter on arterial disease.

MISCELLANEOUS CONDITIONS

Obscure Gastrointestinal Bleeding

Up to 90% of lesions responsible for GI bleeding are within the reach EGD and colonoscopy. *Obscure GI bleeding* refers to GI bleeding for which no source has been identified by routine endoscopic studies (EGD and colonoscopy). *Overt GI* bleeding refers to the presence of hematemesis, melena, or hematochezia. In contrast, *occult GI bleeding* occurs in the absence of overt bleeding and is identified on laboratory tests (e.g., iron-deficiency anemia) or examination of the stool (e.g., positive guaiac test). Obscure GI bleeding is occult in 20% of cases.[67]

Obscure bleeding can be frustrating for both the patient and the clinician, and this is particularly true for obscure-overt bleeding, which cannot be localized despite aggressive diagnostic measures. One study from a tertiary referral center reported that the typical patient with obscure-overt bleeding had suffered intermittent episodes of hemorrhage for 26 months, had undergone up to 20 diagnostic tests, and had received an average of 20 units of blood before reaching a diagnosis.[68] Most of the small bowel is beyond the reach of these examinations and, hence, contains most lesions responsible for obscure GI bleeding. Small-intestinal angiodysplasias account for approximately 75% of cases in adults, and neoplasms account for approximately 10%. Meckel's diverticulum is the most common etiology of obscure GI bleeding in children. Other etiologies of obscure GI bleeding include Crohn's disease, infectious enteritides, nonsteroidal anti-inflammatory drug (NSAID)-induced ulcers and erosions, vasculitis, ischemia, varices, diverticula, and intussusception.

5▶

The diagnostic evaluation of patients with obscure GI bleeding should be tailored to the severity of bleeding and to the availability of technology and expertise. Enteroscopy is playing an increasingly important role. Several endoscopic techniques for visualizing the small intestine are available: push enteroscopy, Sonde enteroscopy, intraoperative enteroscopy, double-balloon endoscopy, and wireless capsule enteroscopy.

Push enteroscopy entails advancing a long endoscope (such as a pediatric or adult colonoscope or a specialized instrument) beyond the ligament of Treitz into the proximal jejunum. This procedure can allow for visualization of approximately 60 cm of the proximal jejunum. Diagnostic yield in patients with obscure GI bleeding ranges from 3% to 65%. In addition to diagnosis, push enteroscopy allows for cauterization of bleeding sites.

In Sonde enteroscopy, a long, thin fiberoptic instrument is propelled through the intestine by peristalsis following inflation of a balloon at the instrument's tip. Visualization is done during instrument withdrawal; approximately 50% to 75% of the small-intestinal mucosa can be examined. However, this instrument lacks biopsy or therapeutic capability. Further, it lacks tip deflection capability, limiting complete mucosal visualization, and has therefore been abandoned in favor of capsule endoscopy.

Wireless capsule enteroscopy relies on a radiotelemetry capsule enteroscope that is small enough to swallow and has no external wires, fiberoptic bundles, or cables. While the capsule is being propelled through the intestine by peristalsis, video images are transmitted using radiotelemetry to an array of detectors attached to the patient's body. These detectors capture the images and permit continuous triangulation of the capsule location in the abdomen, facilitating the localization of lesions detected. The entire system is portable, allowing the patient to be ambulatory during the entire examination. Capsule endoscopy is an excellent tool in the patient who is hemodynamically stable but continues to bleed. This technique has reported success rates as high as 90% in identifying a small bowel pathology. Although many studies have shown an improved diagnostic yield for small bowel lesions with capsule endoscopy, the impact of this new imaging modality on actual patient outcomes was not studied until recently. In a randomized study of patients with obscure GI bleeding, evaluation with capsule endoscopy vs. small bowel contrast study had a much higher diagnostic yield (30% vs. 7%, respectively); however, this did not translate into an improvement in outcomes. The rates of rebleeding, hospitalization, need for blood transfusion, and therapeutic interventions were similar between the two arms.

The inability to perform biopsies or carry out any therapeutic interventions of capsule endoscope likely prevents the improved diagnostic yield of the test from translating into improved patient outcomes and highlights the continuing challenge with evaluation of the small bowel.[69]

For patients in whom bleeding from an obscure GI source has apparently stopped, push enteroscopy or capsule enteroscopy is a reasonable initial study. If these examinations do not reveal a potential source of bleeding, then enteroclysis should be performed. Standard small bowel follow-through examinations are associated with a low diagnostic yield in this setting and should be avoided. If still no diagnosis has been made, a "watch-and-wait" approach is reasonable, although angiography should be considered if the prior episode of bleeding was overt. Angiography can reveal angiodysplasia and vascular tumors in the small intestine even in the absence of ongoing bleeding.

For persistent mild bleeding from an obscure GI source, push and capsule enteroscopy can be used. If these examinations are nondiagnostic, then ^{99m}Tc-labeled RBC scanning should be performed and, if positive, followed by angiography to localize the source of bleeding. ^{99m}Tc-pertechnetate scintigraphy to diagnose Meckel's diverticulum should be considered, although its yield in patients older than 40 years of age is extremely low. Patients who remain undiagnosed but continue to bleed and those with recurrent episodic bleeding significant enough to require blood transfusions should then undergo exploration with intraoperative enteroscopy.

Patients with persistent severe bleeding from an obscure source should undergo angiography to help localize the bleeding source. Therapy can be tailored based on the source. Push enteroscopy can also be attempted, but capsule enteroscopy is too slow to be applicable in this setting. If these examinations fail to localize the source of bleeding, exploratory laparoscopy or laparotomy with intraoperative enteroscopy is indicated. Intraoperative enteroscopy can be done during either laparotomy or laparoscopy. An endoscope (usually a colonoscope) is inserted into the small bowel through peroral intubation or through an enterotomy made in the small bowel or cecum. The endoscope is advanced by successively telescoping short segments of intestine onto the end to the instrument. In addition to the endoscopic image, the transilluminated bowel should be examined externally with the operating room lights dimmed, as this maneuver may facilitate the identification of angiodysplasias. Identified lesions should be marked with a suture placed on the serosal surface of the bowel; these lesions can be resected after completion of endoscopy. Examination should be performed during instrument insertion rather than withdrawal because instrument-induced mucosal trauma can be confused with angiodysplasias.

Fig. 28-29 provides a diagnostic and management algorithm for patients with obscure GI bleeding.

Small Bowel Perforation

Prior to the 1980s, duodenal perforation due to peptic ulcer disease was the most common form of small bowel perforation. Today, iatrogenic injury incurred during GI endoscopy is the most common cause of small bowel perforation. Other etiologies of small bowel perforation include infections (especially tuberculosis, typhoid, and CMV), Crohn's disease, ischemia, drugs (e.g., potassium- and NSAID-induced ulcers), radiation-induced

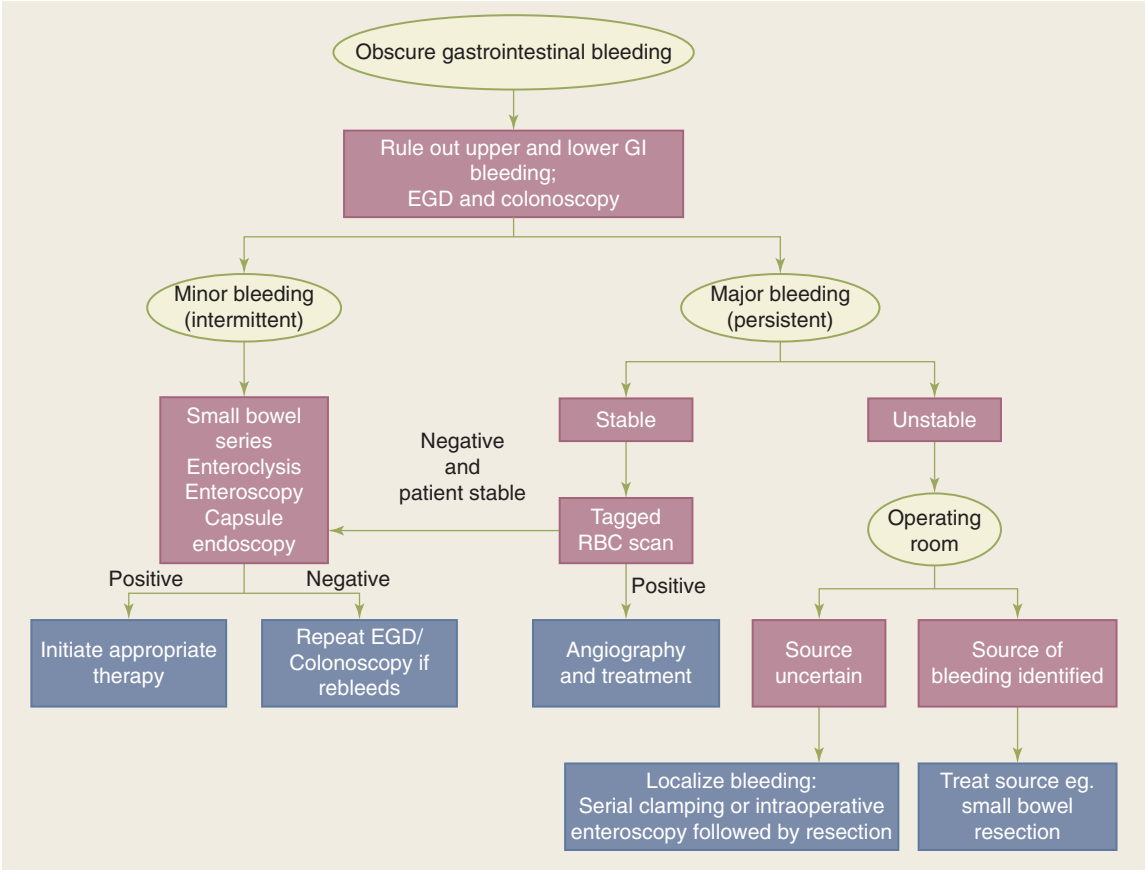

Figure 28-29. Diagnostic and management algorithm for obscure gastrointestinal (GI) bleeding. EGD = esophagogastroduodenoscopy; RBC = red blood cell.

injury, Meckel's and acquired diverticula, neoplasms (especially lymphoma, adenocarcinoma, and melanoma), and foreign bodies.

Among iatrogenic injuries, duodenal perforation during ERCP with endoscopic sphincterotomy (ES) is the most common. This complication occurs in 0.3% to 2.1% of cases. Patients who have undergone Billroth II gastrectomy are at increased risk of duodenal perforations as well as free jejunal perforations during ERCP. Although ERCP-related duodenal perforations can result in a free perforation, most are retroperitoneal. Manifestations of such contained duodenal perforations following ERCP can resemble those of ERCP-induced pancreatitis, including hyperamylasemia.

CT scanning is the most sensitive test for diagnosing duodenal perforations; positive findings include pneumoperitoneum for free perforations, but more commonly retroperitoneal air, contrast extravasation, and paraduodenal fluid collections. If all patients undergoing a therapeutic ERCP are imaged with a CT scan following the procedure, up to 30% will have evidence of air in the retroperitoneum, but the majority are asymptomatic. These patients do not require any specific therapy.[70]

True cases of retroperitoneal perforations of the duodenum can be managed nonoperatively, in the absence of progression and sepsis. However, intraperitoneal duodenal perforations require surgical repair with pyloric exclusion and gastrojejunostomy or tube duodenostomy. Iatrogenic small bowel perforation incurred during endoscopy, if immediately recognized, can sometimes be repaired using endoscopic techniques.

Perforation of the jejunum and ileum occurs into the peritoneal cavity and usually causes overt symptoms and signs, such as abdominal pain, tenderness, and distention accompanied by fever and tachycardia. Plain abdominal radiographs may reveal free intraperitoneal air if intraperitoneal perforation has occurred. If perforation is suspected but not clinically obvious, CT scanning should be performed. Jejunal and ileal perforations require surgical repair or segmental resection.

Chylous Ascites

Chylous ascites refers to the accumulation of triglyceride-rich peritoneal fluid with a milky or creamy appearance, caused by the presence of intestinal lymph in the peritoneal cavity. Chylomicrons, produced by the intestine and secreted into lymph during the absorption of long-chain fatty acids, account for the characteristic appearance and triglyceride content of chyle.

The most common etiologies of chylous ascites in Western countries are abdominal malignancies and cirrhosis. In Eastern and developing countries, infectious etiologies, such as tuberculosis and filariasis, account for most cases. Chylous ascites can also develop as a complication of abdominal and thoracic operations and trauma. Operations particularly associated with this complication include abdominal aortic aneurysm repair, retroperitoneal lymph node dissection, inferior vena cava resection, and liver transplantation. Other etiologies of chylous ascites include congenital lymphatic abnormalities (e.g., primary lymphatic hypoplasia), radiation, pancreatitis, and right-sided heart failure.

Three mechanisms have been postulated to cause chylous ascites: (a) exudation of chyle from dilated lymphatics on the wall of the bowel and in the mesentery caused by obstruction of lymphatic vessels at the base of the mesentery or the cisterna chili (e.g., by malignancies); (b) direct leakage of chyle through

a lymphoperitoneal fistula (e.g., those that develop as a result of trauma or surgery); and (c) exudation of chyle through the wall of dilated retroperitoneal lymphatic vessels (e.g., in congenital lymphangiectasia or thoracic duct obstruction).

Patients with chylous ascites develop abdominal distention over a period of weeks to months. Postoperative chylous ascites can present acutely during the first postoperative week. Delayed presentations following surgery can occur if the mechanism of ascites formation is adhesion-induced lymphatic obstruction rather than lymphatic vessel disruption. Dyspnea may result if abdominal distention is severe enough.

Paracentesis is the most important diagnostic test. Chyle typically has a cloudy and turbid appearance; however, it may be clear in fasting patients (such as those in the immediate postoperative period). Fluid triglyceride concentrations above 110 mg/dL are diagnostic. CT scanning may be useful in identifying pathologic intra-abdominal lymph nodes and masses and in identifying extent and localization of fluid. Lymphangiography and lymphoscintigraphy may help localize lymph leaks and obstruction; this information is particularly useful for surgical planning.

There are few data on optimal management of patients with chylous ascites. The general approach is to focus on evaluating and treating the underlying causes, especially for patients with infectious, inflammatory, or hemodynamic etiologies for this condition.

Most patients respond to administration of a high-protein and low-fat diet supplemented with medium-chain triglycerides. This regimen is designed to minimize chyle production and flow. Medium-chain triglycerides are absorbed by the intestinal epithelium and are transported to liver through the portal vein; they do not contribute to chylomicron formation.

Patients who do not respond to this approach should be fasted and placed on TPN. Octreotide can further decrease lymph flow. Paracentesis is indicated for respiratory difficulties related to abdominal distention. Overall, two thirds of patients will respond to conservative therapy. However, one third of patients will require surgical therapy for chylous ascites. In general, postoperative and trauma-related cases that fail to respond to initial nonoperative therapy are best managed by surgical repair. Lymphatic leaks are localized and repaired with fine nonabsorbable sutures. If extravasation of chyle is localized to the periphery of the small bowel mesentery, then a limited small bowel resection can be performed instead. For patients who are poor surgical candidates and do not respond to prolonged conservative therapy, peritoneovenous shunting may be an option. However, these shunts are associated with high rates of complications, including sepsis and disseminated intravascular coagulation. Because of the viscosity of chyle, these shunts are associated with a high occlusion rate.

Intussusception

Intussusception refers to a condition where one segment of the intestine becomes drawn in to the lumen of the proximal segment of the bowel. It is usually seen in the pediatric population, where the cecum intussuscepts into the ileum (ileocolic intussusception). In children, it is often an idiopathic condition and treated nonsurgically by radiologic reduction.

Adult intussusceptions are far less common and usually have a distinct pathologic lead point, which can be malignant in up to one half of cases.[71] They commonly present with a history of intermittent abdominal pain and signs and symptoms of bowel obstruction. CT scan is the investigation of choice, where a "target sign" may be seen (Fig. 28-30). Treatment is surgical resection of the involved segment and the lead point, which needs to undergo pathologic evaluation to rule out an underlying malignancy.

With increasing use of CT imaging, target signs are sometimes seen on CT scans of patients who do not have a clinical presentation indicative of bowel obstruction. In such cases, the finding is of little clinical significance and is probably related to normal peristalsis.

In patients who have undergone a Roux-en-Y gastric bypass surgery, an atypical form of intussusception has been increasingly described. In these cases, the proximal bowel is drawn in to the lumen of the distal bowel (retrograde intussusception). These intussusceptions are usually not associated with a lead point and may represent a motility disorder of the bowel following the Roux-en-Y reconstruction. Surgical reductions without resection have been successfully reported in these patients.[72]

Pneumatosis Intestinalis

Pneumatosis intestinalis indicates the presence of gas within the bowel wall. It may affect any region of the GI tract, but is most

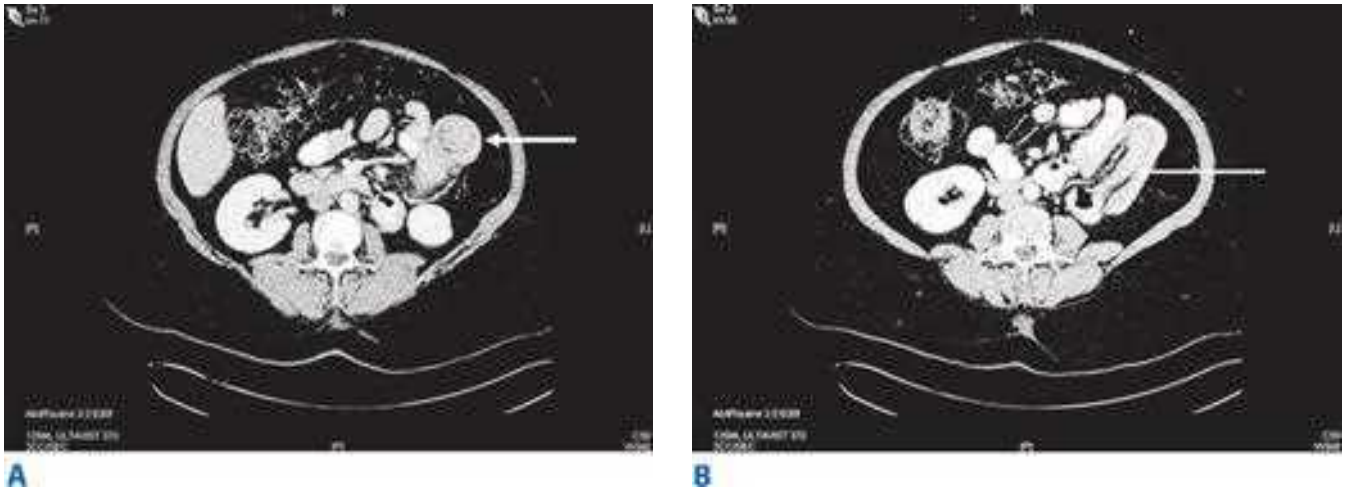

Figure 28-30. Small bowel intussusception. Panel **A** demonstrate the target sign seen on computed tomography scans in patients with small bowel intussusception (*arrow*). Panel **B** demonstrates the distal bowel clearly within the lumen of the proximal bowel (*arrow*).

commonly seen in the jejunum. Pneumatosis intestinalis is not a disease but merely a sign that can be idiopathic or associated with many intestinal or nonintestinal disorders such as obstructive pulmonary disease and asthma. Most cases of pneumatosis intestinalis are secondary to an identifiable cause, and 15% are idiopathic. The pathogenesis of pneumatosis intestinalis is not fully understood.

The surgical interest in this finding is the association of it with bowel ischemia and infarction, both of which necessitate emergent surgical intervention (see Fig. 28-15). Thus, patients with this radiologic finding need to be fully evaluated and monitored closely to rule out such intra-abdominal catastrophes.

SHORT BOWEL SYNDROME

Intestinal resection is performed for many of the diseases discussed in this chapter and generally is associated with minimal morbidity. However, when extent of resection is great enough, a devastating condition known as short bowel syndrome may result. *Short bowel syndrome* has been arbitrarily defined as the presence of less than 200 cm of residual small bowel in adult patients.[73] A functional definition, in which insufficient intestinal absorptive capacity results in the clinical manifestations of diarrhea, dehydration, and malnutrition, is more broadly applicable.

6▶

In adults, the most common etiologies of short bowel syndrome are acute mesenteric ischemia, malignancy, and Crohn's disease. Seventy-five percent of cases result from resection of a large amount of small bowel at a single operation. Twenty-five percent of cases result from the cumulative effects of multiple operations during which small intestine is resected. This latter pattern is typical of patients with Crohn's disease who develop short bowel syndrome; the former is typical of patients with acute mesenteric ischemia who develop intestinal infarction. In pediatric patients, intestinal atresias, volvulus, and necrotizing enterocolitis are the most common etiologies of short bowel syndrome.

The prevalence of short bowel syndrome is hard to estimate. The most recent available data on chronic home total TPN administration were obtained in 1992. At that time, approximately 40,000 patients were receiving TPN chronically at home. The most prevalent indication for TPN among these patients was short bowel syndrome; however, this estimate does not include patients with short bowel syndrome not receiving TPN at home. It also fails to include those who have been weaned off of TPN.[74]

Pathophysiology

Resection of less than 50% of the small intestine is generally well tolerated. However, clinically significant malabsorption occurs when greater than 50% to 80% of the small intestine has been resected. Among adult patients who lack a functional colon, lifelong TPN dependence is likely to persist if there is less than 100 cm of residual small intestine. Among adult patients who have an intact and functional colon, lifelong TPN dependence is likely to persist if there is less than 60 cm of residual small intestine. Among infants with short bowel syndrome, weaning from TPN dependence has been achieved with as little as 10 cm of residual small intestine.

Residual bowel length is not the only factor predictive of achieving independence from TPN (enteral autonomy), however. Other determinants of the severity of malabsorption include the presence or absence of an intact colon, as indicated earlier. The colon has the capacity to absorb large fluid and electrolyte loads. In addition, the colon can play an important, albeit small, role in nutrient assimilation by absorbing short-chain fatty acids. Second, an intact ileocecal valve is believed to be associated with decreased malabsorption. The ileocecal valve delays transit of chyme from the small intestine into the colon, thereby prolonging the contact time between nutrients and the small-intestinal absorptive mucosa. Third, healthy, rather than diseased, residual small intestine is associated with decreased severity of malabsorption. Fourth, resection of jejunum is better tolerated than resection of ileum, as the capacity for bile salt and vitamin B_{12} absorption is specific to the ileum (Table 28-11).

Table 28-11

Risk factors for development of short bowel syndrome after massive small bowel resection

Small bowel length <200 cm
Absence of ileocecal valve
Absence of colon
Diseased remaining bowel (e.g., Crohn's disease)
Ileal resection

During the first 1 to 2 years following massive small bowel resection, the remaining intestine undergoes compensatory adaptation, as discussed earlier. Clinically, the period of adaptation is associated with reductions in volume and frequency of bowel movements, increases in the capacity for enteral nutrient assimilation, and reductions in TPN requirements. As this process completes, some patients are successfully weaned off TPN. Understanding the mechanisms mediating intestinal adaptation may suggest strategies for enhancing adaptation in patients with short bowel syndrome who are unable to achieve independence from TPN. To date, the phenomenon of intestinal adaptation in patients remains poorly understood.[13]

Malabsorption in patients who have undergone massive small bowel resection is exacerbated by a characteristic hypergastrinemia-associated gastric acid hypersecretion that persists for 1 to 2 years postoperatively. The increased acid load delivered to the duodenum inhibits absorption by a variety of mechanisms, including the inhibition of digestive enzymes, most of which function optimally under alkaline conditions.

Therapy

Medical Therapy. For patients having undergone massive small bowel resection, the initial treatment priorities include management of the primary condition precipitating the intestinal resection and the repletion of fluid and electrolytes lost in the severe diarrhea that characteristically occurs. Most patients will require TPN, at least initially. Enteral nutrition should be gradually introduced, once ileus has resolved. High-dose histamine-2 receptor antagonists or proton pump inhibitors should be administered to reduce gastric acid secretion. Antimotility agents, such as loperamide hydrochloride or diphenoxylate, may be administered to delay small-intestinal transit. Octreotide can be administered to reduce the volume of GI secretions, although in animal models, its use is associated with an inhibition of intestinal adaptation.

During the period of adaptation, generally lasting 1 to 2 years postoperatively, TPN and enteral nutrition are titrated

in an attempt to allow for independence from TPN. Patients who remain dependent on TPN face substantial TPN-associated morbidities including catheter sepsis, venous thrombosis, liver and kidney failure, and osteoporosis. Liver failure is a significant source of morbidity and often leads to liver transplantation (always in combination with small bowel transplantation). Due to these complications, patients with short bowel syndrome on TPN have a reduced life expectancy, with 5-year survival rates of 50% to 75%. Costs associated with chronic TPN administration are estimated to be as high as $150,000 per patient annually. Because of these problems, alternative therapies for short bowel syndrome are under investigation.

Nontransplant Surgical Therapy. Among patients with stomas, restoration of intestinal continuity should be performed whenever possible to capitalize on the absorptive capacity of all residual intestine. Other forms of nontransplant surgery designed to improve intestinal absorption are associated with unclear efficacy and/or substantial morbidities and therefore should not be applied routinely.

The goal of these operations is to increase nutrient and fluid absorption by either slowing intestinal transit or increasing intestinal length. Operations designed to slow intestinal transit include segmental reversal of the small bowel, interposition of a segment of colon between segments of small bowel, construction of small-intestinal valves, and electrical pacing of the small intestine. Reported experience with these procedures is limited to case reports or series of a few cases. Objective evidence of increased absorption is lacking; further, these procedures are frequently associated with intestinal obstruction.

The intestinal lengthening operation that has the longest history is the longitudinal intestinal lengthening and tailoring (LILT) procedure, first described by Bianchi in 1980.[75] The procedure entails separation of the dual vasculature of the small intestine, followed by longitudinal division of the bowel with subsequent isoperistaltic end-to-end anastomosis. This procedure has the potential to double the length of small intestine to which it is applied. This procedure has generally been used for pediatric patients with *dilated* residual small bowel.

An alternative surgical approach to lengthening the small bowel is the serial transverse enteroplasty procedure (STEP). This procedure is designed to accomplish lengthening of dilated small intestine without the need for separating its dual vasculature (Fig. 28-31). A recent report from an international registry of 111 patients showed that 47% of patients achieved enteral autonomy at a median follow-up of 21 months.[76]

Intestinal Transplantation. This complex procedure is being increasingly performed to treat patients with short bowel syndrome. Approximately 1850 patients worldwide had undergone this procedure by 2009.[77] The currently accepted indication for intestinal transplantation is the presence of life-threatening complications attributable to intestinal failure and/or long-term TPN therapy. Specific complications for which intestinal transplantation is indicated include (a) impending or overt liver failure, (b) thrombosis of major central veins, (c) frequent episodes of catheter-related sepsis, and (d) frequent episodes of severe dehydration.

Of the transplants involving the intestine, 37% were intestine-alone transplants, 30% included intestine + liver + pancreas, and 24% were intestine + liver.[77]

Isolated intestinal transplantation is used for patients with intestinal failure who have no significant liver disease or failure of other organs. Combined intestine/liver transplantation is used for patients with both intestinal and liver failure. Multivisceral transplantation has been used for patients with giant desmoid tumors involving the vascular supply of the liver and pancreas as well as that of the intestine, for diffuse GI motility disturbances, and for diffuse splanchnic thrombosis.

Nearly 80% of survivors have full intestinal graft function with no need for TPN. However, morbidities associated with intestinal transplantation are substantial and include acute and chronic rejection, CMV infection, and posttransplant lymphoproliferative disease.

Alternative Therapies. Pharmacologic and biologic therapies designed to expand intestinal mucosal surface area or to enhance the efficiency of intestinal absorption are beginning to undergo clinical evaluation. Promising regimens include GLP-2 and the combination of glutamine and growth hormone with a modified, high-carbohydrate diet.

Outcomes

Approximately 50% to 70% of patients with short bowel syndrome who initially require TPN are ultimately able to

Figure 28-31. This figure depicts the serial transverse enteroplasty (STEP) procedure. Lengthening of dilated small intestine is accomplished by serial applications of an intestinal stapling device, with firings oriented perpendicular to the long axis of the intestine. *(Used with permission from Patrick Javid, MD, and Tom Jaksic, MD, Department of Surgery, Children's Hospital, Boston, MA).*

achieve independence from TPN.[73] Prognosis for achieving enteral autonomy is better among pediatric patients than among adults.

Information on survival among patients with short bowel syndrome is limited. In a recently reported study of 124 adults with short bowel syndrome due to nonmalignant etiologies, the survival rates at 2 and 5 years of follow-up were 86% and 45%, respectively.[78] Patients with end-enterostomies and those having less than 50 cm of residual small intestine had significantly worse survivals than those without these features.

No randomized trials comparing intestinal transplantation to chronic TPN administration among patients with short bowel syndrome have been reported. One-, 5-, and 10-year graft survival rates of intestine-alone recipients were 80%, 44%, and 26%; whereas the rates for intestine + liver and intestine + liver + pancreas were 62%, 45%, and 36% and 69%, 48%, and 33%, respectively.[77]

chapter 29

Colon, Rectum, and Anus

Kelli M. Bullard Dunn and David A. Rothenberger

EMBRYOLOGY AND ANATOMY

Embryology

The embryonic gastrointestinal tract begins developing during the fourth week of gestation. The primitive gut is derived from the endoderm and divided into three segments: *foregut, midgut*, and *hindgut*. Both *midgut* and *hindgut* contribute to the colon, rectum, and anus.

The *midgut* develops into the small intestine, ascending colon, and proximal transverse colon, and receives blood supply from the superior mesenteric artery. During the sixth week of gestation, the midgut herniates out of the abdominal cavity, and then rotates 270° counterclockwise around the superior mesenteric artery to return to its final position inside the abdominal cavity during the tenth week of gestation. The *hindgut* develops into the distal transverse colon, descending colon, rectum, and

Key Points

1. Resection principles: The mesenteric clearance technique dictates the extent of resection and is determined by the nature of the primary pathology, the intent of resection, the location of the lesion, and the condition of the mesentery.
2. Function after resection: Bowel function is often compromised after colorectal resection, especially after low anterior resection. For this reason, it is important to obtain a history of prior anorectal trauma and/or incontinence before considering a low anastomosis.
3. Ostomies: Preoperative marking for a planned stoma is critical for a patient's quality of life. Ideally, a stoma should be located within the rectus muscle, in a location where the patient can easily see and manipulate the appliance, and away from previous scars, bony prominences, or abdominal creases.
4. Inflammatory bowel disease: Both Crohn's disease and ulcerative colitis are associated with an increased risk of colorectal carcinoma. Risk depends on the amount of colon involved and the duration of disease.
5. Pathogenesis of colorectal cancer: A variety of mutations have been identified in colorectal cancer. Mutations may cause activation of oncogenes (*K-ras*) and/or inactivation of tumor suppressor genes (adenomatous polyposis coli [*APC*], deleted in colorectal carcinoma [*DCC*], *p53*).
6. Minimally invasive resection: Laparoscopy and HAL have been shown to be both safe and efficacious for colorectal resection.
7. Anal epidermoid carcinoma: Unlike rectal adenocarcinoma, anal epidermoid carcinoma is treated primarily with chemoradiation. Surgery is reserved for patients with persistent or recurrent disease.
8. Rectal prolapse: Rectal prolapse occurs most commonly in elderly women. Transabdominal repair (rectopexy with or without resection) offers more durability than perineal proctosigmoidectomy, but carries greater operative risk.
9. Hemorrhoids: Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth muscle fiber. They are thought to play a role in maintaining continence. Resection is only indicated for refractory symptoms.
10. Fistula in ano: Treatment of fistula in ano depends on the location of the fistula, amount of anal sphincter involved in the fistula, and the underlying disease process.

proximal anus, all of which receive their blood supply from the inferior mesenteric artery. During the sixth week of gestation, the distal-most end of the hindgut, the *cloaca*, is divided by the urorectal septum into the urogenital sinus and the rectum.

The distal anal canal is derived from ectoderm and receives its blood supply from the internal pudendal artery. The dentate line divides the endodermal hindgut from the ectodermal distal anal canal.

Anatomy

The large intestine extends from the ileocecal valve to the anus. It is divided anatomically and functionally into the *colon, rectum*, and *anal canal*. The wall of the colon and rectum comprise five distinct layers: mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa. In the colon, the outer longitudinal muscle is separated into three *teniae coli*, which converge proximally at the appendix and distally at the rectum, where the outer longitudinal muscle layer is circumferential. In the distal rectum, the inner smooth muscle layer coalesces to form the internal anal sphincter. The intraperitoneal colon and proximal one-third of the rectum are covered by serosa; the mid and lower rectum lack serosa.

Colon Landmarks. The colon begins at the junction of the terminal ileum and cecum and extends 3 to 5 feet to the rectum. The rectosigmoid junction is found at approximately the level of the sacral promontory and is arbitrarily described as the point at which the three *teniae coli* coalesce to form the outer longitudinal smooth muscle layer of the rectum. The *cecum* is the widest diameter portion of the colon (normally 7.5–8.5 cm) and has the thinnest muscular wall. As a result, the cecum is most vulnerable to perforation and least vulnerable to obstruction. The ascending colon is usually fixed to the retroperitoneum. The hepatic flexure marks the transition to the transverse colon. The intraperitoneal transverse colon is relatively mobile, but is tethered by the gastrocolic ligament and colonic mesentery. The greater omentum is attached to the anterior/superior edge of the transverse colon. These attachments explain the characteristic triangular appearance of the transverse colon observed during colonoscopy. The splenic flexure marks the transition from the transverse colon to the descending colon. The attachments between the splenic flexure and the spleen (the lienocolic ligament) can be short and dense, making mobilization of this flexure during colectomy challenging. The descending colon is relatively fixed to the retroperitoneum. The sigmoid colon is the narrowest part of the large intestine and is extremely mobile. Although the sigmoid colon is usually located in the left lower quadrant, redundancy and mobility can result in a portion of the sigmoid colon residing in the right lower quadrant. This mobility explains why volvulus is most common in the sigmoid colon and why diseases affecting the sigmoid colon, such as diverticulitis, may occasionally present as right-sided abdominal pain. The narrow caliber of the sigmoid colon makes this segment of the large intestine the most vulnerable to obstruction.

Colon Vascular Supply. The arterial supply to the colon is highly variable (Fig. 29-1). In general, the *superior mesenteric artery* branches into the *ileocolic artery* (absent in up to 20% of people), which supplies blood flow to the terminal ileum and proximal ascending colon; the *right colic artery*, which supplies the ascending colon; and the *middle colic artery*, which supplies the transverse colon. The *inferior mesenteric artery* branches into the *left colic artery*, which supplies the descending colon; several *sigmoidal branches*, which supply the sigmoid colon; and the *superior rectal artery*, which supplies the proximal rectum. The terminal branches of each artery form anastomoses with the terminal branches of the adjacent artery and communicate

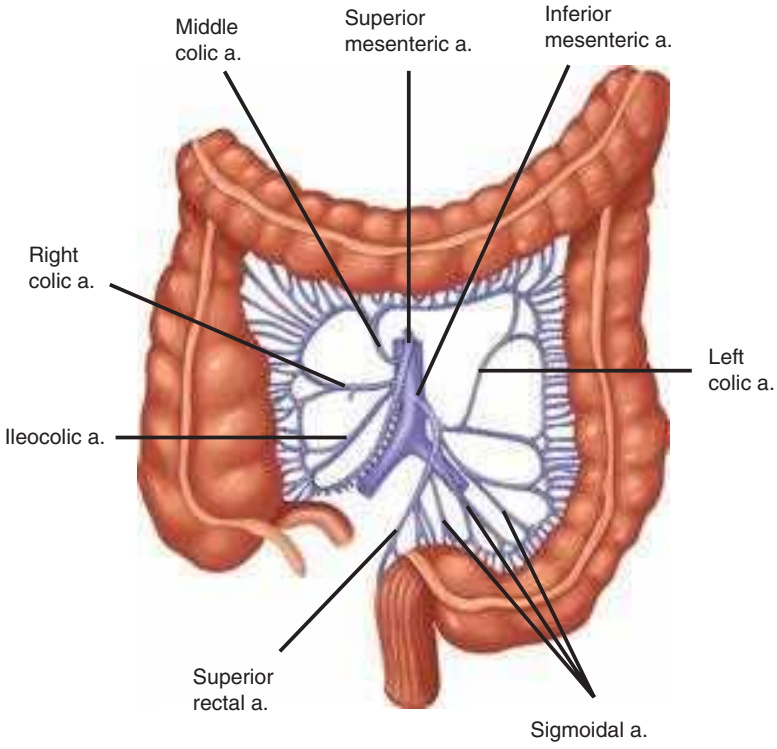

Figure 29-1. Arterial blood supply to the colon. a. = artery.

via the *marginal artery of Drummond*. This arcade is complete in only 15% to 20% of people.

Except for the *inferior mesenteric vein*, the veins of the colon parallel their corresponding arteries and bear the same terminology (Fig. 29-2). The inferior mesenteric vein ascends in the retroperitoneal plane over the psoas muscle and continues posterior to the pancreas to join the splenic vein. During a colectomy, this vein is often mobilized independently and ligated at the inferior edge of the pancreas.

Colon Lymphatic Drainage. The lymphatic drainage of the colon originates in a network of lymphatics in the muscularis mucosa. Lymphatic vessels and lymph nodes follow the regional arteries. Lymph nodes are found on the bowel wall (epicolic), along the inner margin of the bowel adjacent to the arterial arcades (paracolic), around the named mesenteric vessels (intermediate), and at the origin of the superior and inferior mesenteric arteries (main). The *sentinel lymph nodes* are the first one to four lymph nodes to drain a specific segment of the colon and are thought to be the first site of metastasis in colon cancer. The utility of sentinel lymph node dissection and analysis in colon cancer remains controversial.

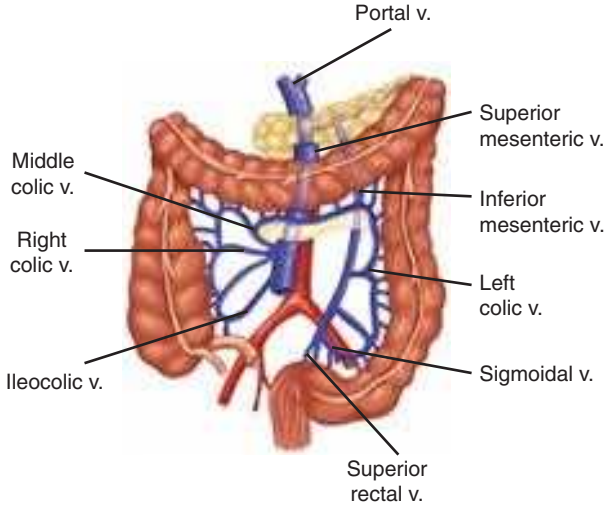

Figure 29-2. Venous drainage of the colon. v. = vein. *(Reproduced with permission from Bell RH, Rikkers LF, Mulholland M, eds.* Digestive Tract Surgery: A Text and Atlas. *Philadelphia: Lippincott Williams & Wilkins; 1996:1459.)*

Colon Nerve Supply. The colon is innervated by both *sympathetic* (inhibitory) and *parasympathetic* (stimulatory) nerves, which parallel the course of the arteries. Sympathetic nerves arise from T6-T12 and L1-L3. The parasympathetic innervation to the right and transverse colon is from the vagus nerve; the parasympathetic nerves to the left colon arise from sacral nerves S2-S4 to form the nervi erigentes.

Anorectal Landmarks. The rectum is approximately 12 to 15 cm in length. Three distinct submucosal folds, the *valves of Houston*, extend into the rectal lumen. Posteriorly, the *presecral fascia* separates the rectum from the presacral venous plexus and the pelvic nerves. At S4, the rectosacral fascia (*Waldeyer's fascia*) extends forward and downward and attaches to the fascia propria at the anorectal junction. Anteriorly, *Denonvilliers' fascia* separates the rectum from the prostate and seminal vesicles in men and from the vagina in women. The *lateral ligaments* support the lower rectum.

The *anatomic anal canal* extends from the dentate or pectinate line to the anal verge. The *dentate* or *pectinate line* marks the transition point between columnar rectal mucosa and squamous anoderm. The *anal transition zone* includes mucosa proximal to the dentate line that shares histologic characteristics of columnar, cuboidal, and squamous epithelium. Although the anal transition zone was long thought to extend only 1 to 2 cm proximal to the dentate line, it is known that the proximal extent of this zone is highly variable and can be as far as 15 cm proximal to

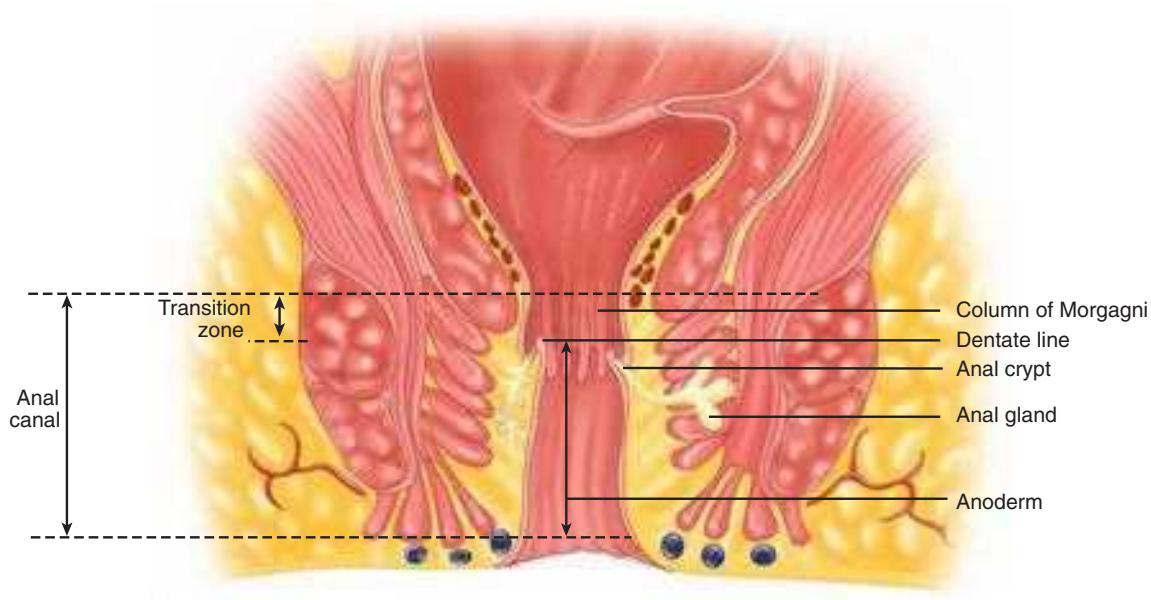

Figure 29-3. The lining of the anal canal. *(From Goldberg SM, Gordon PH, Nivatvongs S, eds.* Essentials of Anorectal Surgery. *Philadelphia: J.B. Lippincott Company; 1980:4. Reproduced with permission from Stanley M. Goldberg, MD.)*

the dentate line. The dentate line is surrounded by longitudinal mucosal folds, known as the *columns of Morgagni*, into which the anal crypts empty. These crypts are the source of cryptoglandular abscesses (Fig. 29-3). In contrast to the anatomic anal canal, the surgical anal canal begins at the anorectal junction and terminates at the anal verge. The surgical anal canal measures 2 to 4 cm in length and is generally longer in men than in women. It begins at the anorectal junction and terminates at the anal verge.

In the distal rectum, the inner smooth muscle is thickened and comprises the *internal anal sphincter* that is surrounded by the *subcutaneous, superficial*, and *deep external sphincter*. The *deep external anal sphincter* is an extension of the *puborectalis muscle*. The *puborectalis, iliococcygeus*, and *pubococcygeus muscles* form the *levator ani muscle* of the pelvic floor (Fig. 29-4).

Anorectal Vascular Supply. The *superior rectal artery* arises from the terminal branch of the inferior mesenteric artery and supplies the upper rectum. The *middle rectal artery* arises from the internal iliac; the presence and size of these arteries are highly variable. The *inferior rectal artery* arises from the internal pudendal artery, which is a branch of the internal iliac artery. A rich network of collaterals connects the terminal arterioles of each of these arteries, thus making the rectum relatively resistant to ischemia (Fig. 29-5).

The venous drainage of the rectum parallels the arterial supply. The *superior rectal vein* drains into the portal system via the inferior mesenteric vein. The *middle rectal vein* drains into the internal iliac vein. The *inferior rectal vein* drains into the internal pudendal vein, and subsequently into the internal iliac vein. A submucosal plexus deep to the columns of Morgagni forms the *hemorrhoidal plexus* and drains into all three veins.

Anorectal Lymphatic Drainage. Lymphatic drainage of the rectum parallels the vascular supply. Lymphatic channels in the upper and middle rectum drain superiorly into the inferior

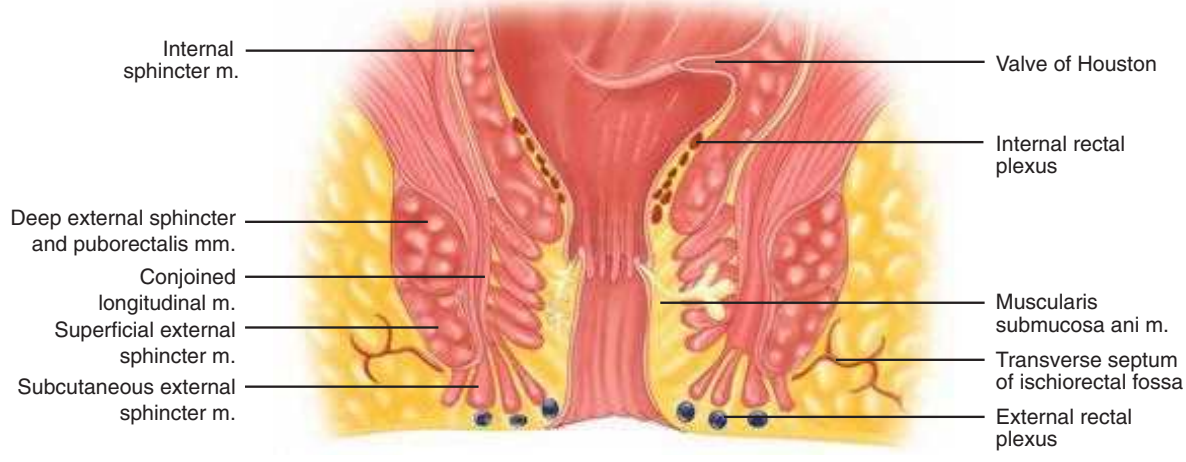

Figure 29-4. The distal rectum and anal canal. m. = muscle.

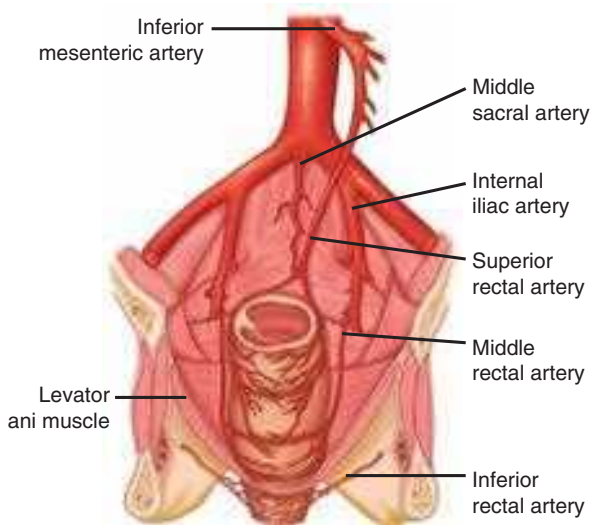

Figure 29-5. Arterial supply to the rectum and anal canal.

mesenteric lymph nodes. Lymphatic channels in the lower rectum drain both superiorly into the inferior mesenteric lymph nodes and laterally into the internal iliac lymph nodes. The anal canal has a more complex pattern of lymphatic drainage. Proximal to the dentate line, lymph drains into both the inferior mesenteric lymph nodes and the internal iliac lymph nodes. Distal to the dentate line, lymph primarily drains into the inguinal lymph nodes, but can also drain into the inferior mesenteric lymph nodes and internal iliac lymph nodes.

Anorectal Nerve Supply. Both sympathetic and parasympathetic nerves innervate the anorectum. Sympathetic nerve fibers are derived from L1-L3 and join the preaortic plexus. The preaortic nerve fibers then extend below the aorta to form the *hypogastric plexus*, which subsequently joins the parasympathetic fibers to form the pelvic plexus. Parasympathetic nerve fibers are known as the *nervi erigentes* and originate from S2-S4. These fibers join the sympathetic fibers to form the pelvic plexus. Sympathetic and parasympathetic fibers then supply the anorectum and adjacent urogenital organs.

The internal anal sphincter is innervated by sympathetic and parasympathetic nerve fibers; both types of fibers inhibit sphincter contraction. The external anal sphincter and puborectalis muscles are innervated by the *inferior rectal branch* of the *internal pudendal nerve*. The levator ani receives innervation from both the *internal pudendal nerve* and direct branches of S3 to S5. Sensory innervation to the anal canal is provided by the *inferior rectal branch* of the *pudendal nerve*. While the rectum is relatively insensate, the anal canal below the dentate line is sensate.

Congenital Anomalies

Perturbation of the embryologic development of the midgut and hindgut may result in anatomic abnormalities of the colon, rectum, and anus. Failure of the midgut to rotate and return to the abdominal cavity during the tenth week of gestation results in varying degrees of intestinal malrotation and colonic nonfixation. Failure of canalization of the primitive gut can result in colonic duplication. Incomplete descent of the urogenital septum may result in imperforate anus and associated fistulas to the genitourinary tract. Many infants with congenital anomalies of the hindgut have associated abnormalities in the genitourinary tract.

NORMAL PHYSIOLOGY

Fluid and Electrolyte Exchanges

Water, Sodium, Potassium, Chloride, Bicarbonate, and Ammonia. The colon is a major site for water absorption and electrolyte exchange. Under normal circumstances, approximately 90% of the water contained in ileal fluid is absorbed in the colon (1000–2000 mL/d), but up to 5000 mL of fluid can be absorbed daily. Sodium is absorbed actively via sodium-potassium (Na^+/K^+) ATPase. The colon can absorb up to 400 mEq of sodium per day. Water accompanies the transported sodium and is absorbed passively along an osmotic gradient. Potassium is actively secreted into the colonic lumen and absorbed by passive diffusion. Chloride is absorbed actively via a chloride-bicarbonate exchange.

Bacterial degradation of protein and urea produces ammonia. Ammonia is subsequently absorbed and transported to the liver. Absorption of ammonia depends in part on intraluminal pH. A decrease in colonic bacteria (e.g., due to broad-spectrum antibiotic use) and/or a decrease in intraluminal pH (e.g., due to lactulose administration) will decrease ammonia absorption.

Short-Chain Fatty Acids

Short-chain fatty acids (acetate, butyrate, and propionate) are produced by bacterial fermentation of dietary carbohydrates. Short-chain fatty acids are an important source of energy for the colonic mucosa, and metabolism by colonocytes provides energy for processes such as active transport of sodium. Lack of a dietary source for production of short-chain fatty acids, or diversion of the fecal stream by an ileostomy or colostomy, may result in mucosal atrophy and inflammation, the latter termed "diversion colitis."

Colonic Microflora and Intestinal Gas

Approximately 30% of fecal dry weight is composed of bacteria (10^{11}–10^{12} bacteria/g of feces). Anaerobes are the predominant class of microorganism, and *Bacteroides* species are the most common (10^{11}–10^{12} organisms/mL). *Escherichia coli* are the most numerous aerobes (10^8–10^{10} organisms/mL). Endogenous microflora are crucial for the breakdown of carbohydrates and proteins in the colon and participate in the metabolism of bilirubin, bile acids, estrogen, and cholesterol. Colonic bacteria also are necessary for production of vitamin K. Endogenous bacteria also are thought to suppress the emergence of pathogenic microorganisms, such as *Clostridium difficile,* a phenomenon termed "colonization resistance." However, the high bacterial load of the large intestine may contribute to sepsis in critically ill patients and may contribute to intra-abdominal sepsis, abscess, and wound infection following colectomy.

Intestinal gas arises from swallowed air, diffusion from the blood, and intraluminal production. Nitrogen, oxygen, carbon dioxide, hydrogen, and methane are the major components of intestinal gas. Nitrogen and oxygen are largely derived from swallowed air. Carbon dioxide is produced by the reaction of bicarbonate and hydrogen ions and by the digestion of triglycerides to fatty acids. Hydrogen and methane are produced by colonic bacteria. The production of methane is highly variable. The gastrointestinal tract usually contains between 100 and 200 mL of gas, and 400 to 1200 mL/d are released as flatus, depending on the type of food ingested.

Motility, Defecation, and Continence

Motility. Unlike the small intestine, the large intestine does not demonstrate cyclic motor activity characteristic of the migratory motor complex. Instead, the colon displays intermittent contractions of either low or high amplitude. Low-amplitude, short-duration contractions occur in bursts and appear to move the colonic contents both antegrade and retrograde. It is thought that these bursts of motor activity delay colonic transit and thus increase the time available for absorption of water and exchange of electrolytes. High-amplitude contractions occur in a more coordinated fashion and create "mass movements." Bursts of "rectal motor complexes" also have been described. In general, cholinergic activation increases colonic motility.

Defecation. Defecation is a complex, coordinated mechanism involving colonic mass movement, increased intra-abdominal and rectal pressure, and relaxation of the pelvic floor. Distention of the rectum causes a reflex relaxation of the internal anal sphincter (the rectoanal inhibitory reflex) that allows the contents to make contact with the anal canal. This "sampling reflex" allows the sensory epithelium to distinguish solid stool from liquid stool and gas. If defecation does not occur, the rectum relaxes and the urge to defecate passes (*accommodation response*). Defecation proceeds by coordination of increasing intra-abdominal pressure via the Valsalva maneuver, increased rectal contraction, relaxation of the puborectalis muscle, and opening of the anal canal.

Continence. The maintenance of fecal continence is at least as complex as the mechanism of defecation. Continence requires adequate rectal wall compliance to accommodate the fecal bolus, appropriate neurogenic control of the pelvic floor and sphincter mechanism, and functional internal and external sphincter muscles. At rest, the puborectalis muscle creates a "sling" around the distal rectum, forming a relatively acute angle that distributes intra-abdominal forces onto the pelvic floor. With defecation, this angle straightens, allowing downward force to be applied along the axis of the rectum and anal canal. The internal and external sphincters are tonically active at rest. The internal sphincter is responsible for most of the resting, involuntary sphincter tone (resting pressure). The external sphincter is responsible for most of the voluntary sphincter tone (squeeze pressure). Branches of the pudendal nerve innervate both the internal and external sphincter. Finally, the hemorrhoidal cushions may contribute to continence by mechanically blocking the anal canal. Thus, impaired continence may result from poor rectal compliance, injury to the internal and/or external sphincter or puborectalis, or nerve damage or neuropathy.

CLINICAL EVALUATION

Clinical Assessment

Obtaining a complete history and performing a physical examination are the starting points for evaluating any patient with suspected disease of the colon, rectum, or anus. Special attention should be paid to the patient's past medical and surgical history to detect underlying conditions that might contribute to a gastrointestinal problem. If patients have had prior intestinal surgery, it is essential that one understand the resultant gastrointestinal anatomy. A history of anorectal surgery may be critical for patients with either abdominal or anorectal complaints. The obstetrical history in women is essential to detect occult pelvic floor and/or anal sphincter damage. Identifying a family history of colorectal disease, especially inflammatory bowel disease, polyps, and colorectal cancer, is crucial. In addition to a family history of colorectal disease, a history of other malignancies may suggest the presence of a genetic syndrome. Medication use must be detailed as many drugs cause gastrointestinal symptoms. Before recommending operative intervention, the adequacy of medical treatment must be ascertained. In addition to examining the abdomen, visual inspection of the anus and perineum and careful digital rectal exam are essential.

Endoscopy

Anoscopy. The anoscope is a useful instrument for examination of the anal canal. Anoscopes are made in a variety of sizes and measure approximately 8 cm in length. A larger anoscope provides better exposure for anal procedures such as rubber band ligation or sclerotherapy of hemorrhoids. The anoscope, with obturator in place, should be adequately lubricated and gently inserted into the anal canal. The obturator is withdrawn, inspection of the visualized anal canal is done, and the anoscope should then be withdrawn. It is rotated 90° and reinserted to allow visualization of all four quadrants of the canal. If the patient complains of severe perianal pain and cannot tolerate a digital rectal examination, anoscopy should not be attempted without anesthesia.

Proctoscopy. The rigid proctoscope is useful for examination of the rectum and distal sigmoid colon and is occasionally used therapeutically. The standard proctoscope is 25 cm in length and available in various diameters. Most often, a 15- or 19-mm diameter proctoscope is used for diagnostic examinations. The large (25-mm diameter) proctoscope is useful for procedures such as polypectomy, electrocoagulation, or detorsion of a sigmoid volvulus. A smaller "pediatric" proctoscope (11-mm diameter) is better tolerated by patients with anal stricture. Suction is necessary for an adequate proctoscopic examination.

Flexible Sigmoidoscopy and Colonoscopy. Video or fiberoptic flexible sigmoidoscopy and colonoscopy provide excellent visualization of the colon and rectum. Sigmoidoscopes measure 60 cm in length. Full depth of insertion may allow visualization as high as the splenic flexure, although the mobility and redundancy of the sigmoid colon often limit the extent of the examination. Partial preparation with enemas is usually adequate for sigmoidoscopy, and most patients can tolerate this procedure without sedation. Colonoscopes measure 100 to 160 cm in length and are capable of examining the entire colon and terminal ileum. A complete oral bowel preparation is usually necessary for colonoscopy, and the duration and discomfort of the procedure usually require conscious sedation. Both sigmoidoscopy and colonoscopy can be used diagnostically and therapeutically. Electrocautery should generally not be used in the absence of a complete bowel preparation because of the risk of explosion of intestinal methane or hydrogen gases. Diagnostic colonoscopes possess a single channel through which instruments such as snares, biopsy forceps, or electrocautery can be passed; this channel also provides suction and irrigation capability. Therapeutic colonoscopes possess two channels to allow simultaneous suction/irrigation and the use of snares, biopsy forceps, or electrocautery.

Capsule Endoscopy. Capsule endoscopy is an emerging technology that uses a small ingestible camera. After swallowing the camera, images of the mucosa of the gastrointestinal tract are captured, transmitted by radiofrequency to a belt-held receiver,

and then downloaded to a computer for viewing and analysis. Capsule endoscopy largely has been used to detect small bowel lesions. However, it has been suggested that this technique might also be useful for diagnosing colorectal disease, although utility in the evaluation of colorectal disease remains unproven.[1-5] Finally, recent advances in the development of maneuverable capsules may improve the sensitivity of this procedure.[5]

Imaging

Plain X-Rays and Contrast Studies. Despite advanced radiologic techniques, plain X-rays and contrast studies continue to play an important role in the evaluation of patients with suspected colon and rectal diseases. Plain X-rays of the abdomen (supine, upright, and diaphragmatic views) are useful for detecting free intra-abdominal air, bowel gas patterns suggestive of small or large bowel obstruction, and volvulus. Contrast studies are useful for evaluating obstructive symptoms, delineating fistulous tracts, and diagnosing small perforations or anastomotic leaks. Although Gastrografin cannot provide the mucosal detail provided by barium, this water-soluble contrast agent is recommended if perforation or leak is suspected. Double-contrast barium enema (use of barium followed by the insufflation of air into the colon) has been reported to be 70% to 90% sensitive for the detection of mass lesions greater than 1 cm in diameter.[6] Detection of small lesions can be extremely difficult, especially in a patient with extensive diverticulosis. For this reason, a colonoscopy is preferred for evaluating nonobstructing mass lesions in the colon. Double-contrast barium enema has been used as a back-up examination if colonoscopy is incomplete.

Computed Tomography. Computed tomography (CT) commonly is employed in the evaluation of patients with abdominal complaints. Its utility is primarily in the detection of extraluminal disease, such as intra-abdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma, because of its sensitivity in detection of hepatic metastases.[7]

Extravasation of oral or rectal contrast may also confirm the diagnosis of perforation or anastomotic leak. Nonspecific findings such as bowel wall thickening or mesenteric stranding may suggest inflammatory bowel disease, enteritis/colitis, or ischemia. A standard CT scan is relatively insensitive for the detection of intraluminal lesions; however, improved CT technology is increasing the ability to assess bulky rectal tumors and perirectal adenopathy.

Computed Tomography Colonography. CT colonography (virtual colonoscopy) is a radiologic technique that is designed to overcome some of the limitations of traditional CT scanning. This technology uses helical CT and three-dimensional reconstruction to detect intraluminal colonic lesions. Oral bowel preparation, oral and rectal contrast, and colon insufflation have been used to maximize sensitivity. Experience with this technology has shown a sensitivity and specificity for detecting 1 cm or larger polyps of 85% to 90% in most studies, making it comparable to traditional colonoscopy. The addition of "fecal tagging" agents that create a distinct difference in appearance between stool and mucosa during imaging studies holds promise for increasing accuracy and possibly decreasing the need for mechanical bowel preparation.[8]

Magnetic Resonance Imaging. The main use of magnetic resonance imaging (MRI) in colorectal disorders is in evaluation of pelvic lesions. MRI is more sensitive than CT for detecting bony involvement or pelvic sidewall extension of rectal tumors. MRI accurately determines the extent of spread of rectal cancer into the adjacent mesorectum and can reliably predict difficulty achieving radial margin clearance of a rectal cancer by surgery alone. When the radial margin is threatened, neoadjuvant chemoradiation is generally indicated. MRI also can be helpful in the detection and delineation of complex fistulas in ano. The use of an endorectal coil may increase sensitivity.

Positron Emission Tomography. Positron emission tomography (PET) is used for imaging tissues with high levels of anaerobic glycolysis, such as malignant tumors.[6] ^{18}F-fluorodeoxyglucose (FDG) is injected as a tracer; metabolism of this molecule then results in positron emission. PET has been used as an adjunct to CT in the staging of colorectal cancer and may prove useful in discriminating recurrent cancer from fibrosis. By combining PET and CT technology (PET/CT), anatomic correlation between regions of high isotope accumulation ("hot spots") on PET and abnormalities on CT can be determined. PET/CT increasingly is used to diagnose recurrent and/or metastatic colorectal cancer. However, the efficacy and utility of this technology remains unproven.

Angiography. Angiography is occasionally used for the detection of bleeding within the colon or small bowel. To visualize hemorrhage angiographically, bleeding must be relatively brisk (approximately 0.5 to 1.0 mL per minute). If extravasation of contrast is identified, infusion of vasopressin or angiographic embolization can be therapeutic. If surgical resection is required, the angiographic catheter can be left in place to assist with identification of the bleeding site intraoperatively.

CT and magnetic resonance angiography are also useful for assessing patency of visceral vessels. This technique uses three-dimensional reconstruction to detect vascular lesions. If an abnormality is found, more traditional techniques (angiography, surgery) may then be used to further define and/or correct the problem.

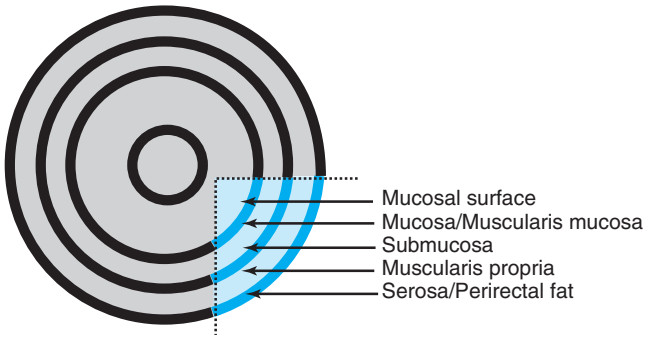
Endorectal and Endoanal Ultrasound. Endorectal ultrasound is primarily used to evaluate the depth of invasion of neoplastic lesions in the rectum. The normal rectal wall appears as a five-layer structure (Fig. 29-6). Ultrasound can reliably differentiate most benign polyps from invasive tumors based on the integrity of the submucosal layer. Ultrasound can also differentiate superficial T1-T2 from deeper T3-T4 tumors. Overall, the accuracy of ultrasound in detecting depth of mural invasion ranges between 81% and 94%.[9] This modality also can detect enlarged perirectal lymph nodes, which may suggest nodal metastases; accuracy of detection of pathologically positive lymph nodes is 58% to 83%. Ultrasound may also prove useful for early detection of local recurrence after surgery.

Endoanal ultrasound is used to evaluate the layers of the anal canal. Internal anal sphincter, external anal sphincter, and puborectalis muscle can be differentiated. Endoanal ultrasound is particularly useful for detecting sphincter defects and for outlining complex anal fistulas.

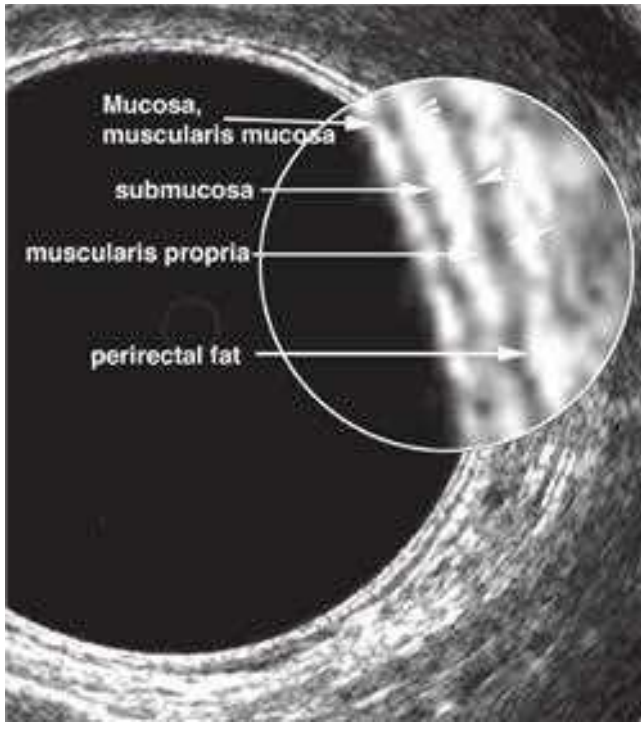
Physiologic and Pelvic Floor Investigations

Anorectal physiologic testing uses a variety of techniques to investigate the function of the pelvic floor. These techniques are useful in the evaluation of patients with incontinence, constipation, rectal prolapse, obstructed defecation, and other disorders of the pelvic floor.

Manometry. Anorectal manometry is performed by placing a pressure-sensitive catheter in the lower rectum. The catheter is



A



B

Figure 29-6. **A.** Schematic of the layers of the rectal wall observed on endorectal ultrasonography. **B.** Normal endorectal ultrasonography. *(A. Used with permission of Charles O. Finne III, MD, Minneapolis, MN.)*

then withdrawn through the anal canal and pressures recorded. A balloon attached to the tip of the catheter also can be used to test anorectal sensation. The *resting pressure* in the anal canal reflects the function of the internal anal sphincter (normal, 40–80 mmHg), whereas the *squeeze pressure*, defined as the maximum voluntary contraction pressure minus the resting pressure, reflects function of the external anal sphincter (normal, 40–80 mmHg above resting pressure). The *high-pressure zone* estimates the length of the anal canal (normal, 2.0–4.0 cm). The *rectoanal inhibitory reflex* can be detected by inflating a balloon in the distal rectum; absence of this reflex is characteristic of Hirschsprung's disease.

Neurophysiology. Neurophysiologic testing assesses function of the pudendal nerves and recruitment of puborectalis muscle fibers. Pudendal nerve terminal motor latency measures the speed of transmission of a nerve impulse through the distal pudendal nerve fibers (normal, 1.8–2.2 ms); prolonged latency suggests the presence of neuropathy. Electromyographic (EMG) recruitment assesses the contraction and relaxation of the puborectalis muscle during attempted defecation. Normally, recruitment increases when a patient is instructed to "squeeze" and decreases when a patient is instructed to "push." Inappropriate recruitment is an indication of paradoxical contraction (nonrelaxation of the puborectalis). Needle EMG has been used to map both the pudendal nerves and the anatomy of the internal and external sphincters. However, this examination is painful and poorly tolerated by most patients. Needle EMG has largely been replaced by pudendal nerve motor latency testing to assess pudendal nerve function and endoanal ultrasound to map the sphincters.

Rectal Evacuation Studies. Rectal evacuation studies include the balloon expulsion test and video defecography. Balloon expulsion assesses a patient's ability to expel an intrarectal balloon. Video defecography provides a more detailed assessment of defecation. In this test, barium paste is placed in the rectum, and defecation is then recorded fluoroscopically. Defecography is used to differentiate nonrelaxation of the puborectalis, obstructed defecation, increased perineal descent, rectal prolapse and intussusception, rectocele, and enterocele. The addition of vaginal contrast and intraperitoneal contrast is useful in delineating complex disorders of the pelvic floor.

Laboratory Studies

Fecal Occult Blood Testing. Fecal occult blood testing (FOBT) has been used as a screening test for colonic neoplasms in asymptomatic, average-risk individuals. The efficacy of this test is based on serial testing because the majority of colorectal malignancies will bleed intermittently. FOBT has been a nonspecific test for peroxidase contained in hemoglobin; consequently, occult bleeding from any gastrointestinal source will produce a positive result. Similarly, many foods (red meat, some fruits and vegetables, and vitamin C) will produce a false-positive result. Increased specificity is now possible by using immunochemical FOBT. These tests rely on monoclonal or polyclonal antibodies to react with the intact globin portion of human hemoglobin and are more specific for identifying occult bleeding from the colon or rectum. Any positive FOBT mandates further investigation, usually by colonoscopy.

Stool Studies. Stool studies are often helpful in evaluating the etiology of diarrhea. Wet-mount examination reveals the presence of fecal leukocytes, which may suggest colonic inflammation or the presence of an invasive organism such as invasive *E. coli* or *Shigella* species. Stool cultures can detect pathogenic bacteria, ova, and/or parasites. *C. difficile* colitis is diagnosed by detecting bacterial toxin in the stool.[10] Steatorrhea may be diagnosed by adding Sudan red stain to a stool sample.

Serum Tests. Specific laboratory tests that should be performed will be dictated by the clinical scenario. Preoperative studies generally include a complete blood count and electrolyte panel. The addition of coagulation studies, liver function tests, and blood typing/cross-matching depends on the patient's medical condition and the proposed surgical procedure.

Tumor Markers. Carcinoembryonic antigen (CEA) may be elevated in 60% to 90% of patients with colorectal cancer. Despite this, CEA is not an effective screening tool for this malignancy. Many practitioners follow serial CEA levels after curative-intent surgery in order to detect early recurrence of

colorectal cancer. However, this tumor marker is nonspecific, and no survival benefit has yet been proven. It is also important to note that CEA may be mildly elevated in patients who smoke tobacco. Other biochemical markers (ornithine decarboxylase, urokinase) have been proposed, but none has yet proven sensitive or specific for detection, staging, or predicting prognosis of colorectal carcinoma.[11]

Genetic Testing. Although familial colorectal cancer syndromes, such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) are rare, information about the specific genetic abnormalities underlying these disorders has led to significant interest in the role of genetic testing for colorectal cancer.[12]

Tests for mutations in the adenomatous polyposis coli (*APC*) gene responsible for FAP and in mismatch repair genes responsible for HNPCC are commercially available and extremely accurate in families with known mutations. However, in the absence of an identified mutation, a negative result is uninformative. For individuals from high-risk families without an identified mutation, increased surveillance is recommended.[13] Although many of these mutations are also present in sporadic colorectal cancer, the accuracy of genetic testing in average-risk individuals is considerably lower, and these tests are not recommended for screening. Because of the potential psychosocial implications of genetic testing, it is strongly recommended that professional genetic counselors be involved in the care of any patient considering these tests.

Evaluation of Common Symptoms

Pain

Abdominal Pain. Abdominal pain is a nonspecific symptom with myriad causes. Abdominal pain related to the colon and rectum can result from obstruction (either inflammatory or neoplastic), inflammation, perforation, or ischemia. Plain X-rays and judicious use of contrast studies and/or a CT scan can often confirm the diagnosis. Gentle retrograde contrast studies (Gastrografin enema) may be useful in delineating the degree of colonic obstruction. Sigmoidoscopy and/or colonoscopy performed by an experienced endoscopist can assist in the diagnosis of ischemic colitis, infectious colitis, and inflammatory bowel disease. However, if perforation or near complete obstruction is suspected, colonoscopy and/or sigmoidoscopy are generally contraindicated. Evaluation and treatment of abdominal pain from a colorectal source should follow the usual surgical principles of a thorough history and physical examination, appropriate diagnostic tests, resuscitation, and appropriately timed surgical intervention.

Pelvic Pain. Pelvic pain can originate from the distal colon and rectum or from adjacent urogenital structures. Tenesmus may result from proctitis or from a rectal or retrorectal mass. Cyclical pain associated with menses, especially when accompanied by rectal bleeding, suggests a diagnosis of endometriosis. Pelvic inflammatory disease also can produce significant abdominal and pelvic pain. The extension of a peridiverticular abscess or periappendiceal abscess into the pelvis may also cause pain. CT scan and/or MRI may be useful in differentiating these diseases. Proctoscopy (if tolerated) also can be helpful. Occasionally, laparoscopy will yield a diagnosis.

Anorectal Pain. Anorectal pain is most often secondary to an anal fissure, perirectal abscess and/or fistula, or a thrombosed hemorrhoid. Physical examination can usually differentiate these conditions. Other, less common causes of anorectal pain include anal canal neoplasms, perianal skin infection, and dermatologic conditions. Proctalgia fugax results from levator spasm and may present without any other anorectal findings. Physical exam is critical in evaluating patients with anorectal pain. If a patient is too tender to examine in the office, an examination under anesthesia is necessary. MRI or other imaging studies may be helpful in select cases where the etiology of pain is elusive.

Lower Gastrointestinal Bleeding. The first goal in evaluating and treating a patient with gastrointestinal hemorrhage is adequate resuscitation. The principles of ensuring a patent airway, supporting ventilation, and optimizing hemodynamic parameters apply, and coagulopathy and/or thrombocytopenia should be corrected. The second goal is to identify the source of hemorrhage. Because the most common source of gastrointestinal hemorrhage is esophageal, gastric, or duodenal, nasogastric aspiration should always be performed; return of bile suggests that the source of bleeding is distal to the ligament of Treitz. If aspiration reveals blood or nonbile secretions, or if symptoms suggest an upper intestinal source, esophagogastroduodenoscopy is performed. Anoscopy and/or limited proctoscopy can identify hemorrhoidal bleeding. A technetium-99 (^{99m}Tc)-tagged red blood cell (RBC) scan is extremely sensitive and is able to detect as little as 0.1 mL/h of bleeding; however, localization is imprecise. If the ^{99m}Tc-tagged RBC scan is positive, angiography can then be both diagnostic and potentially therapeutic. If the patient is hemodynamically stable, a rapid bowel preparation (over 4–6 hours) can be performed to allow colonoscopy. Colonoscopy may identify the cause of the bleeding, and cautery or injection of epinephrine into the bleeding site may be used to control hemorrhage. Colectomy may be required if bleeding persists despite these interventions. Intraoperative colonoscopy and/or enteroscopy may assist in localizing bleeding. If colectomy is required, a segmental resection is preferred if the bleeding source can be localized. "Blind" subtotal colectomy may very rarely be required in a patient who is hemodynamically unstable with ongoing colonic hemorrhage of an unknown source. In this setting, just prior to proceeding with a "blind" subtotal colectomy, it is crucial to irrigate the rectosigmoid and re-examine the mucosa of the anal canal and rectum by anoscopy and proctoscopy to ensure the source of ongoing bleeding is not distal to the planned resection margin (Fig. 29-7).

Occult blood loss from the gastrointestinal tract may manifest as iron-deficiency anemia or may be detected with FOBT. Because colon neoplasms bleed intermittently and rarely present with rapid hemorrhage, the presence of occult fecal blood should always prompt a colonoscopy. Unexplained iron-deficiency anemia is also an indication for colonoscopy.

Hematochezia is commonly caused by hemorrhoids or a fissure. Sharp, knife-like pain and bright red rectal bleeding with bowel movements suggest the diagnosis of fissure. Painless, bright red rectal bleeding with bowel movements is often secondary to a friable internal hemorrhoid that is easily detected by anoscopy. In the absence of a painful, obvious fissure, any patient with rectal bleeding should undergo a careful digital rectal examination, anoscopy, and proctosigmoidoscopy. Failure to diagnose a source in the distal anorectum should prompt colonoscopy.

Constipation and Obstructed Defecation. Constipation is an extremely common complaint, affecting more than 4 million people in the United States. Despite the prevalence of this problem, there is lack of agreement about an appropriate definition of constipation. Patients may describe infrequent bowel

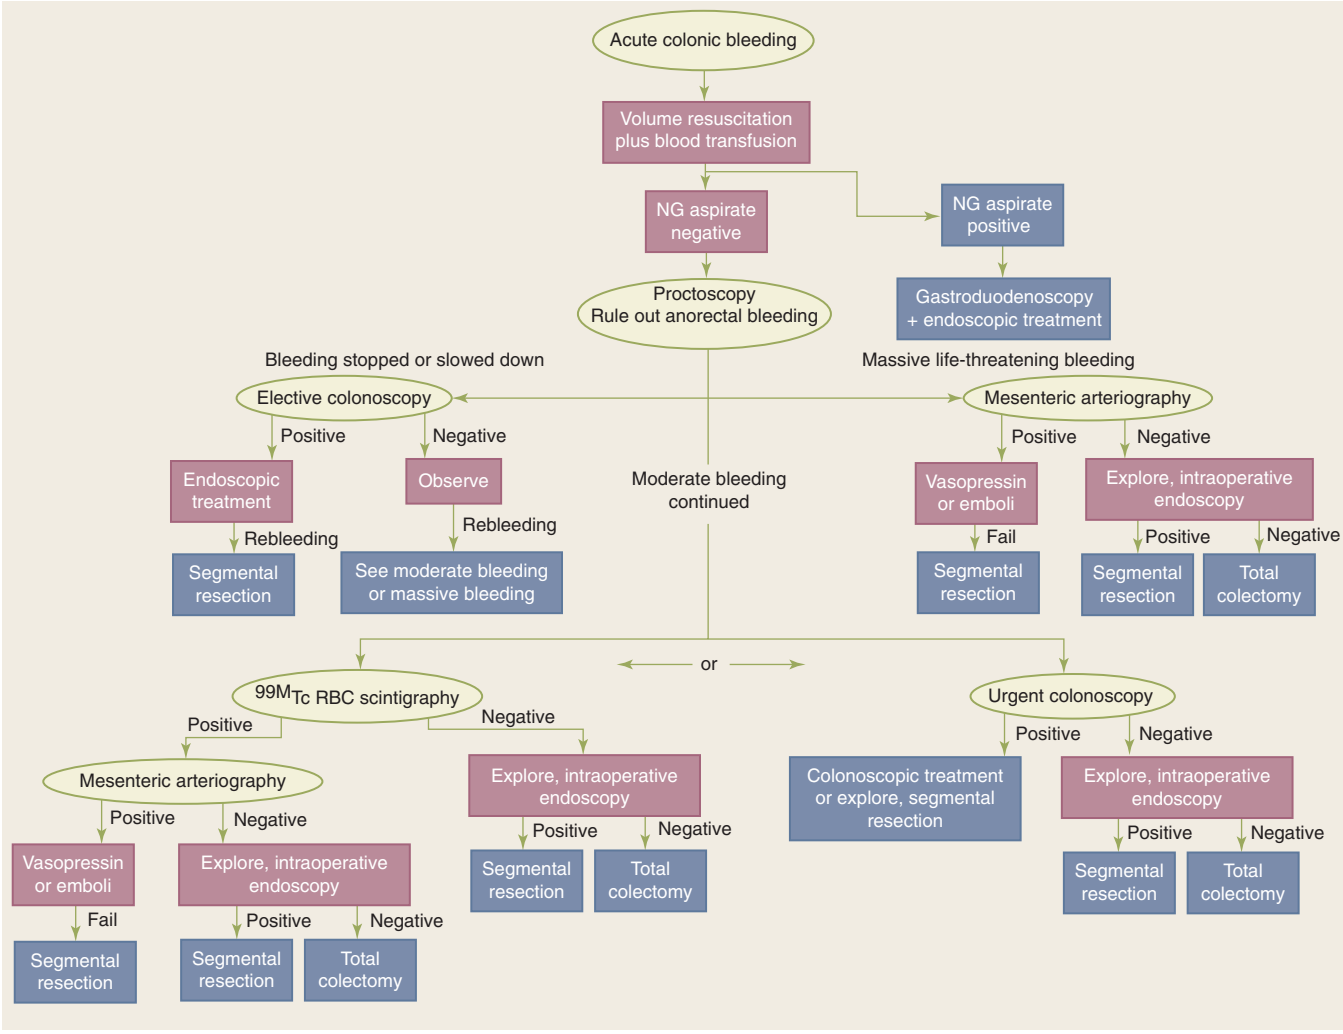


Figure 29-7. Algorithm for treatment of colorectal hemorrhage. movements, hard stools, or excessive straining. A careful history of these symptoms often clarifies the nature of the problem.

Constipation has many causes. Underlying metabolic, pharmacologic, endocrine, psychological, and neurologic causes often contribute to the problem. A stricture or mass lesion should be excluded by colonoscopy, barium enema, or CT colonography. After these causes have been excluded, evaluation focuses on differentiating *slow-transit constipation* from *outlet obstruction*. Transit studies, in which radiopaque markers are swallowed and then followed radiographically, are useful for diagnosing slow-transit constipation. Anorectal manometry and EMG can detect nonrelaxation of the puborectalis, which contributes to outlet obstruction. The absence of an anorectal inhibitory reflex suggests Hirschsprung's disease and may prompt a rectal mucosal biopsy. Defecography can identify rectal prolapse, intussusception, rectocele, or enterocele.

Medical management is the mainstay of therapy for constipation and includes fiber, increased fluid intake, and laxatives. Outlet obstruction from nonrelaxation of the puborectalis often responds to biofeedback.[14] Surgery to correct rectocele and rectal prolapse has a variable effect on symptoms of constipation but can be successful in selected patients. Subtotal colectomy is considered only for patients with severe slow-transit constipation (colonic inertia) refractory to maximal medical interventions. While this operation almost always increases bowel movement frequency, complaints of diarrhea, incontinence, and abdominal pain are not infrequent, and patients should be carefully selected and counseled.[15]

Diarrhea and Irritable Bowel Syndrome. Diarrhea is also a common complaint and is usually a self-limited symptom of infectious gastroenteritis. If diarrhea is chronic or is accompanied by bleeding or abdominal pain, further investigation is warranted. Bloody diarrhea and pain are characteristic of colitis; etiology can be an infection (invasive *E. coli, Shigella, Salmonella, Campylobacter, Entamoeba histolytica*, or *C. difficile*), inflammatory bowel disease (ulcerative colitis or Crohn's colitis), or ischemia. Stool wet-mount and culture can often diagnose infection. Sigmoidoscopy or colonoscopy can be helpful in diagnosing inflammatory bowel disease or ischemia. However, if the patient has abdominal tenderness, particularly with peritoneal signs, or any other evidence of perforation, endoscopy is contraindicated.

Chronic diarrhea may present a more difficult diagnostic dilemma. Chronic ulcerative colitis, Crohn's colitis, infection, malabsorption, and short gut syndrome can cause chronic

diarrhea. Rarely, carcinoid syndrome and islet cell tumors (vasoactive intestinal peptide–secreting tumor [VIPoma], somatostatinoma, gastrinoma) present with this symptom. Large villous lesions may cause secretory diarrhea. Collagenous colitis can cause diarrhea without any obvious mucosal abnormality. Along with stool cultures, tests for malabsorption, and metabolic investigations, colonoscopy can be invaluable in differentiating these causes. Biopsies should be taken even if the colonic mucosa appears grossly normal.

Irritable bowel syndrome is a particularly troubling constellation of symptoms consisting of crampy abdominal pain, bloating, constipation, and urgent diarrhea. Workup reveals no underlying anatomic or physiologic abnormality. Once other disorders have been excluded, dietary restrictions and avoidance of caffeine, alcohol, and tobacco may help to alleviate symptoms. Antispasmodics and bulking agents may be helpful.

Incontinence. The incidence of fecal incontinence has been estimated to occur in 10 to 13 individuals per 1000 people older than age 65 years. Incontinence ranges in severity from occasional leakage of gas and liquid stool to daily loss of solid stool. The underlying cause of incontinence is often multifactorial, and diarrhea is often contributory. In general, causes of incontinence can be classified as *neurogenic* or *anatomic*. Neurogenic causes include diseases of the central nervous system and spinal cord along with pudendal nerve injury. Anatomic causes include congenital abnormalities, procidentia (rectal prolapse), overflow incontinence secondary to impaction or an obstructing neoplasm, and trauma. The most common traumatic cause of incontinence is injury to the anal sphincter during vaginal delivery. Other causes include anorectal surgery, impalement, and pelvic fracture.

After a thorough medical evaluation to detect underlying conditions that might contribute to incontinence, evaluation focuses on assessment of the anal sphincter and pudendal nerves. Pudendal nerve terminal motor latency testing may detect neuropathy. Anal manometry can detect low resting and squeeze pressures. Physical examination and defecography can detect rectal prolapse. Endoanal ultrasound is invaluable in diagnosing sphincter defects (Fig. 29-8).

Therapy depends on the underlying abnormality. Diarrhea should be treated medically (fiber, antidiarrheal agents). Even in the absence of frank diarrhea, the addition of dietary fiber may improve continence. Some patients may respond to biofeedback. Many patients with a sphincter defect are candidates for an overlapping sphincteroplasty. Innovative technologies such as sacral nerve stimulation and the artificial bowel sphincter are proving useful in patients who fail other interventions.[16] The delivery of radiofrequency energy to the anal canal (the Secca procedure) appears to be safe and effective in early studies.[17] Injectable bulking agents are also gaining popularity, but long-term efficacy has not yet been proven.[18] Finally, a stoma can provide relief for severely incontinent patients who have failed or are not candidates for other interventions.[19]

GENERAL SURGICAL CONSIDERATIONS

Colorectal resections are performed for a wide variety of conditions, including neoplasms (benign and malignant), inflammatory bowel diseases, and other benign conditions. Although the indication and urgency for surgery will alter some of the technical details, the operative principles of colorectal resections, anastomoses, and use of ostomies are well established.

Resections

The mesenteric clearance technique dictates the extent of colonic resection and is determined by the nature of the primary pathology (malignant or benign), the intent of the resection (curative or palliative), the precise location(s) of the primary pathology, and the condition of the mesentery (thin and soft or thick and indurated). In general, a proximal mesenteric ligation will eliminate the blood supply to a greater length of colon and require a more extensive "colectomy." Curative resection of a colorectal cancer is usually best accomplished by performing a proximal mesenteric vessel ligation and radical mesenteric clearance of the lymphatic drainage basin of the tumor site (Fig. 29-9). Resection of a benign process does not require wide mesenteric clearance.

1▶

Emergency Resection. Emergency resection may be required because of obstruction, perforation, or hemorrhage. In this setting, the bowel is almost always unprepared and the patient may

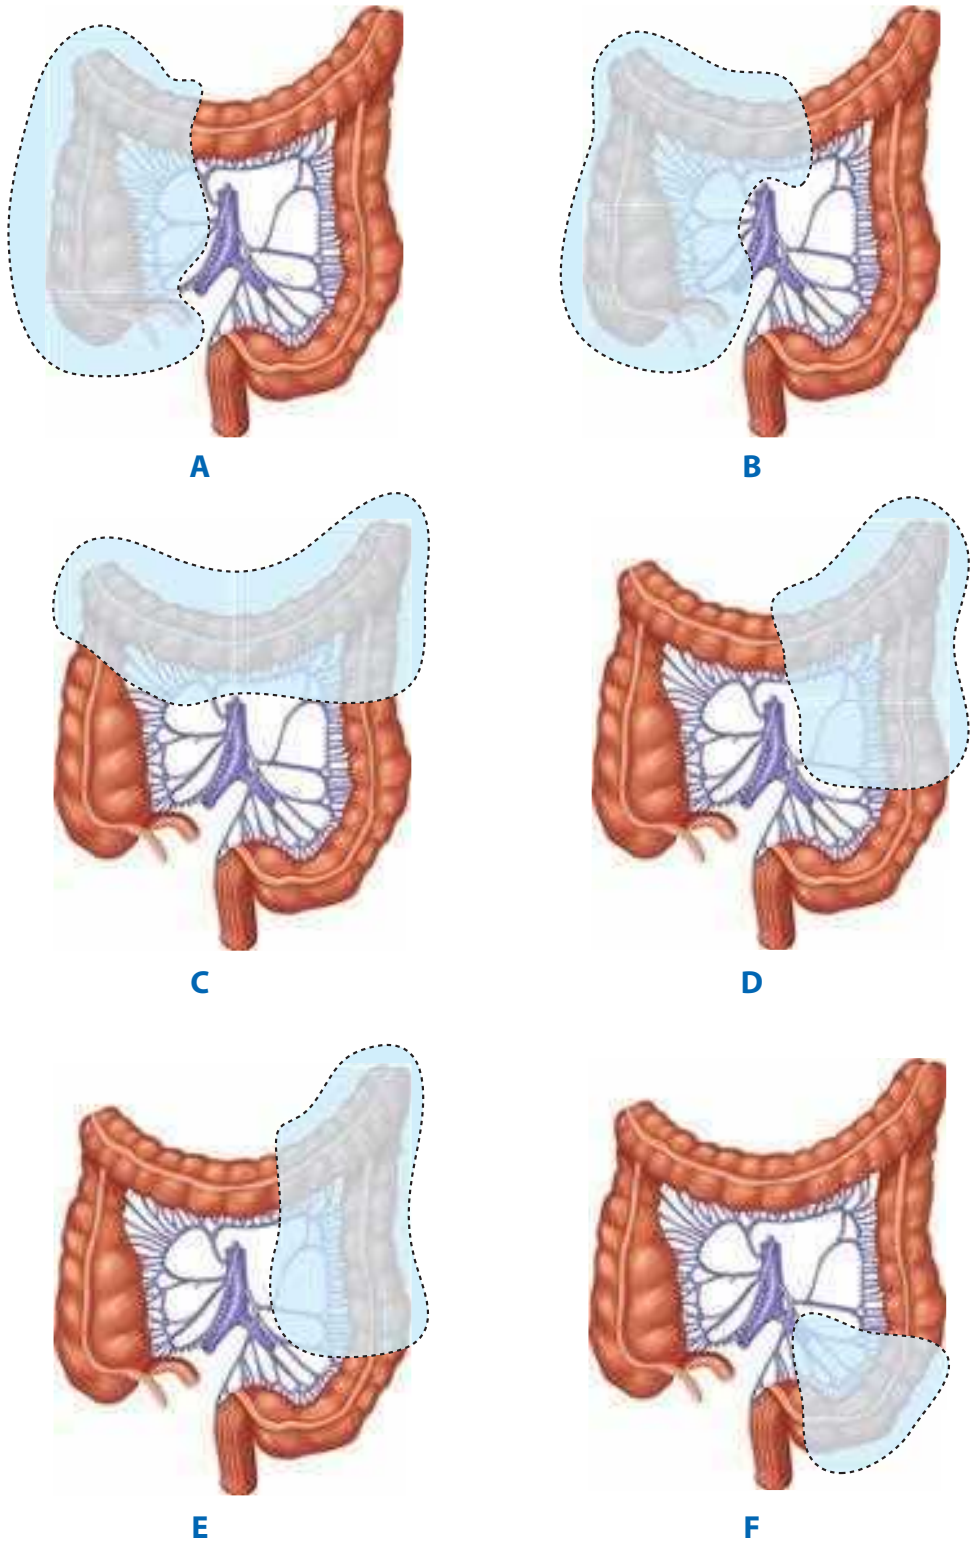

Figure 29-9. Extent of resection for carcinoma of the colon. **A.** Cecal cancer. **B.** Hepatic flexure cancer. **C.** Transverse colon cancer. **D.** Splenic flexure cancer. **E.** Descending colon cancer. **F.** Sigmoid colon cancer.

be unstable. The surgical principles described earlier apply, and an attempt should be made to resect the involved segment along with its lymphovascular supply. If the resection involves the right colon or proximal transverse colon (right or extended right colectomy), a primary ileocolonic anastomosis can usually be performed safely as long as the remaining bowel appears healthy and the patient is stable. For left-sided tumors, the traditional approach has involved resection of the involved bowel and end colostomy, with or without a mucus fistula. However, there is an increasing body of data to suggest that a primary anastomosis without a bowel preparation or with an on-table lavage, with or without a diverting ileostomy, may be equally safe in this setting. If the proximal colon appears unhealthy (vascular compromise, serosal tears, perforation), a subtotal colectomy can

be performed with a small bowel to rectosigmoid anastomosis. Resection and diversion (ileostomy or colostomy) remain safe and appropriate if the bowel appears compromised or if the patient is unstable, malnourished, or immunosuppressed.

Minimally Invasive Techniques of Resection. With advances in minimally invasive technology, many procedures that previously have required laparotomy can now be performed laparoscopically,[20,21] with hand-assisted laparoscopy (HAL), or robotically. Potential advantages of minimally invasive surgery include improved cosmetic result, decreased postoperative pain, and earlier return of bowel function. Moreover, some experimental data suggest that minimally invasive operations have less immunosuppressive impact on the patient and thus might improve postoperative outcome and even long-term survival. To date, most studies have demonstrated equivalence between laparoscopic, HAL, and open resection in terms of extent of resection. Return of bowel function and length of hospital stay are highly variable. Long-term outcome has yet to be determined; however, short-term quality of life appears to be improved by laparoscopy.[22,23] The most recent advances in minimally invasive surgery involve use of *robotics* and *telemanipulation* in which the surgeon operates from a console remote from the patient. These procedures have been rapidly gaining in popularity, especially for pelvic and rectal resections. Early studies suggest equivalence between robotic resections and laparoscopic/HAL resections.[24]

In addition, some proponents have suggested that robotic procedures may be easier to learn (a shorter "learning curve") and that robotic surgery may be ergonomically better for the operating surgeon. Nevertheless, long-term superiority, or even equivalence, has yet to be demonstrated, and these advanced technologies are likely to be associated with significant cost.

Colectomy. A variety of terms are used to describe different types of colectomy (Fig. 29-10).

Ileocolic Resection. An ileocolic resection describes a limited resection of the terminal ileum, cecum, and appendix. It is used to remove disease involving these segments of the intestine (e.g., ileocecal Crohn's disease) and benign lesions or incurable cancers arising in the terminal ileum, cecum, and, occasionally, the appendix. If curable malignancy is suspected, more radical resections, such as a right hemicolectomy, are generally indicated. The ileocolic vessels are ligated and divided. A variable length of small intestine may be resected depending on the disease process. A primary anastomosis is created between the distal small bowel and the ascending colon. It is technically difficult to perform an anastomosis at or just proximal to the ileocecal valve; therefore, if the most distal ileum needs to be resected, the cecum is generally also removed.

Right Colectomy. A right colectomy is used to remove lesions or disease in the right colon and is oncologically the most appropriate operation for curative intent resection of proximal colon carcinoma. The ileocolic vessels, right colic vessels, and right branches of the middle colic vessels are ligated and divided. Approximately 10 cm of terminal ileum are usually included in the resection. A primary ileal-transverse colon anastomosis is almost always possible.

Extended Right Colectomy. An extended right colectomy may be used for curative intent resection of lesions located at the hepatic flexure or proximal transverse colon. A standard right colectomy is extended to include ligation of the middle colic vessels at their base. The right colon and proximal transverse colon are resected, and a primary anastomosis is created between the distal ileum and distal transverse colon. Such an anastomosis relies on the marginal artery of Drummond. If the blood supply to the distal transverse colon is questionable, the resection is extended distally beyond the splenic flexure to well-perfused descending colon where the ileocolic anastomosis can be performed safely.

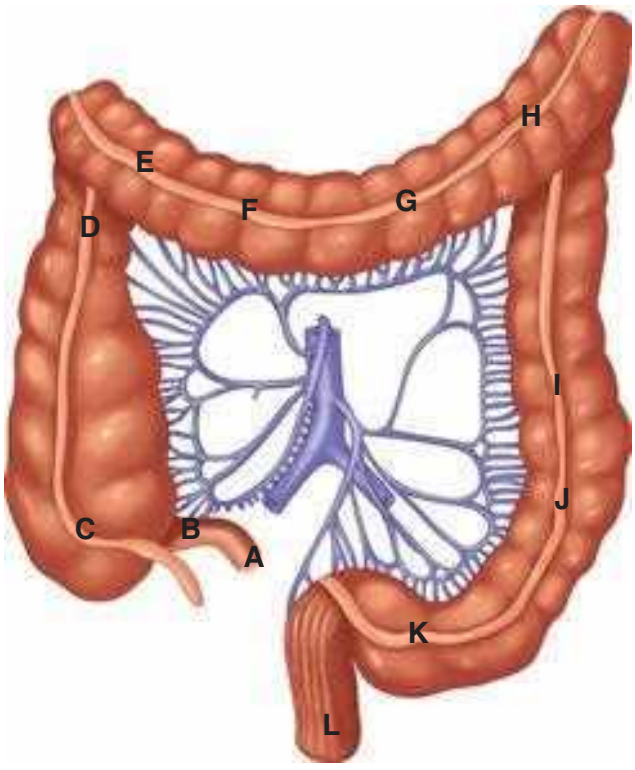

Figure 29-10. Terminology of types of colorectal resections: A→C Ileocecectomy; + A + B→D Ascending colectomy; + A + B→F Right hemicolectomy; + A + B→G Extended right hemicolectomy; + E + F→G + H Transverse colectomy; G→I Left hemicolectomy; F→I Extended left hemicolectomy; J + K Sigmoid colectomy; + A + B→J Subtotal colectomy; + A + B→K Total colectomy; + A + B→L Total proctocolectomy. *(Reproduced with permission from Fielding LP, Goldberg SM, eds.* Rob & Smith's Operative: Surgery of the Colon, Rectum, and Anus. *London: Elsevier Science Ltd; 1993:349.)*

Transverse Colectomy. Lesions in the mid and distal transverse colon may be resected by ligating the middle colic vessels and resecting the transverse colon, followed by a colocolonic anastomosis. However, an extended right colectomy with an anastomosis between the terminal ileum and descending colon may be a safer anastomosis with an equivalent functional result.

Left Colectomy. For lesions or disease states confined to the distal transverse colon, splenic flexure, or descending colon, a left colectomy is performed. The left branches of the middle colic vessels, the left colic vessels, and the first branches of the sigmoid vessels are ligated. A colocolonic anastomosis can usually be performed.

Extended Left Colectomy. An extended left colectomy is an option for removing lesions in the distal transverse colon. In this operation, the left colectomy is extended proximally to include the right branches of the middle colic vessels.

Sigmoid Colectomy. Lesions in the sigmoid colon require ligation and division of the sigmoid branches of the inferior mesenteric artery. In general, the entire sigmoid colon should be

resected to the level of the peritoneal reflection and an anastomosis created between the descending colon and upper rectum. Full mobilization of the splenic flexure is often required to create a tension-free anastomosis.

Total and Subtotal Colectomy. Total or subtotal colectomy is occasionally required for patients with fulminant colitis, attenuated FAP, or synchronous colon carcinomas. In this procedure, the ileocolic vessels, right colic vessels, middle colic vessels, and left colic vessels are ligated and divided. The superior rectal vessels are preserved. If it is desired to preserve the sigmoid, the distal sigmoid vessels are left intact, and an anastomosis is created between the ileum and distal sigmoid colon (subtotal colectomy with ileosigmoid anastomosis). If the sigmoid is to be resected, the sigmoidal vessels are ligated and divided, and the ileum is anastomosed to the upper rectum (total abdominal colectomy with ileorectal anastomosis). If an anastomosis is contraindicated, an end ileostomy is created, and the remaining sigmoid or rectum is managed either as a mucus fistula or a Hartmann's pouch.

Proctocolectomy

Total Proctocolectomy. In this procedure, the entire colon, rectum, and anus are removed and the ileum is brought to the skin as a Brooke ileostomy.

Restorative Proctocolectomy (Ileal Pouch–Anal Anastomosis). The entire colon and rectum are resected, but the anal sphincter muscles and a variable portion of the distal anal canal are preserved. Bowel continuity is restored by anastomosis of an ileal reservoir to the anal canal. The original technique included a transanal mucosectomy and hand-sewn ileoanal anastomosis. Proponents of this technique argue that mucosectomy guarantees removal of all of the diseased mucosa, including the anal transition zone, and therefore decreases the risk of ongoing disease, dysplasia, and carcinoma.[25] Opponents cite the increased risk of incontinence after mucosectomy and argue that even meticulous technique invariably leaves behind mucosal "islands" that are subsequently hidden under the anastomosis. Moreover, the "double-staple" technique using the circular stapling devices is considerably simpler than mucosectomy and a hand-sewn anastomosis and may be associated with a better functional outcome (Fig. 29-11).[26-29] Regardless of the anastomotic technique, many surgeons recommend that patients undergo annual surveillance of the anastomosis and/or anal transition zone by digital rectal exam and anoscopy or proctoscopy.

The neorectum is made by anastomosis of the terminal ileum aligned in a "J," "S," or "W" configuration. Because functional outcomes are similar and because the J-pouch is the simplest to construct, it has become the most used configuration. With increasing experience in laparoscopic and robotic colectomy, some centers have begun performing total proctocolectomy with ileal pouch–anal reconstruction using minimally invasive surgical techniques.[20] Most surgeons perform a proximal ileostomy to divert succus from the newly created pouch in an attempt to minimize the consequences of leak and sepsis, especially in patients who are malnourished or immunosuppressed (Fig. 29-12). The ileostomy is then closed 6 to 12 weeks later, after a contrast study confirms the integrity of the pouch. In low-risk patients, however, there are reports of successful creation of an ileoanal pouch without a diverting stoma.

Anterior Resection. *Anterior resection* is the general term used to describe resection of the rectum from an abdominal approach to the pelvis with no need for a perineal, sacral, or other incision. Three types of anterior resection have been described.

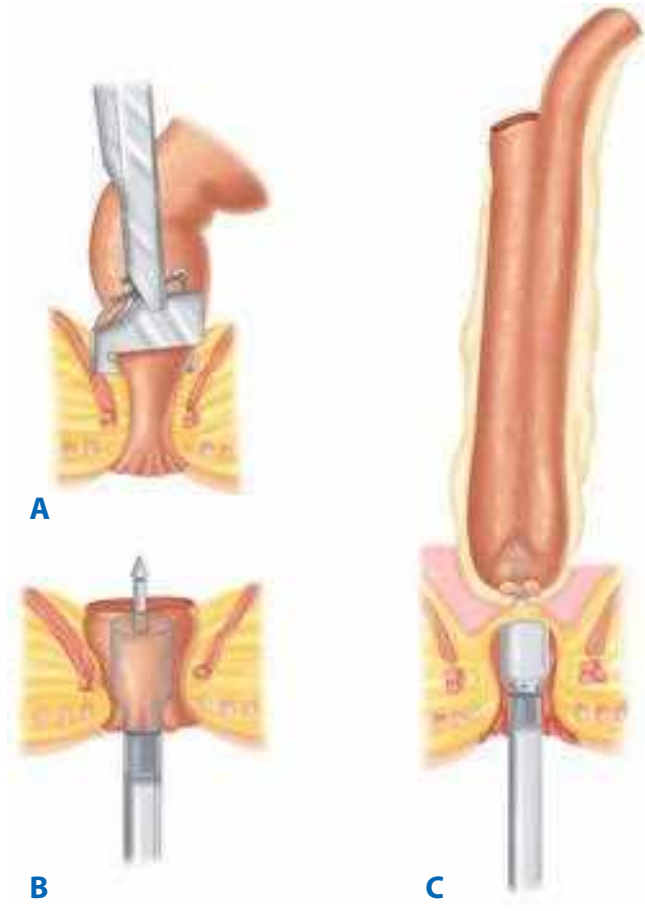

Figure 29-11. After a total colectomy and resection of the rectum (**A**), the anal canal with a short cuff of transitional mucosa and sphincter muscles is preserved (**B**). An ileal J-pouch has been constructed and is anastomosed to the anal canal using a double-staple technique (**C**). *(Reproduced with permission from Bell RH, Rikkers LF, Mulholland M, eds.* Digestive Tract Surgery: A Text and Atlas. *Philadelphia: Lippincott Williams & Wilkins; 1996:1527.)*

High Anterior Resection. A *high anterior resection* is the term used to describe resection of the distal sigmoid colon and upper rectum and is the appropriate operation for benign lesions and disease at the rectosigmoid junction such as diverticulitis. The upper rectum is mobilized, but the pelvic peritoneum is not divided and the rectum is not mobilized fully from the concavity of the sacrum. The inferior mesenteric artery is ligated at its base, and the inferior mesenteric vein, which follows a different course than the artery, is ligated separately. A primary anastomosis (usually end-to-end) between the colon and rectal stump with a short cuff of peritoneum surrounding its anterior two thirds generally can be performed.

Low Anterior Resection. A *low anterior resection* is used to remove lesions in the upper and mid rectum. The rectosigmoid is mobilized, the pelvic peritoneum is opened, and the inferior mesenteric artery is ligated and divided either at its origin from the aorta or just distal to the takeoff of the left colic artery. The rectum is mobilized from the sacrum by sharp dissection under direct view within the endopelvic fascial plane. The dissection may be performed distally to the anorectal ring, extending posteriorly through the rectosacral fascia to the coccyx and

Figure 29-12. Ileal S-pouch anal anastomosis with temporary loop ileostomy. *(Reproduced with permission from Bell RH, Rikkers LF, Mulholland M, eds.* Digestive Tract Surgery: A Text and Atlas. *Philadelphia: Lippincott Williams & Wilkins; 1996:1533.)*

anteriorly through Denonvilliers' fascia to the vagina in women or the seminal vesicles and prostate in men. The rectum and accompanying mesorectum are divided at the appropriate level, depending on the nature of the lesion. A low rectal anastomosis usually requires mobilization of the splenic flexure and ligation and division of the inferior mesenteric vein just inferior to the pancreas. Circular stapling devices have greatly facilitated the conduct and improved the safety of the colon to extraperitoneal rectal anastomosis.

Extended Low Anterior Resection. An *extended low anterior resection* is necessary to remove lesions located in the distal rectum, but several centimeters above the sphincter. The rectum is fully mobilized to the level of the levator ani muscle just as for a low anterior resection, but the anterior dissection is extended along the rectovaginal septum in women and distal to the seminal vesicles and prostate in men. After resection at this level, a *coloanal anastomosis* can be created using one of a variety of techniques. An end-to-end stapled or hand-sewn anastomosis has traditionally been the procedure of choice. However, the functional consequences of a "straight" anastomosis have led to consideration for creation of a colon J-pouch or transverse coloplasty to increase the capacity of the neorectal reservoir.[30] Because the risk of an anastomotic leak and subsequent sepsis is higher when an anastomosis is created in the distal rectum or anal canal, creation of a temporary ileostomy should be considered in this setting.

Although an anastomosis may be technically feasible very low in the rectum or anal canal, it is important to note that postoperative function may be poor. Because the descending colon lacks the distensibility of the rectum, the reservoir function may be compromised. Pelvic radiation, prior anorectal surgery, and obstetrical trauma may cause unsuspected sphincter damage. Finally, a very low anastomosis may involve and compromise the upper sphincter. Creation of a *colon J-pouch* or transverse coloplasty may improve function, but few long-term studies have addressed this issue.[30,31]

A history of sphincter damage or any degree of incontinence is a relative contraindication for a coloanal anastomosis. 2▶ In such patients, an end colostomy may be a more satisfactory option.

Hartmann's Procedure and Mucus Fistula. Hartmann's procedure refers to a colon or rectal resection without an anastomosis in which a colostomy or ileostomy is created and the distal colon or rectum is left as a blind pouch. The term is typically used when the left or sigmoid colon is resected and the closed off rectum is left in the pelvis. If the distal colon is long enough to reach the abdominal wall, a *mucus fistula* can be created by opening the defunctioned bowel and suturing the open lumen to the skin.

Abdominoperineal Resection. An abdominoperineal resection (APR) involves removal of the entire rectum, anal canal, and anus with construction of a permanent colostomy from the descending or sigmoid colon. The abdominal-pelvic portion of this operation proceeds in the same fashion as described for an extended low anterior resection. The perineal dissection can be performed with the patient in lithotomy position (often by a second surgeon) or in the prone position after closure of the abdomen and creation of the colostomy. For cancer, the perineal dissection is designed to excise the anal canal with a wide circumferential margin including a cylindrical cuff of the levator muscle. Primary wound closure is usually successful, but a large perineal defect, especially if preoperative radiation has been used, may require a vascularized flap closure in some patients. For benign disease, proctectomy may be performed using an *intersphincteric dissection* between the internal and external sphincters. This approach minimizes the perineal wound, making it easier to close because the levator muscle remains intact.

Anastomoses

Anastomoses may be created between two segments of bowel in a multitude of ways. The geometry of the anastomosis may be *end-to-end, end-to-side, side-to-end*, or *side-to-side*. The anastomotic technique may be *hand-sewn* or *stapled* (Fig. 29-13). The submucosal layer of the intestine provides the strength of the bowel wall and must be incorporated in the anastomosis to assure healing. The choice of anastomosis depends on the operative anatomy and surgeon preference. Although many surgeons advocate one method over another, none has been proven to be superior. Accurate approximation of two well-vascularized, healthy limbs of bowel without tension in a normotensive, well-nourished patient almost always results in a good outcome. Anastomoses at highest risk of leak or stricture are those that are in the distal rectal or anal canal, involve irradiated or diseased

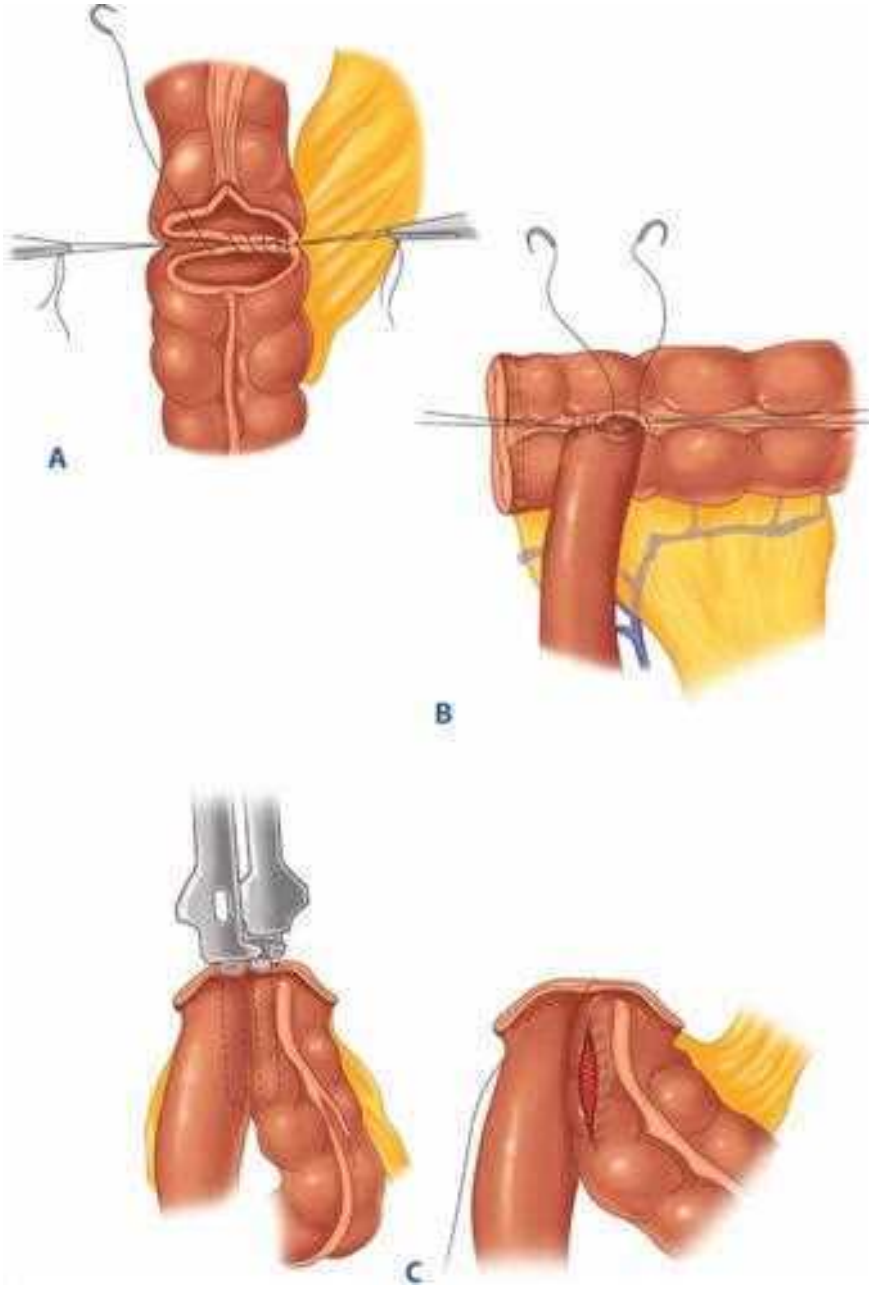

Figure 29-13. **A.** Sutured end-to-end colocolic anastomosis. **B.** Sutured end-to-side ileocolic anastomosis. **C.** Stapled side-to-side, functional end-to-end ileocolic anastomosis. *(Reproduced with permission from Bell RH, Rikkers LF, Mulholland M, eds.* Digestive Tract Surgery: A Text and Atlas*. intestine including perforation with peritoneal soilage, or are performed in malnourished, immunosuppressed, or ill patients.

Anastomotic Configuration

End-to-End. An end-to-end anastomosis can be performed when two segments of bowel are roughly the same caliber. This technique is most often employed in rectal resections, but may be used for colocolostomy or small bowel anastomoses.

End-to-Side. An end-to-side configuration is useful when one limb of bowel is larger than the other. This most commonly occurs in the setting of chronic obstruction.

Side-to-End. A side-to-end anastomosis is used when the proximal bowel is of smaller caliber than the distal bowel. Ileorectal anastomoses commonly make use of this configuration. A side-to-end anastomosis may have a less tenuous blood supply than an end-to-end anastomosis.

Side-to-Side. A side-to-side anastomosis allows a large, well-vascularized connection to be created on the antimesenteric side of two segments of intestine. This technique is commonly used in ileocolic and small bowel anastomoses.

Anastomotic Technique

Hand-Sutured Technique. Any of the configurations described earlier may be created using a hand-sutured or stapled technique. Hand-sutured anastomoses may be *single layer*, using either running or interrupted stitches, or *double layer*. A double-layer anastomosis usually consists of a continuous inner layer and an interrupted outer layer. Suture material may be either permanent

or absorbable. After distal rectal or anal canal resection, a transanal, hand-sewn coloanal anastomosis may be necessary to restore bowel continuity. This can be done in conjunction with an anal canal mucosectomy to allow the anastomosis to be created at the dentate line.

Stapled Techniques. Linear cutting/stapling devices are used to divide the bowel and to create side-to-side anastomoses. The anastomosis may be reinforced with interrupted sutures if desired. Circular cutting/stapling devices can create end-to-end, end-to-side, or side-to-end anastomoses. These instruments are particularly useful for creating low rectal or anal canal anastomoses where the anatomy of the pelvis makes a hand-sewn anastomosis technically difficult or impossible.

Following resection of the colorectum, a stapled end-to-end colorectal, coloanal canal, or ileal pouch–anal canal anastomosis may be created by one of two techniques. With the *open purse-string technique*, the distal rectal stump purse-string is placed by hand, and the assembled circular stapler is inserted into the anus and guided up to the rectal purse-string. The stapler is opened, and the distal purse-string is tied. A purse-string is placed in the distal end of the proximal colon; the proximal colon is placed over the anvil and the purse-string tightened. The stapler is closed and fired (Fig. 29-14). With the alternative *double-staple technique*, the distal rectum or anal canal is closed with a transverse staple line. The circular stapler is inserted through the anus without its anvil until the cartridge effaces the transverse staple line. The stapler is opened, causing the trocar to perforate through the rectal stump adjacent to the transverse staple line. The anastomosis in then completed as described earlier (see Fig. 29-11). After firing and removing the stapler, the resulting anastomotic rings should be inspected to ensure that they are intact. A gap in an anastomotic ring suggests that the circular staple line is incomplete and the anastomosis should be reinforced with suture circumferentially, if technically feasible. A temporary proximal ileostomy may be indicated as well. Most surgeons will also *leak test* an anastomosis by instilling water or saline into the pelvis and insufflating the rectum with air via a proctoscope or alternatively instilling methylene blue or betadine into the rectum to look for extravasation.

Ostomies and Preoperative Stoma Planning

Depending on the clinical situation, a stoma may be temporary or permanent. It may be end-on or a loop. However, regardless

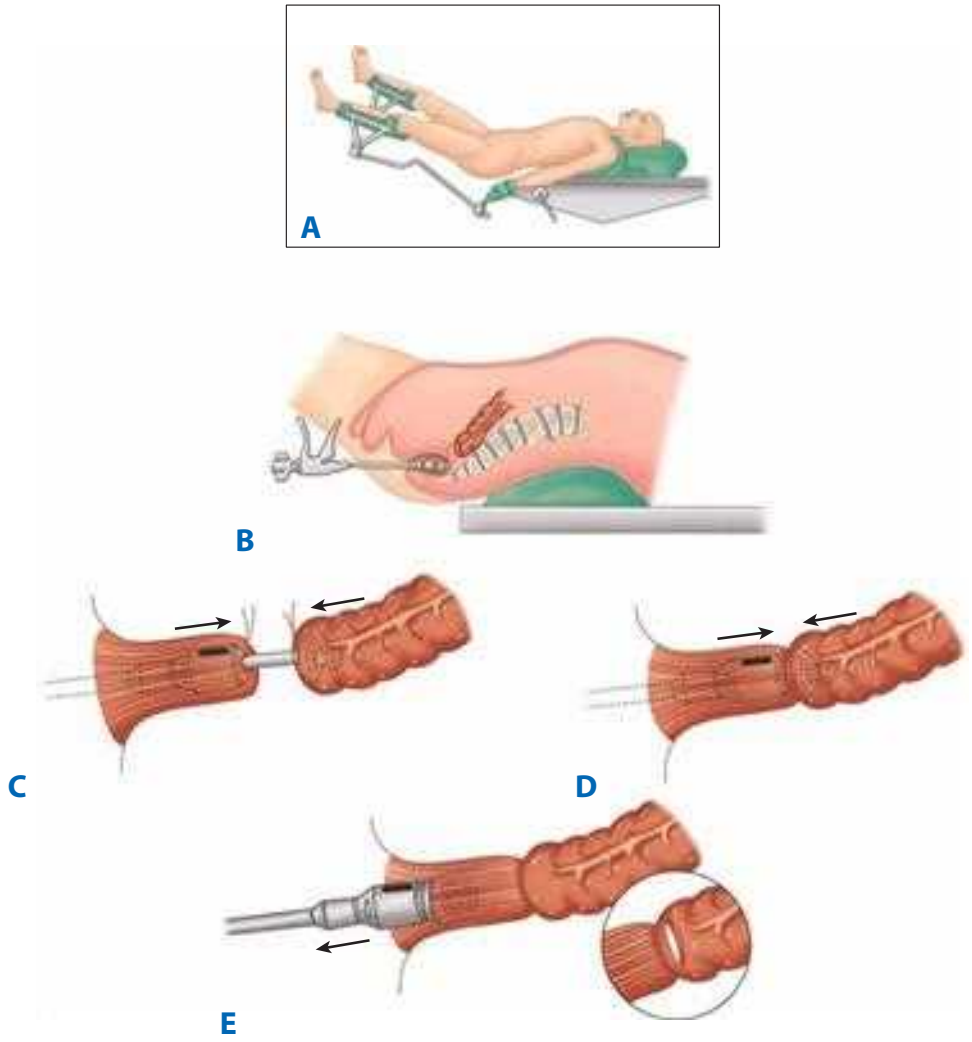

Figure 29-14. Technique of end-to-end colorectal anastomosis using a circular stapler. **A.** The patient is in modified lithotomy position. **B.** After resection of the rectosigmoid and placement of purse-string sutures proximally and distally, the stapler is inserted into the anal canal and opened. **C.** Rectal purse-string suture is tied to secure the rectal stump to the rod of the stapler, and the colonic purse-string is tied to secure the colon to the anvil of the stapler. **D.** The stapler is closed and fired. **E.** The stapler is removed, leaving a circular stapled end-to-end anastomosis.

of the indication for a stoma, placement and construction are crucial for function.

The preoperative preparation of a patient who is expected to require a stoma should include a consultation with an *enterostomal therapy (ET) nurse*. ET nurses are specially trained and credentialed by the Wound, Ostomy and Continence Nurses Society. Preoperative planning includes counseling, education, and stoma siting. Postoperatively, the ET nurse assists with local skin care and pouching. Other considerations in stoma planning include evaluation of other medical conditions that may impact on a patient's ability to manage a stoma (e.g., eyesight, manual dexterity).

Preoperative stoma siting is crucial for a patient's postoperative function and quality of life. A poorly placed stoma can result in leakage and skin breakdown. Ideally, a stoma should be placed in a location that the patient can easily see and manipulate, within the rectus muscle, and below the belt line (see Fig. 29-15). Because the abdominal landmarks in a supine, anesthetized patient may be dramatically different from those in an awake, standing, or sitting patient, the stoma site should always be marked with a tattoo, skin scratch, or permanent marker preoperatively, if possible. In an emergency operation where the stoma site has not been marked, an attempt should be made to place a stoma within the rectus muscle and away from both the costal margin and iliac crest. In emergencies, placement high on the abdominal wall is preferred to a low-lying site.

For all stomas, a circular skin incision is created and the subcutaneous tissue dissected to the level of the anterior rectus sheath. The anterior rectus sheath is incised in a cruciate fashion, the muscle fibers separated bluntly, and the posterior sheath identified and incised. Care should be taken to avoid injuring and causing bleeding from the inferior epigastric artery and vein. The size of the defect depends on the size of the bowel used to create the stoma, but should be as small as possible without compromising the intestinal blood supply (usually the width of two to three fingers). The bowel is then brought through the defect and secured with sutures. The abdominal incision is usually closed and dressed prior to maturing the stoma to avoid contaminating the wound. In order to make appliance use easier, a protruding nipple is fashioned by everting the bowel. Three or four interrupted absorbable sutures are placed through the edge of the bowel, then through the serosa, approximately 2 cm proximal to the edge, and then through the dermis (Brooke technique). After the stoma is everted, the mucocutaneous junction is sutured circumferentially with interrupted absorbable suture (Fig. 29-16).

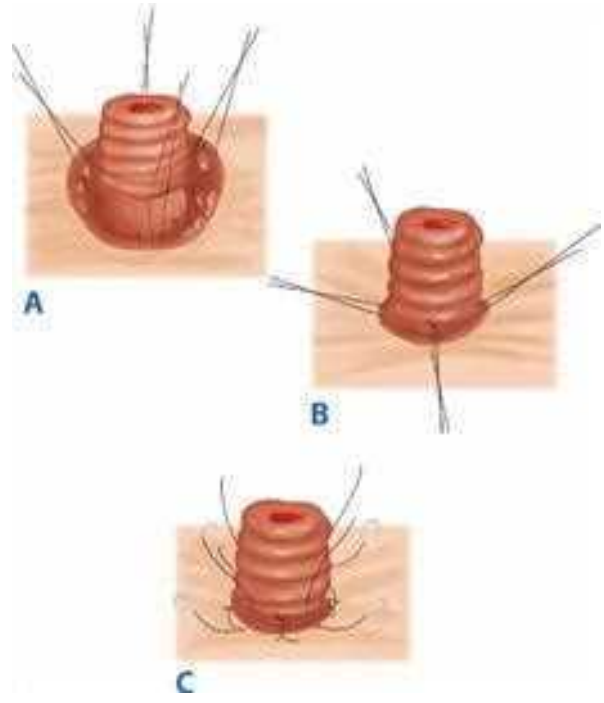

Figure 29-16. Brooke ileostomy. **A.** Four sutures incorporating the cut end of the ileum, the seromuscular layer at the level of the anterior rectus fascia, and the subcuticular edge of the skin are placed at 90° to each other. **B.** The sutures are tied to produce stomal eversion, and (**C**) simple sutures from the cut edge of the bowel to the subcuticular tissue complete the maturation of the ileostomy. *(Reproduced with permission from Bell RH, Rikkers LF, Mulholland M, eds.* Digestive Tract Surgery: A Text and Atlas. *Philadelphia: Lippincott Williams & Wilkins; 1996:1278.)*

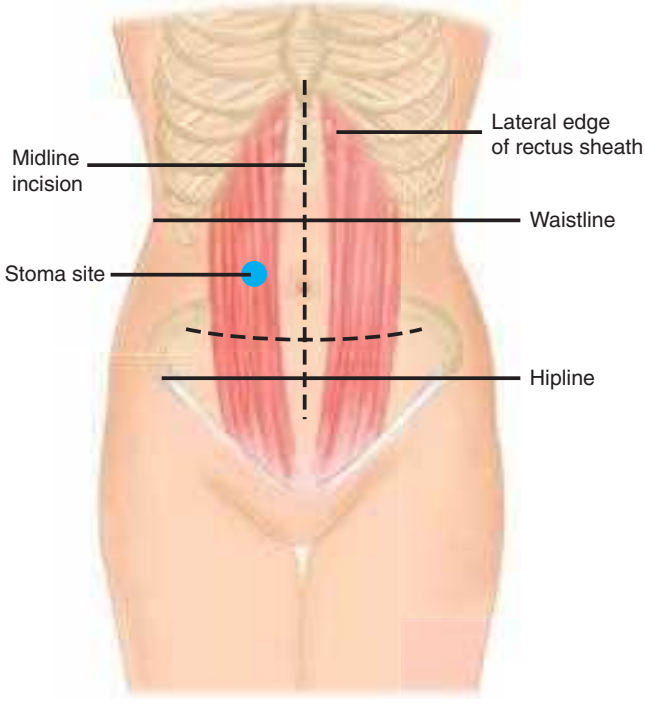

Figure 29-15. Marking of an ideal site for ileostomy. *(Reproduced with permission from Bell RH, Rikkers LF, Mulholland M, eds.* Digestive Tract Surgery: A Text and Atlas. *Philadelphia: Lippincott Williams & Wilkins; 1996:1273.)*

Ileostomy

Temporary Ileostomy. A temporary ileostomy is often used to "protect" an anastomosis that is at risk for leakage (low in the rectum, in an irradiated field, in an immunocompromised or malnourished patient, and during some emergency operations). In this setting, the stoma is often constructed as a *loop ileostomy* (see Fig. 29-12). A segment of distal ileum is brought through the defect in the abdominal wall as a loop. An enterotomy is created and the stoma matured as described earlier. The loop may be secured with or without an underlying rod. A *divided loop* may also be created by firing a linear cutting/stapler across the distal limb of the loop flush with the skin followed by maturation of the proximal limb of the loop.

This technique prevents incomplete diversion that occasionally occurs with a loop ileostomy.

The advantage of a loop or divided loop ileostomy is that subsequent closure can often be accomplished without a formal laparotomy. An elliptical incision is created around the stoma and the bowel gently dissected free of the subcutaneous tissues and fascia. A hand-sewn or stapled anastomosis can then be created and the intestine returned to the peritoneal cavity. This avoids a long laparotomy incision and generally is well tolerated. The timing of ileostomy closure should take into account anastomotic healing as well as the patient's overall condition. A flexible endoscopy exam and a contrast enema (Gastrografin) are recommended prior to closure to ensure that the anastomosis has not leaked and is patent. A patient's nutritional status should be optimized. In cancer patients receiving adjuvant chemotherapy, ileostomy closure should be delayed until the chemotherapy is completed.

Permanent Ileostomy. A permanent ileostomy is sometimes required after total proctocolectomy or in patients with obstruction. An *end ileostomy* is the preferred configuration for a permanent ileostomy because a symmetric protruding nipple can be fashioned more easily than with a loop ileostomy (see Fig. 29-16). The end of the small intestine is brought through the abdominal wall defect and matured. Stitches are often used to secure the bowel to the posterior fascia.

Complications of Ileostomy. Stoma necrosis may occur in the early postoperative period and is usually caused by skeletonizing the distal small bowel and/or creating an overly tight fascial defect. Limited mucosal necrosis above the fascia may be treated expectantly, but necrosis below the level of the fascia requires surgical revision. Stoma retraction may occur early or late and may be exacerbated by obesity. Local revision may be necessary. The creation of an ileostomy bypasses the fluid-absorbing capability of the colon, and dehydration with fluid and electrolyte abnormalities is not uncommon. Ideally, ileostomy output should be maintained at less than 1500 mL/d to avoid this problem. Bulk agents and opioids (Lomotil, Imodium, tincture of opium) are useful. The somatostatin analogue, octreotide, has been used with varying success in this setting. Skin irritation can also occur, especially if the stoma appliance fits poorly. Skin-protecting agents and custom pouches can help to solve this problem. Obstruction may occur intra-abdominally or at the site where the stoma exits the fascia. Parastomal hernia is less common after an ileostomy than after a colostomy but can cause poor appliance fitting, pain, obstruction, or strangulation. In general, symptomatic parastomal hernias should be repaired. A variety of techniques to repair these hernias have been described, including local repair (either with or without mesh), laparoscopic repair, and stoma resiting. Prolapse is a rare, late complication and is often associated with a parastomal hernia.

Colostomy. Most colostomies are created as *end colostomies* rather than *loop colostomies* (Fig. 29-17). The bulkiness of the colon makes a loop colostomy awkward for use of an appliance, and prolapse is more likely with this configuration. Most colostomies are created on the left side of the colon. An abdominal wall defect is created and the end of the colon mobilized through it. Because a protruding stoma is considerably easier to pouch, colostomies should also be matured in a Brooke fashion. The distal bowel may be brought through the abdominal wall as a *mucus fistula* or left intra-abdominally as a *Hartmann's pouch*. Tacking the distal end of the colon to the abdominal wall or tagging it with permanent suture can make identification of the stump easier if the colostomy is closed at a later date. Closure of an end colostomy has traditionally required a laparotomy, but increasingly minimally invasive techniques have been adopted. The stoma is dissected free of the abdominal wall and the distal bowel identified. An end-to-end anastomosis is then created.

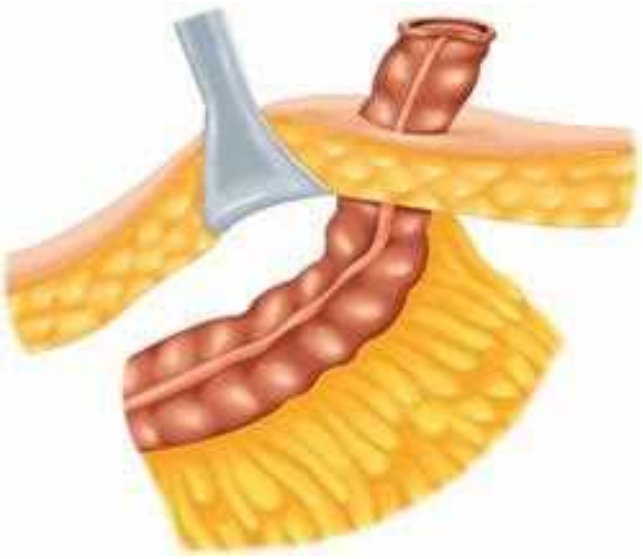

Figure 29-17. Intraperitoneal end colostomy.

Complications of Colostomy. *Colostomy necrosis* may occur in the early postoperative period and results from an impaired vascular supply (skeletonization of the distal colon or a tight fascial defect). Like ileostomy necrosis, limited suprafascial necrosis may be followed expectantly, but necrosis below the fascia requires surgery. *Retraction* may also occur but is less problematic with a colostomy than with an ileostomy because the stool is less irritating to the skin than *succus entericus*. *Obstruction* is unusual, but may also occur. *Parastomal hernia* is the most common late complication of a colostomy and requires repair if it is symptomatic. *Prolapse* occurs rarely, but is more common with a loop colostomy. Interestingly, it is almost always the efferent limb of the loop that prolapses. Dehydration is rare after colostomy, and skin irritation is less common than with ileostomy.

Functional Results

Function following segmental colonic resection and primary anastomosis is generally excellent. A small percentage of patients following subtotal or total colectomy and ileosigmoid or ileorectal anastomosis may experience diarrhea and bowel frequency. This is especially true if the patient is elderly, if significant length of small bowel has been resected, and if residual proctocolitis is poorly controlled. In general, the more distal the anastomosis, the greater is the risk of troublesome diarrhea and frequency. However, some patients develop significant diarrhea after right colectomy due to malabsorption of bile acids; in these cases, bile acid binding resins (e.g., cholestyramine) sometimes can be helpful.

Function following anterior resection is highly dependent on the level of anastomosis, the use of pre- or postoperative pelvic radiation, and underlying sphincter function. Following low anterior or extended low anterior resection, some surgeons

prefer to construct a short (5-cm) colon J-pouch to anastomose to the distal rectum or anal canal or, alternatively, a transverse coloplasty to increase the capacity of the neorectum. The reservoirs are thought to lessen urgency, frequency, and incontinence, but some patients have difficulty initiating defecation, and long-term superiority over a "straight" anastomosis has yet to be proven. In addition, these reservoirs can be technically difficult, especially in an obese male with a narrow pelvis.

The physical and psychological problems associated with a permanent Brooke ileostomy led to development of the continent Kock pouch ileostomy. Unfortunately, complications, especially complications related to valve slippage, are common. Despite variations of technique designed to improve the function of the continent ileostomy, most surgeons have abandoned this operation and instead perform restorative proctocolectomy with ileal pouch–anal anastomosis.

Although ileal pouch–anal reconstruction is anatomically appealing, functional outcome is far from perfect.[6,25] Patients should be counseled to expect 8 to 10 bowel movements per day. Up to 50% have some degree of nocturnal incontinence. Pouchitis occurs in nearly 50% of patients who undergo the operation for chronic ulcerative colitis, and small bowel obstruction is not uncommon. Other less common complications include difficulties with pouch evacuation, pouch-anal and/or pouch-vaginal fistula, and anal stricture. Pouch failure rate averages 5% to 10%. Patients who are subsequently diagnosed with Crohn's disease have a considerably higher pouch failure rate (approximately 50%), whereas patients with indeterminate colitis have a lower pouch failure rate (15%–20%). Despite these drawbacks, the vast majority of patients are satisfied and prefer ileal pouch–anal reconstruction to permanent ileostomy.

Pouchitis is an inflammatory condition that affects both ileoanal pouches and continent ileostomy reservoirs. The incidence of pouchitis ranges from 30% to 55%. Symptoms include increased diarrhea, hematochezia, abdominal pain, fever, and malaise. Diagnosis is made endoscopically with biopsies. Differential diagnosis includes infection and undiagnosed Crohn's disease. The etiology of pouchitis is unknown. Some believe pouchitis results from fecal stasis within the pouch, but emptying studies are not confirmatory. Antibiotics (metronidazole ± ciprofloxacin) are the mainstays of therapy, and most patients will respond rapidly to either oral preparations or enemas.[32,33] Some patients develop chronic pouchitis that necessitates ongoing suppressive antibiotic therapy. Salicylate and corticosteroid enemas have also been used with some success. Reintroduction of normal flora by ingestion of *probiotics* and/or an elemental diet have been suggested as a possible treatment in refractory cases. Occasionally, pouch excision is necessary to control the symptoms of chronic pouchitis.

Anesthesia Considerations

Local Anesthesia. Many anorectal procedures can be performed with local anesthetic alone. Intravenous sedation is often provided to calm the patient. Injection of 0.5% lidocaine (short acting) and 0.25% bupivacaine (long acting) into the perianal skin, sphincter, and area around the pudendal nerves usually provides an adequate block. The addition of dilute epinephrine decreases bleeding and prolongs the anesthetic effect.

Regional Anesthesia. Epidural, spinal, and caudal anesthetics can be used for anorectal procedures and transanal resections. In patients with severe medical comorbidity, regional anesthesia may occasionally be used for laparotomy and colectomy. Postoperative epidural anesthesia provides excellent pain relief and improves pulmonary function.

General Anesthesia. General anesthesia is required for the vast majority of intra-abdominal procedures. Patients should undergo a thorough preoperative cardiovascular evaluation. In patients with significant comorbid disease, an anesthesia consultation may be appropriate.

Positioning. Most abdominal colectomies can be performed in the supine position. Anterior resection and APR require lithotomy positioning to facilitate the pelvic dissection and mobilization of the splenic flexure. Adequate padding should be provided for the patient's sacrum, and care should be taken to avoid stirrup pressure on the peroneal nerves.

Anorectal procedures may be performed in lithotomy or in the prone jackknife position. Some surgeons prefer the prone jackknife position because exposure may be better, especially for anterior lesions. Distal posterior lesions can usually be accessed from either position, but more proximal posterior lesions are better accessed in the prone position.

Operative Preliminaries

Bowel Preparation. The rationale for bowel preparation is that decreasing the bacterial load in the colon and rectum will decrease the incidence of postoperative infection. *Mechanical bowel preparation* uses cathartics to rid the colon of solid stool the night before surgery.[28,29] The most commonly used regimens include polyethylene glycol (PEG) solutions or magnesium citrate. PEG solutions require patients to drink a large volume of fluid and may cause bloating and nausea. Magnesium citrate solutions are generally better tolerated but are more likely to cause fluid and electrolyte abnormalities. Both are equally efficacious in bowel cleansing. Preparatory formulations have been recently introduced in tablet form in an attempt to improve tolerance. However, these methods of bowel cleansing require ingestion of 40 or more tablets with water over several hours. To date, these formulations have not been proven to be superior to the more traditional products.[34] *Antibiotic prophylaxis* also is recommended. The addition of oral antibiotics to the preoperative mechanical bowel preparation has been thought to decrease postoperative infection by further decreasing the bacterial load of the colon. However, the regimens used (neomycin, erythromycin, or metronidazole) frequently caused gastrointestinal upset that interfered with the mechanical preparation, and many surgeons have abandoned oral antibiotic prophylaxis. Nevertheless, a recent analysis of the Surgical Care Improvement Project-1 (SCIP-1) suggests that oral antibiotics do reduce postoperative wound infection, especially if a mechanical bowel preparation is not used.[35]

Prospective randomized trials are needed to better understand the role of oral antibiotic prophylaxis in colorectal surgery. In contrast, longstanding, convincing data support the efficacy of parenteral antibiotic prophylaxis at the time of surgery. Broad-spectrum parenteral antibiotic(s) with activity against aerobic and anaerobic enteric pathogens should be administered just prior to the skin incision and redosed as needed depending on the length of the operation. There is no proven benefit to using antibiotics postoperatively after an uncomplicated colectomy.

Despite widespread use of mechanical bowel preparation, the necessity of bowel cleansing prior to colectomy has been questioned. European surgeons in particular have advocated abandoning this practice. Arguments against mechanical

bowel preparation include dehydration and electrolyte abnormalities that often result from bowel cleansing, as well as the risk of spillage of liquid stool left over from the "prep." Arguments in favor of mechanical bowel preparation included easier manipulation of an "empty" colon (especially in minimally invasive procedures) and avoidance of a "stool column" above an anastomosis, especially in the pelvis. Interestingly, a recent meta-analysis of 14 randomized controlled trials suggested that mechanical bowel preparation does *not* prevent surgical site infection and should be abandoned in clinical practice.[36]

Ureteral Stents. Ureteral stents may be useful for identifying the ureters intraoperatively and are placed via cystoscopy after the induction of general anesthesia and removed at the end of the operation. Stents can be invaluable during reoperative pelvic surgery or when there is significant retroperitoneal inflammation (such as complicated diverticulitis), as well as in obese patients. Lighted stents may be helpful in laparoscopic and robotic resections. Patients often have transient hematuria postoperatively, but major complications are rare.

Multidisciplinary Teams. Patients with complex colorectal disease often benefit from a multidisciplinary approach to their care. Patients with pelvic floor disorders (especially incontinence) often require evaluation by both a colorectal surgeon and a urologist or urogynecologist. Preoperative evaluation of cancer patients by a medical oncologist and/or radiation oncologist is crucial for planning either neoadjuvant or adjuvant therapy. Intraoperatively, complex pelvic resections often require the involvement of not only a colorectal surgeon but also a urologist, gynecologic oncologist, neurosurgeon, and/or plastic surgeon. Radiation oncologists should be involved in the operation if brachytherapy catheters are to be placed for intracavitary radiation or if intraoperative radiation therapy is planned. Rarely, psychiatric disorders may manifest as colorectal problems (especially functional disorders and chronic pain), and involvement of a psychiatrist or psychologist may be beneficial.

INFLAMMATORY BOWEL DISEASE

General Considerations

Epidemiology. Inflammatory bowel disease includes *ulcerative colitis, Crohn's disease*, and *indeterminate colitis. Ulcerative colitis* occurs in 8 to 15 people per 100,000 in the United States and Northern Europe. The incidence is considerably lower in Asia, Africa, and South America, and among the nonwhite population in the United States. Ulcerative colitis incidence peaks during the third decade of life and again in the seventh decade of life. The incidence of Crohn's disease is slightly lower, 1 to 5 people per 100,000. Crohn's disease also affects Northern European and white populations disproportionately. Crohn's disease has a similar bimodal incidence, with most cases occurring between ages 15 to 30 years and ages 55 to 60 years. In 15% of patients with inflammatory bowel disease, differentiation between ulcerative colitis and Crohn's colitis is impossible; these patients are classified as having *indeterminate colitis*.

Etiology. Many different etiologies for inflammatory bowel disease have been proposed, but none are proven. The consistent geographic differences in incidence suggest an environmental factor such as diet or infection. Alcohol and oral contraceptive use have also been implicated. Smoking has been implicated in the etiology and exacerbation of Crohn's disease in particular. Family history may play a role because 10% to 30% of patients with inflammatory bowel disease report a family member with the same disease.[37,38] Other theories focus on an autoimmune mechanism and/or a defect in the intestinal immune system. While there is general agreement that interaction among the immune system, the mucosal barrier of the gut, and a variety of infectious agents is involved in the pathogenesis of inflammatory bowel disease, the mechanism(s) by which these interactions produce disease is poorly understood. Bacteria, such as *Mycobacterium paratuberculosis* and *Listeria monocytogenes*, and viruses, such as paramyxovirus and measles virus, have been suggested as etiologic agents in Crohn's disease. A defect in the gut mucosal barrier, which increases exposure to intraluminal bacteria, toxins, or proinflammatory substances, also has been suggested. Finally, as noted earlier, an autoimmune mechanism has been postulated. Although there is no clear evidence linking an immunologic disorder to inflammatory bowel disease, the similarity of many of the extraintestinal manifestations to rheumatologic disorders has made this theory attractive. Regardless of the underlying cause of either ulcerative colitis or Crohn's disease, both disorders are characterized by intestinal inflammation, and medical therapy is largely based on reducing inflammation.

Pathology and Differential Diagnosis. Although ulcerative colitis and Crohn's colitis share many pathologic and clinical similarities, these conditions may be differentiated in 85% of patients. Ulcerative colitis is a mucosal process in which the colonic mucosa and submucosa are infiltrated with inflammatory cells. The mucosa may be atrophic, and crypt abscesses are common. Endoscopically, the mucosa is frequently friable and may possess multiple inflammatory pseudopolyps. In longstanding ulcerative colitis, the colon may be foreshortened and the mucosa replaced by scar. In quiescent ulcerative colitis, the colonic mucosa may appear normal both endoscopically and microscopically. Ulcerative colitis may affect the rectum (proctitis), rectum and sigmoid colon (proctosigmoiditis), rectum and left colon (left-sided colitis), or the rectum and entire colon (pancolitis). Ulcerative colitis does not involve the small intestine, but the terminal ileum may demonstrate inflammatory changes ("backwash ileitis"). A key feature of ulcerative colitis is the continuous involvement of the rectum and colon; rectal sparing or skip lesions suggest a diagnosis of Crohn's disease. Symptoms are related to the degree of mucosal inflammation and the extent of colitis. Patients typically complain of bloody diarrhea and crampy abdominal pain. Proctitis may produce tenesmus. Severe abdominal pain and fever raise the concern of *fulminant colitis* or *toxic megacolon*. Physical findings are nonspecific and range from minimal abdominal tenderness and distention to frank peritonitis. In the nonemergent setting, the diagnosis is typically made by colonoscopy and mucosal biopsy.

In contrast to ulcerative colitis, Crohn's disease is a transmural inflammatory process that can affect any part of the gastrointestinal tract from mouth to anus. Mucosal ulcerations, an inflammatory cell infiltrate, and noncaseating granulomas are characteristic pathologic findings. Chronic inflammation may ultimately result in fibrosis, strictures, and fistulas in either the colon or small intestine. The endoscopic appearance of Crohn's colitis is characterized by deep serpiginous ulcers and a "cobblestone" appearance. Skip lesions and rectal sparing are common. Symptoms of Crohn's disease depend on the severity of inflammation and/or fibrosis and the location of inflammation in the gastrointestinal tract. Acute inflammation may

produce diarrhea, crampy abdominal pain, and fever. Strictures may produce symptoms of obstruction. Weight loss is common, both because of obstruction and from protein loss. Perianal Crohn's disease may present with pain, swelling, and drainage from fistulas or abscesses. Physical findings are also related to the site and severity of disease.

In 15% of patients with colitis from inflammatory bowel disease, differentiation of ulcerative colitis from Crohn's colitis is impossible either grossly or microscopically (indeterminate colitis). These patients typically present with symptoms similar to ulcerative colitis. Endoscopic and pathologic findings usually include features common to both diseases. Increasingly, serologic markers have been employed to differentiate ulcerative colitis from Crohn's disease. The anti-Saccharomyces cerevisiae antibody (ASCA) and perinuclear anticytoplasmic antibody (pANCA) may be useful in differentiating these two processes but require prospective study.[39]

Further differential diagnoses include infectious colitides, especially *Campylobacter jejuni, Entamoeba histolytica, C. difficile, Neisseria gonorrhoeae, Salmonella*, and *Shigella* species.

Extraintestinal Manifestations. The liver is a common site of extracolonic disease in inflammatory bowel disease. Fatty infiltration of the liver is present in 40% to 50% of patients, and cirrhosis is found in 2% to 5%. Fatty infiltration may be reversed by medical or surgical treatment of colonic disease, but cirrhosis is irreversible. Primary sclerosing cholangitis is a progressive disease characterized by intra- and extrahepatic bile duct strictures. Forty percent to 60% of patients with primary sclerosing cholangitis have ulcerative colitis. Colectomy will not reverse this disease, and the only effective therapy is liver transplantation.[40] Pericholangitis is also associated with inflammatory bowel disease and may be diagnosed with a liver biopsy. Bile duct carcinoma is a rare complication of long-standing inflammatory bowel disease. Patients who develop bile duct carcinoma in the presence of inflammatory bowel disease are, on average, 20 years younger than other patients with bile duct carcinoma.

Arthritis also is a common extracolonic manifestation of inflammatory bowel disease, and the incidence is 20 times greater than in the general population. Arthritis usually improves with treatment of the colonic disease. Sacroiliitis and ankylosing spondylitis are associated with inflammatory bowel disease, although the relationship is poorly understood. Medical and surgical treatment of the colonic disease does not impact symptoms.

Erythema nodosum is seen in 5% to 15% of patients with inflammatory bowel disease and usually coincides with clinical disease activity. Women are affected three to four times more frequently than men. The characteristic lesions are raised, red, and predominantly on the lower legs. Pyoderma gangrenosum is an uncommon but serious condition that occurs almost exclusively in patients with inflammatory bowel disease. The lesion begins as an erythematous plaque, papule, or bleb, usually located on the pretibial region of the leg and occasionally near a stoma. The lesions progress and ulcerate, leading to a painful, necrotic wound. Pyoderma gangrenosum may respond to resection of the affected bowel in some patients. In others, this disorder is unaffected by treatment of the underlying bowel disease.

Up to 10% of patients with inflammatory bowel disease will develop ocular lesions. These include uveitis, iritis, episcleritis, and conjunctivitis. They usually develop during an acute exacerbation of the inflammatory bowel disease. The etiology is unknown.

Principles of Nonoperative Management. Medical therapy for inflammatory bowel disease focuses on decreasing inflammation and alleviating symptoms, and many of the agents used are the same for both ulcerative colitis and Crohn's disease. In general, mild to moderate flares may be treated in the outpatient setting. More severe signs and symptoms mandate hospitalization. Pancolitis generally requires more aggressive therapy than limited disease. Because ulcerative proctitis and proctosigmoiditis are limited to the distal large intestine, topical therapy with salicylate and/or corticosteroid suppositories and enemas can be extremely effective. Systemic therapy is rarely required in these patients.

Salicylates. Sulfasalazine (Azulfidine), 5-acetyl salicylic acid (5-ASA), and related compounds are first-line agents in the medical treatment of mild to moderate inflammatory bowel disease. These compounds decrease inflammation by inhibition of cyclooxygenase and 5-lipoxygenase in the gut mucosa. They require direct contact with affected mucosa for efficacy. Multiple preparations are available for administration to different sites in the small intestine and colon (sulfasalazine, mesalamine [Pentasa, Asacol, Rowasa]).

Antibiotics. Antibiotics are often used to decrease the intraluminal bacterial load in Crohn's disease. Metronidazole has been reported to improve Crohn's colitis and perianal disease, but the evidence is weak. Fluoroquinolones may also be effective in some cases. In the absence of fulminant colitis or toxic megacolon, antibiotics are not used to treat ulcerative colitis.

Corticosteroids. Corticosteroids (either oral or parenteral) are a key component of treatment for an acute exacerbation of either ulcerative colitis or Crohn's disease. Corticosteroids are nonspecific inhibitors of the immune system, and 75% to 90% of patients will improve with the administration of these drugs. However, corticosteroids have a number of serious side effects, and use of these agents should be limited to the shortest course possible. In addition, corticosteroids should be used judiciously in children because of the potential adverse effect on growth. Failure to wean corticosteroids is a relative indication for surgery.

Because of the systemic effects of corticosteroids, an effort has been made to develop drugs that act locally and have limited systemic absorption. Agents such as budesonide, beclomethasone dipropionate, and tixocortol pivalate undergo rapid hepatic degradation that significantly decreases systemic toxicity. Budesonide is available as an oral preparation. Corticosteroid enemas provide effective local therapy for proctitis and proctosigmoiditis and have fewer side effects than systemic corticosteroids.

Immunomodulating Agents. Azathioprine and 6-mercatopurine (6-MP) are antimetabolite drugs that interfere with nucleic acid synthesis and thus decrease proliferation of inflammatory cells. These agents are useful for treating ulcerative colitis and Crohn's disease in patients who have failed salicylate therapy or who are dependent on, or refractory to, corticosteroids. It is important to note, however, that the onset of action of these drugs takes 6 to 12 weeks, and concomitant use of corticosteroids almost always is required.[37]

Cyclosporine is an immunosuppressive agent that interferes with T-lymphocyte function. While cyclosporine is not routinely used to treat inflammatory bowel disease, up to 80% of patients with an acute flare of ulcerative colitis will improve with its use. However, the majority of these patients will ultimately require colectomy. Cyclosporine is also occasionally

used to treat exacerbations of Crohn's disease, and approximately two-thirds of patients will note some improvement. Improvement is generally apparent within 2 weeks of beginning cyclosporine therapy. Long-term use of cyclosporine is limited by its significant toxicities (e.g., nephrotoxicity, hirsutism, gum hypertrophy).

Methotrexate is a folate antagonist that also has been used to treat inflammatory bowel disease. Although the efficacy of this agent is unproven, there are reports that more than 50% of patients will improve with administration of this drug.[41]

Biologic Agents. In an effort to improve treatment for steroid-refractory inflammatory bowel disease, a new class of agents has been developed based on inhibition of tumor necrosis factor alpha (TNF-α). Intravenous infusion of these agents decreases inflammation systemically. Infliximab is a monoclonal antibody directed against TNF-α and was the first biologic agent used to treat Crohn's disease. More than 50% of patients with moderate to severe Crohn's disease will improve with infliximab therapy.[42] This agent also has been useful in treating patients with perianal Crohn's disease. Recurrence is common, however; and many patients require infusions on a bimonthly basis. Newer anti-TNF-α agents, such as adalimumab and certolizumab pegol, also show promise in treating Crohn's disease.[43]

The use of anti-TNF-α agents for the treatment of ulcerative colitis has been less well studied, but there are reports of efficacy in this setting, and adalimumab has been approved for treatment of steroid-refractory ulcerative colitis in Europe.[44,45] Interestingly, anti-TNF-α therapy may also be beneficial in treating the extraintestinal manifestations of inflammatory bowel disease in some patients.[40]

Nutrition. Patients with inflammatory bowel disease are often malnourished. Abdominal pain and obstructive symptoms may decrease oral intake. Diarrhea can cause significant protein loss. Ongoing inflammation produces a catabolic physiologic state. Parenteral nutrition should be strongly considered early in the course of therapy for either Crohn's disease or ulcerative colitis. The nutritional status of the patient also should be considered when planning operative intervention, and nutritional parameters such as serum albumin, prealbumin, and transferrin should be assessed. In extremely malnourished patients, especially those who are also being treated with corticosteroids, creation of a stoma is often safer than a primary anastomosis.

Ulcerative Colitis

Ulcerative colitis is a dynamic disease characterized by remissions and exacerbations. The clinical spectrum ranges from an inactive or quiescent phase to low-grade active disease to fulminant disease. The onset of ulcerative colitis may be insidious, with minimal bloody stools, or the onset can be abrupt, with severe diarrhea and bleeding, tenesmus, abdominal pain, and fever. The severity of symptoms depends on the degree and extent of inflammation. Although anemia is common, massive hemorrhage is rare. Physical findings are often nonspecific.

The diagnosis of ulcerative colitis is almost always made endoscopically. Because the rectum is invariably involved, proctoscopy may be adequate to establish the diagnosis. The earliest manifestation is mucosal edema, which results in a loss of the normal vascular pattern. In more advanced disease, characteristic findings include mucosal friability and ulceration. Pus and mucus may also be present. While mucosal biopsy is often diagnostic in the chronic phase of ulcerative colitis, biopsy in the acute phase will often reveal only nonspecific inflammation. Evaluation with colonoscopy or barium enema during an acute flare is contraindicated because of the risk of perforation.

Barium enema has been used to diagnose chronic ulcerative colitis and to determine the extent of disease. However, this modality is less sensitive than colonoscopy and may not detect early disease. In long-standing ulcerative colitis, the colon is foreshortened and lacks haustral markings ("lead pipe" colon). Because the inflammation in ulcerative colitis is purely mucosal, strictures are highly uncommon. Any stricture diagnosed in a patient with ulcerative colitis must be presumed to be malignant until proven otherwise.

Indications for Surgery. Indications for surgery in ulcerative colitis may be emergent or elective. Emergency surgery is required for patients with massive life-threatening *hemorrhage*, *toxic megacolon*, or *fulminant colitis* who fail to respond rapidly to medical therapy. Patients with signs and symptoms of fulminant colitis should be treated aggressively with bowel rest, hydration, broad-spectrum antibiotics, and parenteral corticosteroids. Colonoscopy and barium enema are contraindicated, and antidiarrheal agents should be avoided. Deterioration in clinical condition or failure to improve within 24 to 48 hours mandates surgery.

Indications for elective surgery include intractability despite maximal medical therapy and high-risk development of major complications of medical therapy such as aseptic necrosis of joints secondary to chronic steroid use. Elective surgery also is indicated in patients at significant risk of developing colorectal carcinoma. The risk of malignancy increases with pancolonic disease and the duration of symptoms and is approximately 2% after 10 years, 8% after 20 years, and 18% after 30 years. Unlike sporadic colorectal cancers, carcinoma developing in the context of ulcerative colitis is more likely to arise from areas of *flat dysplasia* and may be difficult to diagnose at an early stage. For this reason, it is recommended that patients with long-standing ulcerative colitis undergo colonoscopic surveillance with multiple (40–50), random biopsies to identify dysplasia before invasive malignancy develops. However, the adequacy of this type of screening is controversial. Recently, magnifying chromoendoscopy has been used to improve sensitivity.[46,47] This technique uses topical dyes that are applied to the colonic mucosa at the time of endoscopy (Lugol's solution, methylene blue, indigo carmine, and others). These dyes highlight contrast between normal and dysplastic epithelium, allowing more precise biopsy of suspicious areas. Surveillance is recommended annually after 8 years in patients with pancolitis, and annually after 15 years in patients with left-sided colitis. Although low-grade dysplasia was long thought to represent minimal risk, more recent studies show that invasive cancer may be present in up to 20% of patients with low-grade dysplasia. For this reason, any patient with dysplasia should be advised to undergo proctocolectomy. Controversy exists over whether prophylactic proctocolectomy should be recommended for patients who have had chronic ulcerative colitis for greater than 10 years in the absence of dysplasia. Proponents of this approach note that surveillance colonoscopy with multiple biopsies samples only a small fraction of the colonic mucosa, and dysplasia and carcinoma are often missed. Opponents cite the relatively low risk of progression to carcinoma (approximately 2.4%) if all biopsies lack dysplasia. Neither approach has been shown definitively to decrease mortality from colorectal cancer.

Operative Management

Emergent Operation. In a patient with fulminant colitis or toxic megacolon, total abdominal colectomy with end ileostomy (with or without a mucus fistula), rather than total proctocolectomy, is recommended. Although the rectum is invariably diseased, most patients improve dramatically after an abdominal colectomy, and this operation avoids a difficult and time-consuming pelvic dissection in a critically ill patient. Rarely, a loop ileostomy and decompressing colostomy may be necessary if the patient is too unstable to withstand colectomy. Definitive surgery may then be undertaken at a later date once the patient has recovered. Complex techniques, such as an ileal pouch–anal reconstruction, generally are contraindicated in the emergent setting. However, massive hemorrhage that includes bleeding from the rectum may necessitate proctectomy and creation of either a permanent ileostomy or an ileal pouch–anal anastomosis.

Elective Operation. Elective resection for ulcerative colitis usually is performed for refractory inflammation and/or the risk of malignancy (dysplasia). Because of the risk of ongoing inflammation, the risk of malignancy, and the availability of restorative proctocolectomy, most surgeons recommend operations that include resection of the rectum. *Total proctocolectomy with end ileostomy* has been the "gold standard" for treating patients with chronic ulcerative colitis. This operation removes the entire affected intestine and avoids the functional disturbances associated with ileal pouch–anal reconstruction. Most patients function well physically and psychologically after this operation. *Total proctocolectomy with continent ileostomy (Kock's pouch)* was developed to improve function and quality of life after total proctocolectomy, but morbidity is significant, and restorative proctocolectomy is generally preferred today. Since its introduction in 1980, *restorative proctocolectomy with ileal pouch–anal anastomosis* has become the procedure of choice for most patients who require total proctocolectomy but wish to avoid a permanent ileostomy (see Figs. 29-11 and 29-12).[6] Abdominal colectomy with ileorectal anastomosis may be appropriate for a patient with indeterminate colitis and rectal sparing.

Crohn's Disease

Similar to ulcerative colitis, Crohn's disease is characterized by exacerbations and remissions. Crohn's disease, however, may affect any portion of the intestinal tract, from mouth to anus. Diagnosis may be made by colonoscopy or esophagogastroduodenoscopy or by barium small bowel study or enema, depending on which part of the intestine is most affected. The presence of skip lesions is key in differentiating Crohn's colitis from ulcerative colitis, and rectal sparing occurs in approximately 40% of patients. The most common site of involvement of Crohn's disease is the terminal ileum and cecum (*ileocolic* Crohn's disease), followed by the small bowel, and then by the colon and rectum. Perianal and anal canal Crohn's disease manifest by complex anal fistulae and/or abscesses, anal ulcers, and large skin tags may be the initial site of presentation in up to 4% of cases.

Indications for Surgery. Because Crohn's disease can affect any part of the gastrointestinal tract, the therapeutic rationale is fundamentally different from that of ulcerative colitis. Ulcerative colitis may be cured by removal of the affected intestinal segment (the colon and rectum). In Crohn's disease, it is impossible to remove all the at-risk intestine; therefore, surgical therapy is reserved for complications of the disease.

Crohn's disease may present as an *acute inflammatory* process or as a *chronic fibrotic* process. During the acute inflammatory phase, patients may present with intestinal inflammation complicated by fistulae and/or intra-abdominal abscesses. Maximal medical therapy should be instituted, including anti-inflammatory medications, bowel rest, and antibiotics. Parenteral nutrition should be considered if the patient is malnourished. Most intra-abdominal abscesses can be drained percutaneously with the use of CT scan guidance. Although the majority of these patients will ultimately require surgery to remove the diseased segment of bowel, these interventions allow the patient's condition to stabilize, nutrition to be optimized, and inflammation to decrease prior to embarking on a surgical resection. Once an operation is undertaken, fistulae generally require resection of the segment of bowel with active Crohn's disease; the secondary sites of the fistula are often otherwise normal and do not generally require resection after division of the fistula. Simple closure of the secondary fistula site usually suffices.

Chronic fibrosis may result in strictures in any part of the gastrointestinal tract. Because the fibrotic process is gradual, free perforation proximal to the obstructing stricture is rare. Chronic strictures almost never improve with medical therapy. Optimal timing for surgery should take into account the patient's underlying medical and nutritional status.

Strictures may be treated with *resection* or *stricturoplasty*. Distal ileal strictures are sometimes amenable to colonoscopic balloon dilatation.

Once an operation is undertaken for Crohn's disease, several principles should guide intraoperative decision making. In general, a laparotomy for Crohn's disease should be performed through a *midline incision* because of the possible need for a stoma. *Laparoscopy* is also increasingly used in this setting. Because many patients with Crohn's disease often will require multiple operations, *the length of bowel removed should be minimized*. Bowel should be resected to an area with *grossly normal margins;* frozen sections are not necessary. Finally, a primary anastomosis may be created safely if the patient is medically stable, nutritionally replete, and taking few immunosuppressive medications. *Creation of a stoma should be strongly considered* in any patient who is hemodynamically unstable, septic, malnourished, or receiving high-dose immunosuppressive therapy and among patients with extensive intra-abdominal contamination.

Ileocolic and Small Bowel Crohn's Disease. The terminal ileum and cecum are involved in Crohn's disease in up to 41% of patients; the small intestine is involved in up to 35% of patients. The most common indications for surgery are *internal fistula or abscess* (30%–38% of patients) and *obstruction* (35%–37% of patients). *Psoas abscess* may result from ileocolic Crohn's disease. Sepsis should be controlled with percutaneous drainage of abscess(es) and antibiotics, if possible. Parenteral nutrition may be necessary in patients with chronic obstruction. The extent of resection depends on the amount of involved intestine. Short segments of inflamed small intestine and right colon should be resected and a primary anastomosis created if the patient is stable, nutrition is adequate, and immunosuppression is minimal. Isolated chronic strictures should also be resected. In patients with multiple fibrotic strictures that would require extensive small bowel resection, *stricturoplasty* is a safe and effective alternative to resection. Short strictures are amenable to a transverse stricturoplasty, while longer strictures may be treated with a side-to-side small bowel anastomosis (Fig. 29-18).

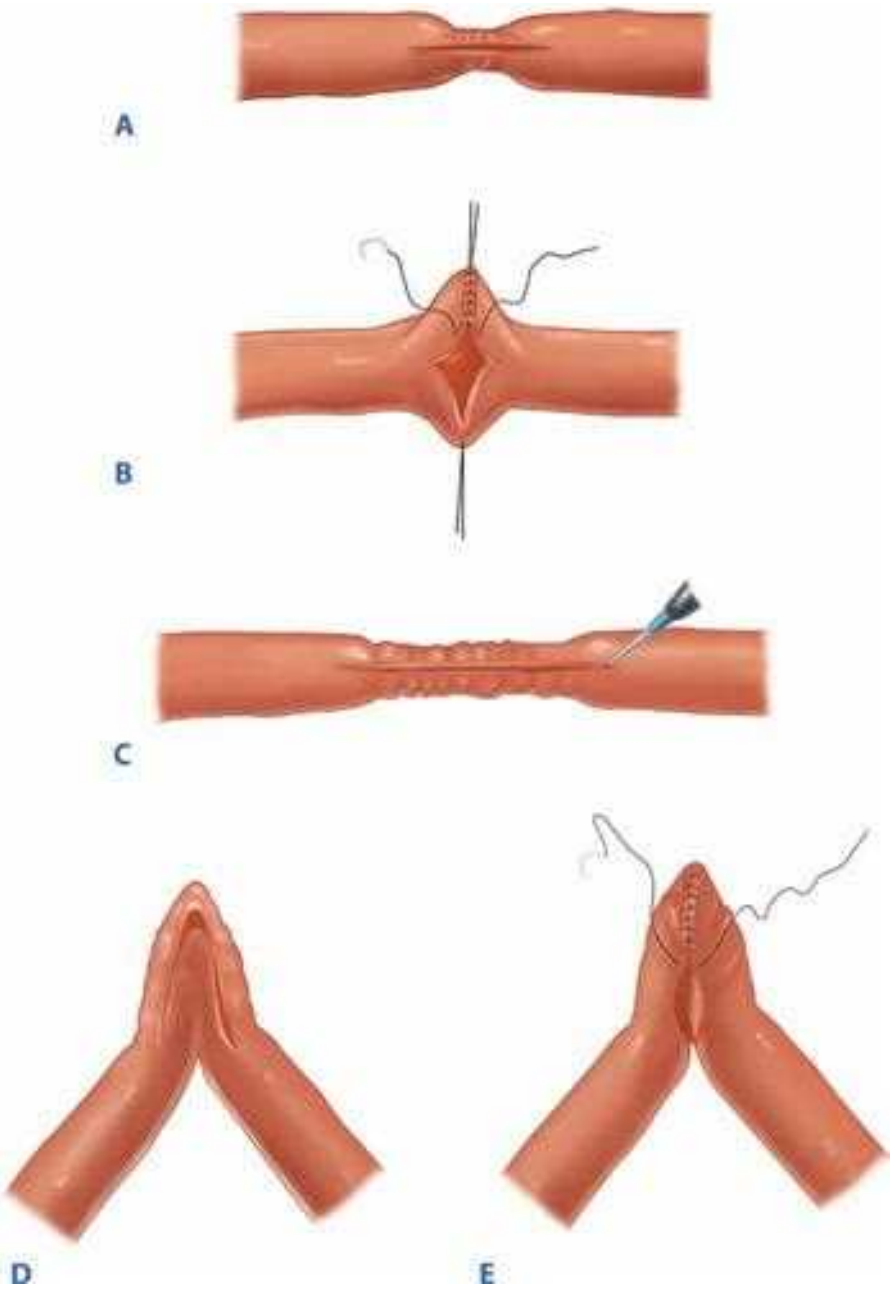

Figure 29-18. Alternative stricturoplasty techniques. **A.** A short stricture is opened along the antimesenteric surface of the bowel wall. **B.** The enterotomy is closed transversely. **C.** A long stricture is opened along the antimesenteric surface of the bowel wall. **D.** The bowel is folded into an inverted "U." **E.** A side-to-side anastomosis is made. *(Reproduced with permission from Corman ML.* Colon & Rectal Surgery. *2nd ed. Philadelphia: Lippincott Williams & Wilkins; 1989:832.)*

Risk of recurrence after resection for ileocolic and small bowel Crohn's disease is high. More than 50% of patients will experience a recurrence within 10 years, and the majority of these will require a second operation.

Crohn's Colitis. Crohn's disease of the large intestine may present as *fulminant colitis* or *toxic megacolon*. In this setting, treatment is identical to treatment of fulminant colitis and toxic megacolon secondary to ulcerative colitis. Resuscitation and medical therapy with bowel rest, broad-spectrum antibiotics, and parenteral corticosteroids should be instituted. If the patient's condition worsens or fails to rapidly improve, total abdominal colectomy with end ileostomy is recommended. An elective proctectomy may be required if the patient has refractory Crohn's proctitis. Alternatively, if the rectum is spared, an ileorectal anastomosis may be appropriate once the patient has recovered.

Other indications for surgery in chronic Crohn's colitis are *intractability, complications of medical therapy*, and *risk of or development of malignancy*. Unlike ulcerative colitis, Crohn's colitis may be segmental, and rectal sparing is often observed. A segmental colectomy may be appropriate if the remaining colon and/or rectum appear normal. An isolated colonic stricture may also be treated by segmental colectomy. Although it was long thought that Crohn's disease did not increase the risk of

colorectal carcinoma, it is now recognized that Crohn's colitis (especially pancolitis) carries nearly the same risk for cancer as ulcerative colitis. Annual surveillance colonoscopy with multiple biopsies is recommended for patients with long-standing Crohn's colitis (>7 years in duration). As in ulcerative colitis, dysplasia is an indication for total proctocolectomy. Ileal pouch–anal reconstruction is not recommended in these patients because of the risk for development of Crohn's disease within the pouch and the high risk of complications, such as fistula, abscess, stricture, pouch dysfunction, and pouch failure.

Anal and Perianal Crohn's Disease. Anal and perianal manifestations of Crohn's disease are very common and occur in 35% of all patients with Crohn's disease. Isolated anal Crohn's disease is uncommon, affecting only 3% to 4% of patients. Detection of anal Crohn's disease, therefore, should prompt evaluation of the remainder of the gastrointestinal tract.

The most common perianal lesions in Crohn's disease are *skin tags* that are minimally symptomatic. *Fissures* are also common. Typically, a fissure from Crohn's disease is particularly deep or broad and perhaps better described as an anal ulcer. These fissures are often multiple and located in a lateral position rather than anterior or posterior midline as seen in an idiopathic fissure in ano. A classic-appearing fissure in ano located laterally should raise the suspicion of Crohn's disease. *Perianal abscess* and *fistulas* are common and can be particularly challenging. Fistulas tend to be complex and often have multiple tracts (Fig. 29-19). *Hemorrhoids* are not more common in patients with Crohn's disease than in the general population, although many patients tend to attribute any anal or perianal symptom to "hemorrhoids."

Treatment of anal and perianal Crohn's disease focuses on alleviation of symptoms. Perianal skin irritation from diarrhea often responds to medical therapy directed at small bowel or colonic disease. In general, skin tags and hemorrhoids should *not* be excised unless they are extremely symptomatic because of the risk of creating chronic, nonhealing wounds. Fissures may respond to local or systemic therapy; sphincterotomy is relatively contraindicated because of the risk of creating a chronic, nonhealing wound and because of the increased risk of incontinence in a patient with diarrhea from underlying colitis or small bowel disease. Anal ulcers associated with Crohn's disease are usually not very painful unless there is an underlying abscess. Thus, in patients with significant anal pain, an examination under anesthesia is indicated to exclude an underlying abscess or fistula and to assess the rectal mucosa. In the absence of active Crohn's proctitis, one can proceed cautiously with a partial internal sphincterotomy if the examination under anesthesia reveals a classic-appearing posterior or anterior fissure and anal stenosis.

Recurrent abscess(es) or complex anal fistulae should raise the possibility of Crohn's disease. Treatment focuses on *control of infection, delineation of complex anatomy, treatment of underlying mucosal disease*, and *sphincter preservation*. Abscesses often can be drained locally, and mushroom catheters are useful for maintaining drainage. Endoanal ultrasound and pelvic MRI are useful for mapping complex fistulous tracts. Liberal use of setons can control many fistulas and avoid division of the sphincter. Many patients with anal Crohn's disease function well with multiple setons left in place for years. Endoanal advancement flaps may be considered for definitive therapy if the rectal mucosa is uninvolved but will not heal due to rectal inflammation. In 10% to 15% of cases, intractable perianal sepsis requires proctectomy.

Figure 29-19. Photograph of a patient with multiple perianal fistulas secondary to Crohn's disease. *(Reproduced with permission from Hamilton SR, Borson BC. Crohn's disease: Pathology. In: Berk JE, ed.* Bockus Gastroenterology. *4th ed. Philadelphia: Saunders; 1985:2229, Fig. 127-5. Copyright Elsevier.)*

Rectovaginal fistula can be a particularly difficult problem in these patients. A rectal or vaginal mucosal advancement flap may be used if the rectal mucosa appears healthy and scarring of the rectovaginal septum is minimal. Occasionally, proctectomy is the best option for women with highly symptomatic rectovaginal fistulae. Although proximal diversion is often employed to protect complex perianal reconstruction, there is no evidence that diversion alone increases healing of anal and perianal Crohn's disease.

Medical treatment of underlying proctitis with salicylate and/or corticosteroid enemas may be helpful; however, control of infection is the primary goal of therapy. Metronidazole has been used with some success in this setting. Anti-TNF-α agents (infliximab and adalimumab) have shown some efficacy in healing chronic fistulas secondary to Crohn's disease. The success of these agents has led to a concerted effort to identify other immunomodulators that might prove useful. Proinflammatory cytokines such as interleukin-12 and interferon-γ are potential targets. Inhibition of immune cell migration has also been suggested as an approach.[48] However, it is of paramount importance to drain any and all abscesses before initiating immunosuppressive therapy such as corticosteroids or anti-TNF-α monoclonal antibodies.

Indeterminate Colitis

Approximately 15% of patients with inflammatory bowel disease manifest clinical and pathologic characteristics of both ulcerative colitis and Crohn's disease. Endoscopy, barium enema, and biopsy may be unable to differentiate ulcerative colitis from Crohn's colitis in this setting. The indications for surgery are the same as those for ulcerative colitis: *intractability, complications of medical therapy*, and *risk of or development of malignancy*. In the setting of indeterminate colitis in a patient who prefers a sphincter-sparing operation, a *total abdominal colectomy with end ileostomy* may be the best initial procedure. Pathologic examination of the entire colon may then allow a more accurate diagnosis. If the diagnosis suggests ulcerative colitis, an ileal pouch–anal anastomosis procedure can be performed. If the diagnosis remains in question, the safest surgical option is completion proctectomy with end ileostomy (similar to Crohn's colitis). Ileal pouch–anal reconstruction may also be considered with the understanding that the pouch failure rate is between 15% and 20%.

DIVERTICULAR DISEASE

Diverticular disease is a clinical term used to describe the presence of symptomatic diverticula. *Diverticulosis* refers to the presence of diverticula without inflammation. *Diverticulitis* refers to inflammation and infection associated with diverticula. The majority of colonic diverticula are *false diverticula* in which the mucosa and muscularis mucosa have herniated through the colonic wall. These diverticula occur between the teniae coli, at points where the main blood vessels penetrate the colonic wall (presumably creating an area of relative weakness in the colonic muscle). They are thought to be *pulsion* diverticula resulting from high intraluminal pressure. *Diverticular bleeding* can be massive but usually is self-limited. *True diverticula*, which comprise all layers of the bowel wall, are rare and are usually congenital in origin.

Diverticulosis is extremely common in the United States and Europe. It is estimated that half of the population older than age 50 years has colonic diverticula. The sigmoid colon is the most common site of diverticulosis (Fig. 29-20). Diverticulosis is thought to be an acquired disorder, but the etiology is poorly understood. The most accepted theory is that a lack of dietary fiber results in smaller stool volume, requiring high intraluminal pressure and high colonic wall tension for propulsion. Chronic contraction then results in muscular hypertrophy and development of the process of segmentation in which the colon acts like separate segments instead of functioning as a continuous tube. As segmentation progresses, the high pressures are directed radially toward the colon wall rather than to development of propulsive waves that move stool distally. The high radial pressures directed against the bowel wall create pulsion diverticula. A loss of tensile strength and a decrease in elasticity of the bowel wall with age have also been proposed etiologies. Although none of these theories has been proven, a high-fiber diet does appear to decrease the incidence of diverticulosis. Although diverticulosis is common, most cases are asymptomatic, and complications occur in the minority of people with this condition.

Inflammatory Complications (Diverticulitis)

Diverticulitis refers to inflammation and infection associated with a diverticulum and is estimated to occur in 10% to 25% of people with diverticulosis. Peridiverticular and pericolic

infection results from a perforation (either macroscopic or microscopic) of a diverticulum, which leads to contamination, inflammation, and infection. The spectrum of disease ranges from mild, uncomplicated diverticulitis that can be treated in the outpatient setting, to free perforation and diffuse peritonitis that requires emergency laparotomy. Most patients present with left-sided abdominal pain, with or without fever, and leukocytosis. A mass may be present. Plain radiographs are useful for detecting free intra-abdominal air. CT scan is extremely useful for defining pericolic inflammation, phlegmon, or abscess. Contrast enemas and/or endoscopy are relatively contraindicated because of the risk of perforation. The differential diagnosis includes malignancy, ischemic colitis, infectious colitis, and inflammatory bowel disease.

Uncomplicated Diverticulitis. *Uncomplicated diverticulitis* is characterized by left lower quadrant pain and tenderness. CT findings include pericolic soft tissue stranding, colonic wall thickening, and/or phlegmon. Most patients with uncomplicated diverticulitis will respond to outpatient therapy with broad-spectrum oral antibiotics and a low-residue diet. Antibiotics should be continued for 7 to 10 days. About 10% to 20% of patients with more severe pain, tenderness, fever, and leukocytosis are treated in the hospital with parenteral antibiotics and bowel rest. Most patients improve within 48 to 72 hours. Failure to improve may suggest abscess formation. CT can be extremely useful in this setting, and many pericolic abscesses can be drained percutaneously (see below). Deterioration in a patient's clinical condition and the development of peritonitis are indications for laparotomy.

Most patients with uncomplicated diverticulitis will recover without surgery, and 50% to 70% will have no further

episodes.[49] It has long been believed that the risk of complications increases with recurrent disease. For this reason, elective sigmoid colectomy has often been recommended after the second episode of diverticulitis, especially if the patient has required hospitalization. Resection has often been recommended after the first episode in very young patients and is often recommended after the first episode of *complicated diverticulitis*. These general guidelines have been questioned in recent years, and more recent studies suggest that the risk of complications and/or need for emergent resection does *not* increase with recurrent disease.[49,50]

Many surgeons now will not advise colectomy even after two documented episodes of diverticulitis assuming the patient is completely asymptomatic and that carcinoma has been excluded by colonoscopy. Immunosuppressed patients are generally still advised to undergo colectomy after a single episode of documented diverticulitis. Medical comorbidities should be considered when evaluating a patient for elective resection, and the risks of recurrent disease should be weighed against the risks of the operation. Because colon carcinoma may present in an identical fashion to diverticulitis (either complicated or uncomplicated), all patients must be evaluated for malignancy after resolution of the acute episode. Colonoscopy is recommended 4 to 6 weeks after recovery. Inability to exclude malignancy is another indication for resection.

In the elective setting, a *sigmoid colectomy with a primary anastomosis* is the procedure of choice. The resection should always be extended to the rectum distally because the risk of recurrence is high if a segment of sigmoid colon is retained. The proximal extent of the resection should include all thickened or inflamed bowel; however, resection of all diverticula is unnecessary. Increasingly, laparoscopy is being used for elective sigmoid colectomy for diverticular disease.

Complicated Diverticulitis. *Complicated diverticulitis* includes diverticulitis with abscess, obstruction, diffuse peritonitis (free perforation), or fistulas between the colon and adjacent structures. Colovesical, colovaginal, and coloenteric fistulas are long-term sequelae of complicated diverticulitis. The *Hinchey staging system* is often used to describe the severity of complicated diverticulitis: Stage I includes colonic inflammation with an associated pericolic abscess; stage II includes colonic inflammation with a retroperitoneal or pelvic abscess; stage III is associated with purulent peritonitis; and stage IV is associated with fecal peritonitis. Treatment depends on the patient's overall clinical condition and the degree of peritoneal contamination and infection. Small abscesses (<2 cm in diameter) may be treated with parenteral antibiotics. Larger abscesses are best treated with CT-guided percutaneous drainage (Fig. 29-21) and antibiotics. Many of these patients will ultimately require resection, but percutaneous drainage may allow a one-stage, elective procedure and may obviate the need for colectomy if full recovery follows the drainage.

Urgent or emergent laparotomy may be required if an abscess is inaccessible to percutaneous drainage, if the patient's condition deteriorates or fails to improve, or if the patient presents with free intra-abdominal air or peritonitis. In almost all cases, an attempt should be made to resect the affected segment of bowel. Patients with small, localized pericolic or pelvic abscesses (Hinchey stages I and II) may be candidates for a sigmoid colectomy with a primary anastomosis (a one-stage operation).[45] Among patients with larger abscesses, peritoneal soiling, or peritonitis, sigmoid colectomy with end colostomy and Hartmann's pouch is the most commonly used procedure.[46] Success also has been reported after sigmoid colectomy, primary anastomosis, with or without on-table lavage, and proximal diversion (loop ileostomy). This option may be appropriate in stable patients and offers the great advantage that the subsequent operation to restore bowel continuity is simpler than is takedown of a Hartmann's pouch. The presence of inflammation and phlegmon may increase the risk of ureteral damage during mobilization of the sigmoid colon, and preoperative placement of ureteral catheters can be invaluable. In extremely unstable patients, or in the presence of such severe inflammation that resection would harm adjacent organs, proximal diversion and local drainage have been employed. However, this approach is generally avoided because of high morbidity and mortality

Finne III, MD, Minneapolis, MN.)*

rates, along with the requirement for multiple operations. More recently, several studies have suggested that laparoscopic lavage and drainage without bowel resection may be safe and effective even in the presence of free perforation. Nevertheless, this approach remains controversial and will require additional prospective trials before it can be recommended under most circumstances.

Obstructive symptoms occur in approximately 67% of patients who develop acute diverticulitis, and complete obstruction occurs in 10%. Patients with incomplete obstruction often respond to fluid resuscitation, nasogastric suction, and gentle, low-volume water or Gastrografin enemas. Relief of obstruction allows full bowel preparation and elective resection. A high-volume oral bowel preparation is contraindicated in the presence of obstructive symptoms. Obstruction that does not rapidly respond to medical management mandates laparotomy. Sigmoid colectomy with end colostomy is the safest procedure to perform in this setting. However, colectomy and primary anastomosis, with or without on-table lavage (depending on extent of fecal load in the proximal colon), and proximal diversion may be appropriate if the patient is stable and the proximal and distal bowel appear healthy.

Approximately 5% of patients with complicated diverticulitis develop fistulas between the colon and an adjacent organ. *Colovesical* fistulas are most common, followed by *colovaginal* and *coloenteric* fistulas. *Colocutaneous* fistulas are a rare complication of diverticulitis. Two key points in the evaluation of fistulas are to *define the anatomy of the fistula* and *exclude other diagnoses*. Contrast enema and/or small bowel studies are extremely useful in defining the course of the fistula. CT scan can identify associated abscesses or masses. The differential diagnosis includes *malignancy, Crohn's disease*, and *radiation-induced fistulas*. While Crohn's disease and radiation injury may be suspected based on the patient's medical history, colonoscopy or sigmoidoscopy usually is required to rule out malignancy. In addition, in a patient who has received radiation therapy, a fistula must be considered to be recurrent cancer until proven otherwise. Once the anatomy of the fistula has been defined and other diagnoses excluded, operative management should include resection of the affected segment of the colon involved with diverticulitis (usually with a primary anastomosis) and simple repair of the secondarily involved organ. Suspicion of carcinoma may mandate a wider, en bloc resection.

Hemorrhage

Bleeding from a diverticulum results from erosion of the peridiverticular arteriole and may result in massive hemorrhage. Most significant lower gastrointestinal hemorrhage occurs in elderly patients in whom both diverticulosis and angiodysplasia are common. Consequently, the exact bleeding source may be difficult to identify. Fortunately, in 80% of patients, bleeding stops spontaneously. Clinical management should focus on resuscitation and localization of the bleeding site as described for lower gastrointestinal hemorrhage. Colonoscopy may occasionally identify a bleeding diverticulum that may then be treated with epinephrine injection or cautery. Angiography may be diagnostic and therapeutic in this setting. In the rare instance in which diverticular hemorrhage persists or recurs, laparotomy and segmental colectomy may be required.

Giant Colonic Diverticulum

Giant colonic diverticula are extremely rare. Most occur on the antimesenteric side of the sigmoid colon. Patients may be asymptomatic or may present with vague abdominal complaints such as pain, nausea, or constipation. Plain radiographs may suggest the diagnosis. Barium enema is usually diagnostic. Complications of a giant diverticulum include perforation, obstruction, and volvulus. Resection of the involved colon and diverticulum is recommended.

Right-Sided Diverticula

The cecum and ascending colon infrequently are involved in diverticulosis coli. Even more uncommon is a true solitary diverticulum, which contains all layers of the bowel wall and is thought to be congenital in origin. Right-sided diverticula occur more often in younger patients than do left-sided diverticula and are more common in people of Asian descent than in other populations. Most patients with right-sided diverticula are asymptomatic. However, diverticulitis does occur occasionally. Because patients are young and present with right lower quadrant pain, they are often thought to suffer from acute appendicitis, and the diagnosis of right-sided diverticulitis is subsequently made in the operating room. If there is a single large diverticulum and minimal inflammation, a diverticulectomy may be performed, but an ileocecal resection is usually the preferred operation in this setting. Hemorrhage rarely occurs and should be treated in the same fashion as hemorrhage from a left-sided diverticulum.

ADENOCARCINOMA AND POLYPS

Incidence

Colorectal carcinoma is the most common malignancy of the gastrointestinal tract. Over 140,000 new cases are diagnosed annually in the United States, and more than 50,000 patients die of this disease each year, making colorectal cancer the third most lethal cancer in the United States.[51]

The incidence is similar in men and women and has remained fairly constant over the past 20 years; however, the widespread adoption of current national screening programs is gradually decreasing the incidence of this common and lethal disease. Early detection and improvements in medical and surgical care are thought to be responsible for the decreasing mortality of colorectal cancer observed in recent years.

Epidemiology (Risk Factors)

Identification of risk factors for development of colorectal cancer is essential to establish screening and surveillance programs in appropriately targeted populations.

Aging. Aging is the dominant risk factor for colorectal cancer, with incidence rising steadily after age 50 years. More than 90% of cases diagnosed are in people older than age 50 years. This is the rationale for initiating screening tests of asymptomatic patients at average risk of developing colorectal cancer at age 50 years. However, individuals of any age can develop colorectal cancer, so symptoms such as a significant change in bowel habits, rectal bleeding, melena, unexplained anemia, or weight loss require a thorough evaluation.

Hereditary Risk Factors. Approximately 80% of colorectal cancers occur sporadically, while 20% arise in patients with a known family history of colorectal cancer. Advances in the understanding of these familial disorders have led to interest in early diagnosis using genetic testing. Because of the medical, legal, and ethical considerations that are involved in this type

of testing, all patients should be offered genetic counseling if a familial syndrome is suspected.

Environmental and Dietary Factors. The observation that colorectal carcinoma occurs more commonly in populations that consume diets high in animal fat and low in fiber has led to the hypothesis that dietary factors contribute to carcinogenesis. A diet high in saturated or polyunsaturated fats increases risk of colorectal cancer, while a diet high in oleic acid (olive oil, coconut oil, fish oil) does not increase risk. Animal studies suggest that fats may be directly toxic to the colonic mucosa and thus may induce early malignant changes. In contrast, a diet high in *vegetable fiber* appears to be protective. A correlation between alcohol intake and incidence of colorectal carcinoma has also been suggested. Ingestion of calcium, selenium, vitamins A, C, and E, carotenoids, and plant phenols may decrease the risk of developing colorectal cancer. Obesity and sedentary lifestyle dramatically increase cancer-related mortality in a number of malignancies, including colorectal carcinoma. This knowledge is the basis for primary prevention strategies to eliminate colorectal cancer by altering diet and lifestyle.[52]

Inflammatory Bowel Disease. Patients with long-standing colitis from inflammatory bowel disease are at increased risk for the development of colorectal cancer. It is hypothesized that chronic inflammation predisposes the mucosa to malignant changes, and there is some evidence that degree of inflammation influences risk. In general, the duration and extent of colitis correlate with risk. Other factors thought to increase risk include the presence of primary sclerosing cholangitis and family history of colorectal cancer.

Other Risk Factors. Cigarette smoking is associated with an increased risk of colonic adenomas, especially after more than 35 years of use. Patients with ureterosigmoidostomy are also at increased risk for both adenoma and carcinoma formation.[53]

Acromegaly, which is associated with increased levels of circulating human growth hormone and insulin-like growth factor-1, increases risk as well. Pelvic irradiation may increase the risk of developing rectal carcinoma. However, it is unclear whether this represents a direct effect of radiation damage or is instead a correlation between the development of rectal cancer and a history of another pelvic malignancy; for example among patients who develop prostate cancer and are treated with radiation, the risk of rectal cancer increases significantly.[54]

Pathogenesis of Colorectal Cancer

Genetic Defects. Over the past two decades, an intense research effort has focused on elucidating the genetic defects and molecular abnormalities associated with the development and progression of colorectal adenomas and carcinoma. Mutations may cause *activation of oncogenes* (*K-ras*) and/or *inactivation of tumor suppressor genes* (*APC*, deleted in colorectal carcinoma [*DCC*], *p53*). Colorectal carcinoma is thought to develop from adenomatous polyps by accumulation of these mutations in what has come to be known as the *adenoma-carcinoma sequence* (Fig. 29-22).

5▶

Defects in the *APC* gene were first described in patients with FAP. By investigating these families, characteristic mutations in the *APC* gene were identified. They are now known to be present in 80% of sporadic colorectal cancers as well.

The *APC* gene is a *tumor suppressor gene*. Mutations in both alleles are necessary to initiate polyp formation. The majority of mutations are premature stop codons, which result in a truncated APC protein. In FAP, the site of mutation correlates with the clinical severity of the disease. For example, mutations in either the 3′ or 5′ end of the gene result in attenuated forms of FAP (AFAP), whereas mutations in the center of the gene result in more virulent disease. Thus, knowledge of the specific mutation in a family may help guide clinical decision making.

APC inactivation alone does not result in a carcinoma. Instead, this mutation sets the stage for the accumulation of genetic damage that results in malignancy. Additional mutations may include activation or inactivation of a variety of genes.

One of the most commonly involved genes in colorectal cancer is *K-ras*. *K-ras*, a signaling molecule in the epidermal growth factor receptor (EGFR) pathway, is classified as a *proto-oncogene* because mutation of only one allele will perturb the cell cycle. The *K-ras* gene product is a G-protein involved in intracellular signal transduction. When active, *K-ras* binds guanosine triphosphate (GTP); hydrolysis of GTP to guanosine diphosphate (GDP) then inactivates the G-protein. Mutation of *K-ras* results in an inability to hydrolyze GTP, thus leaving the G-protein permanently in the active form. It is thought that this then leads to uncontrolled cell division. Other EGFR signaling molecules such as BRAF have also been implicated in colorectal cancer pathogenesis and progression, and ongoing research is focusing on elucidating their roles in this disease.

Another common mutation occurs in the *MYH* gene on chromosome 1p.[55,56] *MYH* is a base excision repair gene, and biallelic deletion results in changes in other downstream molecules. Since its discovery, *MYH* mutations have been associated with an AFAP phenotype in addition to sporadic cancers.[55] Unlike *APC* gene mutations that are expressed in an autosomal dominant pattern, the requirement for biallelic mutation in *MYH* results in an autosomal recessive pattern of inheritance.

The tumor suppressor gene *p53* has been well characterized in a number of malignancies. The p53 protein appears

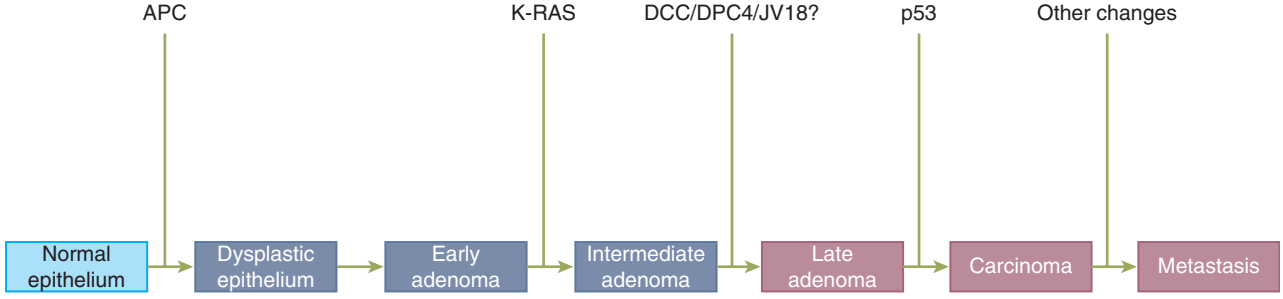

Figure 29-22. Schematic showing progression from normal colonic epithelium to carcinoma of the colon.

to be crucial for initiating apoptosis in cells with irreparable genetic damage. Mutations in *p53* are present in 75% of colorectal cancers.

Deletion of the tumor suppressor phosphatase and tensin homolog (*PTEN*) appears to be involved in a number of hamartomatous polyposis syndromes. Deletions in *PTEN* have been identified in juvenile polyposis, Peutz-Jeghers syndrome, Cowden's syndrome, and *PTEN* hamartoma syndrome, in addition to multiple endocrine neoplasia type IIB.[12]

Genetic Pathways. The mutations involved in colorectal cancer pathogenesis and progression are now recognized to accumulate via one of three major genetic pathways: the *loss of heterozygosity (LOH; chromosomal instability)* pathway, the *microsatellite instability (MSI)* pathway, and the *CpG island methylation (CIMP; serrated methylated)* pathway.

The Loss of Heterozygosity Pathway. The LOH pathway is characterized by chromosomal deletions and tumor aneuploidy. Eighty percent of colorectal carcinomas appear to arise from mutations in the LOH pathway. This pathway was first described in patients with FAP in whom mutations of the *APC* gene were found to be inherited.

Another example of LOH occurs in the region of chromosome 18q. This region has been found to be deleted in up to 70% of colorectal cancers. Two tumor suppressor genes, *DCC* and *SMAD4*, are located in this region, and as such, *deletion of 18q* may result in the loss of one or both of these genes. *DCC* is a tumor suppressor gene, and loss of both alleles is required for malignant degeneration. The main role of this molecule appears to be in the central nervous system, where it is involved in neural differentiation and axonal migration. This observation has led to the hypothesis that DCC may be involved in differentiation and cellular adhesion in colorectal cancer, but this theory remains unproven.[57] *DCC* mutations are present in more than 70% of colorectal carcinomas and may negatively impact prognosis. *SMAD4* functions in the signaling cascade of transforming growth factor beta and beta-catenin (also a downstream effector of the *APC* gene). Loss of either of these genes is thought to promote cancer progression.

The Microsatellite Instability Pathway. Many of the remaining colorectal carcinomas are thought to arise from mutations in the MSI pathway, which is characterized by errors in mismatch repair during DNA replication. These errors in mismatch repair were first described in HNPCC (Lynch's syndrome), but are now recognized to be present in many sporadic tumors as well. A number of genes have been identified that appear to be crucial for recognizing and repairing DNA replication errors. These *mismatch repair genes* include *MSH2*, *MLH1*, *PMS1*, *PMS2*, and *MSH6/GTBP*. A mutation in one of these genes predisposes a cell to mutations, which may occur in proto-oncogenes or tumor suppressor genes. Accumulation of these errors then leads to genomic instability and ultimately to carcinogenesis.

Microsatellites are regions of the genome in which short base-pair segments are repeated several times, regions that are particularly prone to replication error. Consequently, a mutation in a mismatch repair gene produces variable lengths of these repetitive sequences, a finding that has been described as MSI.

Tumors associated with MSI appear to have different biologic characteristics than do tumors that result from the LOH pathway. Tumors with MSI are more likely to be in the right colon and possess diploid DNA and are associated with a better prognosis than tumors that arise from the LOH pathway that are microsatellite stable. Tumors arising from the LOH pathway tend to occur in the more distal colon, often have chromosomal aneuploidy, and are associated with a poorer prognosis.

CpG Island Methylation Pathway. In the recently described CIMP pathway, genes do not accumulate mutations (deletions or insertions of bases), but instead are activated or inactivated by methylation. This process has been called *epigenetic alteration* to differentiate it from the more traditional genetic alterations or true mutations. In normal cells, methylation is critical for regulation of gene expression. In cancer, aberrant methylation (either hyper- or hypomethylation), usually of a promoter region, results in abnormal activation or inactivation of genes. This gene silencing or, alternatively, activation results in a phenotype similar to that present with a true gene mutation. This pathway has also been called the *serrated methylated pathway* because of the observation that *serrated polyps* often harbor aberrant methylation in contrast to adenomatous polyps that are more often associated with mutations in the *APC* gene (LOH pathway).[58]

Although these classifications are useful for understanding the mechanisms underlying carcinogenesis, they are not mutually exclusive. For example, a mismatch repair gene may be inactivated by methylation. Errors in mismatch repair may then allow mutations to inactivate a tumor suppressor gene. In addition, there is considerable interest in targeting molecules in each of these pathways in order to design better anticancer agents. Finally, ongoing research is focusing on the utility of molecular profiling in predicting prognosis and/or response to treatment.

Polyps

It is now well accepted that the majority of colorectal carcinomas evolve from adenomatous polyps; this sequence of events is the *adenoma-carcinoma sequence. Polyp* is a nonspecific clinical term that describes any projection from the surface of the intestinal mucosa regardless of its histologic nature. Colorectal polyps may be classified as *neoplastic (tubular adenoma, villous adenoma, tubulovillous adenomas, serrated adenomas/polyps), hyperplastic, hamartomatous (juvenile, Peutz-Jeghers, Cronkite-Canada), or inflammatory (pseudopolyp, benign lymphoid polyp).*

Neoplastic Polyps. Adenomatous polyps are common, occurring in up to 25% of the population older than 50 years of age in the United States. By definition, these lesions are dysplastic. The risk of malignant degeneration is related to both the size and type of polyp. Tubular adenomas are associated with malignancy in only 5% of cases, whereas villous adenomas may harbor cancer in up to 40%. Tubulovillous adenomas are at intermediate risk (22%). Invasive carcinomas are rare in polyps smaller than 1 cm; the incidence increases with size. The risk of carcinoma in a polyp larger than 2 cm is 35% to 50%. Although most neoplastic polyps do not evolve to cancer, most colorectal cancers originate as a polyp. It is this fact that forms the basis for secondary prevention strategies to eliminate colorectal cancer by targeting the neoplastic polyp for removal before malignancy develops.

Polyps may be *pedunculated* or *sessile*. Most pedunculated polyps are amenable to colonoscopic snare excision. Removal of sessile polyps is often more challenging. Special colonoscopic techniques, including saline lift, piecemeal snare excision, and endoscopic mucosal resection facilitate successful removal of many sessile polyps. For rectal sessile polyps, transanal operative excision is preferred because it produces an

intact, single pathology specimen that can be used to determine the need for further therapy. Interpretation of the precise depth of invasion of a cancer arising in a sessile polyp after piecemeal excision is often impossible. The site of sessile polypectomies should be marked by injection of India ink to guide follow-up colonoscopy sessions to ensure that the polyp has been completely removed and to facilitate identification of the involved bowel segment should operative resection be necessary. Colectomy is reserved for cases in which colonoscopic removal is impossible, such as large, flat lesions, or if a focus of invasive cancer is confirmed in the specimen.

Complications of polypectomy include *perforation* and *bleeding*. A small perforation (*microperforation*) in a fully prepared, stable patient may be managed with bowel rest, broad-spectrum antibiotics, and close observation. Signs of sepsis, peritonitis, or deterioration in clinical condition are indications for laparotomy. Bleeding may occur immediately after polypectomy or may be delayed. The bleeding will usually stop spontaneously, but colonoscopy may be required to resnare a bleeding stalk or cauterize the lesion. Occasionally angiography and infusion of vasopressin may be necessary. Rarely, colectomy is required.

Hyperplastic Polyps. Hyperplastic polyps are extremely common in the colon. These polyps are usually small (<5 mm) and show histologic characteristics of hyperplasia without any dysplasia. They are not considered premalignant, but cannot be distinguished from adenomatous polyps colonoscopically and are therefore often removed. In contrast, large hyperplastic polyps (>2 cm) may have a slight risk of malignant degeneration. Moreover, large polyps may harbor foci of adenomatous tissue and dysplasia. *Hyperplastic polyposis* is a rare disorder in which multiple large hyperplastic polyps occur in young adults. These patients are at slightly increased risk for the development of colorectal cancer.

Serrated Polyps. Serrated polyps are a recently recognized, histologically distinct group of neoplastic polyps. These lesions were long thought to be similar to hyperplastic polyps with minimal malignant potential. However, it has become clear that some of these polyps will develop into invasive cancers. In addition, a familial *serrated polyposis syndrome* has recently been described. Serrated polyps should be treated like adenomatous polyps.[59]

Hamartomatous Polyps (Juvenile Polyps). In contrast to adenomatous and serrated polyps, hamartomatous polyps (juvenile polyps) usually are not premalignant. These lesions are the characteristic polyps of childhood but may occur at any age. Bleeding is a common symptom, and intussusception and/or obstruction may occur. Because the gross appearance of these polyps is identical to adenomatous polyps, these lesions should also be treated by polypectomy. In contrast to adenomatous polyposis syndromes, these conditions are often associated with mutation in *PTEN*.

Familial juvenile polyposis is an autosomal dominant disorder in which patients develop hundreds of polyps in the colon and rectum. Unlike solitary juvenile polyps, these lesions may degenerate into adenomas and eventually carcinoma. Annual screening should begin between the ages of 10 and 12 years. Treatment is surgical and depends in part on the degree of rectal involvement. If the rectum is relatively spared, a total abdominal colectomy with ileorectal anastomosis may be performed with subsequent close surveillance of the retained rectum. If the rectum is carpeted with polyps, total proctocolectomy is the more appropriate operation. These patients are candidates for ileal pouch–anal reconstruction to avoid a permanent stoma.

Peutz-Jeghers syndrome is characterized by polyposis of the small intestine and, to a lesser extent, polyposis of the colon and rectum. Characteristic melanin spots are often noted on the buccal mucosa and lips of these patients. The polyps of Peutz-Jeghers syndrome are generally considered to be hamartomas and are not thought to be at significant risk for malignant degeneration. However, carcinoma may occasionally develop. Because the entire length of the gastrointestinal tract may be affected, surgery is reserved for symptoms such as obstruction or bleeding or for patients in whom polyps develop adenomatous features. Screening consists of a baseline colonoscopy and upper endoscopy at age 20 years, followed by annual flexible sigmoidoscopy thereafter.

Cronkite-Canada syndrome is a disorder in which patients develop gastrointestinal polyposis in association with alopecia, cutaneous pigmentation, and atrophy of the fingernails and toenails. Diarrhea is a prominent symptom, and vomiting, malabsorption, and protein-losing enteropathy may occur. Most patients die of this disease despite maximal medical therapy, and surgery is reserved for complications of polyposis such as obstruction.

Cowden's syndrome is an autosomal dominant disorder with hamartomas of all three embryonal cell layers. Facial trichilemmomas, breast cancer, thyroid disease, and gastrointestinal polyps are typical of the syndrome. Patients should be screened for cancers. Treatment is otherwise based on symptoms.

Inflammatory Polyps (Pseudopolyps). Inflammatory polyps occur most commonly in the context of inflammatory bowel disease, but may also occur after amebic colitis, ischemic colitis, and schistosomal colitis. These lesions are not premalignant, but they cannot be distinguished from adenomatous polyps based on gross appearance and therefore should be removed. Microscopic examination shows islands of normal, regenerating mucosa (the polyp) surrounded by areas of mucosal loss. Polyposis may be extensive, especially in patients with severe colitis, and may mimic FAP.

Inherited Colorectal Carcinoma

Many of the genetic defects originally described in hereditary cancers have subsequently been found in sporadic tumors. Although the majority of colorectal cancer is sporadic, several hereditary syndromes provide paradigms for the study of this disease. Insight gained from studying inherited colorectal cancer syndromes has led to better understanding of the genetics of colorectal carcinoma.

Familial Adenomatous Polyposis. This rare autosomal dominant condition accounts for only about 1% of all colorectal adenocarcinomas. Nevertheless, this syndrome has provided tremendous insight into the molecular mechanisms underlying colorectal carcinogenesis. The genetic abnormality in FAP is a mutation in the *APC* gene, located on chromosome 5q. Of patients with FAP, *APC* mutation testing is positive in 75% of cases. While most patients with FAP will have a known family history of the disease, up to 25% present without other affected family members. Clinically, patients develop hundreds to thousands of adenomatous polyps shortly after puberty. The lifetime risk of colorectal cancer in FAP patients approaches 100% by age 50 years.

Flexible sigmoidoscopy of first-degree relatives of FAP patients beginning at age 10 to 15 years has been the traditional

mainstay of screening. Today, following genetic counseling, *APC* gene testing may be used to screen family members, providing an *APC* mutation has been identified. If *APC* testing is positive in a relative of a patient with a known *APC* mutation, annual flexible sigmoidoscopy beginning at age 10 to 15 years is done until polyps are identified. If *APC* testing is negative, the relative can be screened starting at age 50 years per average-risk guidelines. If *APC* testing is refused or unavailable, or if a mutation cannot be identified, annual flexible sigmoidoscopy beginning at age 10 to 15 years is performed until age 24 years. Screening flexible sigmoidoscopy is then done every 2 years until age 34 years, every 3 years until age 44 years, and then every 3 to 5 years.

FAP patients are also at risk for the development of adenomas anywhere in the gastrointestinal tract, particularly in the duodenum. Periampullary carcinoma is a particular concern. Upper endoscopy is therefore recommended for surveillance every 1 to 3 years beginning at age 25 to 30 years.

Once the diagnosis of FAP has been made and polyps are developing, treatment is surgical. Four factors affect the choice of operation: age of the patient; presence and severity of symptoms; extent of rectal polyposis; and presence and location of cancer or desmoid tumors. Three operative procedures can be considered: total proctocolectomy with an end (Brooke) ileostomy; total abdominal colectomy with ileorectal anastomosis; and restorative proctocolectomy with ileal pouch–anal anastomosis with or without a temporary ileostomy. Most patients elect to have an ileal pouch–anal anastomosis in the absence of a distal rectal cancer, a mesenteric desmoid tumor that prevents the ileum from reaching the anus, or poor sphincter function. Mucosectomy has been advocated in patients with FAP undergoing ileal pouch–anal anastomosis because of the risk of neoplasia in the anal transition zone, but the requirement for this procedure remains controversial. Although patient satisfaction with this procedure remains high, function may not be ideal, and up to 50% of patients experience some degree of incontinence. Total abdominal colectomy with an ileorectal anastomosis is also an option in these patients, but requires vigilant surveillance of the retained rectum for development of rectal cancer. There is increasing data suggesting that the administration of cyclooxygenase-2 (COX-2) inhibitors (celecoxib, sulindac) may slow or prevent the development of polyps.[60]

FAP may be associated with extraintestinal manifestations such as congenital hypertrophy of the retinal pigmented epithelium, desmoid tumors, epidermoid cysts, mandibular osteomas (Gardner's syndrome), and central nervous system tumors (Turcot's syndrome). Desmoid tumors in particular, can make surgical management difficult and are a source of major morbidity and mortality in these patients. Desmoid tumors are often hormone responsive, and growth may be inhibited in some patients with tamoxifen. COX-2 inhibitors and nonsteroidal, anti-inflammatory drugs may also be beneficial in this setting.

Attenuated Familial Adenomatous Polyposis. AFAP is a recognized variant of FAP. Patients present later in life with fewer polyps (usually 10–100) predominantly located in the right colon, when compared to classic FAP. Colorectal carcinoma develops in more than 50% of these patients, but occurs later (average age, 55 years). Patients are also at risk for duodenal polyposis. However, in contrast to FAP, *APC* gene mutations are present in only about 30% of patients with AFAP. When present, these mutations are expressed in an autosomal dominant pattern.

Mutations in *MYH* also result in the AFAP phenotype but are expressed in an autosomal recessive pattern. It has been suggested that *MYH* mutations may be responsible for AFAP in patients who do not have a detectable *APC* gene mutation.[61]

Genetic testing is often offered to patients with suspected AFAP. When positive, genetic counseling and testing may be used to screen at-risk family members. If the family mutation is unknown, screening colonoscopy is recommended beginning at age 13 to 15 years, then every 4 years to age 28 years, and then every 3 years. These patients are often candidates for a total abdominal colectomy with ileorectal anastomosis because the limited polyposis in the rectum can usually be treated by colonoscopic snare excision.[62,63] Prophylaxis with COX-2 inhibitors also may be appropriate. Because of the more subtle phenotype in these patients, it is important to rule out other familial syndromes such as HNPCC (Lynch's syndrome) and the more common familial colorectal cancer.

Hereditary Nonpolyposis Colon Cancer (Lynch's Syndrome). HNPCC (Lynch's syndrome) is more common than FAP, but is still extremely rare (1%–3% of all colon cancers). The genetic defects associated with HNPCC arise from errors in *mismatch repair*, the phenotypic result being MSI. HNPCC is inherited in an autosomal dominant pattern and is characterized by the development of colorectal carcinoma at an early age (average age, 40–45 years). Approximately 70% of affected individuals will develop colorectal cancer. Cancers appear in the proximal colon more often than in sporadic colorectal cancer and have a better prognosis regardless of stage. The risk of synchronous or metachronous colorectal carcinoma is 40%. HNPCC may also be associated with extracolonic malignancies, including endometrial carcinoma, which is most common, and ovarian, pancreas, stomach, small bowel, biliary, and urinary tract carcinomas. The diagnosis of HNPCC is made based on family history. The *Amsterdam criteria* for clinical diagnosis of HNPCC are three affected relatives with histologically verified adenocarcinoma of the large bowel (one must be a first-degree relative of one of the others) in two successive generations of a family with one patient diagnosed before age 50 years. The presence of other HNPCC-related carcinomas should raise the suspicion of this syndrome. In a patient with an established diagnosis of colorectal cancer, tumor testing for presence of mismatch repair gene products (immunohistochemistry) and/or MSI can sometimes serve as screening for this syndrome.[64,65]

HNPCC results from mutations in mismatch repair genes, and like FAP, specific mutations are associated with different phenotypes. For example, mutations in *PMS2* or *MSH6* result in a more attenuated form of HNPCC when compared to mutations in other genes. *MSH6* inactivation also appears to be associated with a higher risk for endometrial cancer. Further significance of these specific mutations remains to be determined.

Screening colonoscopy is recommended annually for at-risk patients beginning at either age 20 to 25 years or 10 years younger than the youngest age at diagnosis in the family, whichever comes first.[66] Because of the high risk of endometrial carcinoma, transvaginal ultrasound or endometrial aspiration biopsy is also recommended annually after age 25 to 35 years. Because there is a 40% risk of developing a second colon cancer, total colectomy with ileorectal anastomosis is recommended once adenomas or a colon carcinoma is diagnosed. Annual proctoscopy is necessary because the risk of developing rectal cancer remains high. Similarly, prophylactic hysterectomy and bilateral

salpingo-oophorectomy should be considered in women who have completed childbearing.

Familial Colorectal Cancer. Nonsyndromic familial colorectal cancer accounts for 10% to 15% of patients with colorectal cancer. The lifetime risk of developing colorectal cancer increases with a family history of the disease. The lifetime risk of colorectal cancer in a patient with no family history of this disease (average-risk population) is approximately 6%, but rises to 12% if one first-degree relative is affected and to 35% if two first-degree relatives are affected. Age of onset also impacts risk, and a diagnosis before the age of 50 years is associated with a higher incidence in family members. Screening colonoscopy is recommended every 5 years beginning at age 40 years or beginning 10 years before the age of the earliest diagnosed patient in the pedigree. While there are no specific genetic abnormalities that are associated with familial colorectal cancer, any of the defects found in either the LOH pathway or MSI pathway may be present in these patients.

Prevention: Screening and Surveillance

Because the majority of colorectal cancers are thought to arise from adenomatous polyps, preventive measures focus on identification and removal of these premalignant lesions. In addition, many cancers are asymptomatic, and screening may detect these tumors at an early and curable stage (Table 29-1). Although screening for colorectal cancer decreases the incidence of cancer and cancer-related mortality, the optimal method of screening remains controversial. Screening guidelines are meant for *asymptomatic* patients.[61,66-68] Any patient with a gastrointestinal complaint (bleeding, change in bowel habits, pain, etc.) requires a complete evaluation, usually by colonoscopy.

Fecal Occult Blood Testing. FOBT is known to reduce colorectal cancer mortality by 33% and metastatic disease by 50%. However, FOBT is relatively insensitive, missing up to 50% of cancers and the majority of adenomas. Its specificity is low because 90% of patients with positive tests do not have colorectal cancer. Compliance with annual testing is low and costs are significant if one includes the colonoscopy examinations done to evaluate patients with positive FOBT. Nonetheless, the direct evidence that FOBT screening is efficacious and decreases both the incidence and mortality of colorectal cancer is so strong that national guidelines recommend annual FOBT screening for asymptomatic, average-risk Americans older than 50 years of age as one of several accepted strategies. Newer immunohistochemical methods for detecting human globin may prove to be more sensitive and specific.[69] A positive FOBT test should be followed by colonoscopy.

Flexible Sigmoidoscopy. Screening by flexible sigmoidoscopy every 5 years may lead to a 60% to 70% reduction in mortality from colorectal cancer, chiefly by identifying high-risk individuals with adenomas. However, it is important to recognize that lesions in the proximal colon cannot be identified, and for this reason, flexible sigmoidoscopy has often been paired with *air-contrast barium enema* to detect transverse and right colon lesions. Patients found to have a polyp, cancer, or other lesion on flexible sigmoidoscopy will require colonoscopy.[70]

Fecal Occult Blood Testing and Flexible Sigmoidoscopy. Several trials have shown that FOBT screening is least effective at detecting rectosigmoid cancers.[69,71] This is precisely the area screened by flexible sigmoidoscopy; thus, the combination of the two tests has been suggested as a reasonable screening

Table 29-1

Advantages and disadvantages of screening modalities for asymptomatic individuals

	ADVANTAGES	DISADVANTAGES
Fecal occult blood testing	Ease of use and noninvasive Low cost Good sensitivity with repeat testing	May not detect most polyps Low specificity Colonoscopy required for positive result Poor compliance with serial testing
Sigmoidoscopy	Examines colon most at risk Very sensitive for polyp detection in left colon Does not require full bowel preparation (enemas only)	Invasive Uncomfortable Slight risk of perforation or bleeding May miss proximal lesions Colonoscopy required if polyp identified
Colonoscopy	Examines entire colon Highly sensitive and specific Therapeutic	Most invasive Uncomfortable and requires sedation Requires bowel preparation Risk of perforation or bleeding Costly
Double-contrast barium enema	Examines entire colon Good sensitivity for polyps >1 cm Examines entire colon	Requires bowel preparation Less sensitivity for polyps <1 cm May miss lesions in the sigmoid colon Colonoscopy required for positive result
Computed tomography colonography (virtual colonoscopy)	Noninvasive Sensitivity may be as good as colonoscopy	Requires bowel preparation Insensitive for small polyps Minimal experience and data Colonoscopy required for positive result

strategy. Winawer and colleagues, in a study of 12,479 subjects, showed that the combination of FOBT annually with flexible sigmoidoscopy every 5 years resulted in lower mortality from colorectal cancer and better survival in patients with colorectal cancer.[72] Such data led to the American Cancer Society recommendations that one of the acceptable screening regimens for average-risk Americans is the combination of FOBT annually and flexible sigmoidoscopy every 5 years; this combination was preferred over either test alone. The addition of air-contrast barium enema to assess the proximal colon may improve sensitivity as well.

Colonoscopy. Colonoscopy is currently the most accurate and most complete method for examining the large bowel. This procedure is highly sensitive for detecting even small polyps (<1 cm) and allows biopsy, polypectomy, control of hemorrhage, and dilation of strictures. However, colonoscopy does require mechanical bowel preparation, and the discomfort associated with the procedure requires conscious sedation in most patients. Colonoscopy is also considerably more expensive than other screening modalities and requires a well-trained endoscopist. The risk of a major complication after colonoscopy (perforation and hemorrhage) is extremely low (0.2%–0.3%). Nevertheless, deaths have been reported.

Air-Contrast Barium Enema. Air-contrast barium enema is also highly sensitive for detecting polyps greater than 1 cm in diameter (90% sensitivity). Unfortunately, there are no studies proving its efficacy for screening large populations. Accuracy is greatest in the proximal colon but may be compromised in the sigmoid colon if there is significant diverticulosis. The major disadvantages of barium enema are the need for mechanical bowel preparation and the requirement for colonoscopy if a lesion is discovered.

Computed Tomography Colonography (Virtual Colonoscopy). Advances in imaging technology have created a number of less invasive, but highly accurate tools for screening. CT colonography makes use of helical CT technology and three-dimensional reconstruction to image the intraluminal colon. A present, patients require a mechanical bowel preparation. The colon is then insufflated with air, a spiral CT is performed, and both two-dimensional and three-dimensional images are generated. In the hands of a qualified radiologist, sensitivity appears to be as good as colonoscopy for colorectal cancers and polyps greater than 1 cm in size.[73] Colonoscopy is required if a lesion is identified. CT colonography is also useful for imaging the proximal colon in cases of obstruction or if a colonoscopy cannot be completed. Limitations of this technique include false-positive results from retained stool, diverticular disease, haustral folds, motion artifacts, and an inability to detect flat adenomas.

Guidelines for Screening. Current American Cancer Society guidelines advocate screening for the average-risk population (asymptomatic, no family history of colorectal carcinoma, no personal history of polyps or colorectal carcinoma, no familial syndrome) beginning at age 50 years. Recommended procedures include yearly FOBT, flexible sigmoidoscopy every 5 years, FOBT and flexible sigmoidoscopy in combination, air-contrast barium enema every 5 years, or colonoscopy every 10 years.[66] Patients with other risk factors should be screened earlier and more frequently (Table 29-2).

Routes of Spread and Natural History

Carcinoma of the colon and rectum arises in the mucosa. The tumor subsequently invades the bowel wall and eventually adjacent tissues and other viscera. Tumors may become bulky and circumferential, leading to colon obstruction. Local extension (especially in the rectum) may occasionally cause obstruction of other organs such as the ureter.

Regional lymph node involvement is the most common form of spread of colorectal carcinoma and usually precedes distant metastasis or the development of carcinomatosis. The likelihood of nodal metastasis increases with tumor size, poorly differentiated histology, lymphovascular invasion, and depth of invasion. The T stage (depth of invasion) is the single most significant predictor of lymph node spread. Carcinoma in situ (Tis) in which there is no penetration of the muscularis mucosa (basement membrane) has also been called *high-grade dysplasia* and should carry no risk of lymph node metastasis. Small lesions confined to the bowel wall (T1 and T2) are associated with lymph node metastasis in 5% to 20% of cases, whereas larger tumors that invade through the bowel wall or into adjacent organs (T3 and T4) are likely to have lymph node metastasis in more than 50% of cases. The number of lymph nodes with metastases correlates with the presence of distant disease and inversely with survival. Four or more involved lymph nodes predict a poor prognosis. In colon cancer, lymphatic spread usually follows the major venous outflow from the involved segment of the colon. Lymphatic spread from the rectum follows two routes. In the upper rectum, drainage ascends along the superior rectal vessels to the inferior mesenteric nodes. In the lower rectum, lymphatic drainage may course along the middle rectal vessels. Nodal spread along the inferior rectal vessels to the internal iliac nodes or groin is rare unless the tumor involves the anal canal or the proximal lymphatics are blocked with tumor (Fig. 29-23).

The most common site of distant metastasis from colorectal cancer is the liver. These metastases arise from hematogenous spread via the portal venous system. Like lymph node metastasis, the risk of hepatic metastasis increases with tumor size and tumor grade. However, even small tumors may produce distant metastasis. The lung is also a site of hematogenous spread, but this rarely occurs in isolation. Carcinomatosis (diffuse peritoneal metastases) occurs by peritoneal seeding and has a dismal prognosis.

Staging and Preoperative Evaluation

Clinical Presentation. Symptoms of colon and rectal cancers are nonspecific and generally develop when the cancer is locally advanced. The classic first symptoms are a change in bowel habits and rectal bleeding. Abdominal pain, bloating, and other signs of obstruction typically occur with larger tumors and suggest more advanced disease. Because of the caliber of the bowel and the consistency of the stool, left-sided tumors are more likely to cause obstruction than are right-sided tumors. Rectal tumors may cause bleeding, tenesmus, and pain. Alternatively, patients may be asymptomatic and/or present with unexplained anemia, weight loss, or poor appetite.

Staging. Colorectal cancer staging is based on tumor depth and the presence or absence of nodal or distant metastases. Older staging systems, such as the Dukes' Classification and its Astler-Coller modification, have been replaced by the tumor-node-metastasis (TNM) staging system (Table 29-3).[74] Stage I disease includes adenocarcinomas that are invasive through the muscularis mucosa but are confined to the submucosa (T1) or the muscularis propria (T2) in the absence of nodal metastases. Stage II disease consists of tumors that invade through the

Table 29-2

Screening guidelines for colorectal cancer

POPULATION	INITIAL AGE	RECOMMENDED SCREENING TEST
Average risk	50 y	Annual FOBT or Flexible sigmoidoscopy every 5 y or Annual FOBT and flexible sigmoidoscopy every 5 y or Air-contrast barium enema every 5 y or Colonoscopy every 10 y
Adenomatous polyps	50 y	Colonoscopy at first detection; then colonoscopy in 3 y If no further polyps, colonoscopy every 5 y If polyps, colonoscopy every 3 y Annual colonoscopy for >5 adenomas
Colorectal cancer	At diagnosis	Pretreatment colonoscopy; then at 12 mo after curative resection; then colonoscopy after 3 y; then colonoscopy every 5 y, if no new lesions
Ulcerative colitis, Crohn's colitis	At diagnosis; then after 8 y for pancolitis, after 15 y for left-sided colitis	Colonoscopy with multiple biopsies every 1–2 y
FAP	10–12 y	Annual flexible sigmoidoscopy Upper endoscopy every 1–3 y after polyps appear
Attenuated FAP	20 y	Annual flexible sigmoidoscopy Upper endoscopy every 1–3 y after polyps appear
HNPCC	20–25 y	Colonoscopy every 1–2 y Endometrial aspiration biopsy every 1–2 y
Familial colorectal cancer first-degree relative	40 y or 10 y before the age of the youngest affected relative	Colonoscopy every 5 y Increase frequency if multiple family members are affected, especially before 50 y

FAP = familial adenomatous polyposis; FOBT = fecal occult blood testing; HNPCC = hereditary nonpolyposis colon cancer.

bowel wall into the subserosa or nonperitonealized pericolic or perirectal tissues (T3) or into other organs or tissues or through the visceral peritoneum (T4) without nodal metastases. Stage III disease includes any T stage with nodal metastases, and stage IV disease denotes distant metastases.

The preoperative evaluation usually identifies stage IV disease. In colon cancer, differentiating stages I, II, and III depends on examination of the resected specimen. In rectal cancer, endorectal ultrasound or MRI may predict the stage (ultrasound stage, uTxNx) preoperatively, but the final determination depends on pathologic examination of the resected tumor and adjacent lymph nodes (pathologic stage, pTxNx). Disease stage correlates with 5-year survival. Patients with stages I and II disease can expect excellent survival rates. The presence of nodal metastases (stage III) decreases survival (Table 29-4). The 5-year survival rate with stage IV disease is less than 16%. However, in well-selected patients, metastasectomy, especially of isolated liver or lung lesions, can result in cure. In rectal cancer, staging has been further refined, and outcomes suggest that subgroups of patients within each stage may have very different prognoses (Table 29-5). If the mesorectum around a rectal cancer is involved or threatened (only 1–2 mm of clearance), there is a very high likelihood of local recurrence and a poor

Table 29-3

TNM staging of colorectal carcinoma

	DEFINITION
Tumor stage (T)	
TX	Cannot be assessed
T0	No evidence of cancer
Tis	Carcinoma in situ
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria into subserosa or into nonperitonealized pericolic or perirectal tissues
T4	Tumor directly invades other organs or tissues or perforates the visceral peritoneum of specimen
Nodal stage (N)	
NX	Regional lymph nodes cannot be assessed
N0	No lymph node metastasis
N1	Metastasis to one to three pericolic or perirectal lymph nodes
N2	Metastasis to four or more pericolic or perirectal lymph nodes
N3	Metastasis to any lymph node along a major named vascular trunk
Distant metastasis (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

TNM = tumor-node-metastasis.

prognosis. This circumferential or radial margin is probably best assessed preoperatively by MRI. Although nodal involvement is the single most important prognostic factor in colorectal carcinoma, tumor characteristics, such as degree of differentiation, mucinous or signet-ring cell histology, vascular invasion, and DNA aneuploidy, also adversely affect prognosis. Molecular profiling is currently being studied in an effort to further improve prognostic indicators.

Preoperative Evaluation. Once a colon or rectal carcinoma has been diagnosed, a staging evaluation should be undertaken. The colon must be evaluated for synchronous tumors, usually by colonoscopy. Synchronous disease will be present in up to 5% of patients. For rectal cancers, digital rectal examination and rigid or flexible proctoscopy with biopsy should be performed to assess tumor size, location, morphology, histology, and fixation. Endorectal ultrasound or MRI can be invaluable in staging rectal cancer and is used to classify the ultrasound T and N stage of rectal cancers (Fig. 29-24). A chest/abdominal/pelvic

CT scan should be obtained to evaluate for distant metastases. Pelvic CT scan, and sometimes MRI, can be useful in large rectal tumors and in recurrent disease to determine the extent of local invasion. Among patients with obstructive symptoms, a water-soluble contrast study (Gastrografin enema) may be useful for delineating the degree of obstruction. It is important to avoid mechanical bowel preparation (for either colonoscopy or surgery) in a patient who appears to be obstructed. PET scan may be useful in evaluating lesions seen on CT scan and in patients in whom a risky or highly morbid operation is planned (pelvic exenteration, sacrectomy). Preoperative CEA is often obtained and may be useful for postoperative follow-up.

Therapy for Colonic Carcinoma

Principles of Resection. The objective in treatment of carcinoma of the colon is to remove the primary tumor along with its lymphovascular supply. Because the lymphatics of the colon accompany the main arterial supply, the length of bowel resected depends on which vessels are supplying the segment involved with the cancer. Any adjacent organ or tissue, such as the omentum, that has been invaded should be resected en bloc with the tumor. If all of the tumor cannot be removed, a palliative procedure should be considered, although it important to note that "debulking" is rarely effective in colorectal adenocarcinoma.

The presence of synchronous cancers or adenomas or a strong family history of colorectal neoplasms suggests that the entire colon is at risk for carcinoma (often called a *field defect*), and a subtotal or total colectomy should be considered. Metachronous tumors (a *second primary colon cancer)* identified during follow-up studies should be treated similarly. However, the surgeon must be aware of which mesenteric vessels have been ligated at the initial colectomy because that may influence the choice of procedure.

The number of lymph nodes recovered in the surgical specimen has long served as a proxy for the oncologic adequacy of resection. A number of studies previously have suggested that a minimum of 12 lymph nodes in the resected specimen are necessary for adequate staging. In addition, patients in whom more nodes are harvested have better long-term outcome.[76,77] As such, a 12-node minimum has been suggested as an appropriate benchmark for assessing quality of care. However, several investigators recently have called this into question, noting that the number of lymph nodes examined does not correlate with staging, use of adjuvant chemotherapy, or patient survival.[70] Others have suggested that the number of negative lymph nodes and/or the lymph node ratio (positive lymph nodes to total lymph nodes) may further improve staging.[78-80]

If unexpected metastatic disease is encountered at the time of a laparotomy, the decision about whether to proceed with resection of the primary tumor depends on the volume of distant disease, location and size of the primary tumor, the operation required to remove the primary tumor, and the operative approach. If the metastatic disease is low volume (isolated or potentially resectable liver lesions) and the resection of the primary tumor is straightforward (segmental abdominal colectomy), it is probably reasonable to proceed with resection. On the other hand, if the metastatic disease is high volume (carcinomatosis), especially if the primary tumor is minimally symptomatic, the operation should be aborted in order to facilitate early systemic chemotherapy. Some centers favor starting the operation with a diagnostic laparoscopy in cases where risk of discovering metastasis is high in order to minimize the magnitude of the operation should surgery be aborted. With recent advances in chemotherapy, many of these patients will never develop a complication from the primary tumor requiring surgical intervention.[81]

Other palliative approaches include a bypass or proximal stoma for obstructing lesions.

Stage-Specific Therapy

Stage 0 (Tis, N0, M0). Polyps containing carcinoma in situ (high-grade dysplasia) carry no risk of lymph node metastasis. However, the presence of high-grade dysplasia increases the risk of finding an invasive carcinoma within the polyp. For this reason, these polyps should be excised completely, and pathologic margins should be free of dysplasia. Most pedunculated polyps and many sessile polyps may be completely removed endoscopically. These patients should be followed with frequent colonoscopy to ensure that the polyp has not recurred and that an invasive carcinoma has not developed. In cases where the polyp cannot be removed entirely, a segmental resection is recommended.

Stage I: The Malignant Polyp (T1, N0, M0). Occasionally a polyp that was thought to be benign will be found to harbor invasive carcinoma after polypectomy. Treatment of a *malignant polyp* is based on the risk of local recurrence and the risk of lymph node metastasis.[64] The risk of lymph node metastases depends primarily on the depth of invasion. Invasive carcinoma in the head of a pedunculated polyp with no stalk involvement carries a low risk of metastasis (<1%) and may be completely resected endoscopically. However, lymphovascular invasion, poorly differentiated histology, or tumor within 1 mm of the resection margin greatly increases the risk of local recurrence and metastatic spread. Segmental colectomy is then indicated. Invasive carcinoma arising in a sessile polyp extends into the submucosa and is usually best treated with segmental colectomy (Fig. 29-25).

Stages I and II: Localized Colon Carcinoma (T1-3, N0, M0). The majority of patients with stages I and II colon cancer will be cured with surgical resection. Few patients with completely resected stage I disease will develop either local or distant recurrence, and adjuvant chemotherapy does not improve

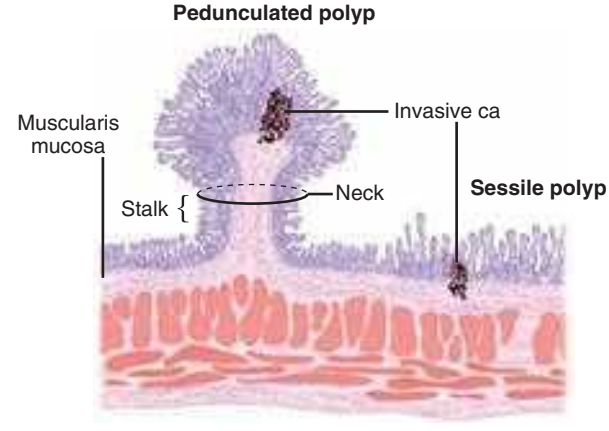

Figure 29-25. Levels of invasive carcinoma in pedunculated and sessile polyps. ca = carcinoma.

survival in these patients. However, up to 46% of patients with completely resected stage II disease will ultimately die from colon cancer. For this reason, adjuvant chemotherapy has been suggested for selected patients with stage II disease (young patients, tumors with "high-risk" histologic findings). It remains controversial as to whether chemotherapy improves survival rates in these patients. Molecular profiling holds promise for improving patient selection in these early cancers.

Stage III: Lymph Node Metastasis (Tany, N1, M0). Patients with lymph node involvement are at significant risk for both local and distant recurrence, and adjuvant chemotherapy has been recommended routinely in these patients. 5-Fluorouracil–based regimens (with leucovorin) and oxaliplatin (FOLFOX) reduce recurrences and improve survival in this patient population.[69] It is important to note, however, that a subgroup of patients with stage III disease will do well without chemotherapy. MSI status in particular predicts good prognosis. Subset analysis from the CRYSTAL trial has shown that patients with MSI-high stage III disease do not benefit from 5-fluorouracil–based chemotherapy. Molecular profiling, therefore, may be helpful in determining which stage III patients can safely avoid systemic chemotherapy.[82]

Stage IV: Distant Metastasis (Tany, Nany, M1). Survival is extremely limited in stage IV colon carcinoma. However, unlike many other malignancies, highly selected patients with isolated, resectable metastases may benefit from resection (metastasectomy). The most common site of metastasis is the liver. Of patients with systemic disease, approximately 15% will have metastases limited to the liver. Of these, 20% are potentially resectable for cure. Survival is improved in these patients (20% –40% 5-year survival) when compared to patients who do not undergo resection. Hepatic resection of synchronous metastases from colorectal carcinoma may be performed as a combined procedure or in two stages. All patients require adjuvant chemotherapy. The second most common site of metastasis is the lung, occurring in approximately 20% of patients with colorectal carcinoma. Although very few of these patients will be potentially resectable, among those who are (about 1%–2% of all colorectal cancer patients), long-term survival benefit is approximately 30% to 40%.[83] There are limited reports of successful resection of metastases in other sites (ovary and retroperitoneum are most common).

The remainder of patients with stage IV disease cannot be cured surgically, and therefore, the focus of treatment should be palliation.[84] Methods such as colonic stenting for obstructing lesions of the left colon also provide good palliation. More limited surgical intervention such as a diverting stoma or bypass procedure may be appropriate in patients with stage IV disease who develop obstruction. Hemorrhage in an unresectable tumor can sometimes be controlled with angiographic embolization. External beam radiation also has been used for palliation.

Therapy for Rectal Carcinoma

Principles of Resection. The biology of rectal adenocarcinoma is thought to be identical to the biology of colonic adenocarcinoma, and the operative principles of complete resection of the primary tumor, its lymphatic bed, and any other involved organ apply to surgical resection of rectal carcinoma. However, the anatomy of the pelvis and proximity of other structures (ureters, bladder, prostate, vagina, iliac vessels, and sacrum) make resection more challenging and often require a different approach than for colonic adenocarcinoma. Moreover, it is more difficult to achieve negative radial margins in rectal cancers that extend through the bowel wall because of the anatomic limitations of the pelvis. Therefore, local recurrence is higher than with similar stage colon cancers. However, unlike the intraperitoneal colon, the relative paucity of small bowel and other radiation-sensitive structures in the pelvis makes it easier to treat rectal tumors with radiation. Therapeutic decisions, therefore, are based on the location and depth of the tumor and its relationship to other structures in the pelvis.

Local Therapy. The distal 10 cm of the rectum are accessible transanally. For this reason, several local approaches have been proposed for treating rectal neoplasms. *Transanal excision* (full thickness or mucosal) is an excellent approach for noncircumferential, benign, villous adenomas of the rectum. *Transanal endoscopic microsurgery (TEM)* and *transanal minimally invasive surgery (TAMIS)* make use of a specially designed proctoscope, magnifying system, and instruments similar to those used in laparoscopy to allow local excision of lesions higher in the rectum (up to 15 cm). Although this technique has been used for selected T1, and some T2, carcinomas, local excision does not allow pathologic examination of the lymph nodes and might therefore understage patients. Moreover, local recurrence rates are high after transanal excision, and salvage surgery, while often curative, is associated with poorer survival than with initial radical surgery. Local excision of any rectal neoplasm should be considered an *excisional biopsy* because final pathologic examination of the specimen may reveal an invasive carcinoma that then mandates more radical therapy.

Ablative techniques, such as electrocautery or endocavitary radiation, also have been used. The disadvantage of these techniques is that no pathologic specimen is retrieved to confirm the tumor stage. Fulguration is generally reserved for extremely high-risk patients with a limited life span who cannot tolerate more radical surgery.

Radical Resection. Radical resection is preferred to local therapy for most rectal carcinomas. Radical resection involves removal of the involved segment of the rectum along with its lymphovascular supply. Although any microscopically negative margin has been suggested to be adequate, most surgeons still attempt to obtain a 2-cm distal mural margin for curative resections.

Total mesorectal excision (TME) is a technique that uses sharp dissection along anatomic planes to ensure complete resection of the rectal mesentery during low and extended low anterior resections. For upper rectal or rectosigmoid resections, a partial mesorectal excision of at least 5 cm distal to the tumor appears adequate. TME both decreases local recurrence rates and improves long-term survival rates. Moreover, this technique is associated with less blood loss and less risk to the pelvic nerves and presacral plexus than is blunt dissection. The principles of TME should be applied to all radical resections for rectal cancer.

Recurrence of rectal cancer generally has a poor prognosis. Extensive involvement of other pelvic organs (usually occurring in the setting of tumor recurrence) may require a *pelvic exenteration*. The rectal and perineal portions of this operation are similar to an APR, but en bloc resection of the ureters, bladder, and prostate or uterus and vagina are also performed. A permanent colostomy and an ileal conduit to drain the urinary tract may be necessary. The sacrum may also be resected if necessary (*sacrectomy*) up to the level of the S2-S3 junction. These operations are best performed in tertiary centers with multidisciplinary teams consisting of a colon and rectal surgeon, urologist, neurosurgeon, and plastic surgeon.

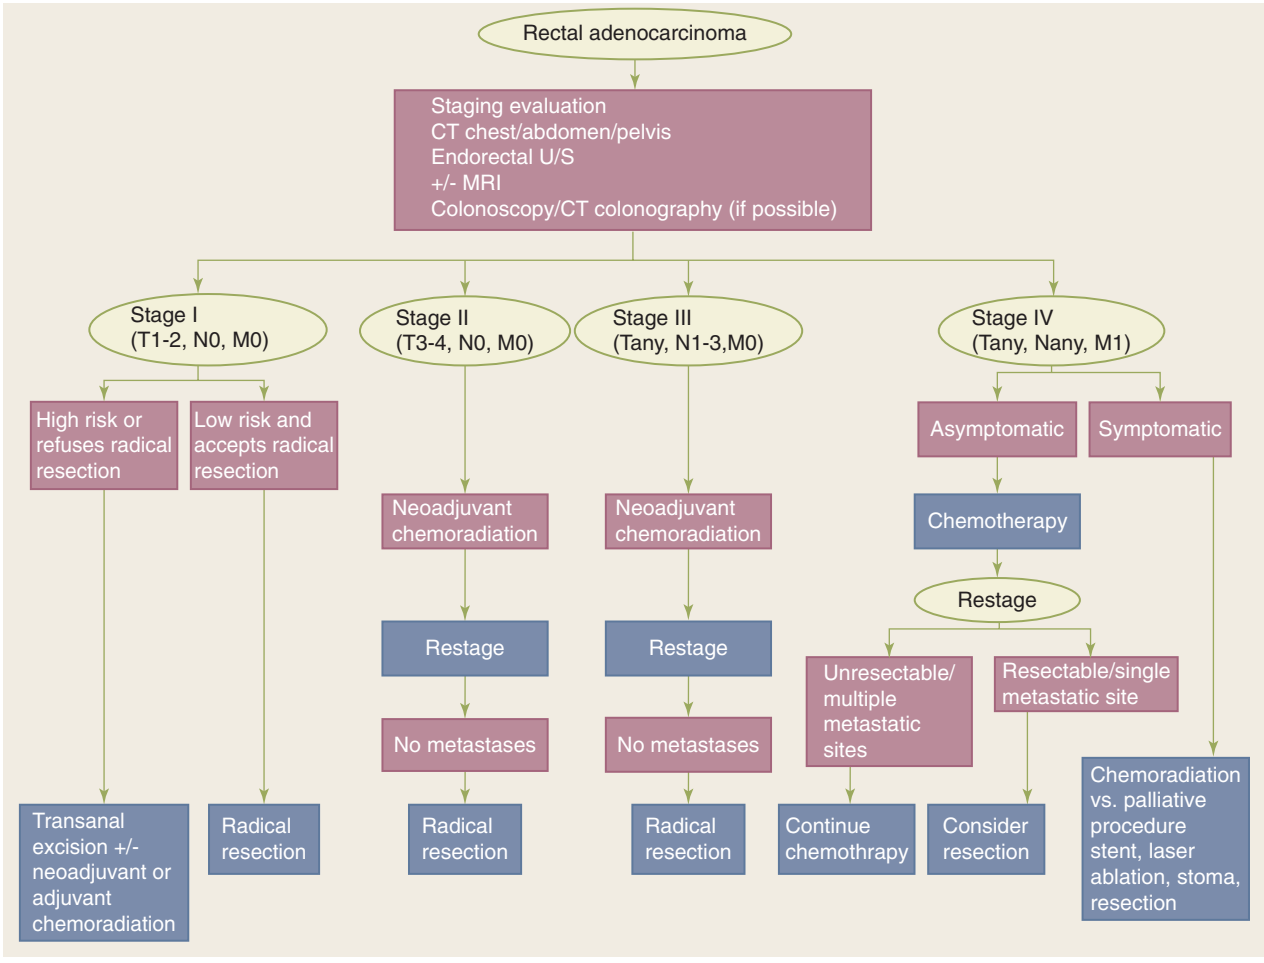

Figure 29-26. Diagnostic algorithm for rectal cancer. CT = computed tomography; MRI = magnetic resonance imaging; U/S = ultrasound.

Stage-Specific Therapy (Fig. 29-26). Pretreatment staging of rectal carcinoma often relies on endorectal ultrasound to determine the T and N status of a rectal cancer. Ultrasound is highly accurate at assessing tumor depth, but less accurate in diagnosing nodal involvement. Ultrasound evaluation can guide choice of therapy in most patients. MRI is useful to assess mesorectal involvement. When the radial margin is threatened or involved, neoadjuvant chemoradiation is recommended.

Stage 0 (Tis, N0, M0). Villous adenomas harboring carcinoma in situ (high-grade dysplasia) are ideally treated with local excision. A 1-cm margin should be obtained. Rarely, radical resection will be necessary if transanal excision is not technically possible (large circumferential lesions).

Stage I: Localized Rectal Carcinoma (T1-2, N0, M0). Although local excision has been used for small, favorable sessile uT1N0 and uT2N0 rectal cancers, local recurrence rates may be as high as 20% and 40%, respectively. For this reason, radical resection is strongly recommended in all good-risk patients. Lesions with unfavorable histologic characteristics and those located in the distal third of the rectum, in particular, are prone to recurrence. In high-risk patients and in patients who refuse radical surgery because of the risk of need for a permanent colostomy, local excision may be adequate, but strong consideration should be given to adjuvant or neoadjuvant chemoradiation to improve local control. The efficacy of adjuvant or neoadjuvant chemoradiation followed by transanal excision in patients who can tolerate radical surgery has been controversial. Early results from ACOSOG Z6041, in which patients with T2 rectal cancers received neoadjuvant chemoradiation followed by transanal excision, showed a pathologic complete response rate of 44%. Long-term outcomes, however, are not yet known.[85]

Locally Advanced Rectal Cancer (Stages II and III)

Stage II: Localized Rectal Carcinoma (T3-4, N0, M0). Larger rectal tumors, especially if located in the distal rectum, are more likely to recur locally. There are two schools of thought, each differing in their approach to control local recurrences. Advocates of total mesorectal resection suggest that optimization of operative technique will obviate the need for any adjuvant chemoradiation to control local recurrence after resection of stages I, II, and III rectal cancers. The opposing school suggests that stages II and III rectal cancers will benefit from chemoradiation. They argue that such therapy reduces local recurrences and prolongs survival whether given preoperatively or postoperatively. The advantages of preoperative chemoradiation include tumor shrinkage, increased likelihood of resection and of a sphincter-sparing procedure, tumor downstaging by treating locally involved lymph nodes, and decreased risk to the small intestine. Disadvantages include possible overtreatment of early-stage tumors, impaired wound healing, and pelvic fibrosis increasing the risk of operative complications. Postoperative radiation allows accurate pathologic staging of the resected tumor and lymph nodes and avoids the wound healing problems

associated with preoperative radiation. However, bulky tumors, tumors involving adjacent organs, and very low rectal tumors may be much more difficult to resect without preoperative radiation and may require a more extensive operation.

Stage III: Lymph Node Metastasis (T*any*, N1, M0). Many surgeons now recommend chemotherapy and radiation either pre- or postoperatively for node-positive rectal cancers. The advantages and disadvantages are similar to those listed for stage II disease, except that the likelihood of overtreating an early-stage lesion is considerably less.

Over the past two decades, a wide variety of studies have addressed the issue of adjuvant and neoadjuvant therapy for locally advanced rectal cancer. Many of these studies demonstrated both improved local control and prolonged survival and resulted in the 1990 National Institutes of Health (NIH) consensus conference recommendation for postoperative chemoradiation therapy in these patients. There is little controversy regarding chemoradiation therapy for stage III (node-positive) disease. However, advances in surgical technique, such as TME, for locally advanced node-negative cancers (T3-4, N0; stage II) have improved local control with surgery alone, prompting some to abandon adjuvant chemoradiation in these patients, especially for those with cancers in the proximal rectum. Although the data from these studies are intriguing, other reports have shown that chemoradiation improves local control and survival even in patients who undergo TME. Thus, most colorectal surgeons in the United States continue to recommend adjuvant or neoadjuvant therapy for patients with locally advanced disease. Many European surgeons now rely heavily on MRI staging to determine the need for neoadjuvant chemoradiation. They use neoadjuvant chemoradiation if the radial margin is threatened or involved by the cancer or if anal sphincter or other local organ invasion is present. In the United States, chemoradiation therapy is still recommended for all patients with stage III disease and the majority of patients with stage II disease. In select patients with T3 tumors, favorable histology, and negative radial margins, chemoradiation may not be necessary, but larger prospective studies are required before this approach can be recommended.

Appropriate timing of chemoradiation for locally advanced rectal cancer has been debated. Historically, preoperative chemoradiation has been advocated based on tumor shrinkage/downstaging, improved resectability, and the possibility of performing a sphincter-sparing operation in some patients. In addition, the absence of small bowel adhesions in the pelvis may decrease toxicity. However, preoperative radiation therapy may increase operative complications and impairs wound healing. Although preoperative endorectal ultrasound and MRI have improved our ability to stage rectal cancer, clinical "overstaging" can be problematic, and neoadjuvant therapy may therefore overtreat patients with pT1-2, N0 tumors. Advocates of postoperative radiation therapy cite more accurate pathologic staging and fewer operative/postoperative complications. However, large, bulky tumors may be unresectable or require a more extensive operation (APR, pelvic exenteration) without preoperative therapy. In addition, postoperative pelvic radiation may compromise function of the neorectum.

Comparisons of perioperative toxicity and oncologic outcome have been addressed by the German CAO/ARO/AIO-94 trial. In this study, pre- and postoperative chemoradiation were associated with equivalent acute toxicity and equivalent postoperative complication rates. Postoperative chemoradiation, however, doubled the risk of postoperative stricture formation. In addition, preoperative chemoradiation halved the risk of local recurrence (6% vs. 12%). Based on these data, most surgeons consider preoperative chemoradiation to be the most appropriate therapy for locally advanced rectal cancer.[86]

Stage IV: Distant Metastasis (T*any*, N*any*, M1). Like stage IV colon carcinoma, survival is limited in patients with distant metastasis from rectal carcinoma. Isolated hepatic and/or pulmonary metastases are rare, but when present may be resected for cure in selected patients.[83] Some patients will require palliative procedures. Radical resection may be required to control pain, bleeding, or tenesmus, but highly morbid procedures such as pelvic exenteration and sacrectomy should generally be avoided in this setting. Local therapy using cautery, endocavitary radiation, or laser ablation may be adequate to control bleeding or prevent obstruction. Intraluminal stents may be useful in the uppermost rectum but often cause pain and tenesmus lower in the rectum. Occasionally, a proximal diverting colostomy will be required to alleviate obstruction. A mucus fistula should be created if possible to vent the distal colon. It is critical that the morbidity of any procedure be realistically weighed against potential benefit in these patients with limited life expectancy. The assistance of a palliative care team can be invaluable in this setting.[84]

Follow-Up and Surveillance

Patients who have been treated for one colorectal cancer are at risk for the development of recurrent disease (either locally or systemically) or metachronous disease (a second primary tumor). In theory, metachronous cancers should be preventable by using surveillance colonoscopy to detect and remove polyps before they progress to invasive cancer. For most patients, a colonoscopy should be performed within 12 months after the diagnosis of the original cancer (or sooner if the colon was not examined in its entirety prior to the original resection). If that study is normal, colonoscopy should be repeated every 3 to 5 years thereafter.

The optimal method of following patients for recurrent cancer remains controversial. The goal of close follow- up observation is to *detect resectable recurrence* and to *improve survival*. Re-resection of local recurrence and resection of distant metastasis to liver, lung, or other sites are often technically challenging and highly morbid, with only a limited chance of achieving long-term survival. Thus, only selected patients who would tolerate such an approach should be followed intensively. Because most recurrences occur within 2 years of the original diagnosis, surveillance focuses on this time period. Patients who have undergone local resection of rectal tumors probably also should be followed with frequent endoscopic examinations (every 3–6 months for 3 years, then every 6 months for 2 years). CEA is often followed every 3 to 6 months for 2 years. CT scans are often performed annually for 5 years, but there are few data to support this practice. More intensive surveillance is appropriate in high-risk patients such as those with possible HNPCC syndrome or T3, N+ cancers. Although intensive surveillance improves detection of resectable recurrences, it is important to note that a survival benefit has never been proven. Therefore, the risks and benefits of intensive surveillance must be weighed and treatment individualized.

Treatment of Recurrent Colorectal Carcinoma

Between 20% and 40% of patients who have undergone curative intent surgery for colorectal carcinoma will eventually

develop recurrent disease. Most recurrences occur within the first 2 years after the initial diagnosis, but preoperative chemoradiation therapy may delay recurrence. While most of these patients will present with distant metastases, a small proportion will have isolated local recurrence and may be considered for *salvage surgery*. Recurrence after colon cancer resection usually occurs at the local site within the abdomen or in the liver or lungs. Resection of other involved organs may be necessary. Recurrence of rectal cancer can be considerably more difficult to manage because of the proximity of other pelvic structures. If the patient has not received chemotherapy and radiation, then adjuvant therapy should be administered prior to salvage surgery. Radical resection may require extensive resection of pelvic organs (pelvic exenteration with or without sacrectomy). Ideally, the aim of a salvage operation should be to resect all of the tumor with negative margins. However, if the ability to achieve a negative margin is in question, the addition of intraoperative radiation therapy (usually brachytherapy) can help improve local control. Pelvic MRI is useful for identifying tumor extension that would prevent successful resection (extension of tumor into the pelvic sidewall, involvement of the iliac vessels or bilateral sacral nerves, sacral invasion above the S2-S3 junction). Patients should also undergo a thorough preoperative evaluation to identify distant metastases (CT of chest, abdomen, and pelvis, and PET scan) before undergoing such an extensive procedure. Nevertheless, radical salvage surgery can prolong survival in selected patients.

Minimally Invasive Techniques For Resection

Laparoscopic colectomy for cancer has been controversial. Early reports of high port site recurrence dampened enthusiasm for this technique.[87] The ability to perform an adequate oncologic resection for cancer has also been questioned. Several trials have laid to rest many of these fears. The Clinical 6▶ Outcomes of Surgical Therapy Study Group (COST), the Colon Carcinoma Laparoscopic or Open Resection (COLOR) trial, and the United Kingdom Medical Research Council Conventional versus Laparoscopic-Assisted Surgery in Colorectal Cancer (CLASSICC) trial all have shown oncologic equivalence between open and laparoscopic techniques. In these multi-institutional studies, the rates of cancer recurrence, survival, and quality of life were similar, suggesting that, in the hands of an appropriately trained surgeon, laparoscopic colectomy is appropriate for cancer.[88-90] The recent introduction of robotic surgery offers an additional minimally invasive approach. Early studies suggest that robotic surgery may be the oncologic equivalent to laparoscopic surgery for colorectal cancer. A prospective, randomized, multicenter trial, Robotic versus Laparoscopic Resection for Rectal Cancer (ROLARR) is under way in hopes of answering this question.[91]

OTHER NEOPLASMS

Rare Colorectal Tumors

Carcinoid Tumors. Carcinoid tumors occur most commonly in the gastrointestinal tract, and up to 25% of these tumors are found in the rectum. Most small rectal carcinoids are benign, and overall survival is greater than 80%. However, the risk of malignancy increases with size, and more than 60% of tumors greater than 2 cm in diameter are associated with distant metastases. Rectal carcinoids appear to be less likely to secrete vasoactive substances than carcinoids in other locations, and carcinoid syndrome is uncommon in the absence of hepatic metastases. Small carcinoids can be locally resected transanally. Larger tumors or tumors with obvious invasion into the muscularis require more radical surgery. Carcinoid tumors in the proximal colon are less common and are more likely to be malignant. Size also correlates with risk of malignancy, and tumors less than 2 cm in diameter rarely metastasize. However, the majority of carcinoid tumors in the proximal colon present as bulky lesions, and up to two thirds of patients will have metastatic spread at the time of diagnosis. These tumors should usually be treated with radical resection. Because carcinoid tumors are typically slow growing, patients with distant metastases may expect reasonably long survival. Symptoms of carcinoid syndrome can often be alleviated with somatostatin analogues (octreotide) and/or interferon-α. Tumor debulking can offer effective palliation in selected patients.

Carcinoid Carcinomas. Composite carcinoid carcinomas (adenocarcinoids) have histologic features of both carcinoid tumors and adenocarcinomas. The natural history of these tumors more closely parallels that of adenocarcinomas than carcinoid tumors, and regional and systemic metastases are common. Carcinoid carcinoma of the colon and rectum should be treated according to the same oncologic principles as followed for management of adenocarcinoma.

Lipomas. Lipomas occur most commonly in the submucosa of the colon and rectum. They are benign lesions, but rarely may cause bleeding, obstruction, or intussusception, especially when greater than 2 cm in diameter. Small asymptomatic lesions do not require resection. Larger lipomas should be resected by colonoscopic techniques or by a colotomy and enucleation or limited colectomy.

Lymphoma. Lymphoma involving the colon and rectum is rare but accounts for about 10% of all gastrointestinal lymphomas. The cecum is most often involved, probably as a result of spread from the terminal ileum. Symptoms include bleeding and obstruction, and these tumors may be clinically indistinguishable from adenocarcinomas. Bowel resection is the treatment of choice for isolated colorectal lymphoma. Adjuvant therapy may be given based on the stage of disease.

Leiomyoma and Leiomyosarcoma. Leiomyomas are benign tumors of the smooth muscle of the bowel wall and occur most commonly in the upper gastrointestinal tract. Most patients are asymptomatic, but large lesions can cause bleeding or obstruction. Because it is difficult to differentiate a benign leiomyoma from a malignant leiomyosarcoma, these lesions should be resected. Recurrence is common after local resection, but most small leiomyomas can be adequately treated with limited resection. Lesions larger than 5 cm should be treated with radical resection because the risk of malignancy is high.

Leiomyosarcoma is rare in the gastrointestinal tract. When this malignancy occurs in the large intestine, the rectum is the most common site. Symptoms include bleeding and obstruction. A radical resection is indicated for these tumors.

Gastrointestinal Stromal Tumor. These rare tumors occur most commonly in the stomach and small intestine, but 5% to 10% arise in the colon or rectum. They are often mistaken for leiomyomas. Thirty percent to 50% are malignant; thus all lesions should be resected.

Retrorectal/Presacral Tumors

Tumors occurring in the retrorectal space are rare. This region lies between the upper two thirds of the rectum and the sacrum above the rectosacral fascia. It is bound by the rectum anteriorly, the presacral fascia posteriorly, and the endopelvic fascia laterally (lateral ligaments). The retrorectal space contains multiple embryologic remnants derived from a variety of tissues (neuroectoderm, notochord, and hindgut). Tumors that develop in this space are often heterogeneous.

Congenital lesions are most common, comprising almost two thirds of retrorectal lesions. The remainder are classified as neurogenic, osseous, inflammatory, or miscellaneous lesions. Malignancy is more common in the pediatric population than in adults, and solid lesions are more likely to be malignant than are cystic lesions. Inflammatory lesions may be solid or cystic (abscess) and usually represent extensions of infection either in the perirectal space or in the abdomen.

Developmental cysts constitute the majority of congenital lesions and may arise from all three germ cell layers. Dermoid and epidermoid cysts are benign lesions that arise from the ectoderm. Enterogenous cysts arise from the primitive gut. Anterior meningocele and myelomeningocele arise from herniation of the dural sac through a defect in the anterior sacrum. A "scimitar sign" (sacrum with a rounded, concave border without any bony destruction) is the pathognomonic radiographic appearance of this condition.

Solid lesions include teratomas, chordomas, neurologic tumors, or osseous lesions. Teratomas are true neoplasms and contain tissue from each germ cell layer. They often contain both cystic and solid components. Teratomas are more common in children than in adults, but when found in adults, 30% are malignant. Chordomas arise from the notochord and are the most common malignant tumor in this region. These are slow-growing, invasive cancers that show characteristic bony destruction. Neurogenic tumors include neurofibromas and sarcomas, neurilemomas, ependymomas, and ganglioneuromas. Osseous lesions include osteomas and bone cysts, as well as neoplasms such as osteogenic sarcoma, Ewing's tumor, chondromyxosarcoma, and giant cell tumors.

Patients may present with pain (lower back, pelvic, or lower extremity), gastrointestinal symptoms, or urinary tract symptoms. Most lesions are palpable on digital rectal examination. While plain X-rays and CT scans often are used to evaluate these lesions, pelvic MRI is the most sensitive and specific imaging study. Myelogram is occasionally necessary if there is central nervous system involvement. Treatment is almost always surgical resection. The approach depends in part on the nature of the lesion and its location. Lesions high in the pelvis may be approached via a transabdominal route, whereas low lesions may be resected transsacrally. Intermediate lesions may require a combined abdominal and sacral operation. Although survival is excellent after resection of benign lesions, local recurrence is not uncommon. Prognosis after resection of malignant lesions is highly variable and reflects the biology of the underlying tumor.

The role of biopsy in this setting has been controversial. Historically, the recommendation was to *avoid* biopsy because of the risk of infection or needle tract seeding. This recommendation has recently been challenged, especially for large and/or unusual tumors that would be better treated with multimodality neoadjuvant therapy (sarcomas, for example). A recent study confirmed the utility of needle biopsy of solid lesions and refuted concerns about needle tract seeding.[92] As such, most solid lesions should be biopsied regardless of resectability. Biopsy of cystic lesions, especially meningoceles, should still be avoided because of the risk of infection.

Anal Canal and Perianal Tumors

Cancers of the anal canal are uncommon and account for approximately 2% of all colorectal malignancies. Neoplasms of the anal canal have traditionally been divided into those affecting the *anal margin* (distal to the dentate line) and those affecting the *anal canal* (proximal to the dentate line) based on lymphatic drainage patterns. Lymphatics from the anal canal proximal to the dentate line drain cephalad via the superior rectal lymphatics to the inferior mesenteric nodes and laterally along both the middle rectal vessels and inferior rectal vessels through the ischiorectal fossa to the internal iliac nodes. Lymph from the anal canal distal to the dentate line usually drains to the inguinal nodes. It can also drain to the superior rectal lymph nodes or along the inferior rectal lymphatics to the ischiorectal fossa if primary drainage routes are blocked with tumor (Fig. 29-27).

A more clinically useful classification divides anal lesions into those that are *perianal* (can be completely visualized with gentle eversion of the buttocks) and those that are *intra-anal* (cannot be completely visualized with gentle eversion of the buttocks). In many cases, therapy depends on whether the tumor is perianal or intra-anal.

Squamous Intraepithelial Lesions. Anal canal and perianal dysplasia have long had a potpourri of nomenclature. Anal intraepithelial neoplasia (AIN), Bowen's disease, and carcinoma in situ all refer to human papillomavirus (HPV)–induced dysplasia. Because these entities are pathologically identical, there has been a recent effort to standardize nomenclature. *High-grade squamous intraepithelial lesions (HSIL)* include high- and intermediate-grade dysplasia, AIN2 and AIN3, Bowen's

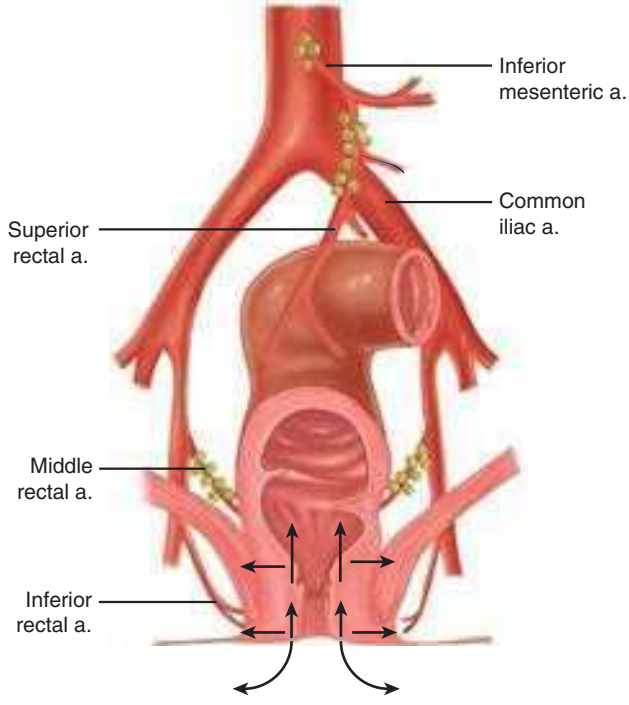

Figure 29-27. Lymphatic drainage of the anal canal. a. = artery.

disease, and carcinoma in situ. *Low-grade squamous intraepithelial lesions (LSIL)* include low-grade dysplasia and AIN1.[93]

HSIL is a precursor to an invasive squamous cell carcinoma (epidermoid carcinoma). HSIL may appear as a plaque-like lesion or may only be apparent with high-resolution anoscopy and application of acetic acid or Lugol's iodine solution. Both HSIL and LSIL are associated with infection with HPV, especially types 16 and 18. The incidence of both squamous intraepithelial lesions and epidermoid carcinoma of the anus has increased dramatically among human immunodeficiency virus (HIV)–positive, homosexual men. This increase is thought to result from increased rates of HPV infection along with HIV-induced immunosuppression. Treatment of HSIL is *ablation*. Because of a high recurrence and/or reinfection rate, these patients require extremely close surveillance. High-risk patients should be followed with frequent anal Papanicolaou (Pap) smears every 3 to 6 months. An abnormal Pap smear should be followed by an examination under anesthesia and anal mapping using high-resolution anoscopy. High-resolution anoscopy shows areas with abnormal telangiectasias that are consistent with high-grade dysplasia (HSIL). Many centers now consider this technique for repeated ablation of HSIL to be the optimal method for following these patients. It should be noted, however, that the practice has not been universally adopted, and it is unclear whether close surveillance in lower risk (nonimmunosuppressed) patients is necessary. Rarely, extensive disease may require resection with flap closure. Medical therapy for HPV has also been proposed. Topical immunomodulators such as imiquimod (Aldara) have been shown to induce regression in some series.[94] Topical 5-fluorouracil has also been used in this setting. Finally, the introduction of a vaccine against HPV may help decrease the incidence of this disease in the future.

Epidermoid Carcinoma. Epidermoid carcinoma of the anus includes squamous cell carcinoma, cloacogenic carcinoma, transitional carcinoma, and basaloid carcinoma. The clinical behavior and natural history of these tumors are similar. Epidermoid carcinoma is a slow-growing tumor and usually presents as an intra-anal or perianal mass. Pain and bleeding may be present. Perianal epidermoid carcinoma may be treated in a similar fashion as squamous cell carcinoma of the skin in other locations because wide local excision can usually be achieved without resecting the anal sphincter. Intra-anal epidermoid carcinoma cannot be excised locally, and first-line therapy relies on chemotherapy and radiation (the *Nigro protocol:* 5-fluorouracil, mitomycin C, and 30 Gy of external beam radiation). More than 80% of these tumors can be cured by using this regimen. Recurrence usually requires radical resection (APR). Metastasis to inguinal lymph nodes is a poor prognostic sign.

7▶

Verrucous Carcinoma (Buschke-Lowenstein Tumor, Giant Condyloma Acuminata). Verrucous carcinoma is a locally aggressive form of condyloma acuminata. Although these lesions do not metastasize, they can cause extensive local tissue destruction and may be grossly indistinguishable from epidermoid carcinoma. Wide local excision is the treatment of choice when possible, but radical resection may sometimes be required. Very large lesions may respond to external beam radiation, but resection is almost always required.

Basal Cell Carcinoma. Basal cell carcinoma of the anus is rare and resembles basal cell carcinoma elsewhere on the skin (raised, pearly edges with central ulceration). This is a slow-growing tumor that rarely metastasizes. Wide local excision is the treatment of choice, but recurrence occurs in up to 30% of patients. Radical resection and/or radiation therapy may be required for large lesions.

Adenocarcinoma. Adenocarcinoma of the anus is extremely rare and usually represents downward spread of a low rectal adenocarcinoma. Adenocarcinoma may occasionally arise from the anal glands or may develop in a chronic fistula. Radical resection with or without adjuvant chemoradiation is usually required.

Extramammary perianal *Paget's disease* is *adenocarcinoma in situ* arising from the apocrine glands of the perianal area. The lesion is typically plaque-like and may be indistinguishable from HSIL. Characteristic *Paget's cells* are seen histologically. These tumors are often associated with a synchronous gastrointestinal adenocarcinoma, so a complete evaluation of the intestinal tract should be performed. Wide local excision is usually adequate treatment for perianal Paget's disease.

Melanoma. Anorectal melanoma is rare, comprising less than 1% of all anorectal malignancies and 1% to 2% of melanomas. Despite many advances in the treatment of melanoma, prognosis for patients with anorectal disease remains poor. Overall 5-year survival is less than 10%, and many patients present with systemic metastasis and/or deeply invasive tumors at the time of diagnosis. A few patients with anorectal melanoma, however, present with isolated local or locoregional disease that is potentially resectable for cure, and both radical resection (APR) and wide local excision have been advocated. Recurrence is common and usually occurs systemically regardless of the initial surgical procedure. Local resection with free margins does not increase the risk of local or regional recurrence, and APR offers no survival advantage over local excision. Because of the morbidity associated with APR, wide local excision is recommended for initial treatment of localized anal melanoma. In some patients, wide local excision may not be technically feasible, and APR may be required if the tumor involves a significant portion of the anal sphincter or is circumferential. The addition of adjuvant chemotherapy, biochemotherapy, vaccines, or radiotherapy may be of benefit in some patients, but efficacy remains unproven.[95]

OTHER BENIGN COLORECTAL CONDITIONS

Rectal Prolapse and Solitary Rectal Ulcer Syndrome

Rectal Prolapse. Rectal prolapse refers to a circumferential, full-thickness protrusion of the rectum through the anus and has also been called "first-degree" prolapse, "complete" prolapse, or procidentia. Internal prolapse occurs when the rectal wall intussuscepts but does not protrude and is probably more accurately described as internal intussusception. Mucosal prolapse is a partial-thickness protrusion often associated with hemorrhoidal disease and is usually treated with banding or hemorrhoidectomy.

In adults, this condition is far more common among women, with a female-to-male ratio of 6:1. Prolapse becomes more prevalent with age in women and peaks in the seventh decade of life. In men, prevalence is unrelated to age. Symptoms include tenesmus, a sensation of tissue protruding from the anus that may or may not spontaneously reduce, and a sensation of incomplete evacuation. Mucus discharge and leakage may accompany the protrusion. Patients also present with a myriad of functional complaints, from incontinence and diarrhea to constipation and outlet obstruction.

8▶

A thorough preoperative evaluation, including colonic transit studies, anorectal manometry, tests of pudendal nerve terminal motor latency, EMG, and cinedefecography, may be useful. The colon should be evaluated by colonoscopy, air-contrast barium enema, or CT colonography to exclude neoplasms or diverticular disease. Cardiopulmonary condition should be thoroughly evaluated because comorbidities may influence the choice of surgical procedure.

The primary therapy for rectal prolapse is surgery, and more than 100 different procedures have been described to treat this condition. Operations can be categorized as either *abdominal* or *perineal*. Abdominal operations have taken three major approaches: (a) reduction of the perineal hernia and closure of the cul-de-sac (*Moschowitz repair*); (b) fixation of the rectum, either with a prosthetic sling (*Ripsten* and *Wells rectopexy*) or by *suture rectopexy;* or (c) resection of redundant sigmoid colon (Fig. 29-28). In some cases, resection is combined with rectal fixation (*resection rectopexy*). Abdominal rectopexy with or without resection also is increasingly performed laparoscopically or robotically. Perineal approaches have focused on tightening the anus with a variety of prosthetic materials, reefing the rectal mucosa (*Delorme procedure*), or resecting the prolapsed bowel from the perineum (*perineal rectosigmoidectomy* or *Altemeier procedure*) (Fig. 29-29).

Because rectal prolapse occurs most commonly in elderly women, the choice of operation depends in part on the patient's overall medical condition. Abdominal rectopexy (with or without sigmoid resection) offers the most durable repair, with recurrence occurring in less than 10% of patients. Perineal rectosigmoidectomy avoids an abdominal operation and may be preferable in high-risk patients but is associated with a higher recurrence rate. Reefing the rectal mucosa is effective for patients with limited prolapse. Anal encirclement procedures generally have been abandoned.

Solitary Rectal Ulcer Syndrome. Solitary rectal ulcer syndrome and colitis cystica profunda are commonly associated with internal intussusception. Patients may complain of pain, bleeding, mucus discharge, or outlet obstruction. In solitary rectal ulcer syndrome, one or more ulcers are present in the distal rectum, usually on the anterior wall. In colitis cystica profunda, nodules or a mass may be found in a similar location. Evaluation should include anorectal manometry, defecography, and either colonoscopy or barium enema to exclude other diagnoses. Biopsy of an ulcer or mass is mandatory to exclude malignancy or infection due to cytomegalovirus (CMV) in an immunosuppressed patient. Nonoperative therapy (high-fiber diet, defecation training to avoid straining, and laxatives or enemas) is effective in the majority of patients. Biofeedback has also been reported to be effective in some patients. Surgery (either abdominal or perineal repair of prolapse as described earlier) is reserved for highly symptomatic patients who have failed all medical interventions.[72]

Volvulus

Volvulus occurs when an air-filled segment of the colon twists about its mesentery. The sigmoid colon is involved in up to 90% of cases, but volvulus can involve the cecum (<20%) or transverse colon. A volvulus may reduce spontaneously, but more commonly produces bowel obstruction, which can progress to strangulation, gangrene, and perforation. Chronic constipation may produce a large, redundant colon (*chronic megacolon*) that predisposes to volvulus, especially if the mesenteric base is narrow.

The symptoms of volvulus are those of acute bowel obstruction. Patients present with abdominal distention, nausea, and vomiting. Symptoms rapidly progress to generalized abdominal pain and tenderness. Fever and leukocytosis are heralds of gangrene and/or perforation. Occasionally, patients will report a long history of intermittent obstructive symptoms and distention, suggesting intermittent chronic volvulus.

Sigmoid Volvulus. Sigmoid volvulus can often be differentiated from cecal or transverse colon volvulus by the appearance of plain X-rays of the abdomen. Sigmoid volvulus produces a characteristic *bent inner tube* or *coffee bean* appearance, with the convexity of the loop lying in the right upper quadrant (opposite the site of obstruction). Gastrografin enema shows a narrowing at the site of the volvulus and a pathognomonic *bird's beak* (Fig. 29-30).

Unless there are obvious signs of gangrene or peritonitis, the initial management of sigmoid volvulus is resuscitation followed by endoscopic detorsion. Detorsion is usually most easily accomplished by using a rigid proctoscope, but a flexible sigmoidoscope or colonoscope may also be effective. A rectal tube may be inserted to maintain decompression. Although these techniques are successful in reducing sigmoid volvulus in the majority of patients, the risk of recurrence is high (up to 40%). For this reason, an elective sigmoid colectomy should be performed after the patient has been stabilized and undergone an adequate bowel preparation.

Clinical evidence of gangrene or perforation mandates immediate surgical exploration without an attempt at endoscopic decompression. Similarly, the presence of necrotic mucosa, ulceration, or dark blood noted on endoscopy examination suggests strangulation and is an indication for operation.

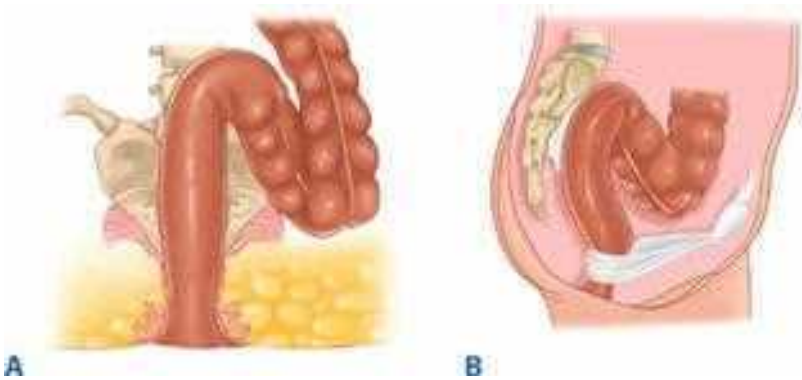

Figure 29-28. Transabdominal proctopexy for rectal prolapse. The fully mobilized rectum is sutured to the presacral fascia. **A.** Anterior view. **B.** Lateral view. If desired, a sigmoid colectomy can be performed concomitantly to resect the redundant colon.

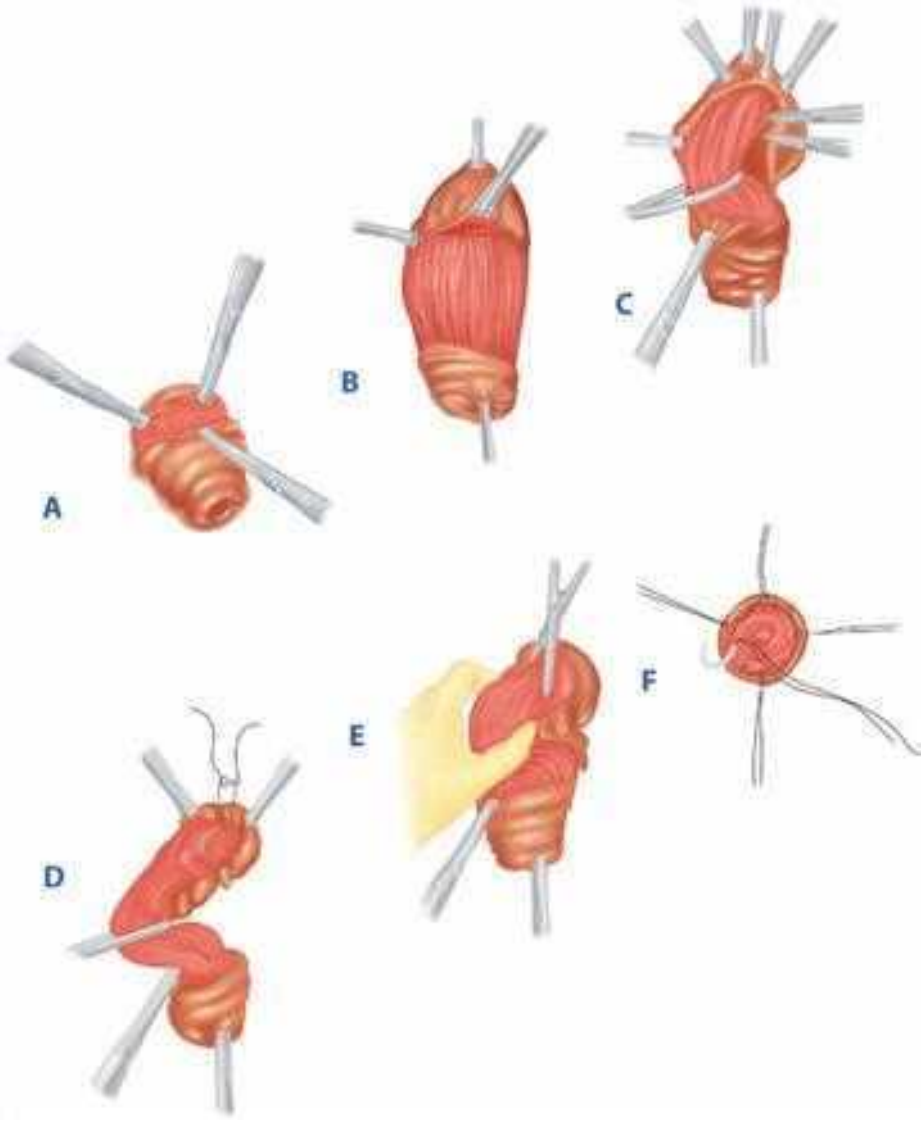

Figure 29-29. Perineal rectosigmoidectomy shown in lithotomy position. **A.** A circular incision is made 2 cm proximal to the dentate line. **B.** The anterior peritoneal reflection is opened. **C.** The mesentery is divided and ligated. **D.** The peritoneum may be sutured to the bowel wall. **E.** The bowel is resected. **F.** A hand-sewn anastomosis is performed.

If dead bowel is present at laparotomy, a sigmoid colectomy with end colostomy (Hartmann's procedure) may be the safest operation to perform.

Cecal Volvulus. Cecal volvulus results from nonfixation of the right colon. In the majority of cases, rotation occurs around the ileocolic blood vessels and vascular impairment occurs early, although 10% to 30% of the cecum folds upon itself (cecal bascule). Plain X-rays of the abdomen show a characteristic kidney-shaped, air-filled structure in the left upper quadrant (opposite the site of obstruction), and a Gastrografin enema confirms obstruction at the level of the volvulus.

Unlike sigmoid volvulus, cecal volvulus can almost never be detorsed endoscopically. Moreover, because vascular compromise occurs early in the course of cecal volvulus, surgical exploration is necessary when the diagnosis is made. Right hemicolectomy with a primary ileocolic anastomosis can usually be performed safely and prevents recurrence. Simple detorsion or detorsion and cecopexy are associated with a high rate of recurrence.

Transverse Colon Volvulus. Transverse colon volvulus is extremely rare. Nonfixation of the colon and chronic constipation with megacolon may predispose to transverse colon volvulus. The radiographic appearance of transverse colon volvulus resembles sigmoid volvulus, but Gastrografin enema will reveal a more proximal obstruction. Although colonoscopic detorsion is occasionally successful in this setting, most patients require emergent exploration and resection.

Megacolon

Megacolon describes a chronically dilated, elongated, hypertrophied large bowel. Megacolon may be congenital or acquired and is usually related to chronic mechanical or functional obstruction. In general, the degree of megacolon is related to the duration of obstruction. Evaluation must always include examination of the colon and rectum (either endoscopically or radiographically) to exclude a surgically correctable mechanical obstruction.

Congenital megacolon caused by Hirschsprung's disease results from the failure of migration of neural crest cells to the distal large intestine. The resulting absence of ganglion cells in the distal colon results in a failure of relaxation and causes a functional obstruction. The proximal, healthy bowel becomes progressively dilated. Surgical resection of the aganglionic segment is curative. Although Hirschsprung's disease primarily is a disease of infants and children, it occasionally presents

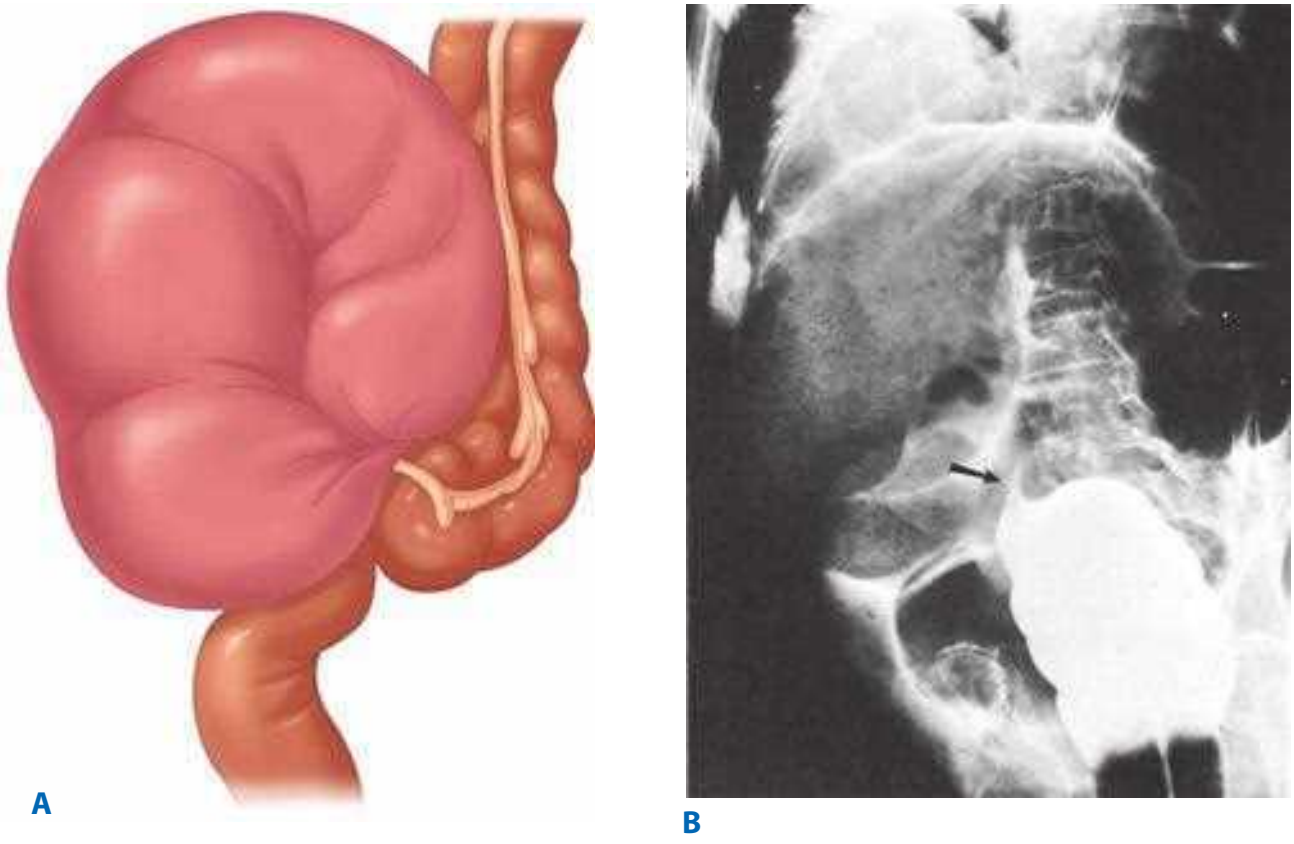

Figure 29-30. Sigmoid volvulus: (**A**) Illustration and (**B**) Gastrografin enema showing "bird-beak" sign (*arrow*). *(**B:** Reproduced with permission from Nivatvongs S, Becker ER. Colon, rectum, and anal canal. In: James EC, Corry RJ, Perry JCF Jr, eds.* Basic Surgical Practice. *Philadelphia: Hanley & Belfus; 1987. Copyright Elsevier.)*

later in adulthood, especially if an extremely short segment of the bowel is affected (*ultrashort-segment Hirschsprung's disease*).

Acquired megacolon may result from infection or chronic constipation. Infection with the protozoan *Trypanosoma cruzi (Chagas' disease)* destroys ganglion cells and produces both megacolon and megaesophagus. Chronic constipation from slow transit or secondary to medications (especially anticholinergic medications) or neurologic disorders (paraplegia, poliomyelitis, amyotrophic lateral sclerosis, multiple sclerosis) may produce progressive colonic dilatation. Diverting ileostomy or subtotal colectomy with an ileorectal anastomosis is occasionally necessary in these patients.

Colonic Pseudo-obstruction (Ogilvie's Syndrome)

Colonic pseudo-obstruction (Ogilvie's syndrome) is a functional disorder in which the colon becomes massively dilated in the absence of mechanical obstruction. Pseudo-obstruction most commonly occurs in hospitalized patients and is associated with the use of narcotics, bed rest, and comorbid disease. Pseudo-obstruction is thought to result from autonomic dysfunction and severe adynamic ileus. The diagnosis is made based on the presence of massive dilatation of the colon (usually predominantly the *right* and *transverse* colon) in the absence of a mechanical obstruction. Initial treatment consists of cessation of narcotics, anticholinergics, or other medications that may contribute to ileus. Strict bowel rest and intravenous hydration are crucial. Most patients will respond to these measures. In patients who fail to improve, colonoscopic decompression often is effective. However, this procedure is technically challenging, and great care must be taken to avoid causing perforation. Up to 40% of patients recur. Intravenous neostigmine (an acetylcholinesterase inhibitor) also is extremely effective in decompressing the dilated colon and is associated with a low rate of recurrence (20%). However, neostigmine may produce transient but profound bradycardia and may be inappropriate in patients with cardiopulmonary disease. Because the colonic dilatation is typically greatest in the proximal colon, placement of a rectal tube is rarely effective. It is crucial to exclude mechanical obstruction (usually with a Gastrografin enema) prior to medical or endoscopic treatment.

Ischemic Colitis

Intestinal ischemia occurs most commonly in the colon. Unlike small bowel ischemia, colonic ischemia rarely is associated with major arterial or venous occlusion. Instead, most colonic ischemia appears to result from low flow and/or small vessel occlusion. Risk factors include vascular disease, diabetes mellitus, vasculitis, hypotension, and tobacco use. In addition, ligation of the inferior mesenteric artery during aortic surgery predisposes to colonic ischemia. Occasionally, thrombosis or embolism may cause ischemia. Although the splenic flexure is the most common site of ischemic colitis, any segment of the colon may be affected. The rectum is relatively spared because of its rich collateral circulation.

Signs and symptoms of ischemic colitis reflect the extent of bowel ischemia. In mild cases, patients may have diarrhea (usually bloody) without abdominal pain. With more severe ischemia, intense abdominal pain (often out of proportion to the clinical examination), tenderness, fever, and leukocytosis are present. Peritonitis and/or systemic toxicity are signs of full-thickness necrosis and perforation.

The diagnosis of ischemic colitis is often based on the clinical history and physical examination. Plain films may reveal *thumb printing*, which results from mucosal edema and submucosal hemorrhage. CT often shows nonspecific colonic wall thickening and pericolic fat stranding. Angiography is usually not helpful because major arterial occlusion is rare. While sigmoidoscopy may reveal characteristic dark, hemorrhagic mucosa, the risk of precipitating perforation is high. For this reason, *sigmoidoscopy is relatively contraindicated* in any patient with significant abdominal tenderness. Contrast studies (Gastrografin or barium enema) are similarly contraindicated during the acute phase of ischemic colitis.

Treatment of ischemic colitis depends on clinical severity. Unlike ischemia of the small bowel, the majority of patients with ischemic colitis can be treated medically. Bowel rest and broad-spectrum antibiotics are the mainstay of therapy, and 80% of patients will recover with this regimen. Hemodynamic parameters should be optimized, especially if hypotension and low flow appear to be the inciting cause. Long-term sequelae include stricture (10%–15%) and chronic segmental ischemia (15%–20%). Colonoscopy should be performed after recovery to evaluate strictures and to rule out other diagnoses such as inflammatory bowel disease or malignancy. Failure to improve after 2 to 3 days of medical management, progression of symptoms, and deterioration in clinical condition are indications for surgical exploration. In this setting, all necrotic bowel should be resected. Primary anastomosis should be avoided. Occasionally, repeated exploration (a *second-look operation*) may be necessary.

Infectious Colitis

Pseudomembranous Colitis (*Clostridium difficile* Colitis). *Pseudomembranous colitis* is caused by *C. difficile*, a gram-positive anaerobic bacillus. *C. difficile colitis* is extremely common and is the leading cause of nosocomially acquired diarrhea.[6,88] The spectrum of disease ranges from watery diarrhea to fulminant, life-threatening colitis. *C. difficile* is carried in the large intestine of many healthy adults. Colitis is thought to result from overgrowth of this organism after depletion of the normal commensal flora of the gut with the use of antibiotics. Although clindamycin was the first antimicrobial agent associated with *C. difficile* colitis, almost any antibiotic may cause this disease. Moreover, although the risk of *C. difficile* colitis increases with prolonged antibiotic use, even a single dose of an antibiotic may cause the disease. Immunosuppression, medical comorbidities, prolonged hospitalization or nursing home residence, and bowel surgery increase the risk.

The pathogenic changes associated with *C. difficile* colitis result from production of two toxins: *toxin A* (an enterotoxin) and *toxin B* (a cytotoxin). Diagnosis of this disease was traditionally made by culturing the organism from the stool. Detection of one or both toxins (either by cytotoxic assays or by immunoassays) has proven to be more rapid, sensitive, and specific. The diagnosis may also be made endoscopically by detection of characteristic ulcers, plaques, and pseudomembranes.

Management should include immediate cessation of the offending antimicrobial agent. Patients with mild disease (diarrhea but no fever or abdominal pain) may be treated as outpatients with a 10-day course of oral metronidazole. Oral vancomycin is a second-line agent used in patients allergic to metronidazole or in patients with recurrent disease. More severe diarrhea associated with dehydration and/or fever and abdominal pain is best treated with bowel rest, intravenous hydration, and oral metronidazole or vancomycin. Proctosigmoiditis may respond to vancomycin enemas. Recurrent colitis occurs in up to 20% of patients and may be treated by a longer course of oral metronidazole or vancomycin (up to 1 month) or rifaximin (a rapamycin derivative). Reintroduction of normal flora by ingestion of *probiotics* or *stool transplantation* has been suggested as a possible treatment for recurrent or refractory disease. Fulminant colitis, characterized by septicemia and/or evidence of perforation, requires emergent laparotomy. A total abdominal colectomy with end ileostomy may be lifesaving. Over the past decade, *C. difficile* colitis has increased in prevalence, and new, more virulent strains have appeared, making this disease increasingly challenging to treat.[96]

Other Infectious Colitides. A variety of other infections with bacteria, parasites, fungi, or viruses may cause colonic inflammation. Common bacterial infections include enterotoxic *E. coli*, *Campylobacter jejuni*, *Yersinia enterocolitica*, *Salmonella typhi*, *Shigella*, and *N. gonorrhoeae*. Less commonly, *Mycobacterium tuberculosis, Mycobacterium bovis, Actinomycosis israelii*, or *Treponema pallidum* (syphilis) may cause colitis or proctitis. Parasitic infections such as amebiasis, cryptosporidiosis, and giardiasis are also relatively common. Fungal infections (*Candida* species, histoplasmosis) are extremely rare in otherwise healthy individuals. The most common viral infections that produce colitic symptoms are HIV, herpes simplex viruses, and CMV.

Most symptoms are nonspecific and consist of diarrhea (with or without bleeding), crampy abdominal pain, and malaise. A thorough history may offer clues to the etiology (other medical conditions, especially immunosuppression; recent travel or exposures; and ingestions). Diagnosis is usually made by identification of a pathogen in the stool, either by microscopy or culture. Serum immunoassays may also be useful (amebiasis, HIV, CMV). Occasionally, endoscopy with biopsy may be required. Treatment is tailored to the infection.

ANORECTAL DISEASES

Any patient with anal/perianal symptoms requires a careful history and physical, including a digital rectal examination. Other studies such as defecography, manometry, CT scan, MRI, contrast enema, endoscopy, endoanal ultrasound, or exam under anesthesia may be required to arrive at an accurate diagnosis.

Hemorrhoids

Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth muscle fibers that are located in the anal canal (see Fig. 29-4). Three hemorrhoidal cushions are found in the left lateral, right anterior, and right posterior positions. Hemorrhoids are thought to function as part of the continence mechanism and aid in complete closure of the anal canal at rest. Because hemorrhoids are a normal part of anorectal anatomy, treatment is only indicated if they become symptomatic. Excessive straining, increased abdominal

9▶

pressure, and hard stools increase venous engorgement of the hemorrhoidal plexus and cause prolapse of hemorrhoidal tissue. Bleeding, thrombosis, and symptomatic hemorrhoidal prolapse may result.

External hemorrhoids are located distal to the dentate line and are covered with anoderm. Because the anoderm is richly innervated, thrombosis of an external hemorrhoid may cause significant pain. It is for this reason that external hemorrhoids should not be ligated or excised without adequate local anesthetic. A *skin tag* is redundant fibrotic skin at the anal verge, often persisting as the residua of a thrombosed external hemorrhoid. Skin tags are often confused with symptomatic hemorrhoids. External hemorrhoids and skin tags may cause itching and difficulty with hygiene if they are large. Treatment of external hemorrhoids and skin tags is only indicated for symptomatic relief.

Internal hemorrhoids are located proximal to the dentate line and covered by insensate anorectal mucosa. Internal hemorrhoids may prolapse or bleed, but rarely become painful unless they develop thrombosis and necrosis (usually related to severe prolapse, incarceration, and/or strangulation). Internal hemorrhoids are graded according to the extent of prolapse. *First-degree hemorrhoids* bulge into the anal canal and may prolapse beyond the dentate line on straining. *Second-degree hemorrhoids* prolapse through the anus but reduce spontaneously. *Third-degree hemorrhoids* prolapse through the anal canal and require manual reduction. *Fourth-degree hemorrhoids* prolapse but cannot be reduced and are at risk for strangulation.

Combined internal and external hemorrhoids straddle the dentate line and have characteristics of both internal and external hemorrhoids. Hemorrhoidectomy is often required for large, symptomatic, combined hemorrhoids. *Postpartum hemorrhoids* result from straining during labor, which results in edema, thrombosis, and/or strangulation. Hemorrhoidectomy is often the treatment of choice, especially if the patient has had chronic hemorrhoidal symptoms. *Portal hypertension* was long thought to increase the risk of hemorrhoidal bleeding because of the anastomoses between the portal venous system (middle and upper hemorrhoidal plexuses) and the systemic venous system (inferior rectal plexuses). It is now understood that hemorrhoidal disease is no more common in patients with portal hypertension than in the normal population. *Rectal varices*, however, may occur and may cause hemorrhage in these patients. In general, rectal varices are best treated by lowering portal venous pressure. Rarely, suture ligation may be necessary if massive bleeding persists. Surgical hemorrhoidectomy should be avoided in these patients because of the risk of massive, difficult-to-control variceal bleeding.

Treatment

Medical Therapy. Bleeding from first- and second-degree hemorrhoids often improves with the addition of dietary fiber, stool softeners, increased fluid intake, and avoidance of straining. Associated pruritus often may improve with improved hygiene. Many over-the-counter topical medications are desiccants and are relatively ineffective for treating hemorrhoidal symptoms.

Rubber Band Ligation. Persistent bleeding from first-, second-, and selected third-degree hemorrhoids may be treated by rubber band ligation.

Mucosa located 1 to 2 cm proximal to the dentate line is grasped and pulled into a rubber band applier. After firing the ligator, the rubber band strangulates the underlying tissue, causing scarring and preventing further bleeding or prolapse (Fig. 29-31). In general, only one or two quadrants are banded per visit. Severe pain will occur if the rubber band is placed at or distal to the dentate line where sensory nerves are located. Other complications of rubber band ligation include *urinary retention, infection*, and *bleeding*. Urinary retention occurs in approximately 1% of patients and is more likely if the ligation has inadvertently included a portion of the internal sphincter. *Necrotizing infection* is an uncommon, but life-threatening complication. Severe pain, fever, and urinary retention are early signs of infection and should prompt immediate evaluation of the patient usually with an exam under anesthesia. Treatment includes débridement of necrotic tissue, drainage of associated abscesses, and broad-spectrum antibiotics. *Bleeding* may occur approximately 7 to 10 days after rubber band ligation, at the time when the ligated pedicle necroses and sloughs. Bleeding is usually self-limited, but persistent hemorrhage may require exam under anesthesia and suture ligation of the pedicle.

Infrared Photocoagulation. Infrared photocoagulation is an effective office treatment for small first- and second-degree hemorrhoids. The instrument is applied to the apex of each hemorrhoid to coagulate the underlying plexus. All three quadrants may be treated during the same visit. Larger hemorrhoids and hemorrhoids with a significant amount of prolapse are not effectively treated with this technique.

Sclerotherapy. The injection of bleeding internal hemorrhoids with sclerosing agents is another effective office technique for treatment of first-, second-, and some third-degree hemorrhoids. One to 3 mL of a sclerosing solution (phenol in olive oil, sodium morrhuate, or quinine urea) is injected into the submucosa of each hemorrhoid. Few complications are associated with sclerotherapy, but infection and fibrosis have been reported.

Excision of Thrombosed External Hemorrhoids. Acutely thrombosed external hemorrhoids generally cause intense pain and a palpable perianal mass during the first 24 to 72 hours after thrombosis. The thrombosis can be effectively treated with an elliptical excision performed in the office under local anesthesia. Because the clot is usually loculated, simple incision and drainage is rarely effective. After 72 hours, the clot begins to resorb, and the pain resolves spontaneously. Excision is unnecessary, but sitz baths and analgesics are often helpful.

Operative Hemorrhoidectomy. A number of surgical procedures have been described for elective resection of symptomatic hemorrhoids. All are based on decreasing blood flow to the hemorrhoidal plexuses and excising redundant anoderm and mucosa.

Closed Submucosal Hemorrhoidectomy. The Parks or Ferguson hemorrhoidectomy involves resection of hemorrhoidal tissue and closure of the wounds with absorbable suture. The procedure may be performed in the prone or lithotomy position under local, regional, or general anesthesia. The anal canal is examined and an anal speculum inserted. The hemorrhoid cushions and associated redundant mucosa are identified and excised using an elliptical incision starting just distal to the anal verge and extending proximally to the anorectal ring. It is crucial to identify the fibers of the internal sphincter and carefully brush these away from the dissection in order to avoid injury to the sphincter. The apex of the hemorrhoidal plexus is then ligated and the hemorrhoid excised. The wound is then closed with a running absorbable suture. All three hemorrhoidal cushions may

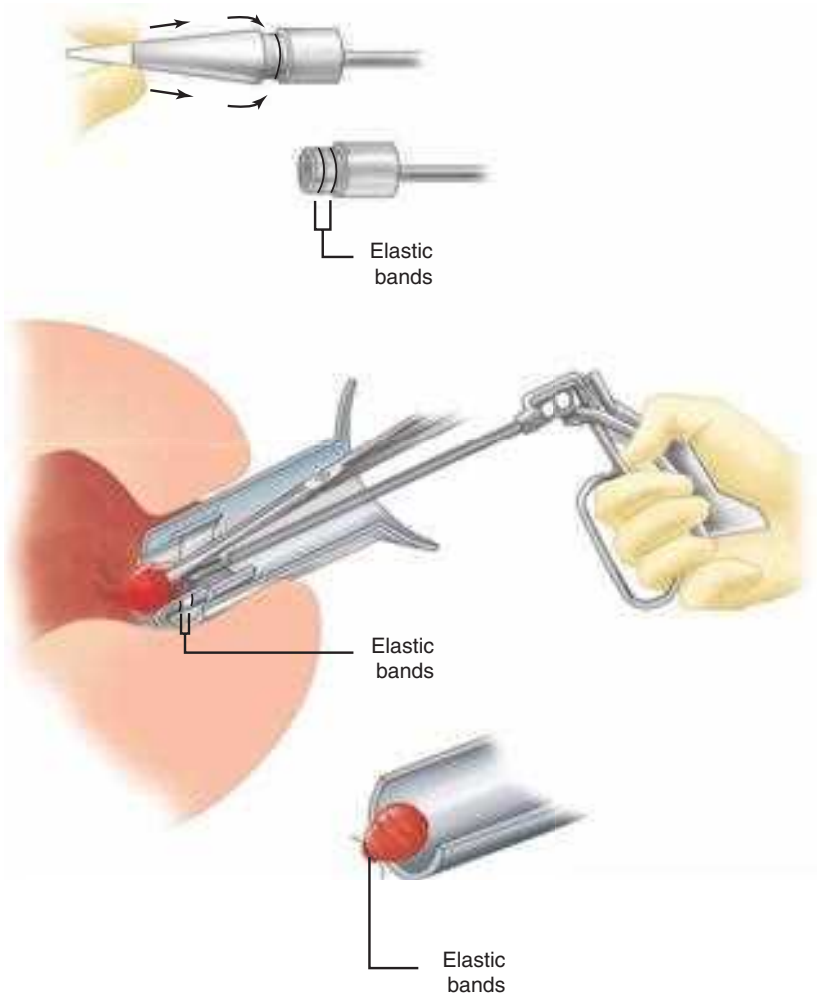

Figure 29-31. Rubber band ligation of internal hemorrhoids. The mucosa just proximal to the internal hemorrhoids is banded.

be removed using this technique; however, care should be taken to avoid resecting a large area of perianal skin in order to avoid postoperative anal stenosis (Fig. 29-32).

Open Hemorrhoidectomy. This technique, often called the Milligan and Morgan hemorrhoidectomy, follows the same principles of excision described earlier, but the wounds are left open and allowed to heal by secondary intention.

Whitehead's Hemorrhoidectomy. Whitehead's hemorrhoidectomy involves circumferential excision of the hemorrhoidal cushions just proximal to the dentate line. After excision, the rectal mucosa is then advanced and sutured to the dentate line. While some surgeons still use Whitehead's hemorrhoidectomy, most have abandoned this approach because of the risk of ectropion (*Whitehead's deformity*).

Procedure for Prolapse and Hemorrhoids/Stapled Hemorrhoidectomy. Procedure for prolapse and hemorrhoids (PPH) has been proposed as an alternative surgical approach. The term PPH has largely replaced stapled hemorrhoidectomy because the procedure does not involve excision of hemorrhoidal tissue, but instead pexes the redundant mucosa above the dentate line. PPH removes a short circumferential segment of rectal mucosa proximal to the dentate line using a circular stapler. This effectively ligates the venules feeding the hemorrhoidal plexus and fixes redundant mucosa higher in the anal canal. Several studies suggest that this procedure is safe and effective, is associated with less postoperative pain and disability, and has an equivalent risk of postoperative complications when compared to traditional hemorrhoidectomy.[97,98] Nevertheless, with increased use of this technique, serious and occasionally life-threatening complications have been described.[99]

Doppler-Guided Hemorrhoidal Artery Ligation. Another recent approach to treating symptomatic hemorrhoids is Doppler-guided hemorrhoidal artery ligation (also called transanal hemorrhoidal dearterioalization). In this procedure, a Doppler probe is used to identify the artery or arteries feeding the hemorrhoidal plexus. These vessels are then ligated. Early reports have shown promise, but long-term durability remains to be determined.[100]

Complications of Hemorrhoidectomy. Postoperative pain following excisional hemorrhoidectomy requires analgesia usually with oral narcotics. Nonsteroidal anti-inflammatory drugs, muscle relaxants, topical analgesics, and comfort measures, including sitz baths, are often useful as well. Urinary retention is a common complication following hemorrhoidectomy and occurs in 10% to 50% of patients. The risk of urinary retention can be minimized by limiting intraoperative and perioperative intravenous fluids and by providing adequate analgesia. Pain can also lead to *fecal impaction*. Risk of impaction may be decreased by preoperative enemas or a limited mechanical bowel preparation, liberal use of laxatives postoperatively, and adequate pain control. While a small amount of *bleeding*, especially with bowel movements, is to be expected, massive hemorrhage can occur after hemorrhoidectomy. Bleeding may occur

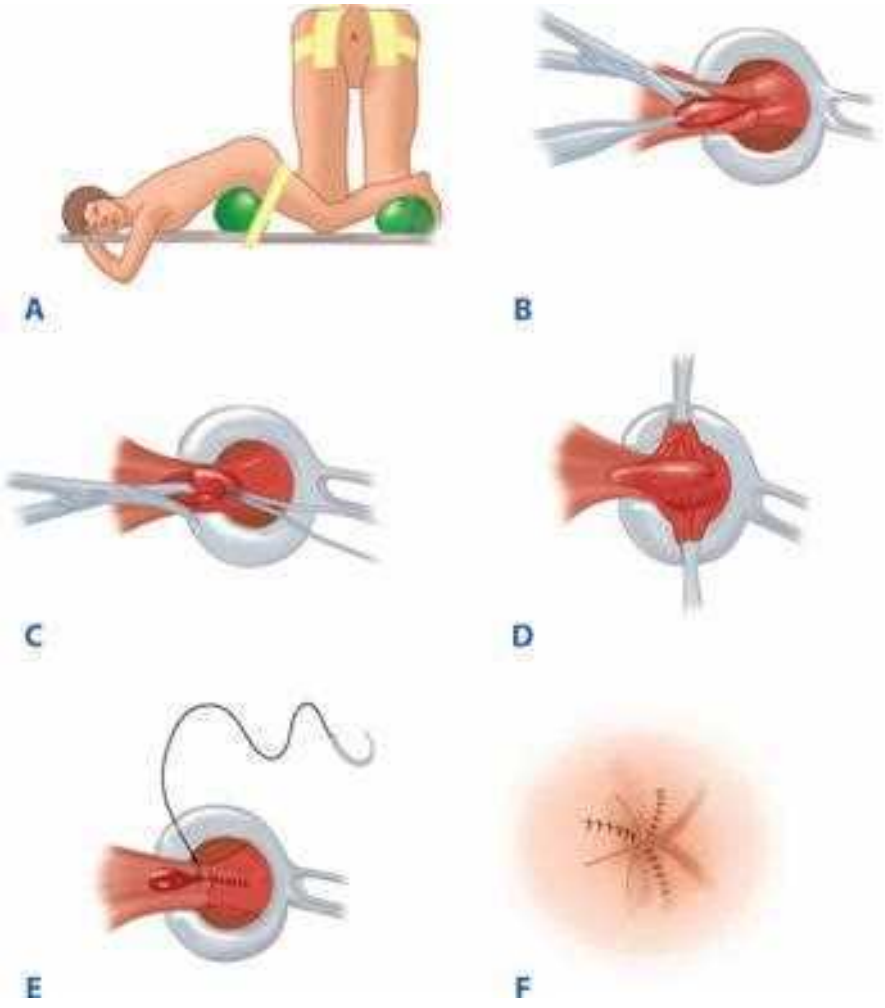

Figure 29-32. Technique of closed submucosal hemorrhoidectomy. **A.** The patient is in prone jackknife position. **B.** A Fansler anoscope is used for exposure. **C.** A narrow ellipse of anoderm is excised. **D.** A submucosal dissection of the hemorrhoidal plexus from the underlying anal sphincter is performed. **E.** Redundant mucosa is anchored to the proximal anal canal, and the wound is closed with a running absorbable suture. **F.** Additional quadrants are excised to complete the procedure.

in the immediate postoperative period (often in the recovery room) as a result of inadequate ligation of the vascular pedicle. This type of hemorrhage mandates an urgent return to the operating room where suture ligation of the bleeding vessel will often solve the problem. Bleeding may also occur 7 to 10 days after hemorrhoidectomy when the necrotic mucosa overlying the vascular pedicle sloughs. While some of these patients may be safely observed, others will require an exam under anesthesia to ligate the bleeding vessel or to oversew the wounds if no specific site of bleeding is identified. *Infection* is uncommon after hemorrhoidectomy; however, necrotizing soft tissue infection can occur with devastating consequences. Severe pain, fever, and urinary retention may be early signs of infection. If infection is suspected, emergent examination under anesthesia, drainage of abscess, and/or débridement of all necrotic tissue are required.

Long-term sequelae of hemorrhoidectomy include *incontinence, anal stenosis*, and *ectropion (Whitehead's deformity)*. Many patients experience transient incontinence to flatus, but these symptoms are usually short-lived, and few patients have permanent fecal incontinence. Anal stenosis may result from scarring after extensive resection of perianal skin. Ectropion may occur after Whitehead's hemorrhoidectomy.

Anal Fissure

A fissure in ano is a tear in the anoderm distal to the dentate line. The pathophysiology of anal fissure is thought to be related to trauma from either the passage of hard stool or prolonged diarrhea. A tear in the anoderm causes spasm of the internal anal sphincter, which results in pain, increased tearing, and decreased blood supply to the anoderm. This cycle of pain, spasm, and ischemia contributes to development of a poorly healing wound that becomes a *chronic fissure*. The vast majority of anal fissures occur in the posterior midline. Ten percent to 15% occur in the anterior midline. Less than 1% of fissures occur off midline.

Symptoms and Findings. Anal fissure is extremely common. Characteristic symptoms include tearing pain with defecation and hematochezia (usually described as blood on the toilet paper). Patients may also complain of a sensation of intense and painful anal spasm lasting for several hours after a bowel movement. On physical examination, the fissure can often be seen in the anoderm by gently separating the buttocks. Patients are often too tender to tolerate digital rectal examination, anoscopy, or proctoscopy. An *acute fissure* is a superficial tear of the distal anoderm and almost always heals with medical management. *Chronic fissures* develop ulceration and heaped-up edges with the white fibers of the internal anal sphincter visible at the base of the ulcer. There often is an associated external skin tag and/or a hypertrophied anal papilla internally. These fissures are more challenging to treat and may require surgery. A lateral location of a chronic anal fissure may be evidence of an underlying disease such as Crohn's disease, HIV, syphilis, tuberculosis,

or leukemia. If the diagnosis is in doubt or there is suspicion of another cause for the perianal pain such as abscess or fistula, an examination under anesthesia may be necessary.

Treatment. Therapy focuses on breaking the cycle of pain, spasm, and ischemia thought to be responsible for development of fissure in ano. First-line therapy to minimize anal trauma includes bulk agents, stool softeners, and warm sitz baths. The addition of 2% lidocaine jelly or other analgesic creams can provide additional symptomatic relief. Nitroglycerin ointment has been used locally to improve blood flow but often causes severe headaches. Both oral and topical calcium channel blockers (diltiazem and nifedipine) have also been used to heal fissures and may have fewer side effects than topical nitrates.[97] Newer agents, such as arginine (a nitric oxide donor) and topical bethanechol (a muscarinic agonist), have also been used to treat fissures. Medical therapy is effective in most acute fissures, but will heal only approximately 50% of chronic fissures.

Botulinum toxin (Botox) causes temporary muscle paralysis by preventing acetylcholine release from presynaptic nerve terminals. Injection of botulinum toxin is used in some centers as an alternative to surgical sphincterotomy for chronic fissure. Although there are few long-term complications from the use of botulinum toxin, healing appears to be equivalent to other medical therapies.[98,101]

Surgical therapy has traditionally been recommended for chronic fissures that have failed medical therapy, and lateral internal sphincterotomy is the procedure of choice. The aim of this procedure is to decrease spasm of the internal sphincter by dividing a portion of the muscle. Approximately 30% of the internal sphincter fibers are divided laterally by using either an open (Fig. 29-33) or closed (Fig. 29-34) technique. Healing is achieved in more than 95% of patients using this technique,

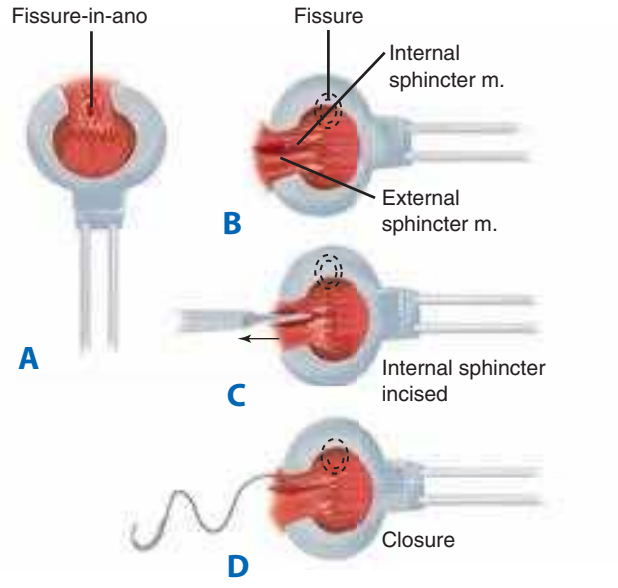

Figure 29-33. **A** through **D.** Open lateral internal sphincterotomy for fissure in ano. m = muscle.

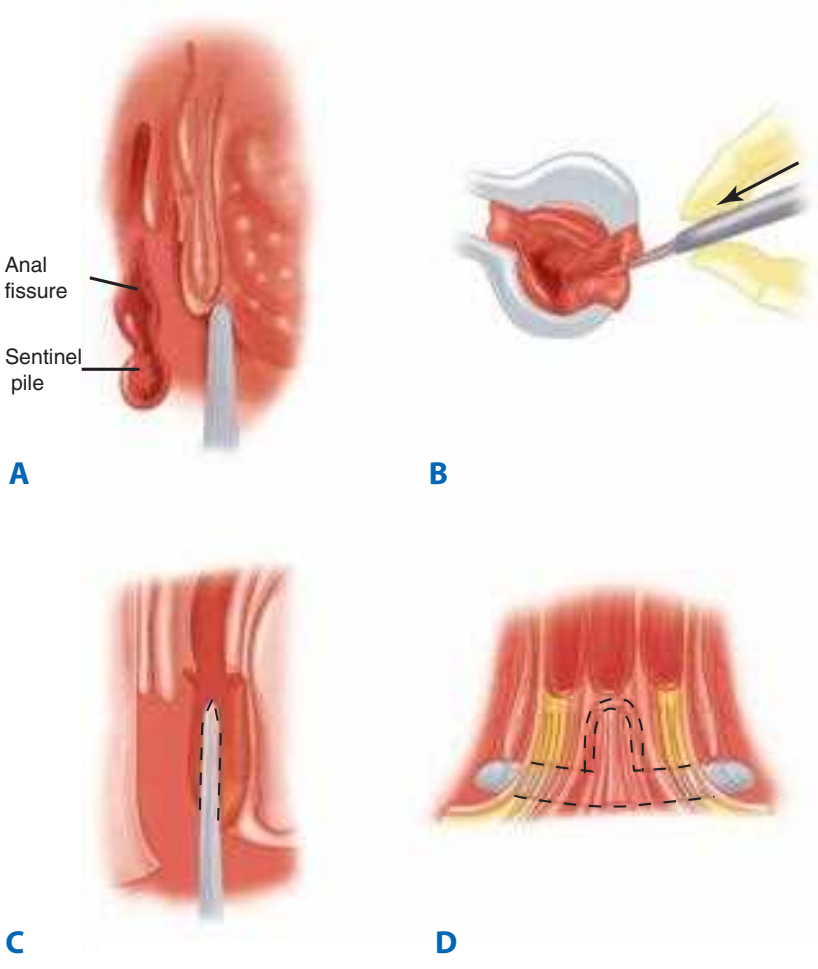

Figure 29-34. **A** through **D.** Closed lateral internal sphincterotomy for fissure in ano.

and most patients experience immediate pain relief. Recurrence occurs in less than 10% of patients, and the risk of incontinence (usually to flatus) ranges from 5% to 15%. Advancement flaps (VY) with or without sphincterotomy have also been reported to successfully treat chronic fissures.

Anorectal Sepsis and Cryptoglandular Abscess

Relevant Anatomy. The majority of anorectal suppurative disease results from infections of the anal glands (cryptoglandular infection) found in the intersphincteric plane. Their ducts traverse the internal sphincter and empty into the anal crypts at the level of the dentate line. Infection of an anal gland results in the formation of an abscess that enlarges and spreads along one of several planes in the perianal and perirectal spaces. The *perianal space* surrounds the anus and laterally becomes continuous with the fat of the buttocks. The *intersphincteric space* separates the internal and external anal sphincters. It is continuous with the perianal space distally and extends cephalad into the rectal wall. The *ischiorectal space (ischiorectal fossa)* is located lateral and posterior to the anus and is bounded medially by the external sphincter, laterally by the ischium, superiorly by the levator ani, and inferiorly by the transverse septum. The ischiorectal space contains the inferior rectal vessels and lymphatics. The two ischiorectal spaces connect posteriorly above the anococcygeal ligament but below the levator ani muscle, forming the *deep postanal space*. The *supralevator spaces* lie above the levator ani on either side of the rectum and communicate posteriorly. The anatomy of these spaces influences the location and spread of cryptoglandular infection (Fig. 29-35).

As an abscess enlarges, it spreads in one of several directions. A *perianal abscess* is the most common manifestation and appears as a painful swelling at the anal verge. Spread through the external sphincter below the level of the puborectalis produces an *ischiorectal abscess*. These abscesses may become extremely large and may not be visible in the perianal region. Digital rectal exam will reveal a painful swelling laterally in the ischiorectal fossa. *Intersphincteric abscesses* occur in the intersphincteric space and are notoriously difficult to diagnose, often requiring an examination under anesthesia. *Pelvic* and *supralevator abscesses* are uncommon and may result from extension of an intersphincteric or ischiorectal abscess upward or extension of an intraperitoneal abscess downward (Fig. 29-36).

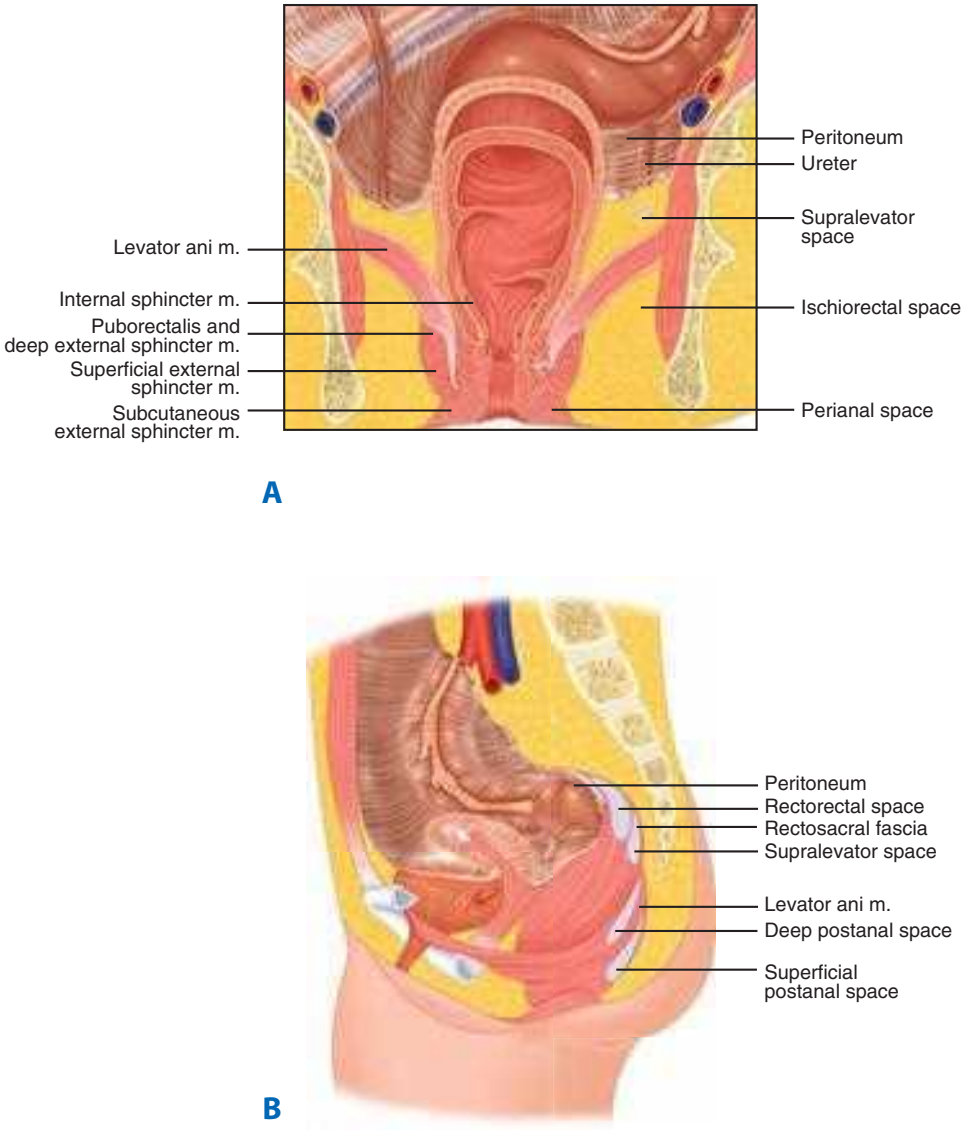

Figure 29-35. Anatomy of perianorectal spaces. (**A**) Anterior view and (**B**) lateral view. m = muscle.

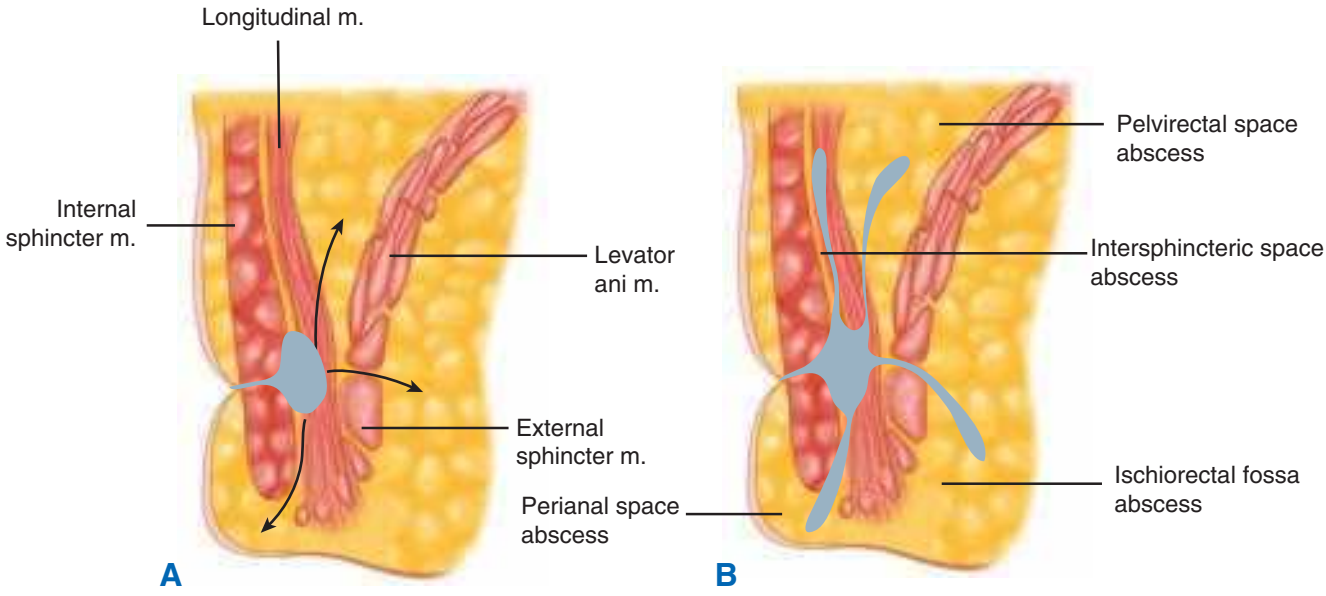

Figure 29-36. **A** and **B.** Pathways of anorectal infection in perianal spaces. m = muscle.

Diagnosis. Severe anal pain is the most common presenting complaint. A palpable mass is often detected by inspection of the perianal area or by digital rectal examination. Occasionally, patients will present with fever, urinary retention, or life-threatening sepsis. The diagnosis of a perianal or ischiorectal abscess can usually be made with physical exam alone (either in the office or in the operating room). However, complex or atypical presentations may require imaging studies such as CT or MRI to fully delineate the anatomy of the abscess.

Treatment. Anorectal abscesses should be treated by drainage as soon as the diagnosis is established. If the diagnosis is in question, an examination and drainage under anesthesia are often the most expeditious ways both to confirm the diagnosis and to treat the problem. Delayed or inadequate treatment may occasionally cause extensive and life-threatening suppuration with massive tissue necrosis and septicemia. Antibiotics are only indicated if there is extensive overlying cellulitis or if the patient is immunocompromised, has diabetes mellitus, or has valvular heart disease. Antibiotics alone are ineffective at treating perianal or perirectal infection.

Perianal Abscess

Most perianal abscesses can be drained under local anesthesia in the office, clinic, or emergency room. Larger, more complicated abscesses may require drainage in the operating room. A skin incision is created, and a disk of skin excised to prevent premature closure. No packing is necessary, and sitz baths are started the next day (Fig. 29-37).

Ischiorectal Abscess

An ischiorectal abscess causes diffuse swelling in the ischiorectal fossa that may involve one or both sides, forming a "horseshoe" abscess. Simple ischiorectal abscesses are drained through an incision in the overlying skin. Horseshoe abscesses require drainage of the deep postanal space and often require counterincisions over one or both ischiorectal spaces (Fig. 29-38).

Intersphincteric Abscess

Intersphincteric abscesses are notoriously difficult to diagnose because they produce little swelling and few perianal signs of infection. Pain is typically described as being deep and "up inside" the anal area and is usually exacerbated by coughing or sneezing. The pain is so intense that it usually precludes a digital rectal examination. The diagnosis is made based on a high index of suspicion and usually requires an examination under anesthesia. Once identified, an intersphincteric abscess can be drained through a limited, usually posterior, internal sphincterotomy.

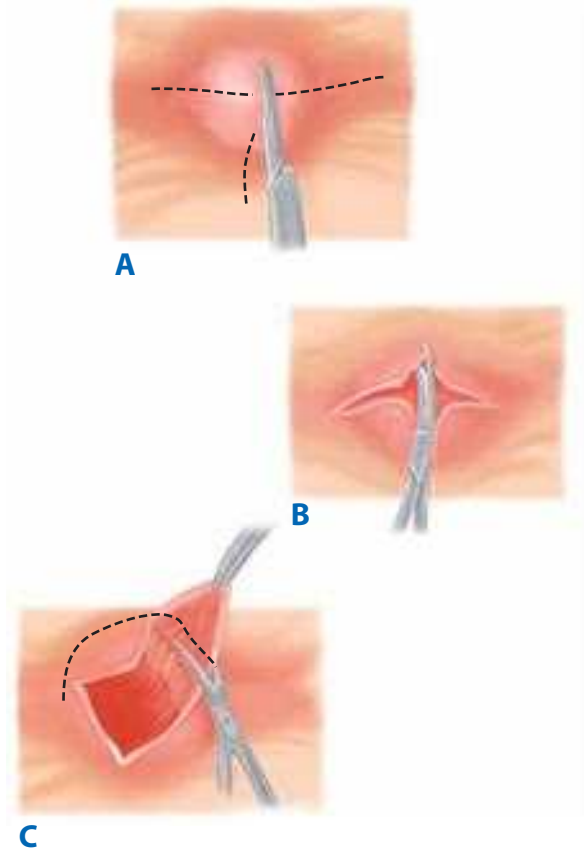

Figure 29-37. **A** through **C.** Technique of drainage of perianal abscess.

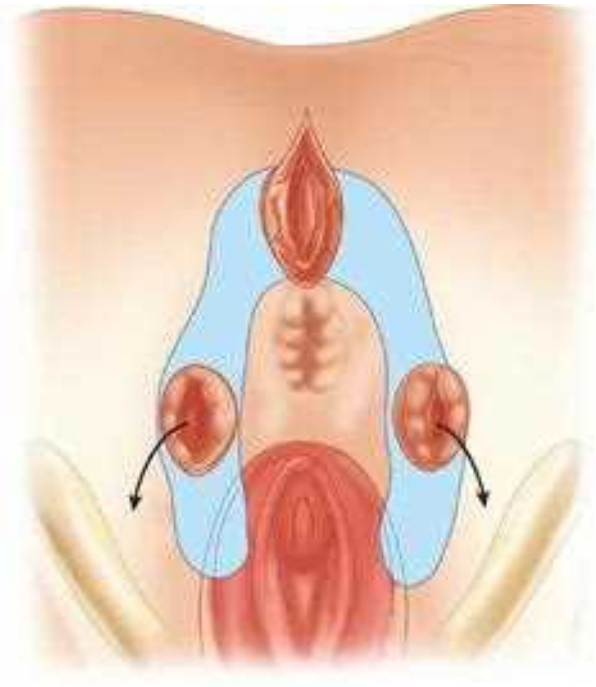

Figure 29-38. Drainage of horseshoe abscess. The deep postanal space is entered, incising the anococcygeal ligament. Counter drainage incisions are made for each limb of the ischiorectal space.

Supralevator Abscess

This type of abscess is uncommon and can be difficult to diagnose. Because of its proximity to the peritoneal cavity, supralevator abscesses can mimic intra-abdominal conditions. Digital rectal examination may reveal an indurated, bulging mass above the anorectal ring. It is essential to identify the origin of a supralevator abscess prior to treatment. If the abscess is secondary to an upward extension of an intersphincteric abscess, it should be drained through the rectum. If it is drained through the ischiorectal fossa, a complicated, suprasphincteric fistula may result. If a supralevator abscess arises from the upward extension of an ischiorectal abscess, it should be drained through the ischiorectal fossa. Drainage of this type of abscess through the rectum may result in an extrasphincteric fistula. If the abscess is secondary to intra-abdominal disease, the primary process requires treatment and the abscess is drained via the most direct route (transabdominally, rectally, or through the ischiorectal fossa).

Perianal Sepsis in the Immunocompromised Patient

The immunocompromised patient with perianal pain presents a diagnostic dilemma. Because of leukopenia, these patients may develop serious perianal infection without any of the cardinal signs of inflammation. While broad-spectrum antibiotics may cure some of these patients, an exam under anesthesia should not be delayed because of neutropenia. An increase in pain or fever and/or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.[102]

Necrotizing Soft Tissue Infection of the Perineum

Necrotizing soft tissue infection of the perineum is a rare, but lethal, condition. Most of these infections are polymicrobial and synergistic. The source of sepsis is commonly an undrained or inadequately drained cryptoglandular abscess or a urogenital infection. Occasionally, these infections may be encountered postoperatively (e.g., after hemorrhoidectomy). Immunocompromised patients and diabetic patients are at increased risk.

Physical examination may reveal necrotic skin, bullae, or crepitus. Patients often have signs of systemic toxicity and may be hemodynamically unstable. A high index of suspicion is necessary because perineal signs of severe infection may be minimal and prompt surgical intervention can be lifesaving.

Surgical débridement of all nonviable tissue is required to treat all necrotizing soft tissue infections. Multiple operations may be necessary to ensure that all necrotic tissue has been resected. Broad-spectrum antibiotics are frequently employed, but adequate surgical débridement remains the mainstay of therapy. Colostomy may be required if extensive resection of the sphincter is required or if stool contamination of the perineum makes wound management difficult. Despite early recognition and adequate surgical therapy, the mortality of necrotizing perineal soft tissue infections remains approximately 50%.

Fistula In Ano

Drainage of an anorectal abscess results in cure for about 50% of patients. The remaining 50% develop a persistent *fistula in ano*. The fistula usually originates in the infected crypt (*internal opening*) and tracks to the *external opening*, usually the site of prior drainage. The course of the fistula can often be predicted by the anatomy of the previous abscess.

While the majority of fistulas are cryptoglandular in origin, trauma, Crohn's disease, malignancy, radiation, or unusual infections (tuberculosis, actinomycosis, and chlamydia) may also produce fistulas. A complex, recurrent, or nonhealing fistula should raise the suspicion of one of these diagnoses.

Diagnosis. Patients present with persistent drainage from the internal and/or external openings. An indurated tract is often palpable. Although the external opening is often easily identifiable, identification of the internal opening may be more challenging. Goodsall's rule can be used as a guide in determining the location of the internal opening (Fig. 29-39). In general, fistulas with an external opening *anteriorly* connect to the internal opening by a *short, radial tract*. Fistulas with an external opening *posteriorly* track in a *curvilinear fashion to the posterior midline*. However, exceptions to this rule often occur if an anterior

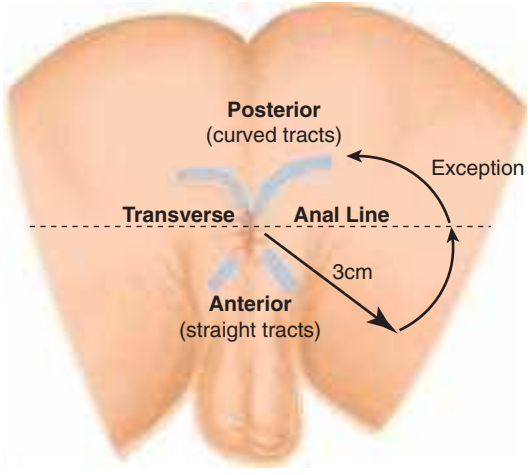

Figure 29-39. Goodsall's rule to identify the internal opening of fistulas in ano.

external opening is greater than 3 cm from the anal margin. Such fistulas usually track to the posterior midline.

Fistulas are categorized based on their relationship to the anal sphincter complex, and treatment options are based on these classifications. An *intersphincteric fistula* tracks through the distal internal sphincter and intersphincteric space to an external opening near the anal verge (Fig. 29-40A). A *transsphincteric fistula* often results from an ischiorectal abscess and extends through both the internal and external sphincters (Fig. 29-40B). A *suprasphincteric fistula* originates in the intersphincteric plane and tracks up and around the entire external sphincter (Fig. 29-40C). An *extrasphincteric fistula* originates in the rectal wall and tracks around both sphincters to exit laterally, usually in the ischiorectal fossa (Fig. 29-40D).

Treatment. The goal of treatment of fistula in ano is eradication of sepsis without sacrificing continence. Because fistulous tracks encircle variable amounts of the sphincter complex, surgical treatment is dictated by the location of the internal and external openings and the course of the fistula. The external opening is usually visible as a red elevation of granulation tissue with or without concurrent drainage. The internal opening may be more difficult to identify. Injection of hydrogen peroxide or dilute methylene blue may be helpful. Care must be taken to avoid creating an artificial internal opening (thus often converting a simple fistula into a complex fistula).

10 ▶

Simple intersphincteric fistulas can often be treated by *fistulotomy* (opening the fistulous tract), curettage, and healing by secondary intention (see Fig. 29-40A). *"Horseshoe" fistulas* usually have an internal opening in the posterior midline and extend anteriorly and laterally to one or both ischiorectal spaces by way of the deep postanal space. Treatment of a transsphincteric fistula depends on its location in the sphincter complex.

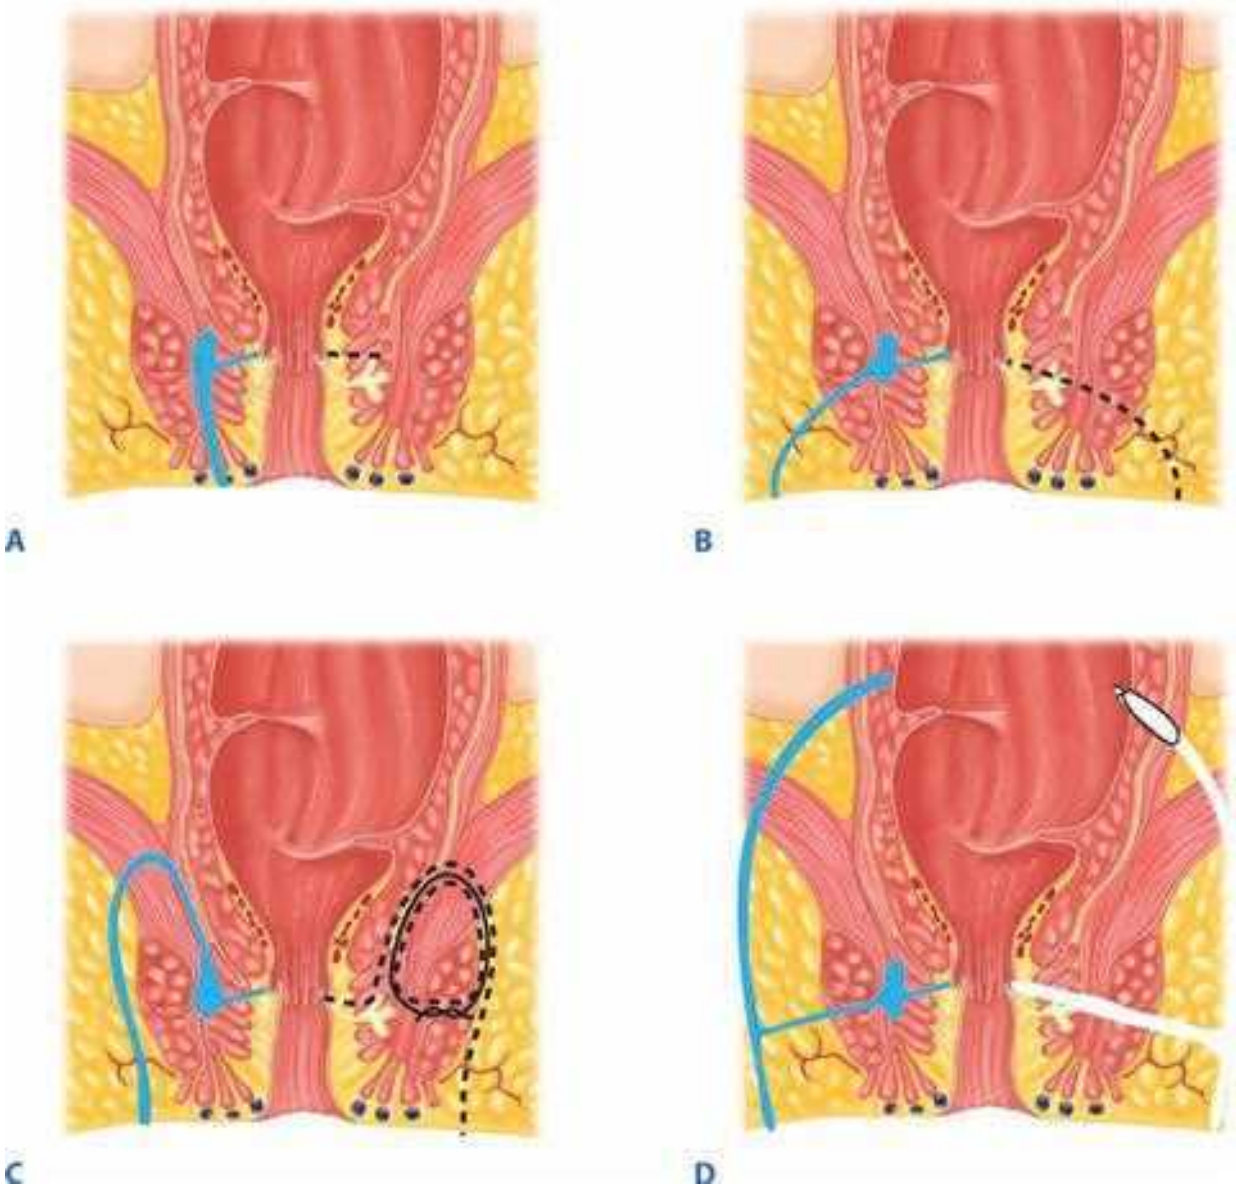

Figure 29-40. The four major categories of fistula in ano (*left side of drawings*) and the usual operative procedure to correct the fistula (*right side of drawings*). **A.** Intersphincteric fistula with simple low tract. **B.** Uncomplicated transsphincteric fistula. **C.** Uncomplicated suprasphincteric fistula. **D.** Extrasphincteric fistula secondary to anal fistula. *(Data from Gordon PH, Nivatvongs S, eds.* Principles and Practice of Surgery for the Colon, Rectum, and Anus. *2nd ed. New York: Marcel Dekker, Inc.; 1999:256-260.)*

Fistulas that include less than 30% of the sphincter muscles can often be treated by sphincterotomy without significant risk of major incontinence (see Fig. 29-40B). High transsphincteric fistulas, which encircle a greater amount of muscle, are more safely treated by initial placement of a *seton* (see below). Similarly, suprasphincteric fistulas are usually treated with seton placement (see Fig. 29-40C). Extrasphincteric fistulas are rare, and treatment depends on both the anatomy of the fistula and its etiology. In general, the portion of the fistula outside the sphincter should be opened and drained. A primary tract at the level of the dentate line may also be opened if present. Complex fistulas with multiple tracts may require numerous procedures to control sepsis and facilitate healing. Liberal use of drains and setons is helpful. Failure to heal may ultimately require fecal diversion (see Fig. 29-40D). Complex and/or nonhealing fistulas may result from Crohn's disease, malignancy, radiation proctitis, or unusual infection. Proctoscopy should be performed in all cases of complex and/or nonhealing fistulas to assess the health of the rectal mucosa. Biopsies of the fistula tract should be taken to rule out malignancy.

A *seton* is a drain placed through a fistula to maintain drainage and/or induce fibrosis. *Cutting setons* consist of a suture or a rubber band that is placed through the fistula and intermittently tightened in the office. Tightening the seton results in fibrosis and gradual division of the sphincter, thus eliminating the fistula while maintaining continuity of the sphincter. A *noncutting seton* is a soft plastic drain (often a vessel loop) placed in the fistula to maintain drainage. The fistula tract may subsequently be laid open with less risk of incontinence because scarring prevents retraction of the sphincter. Alternatively, the seton may be left in place for chronic drainage. Higher fistulas may be treated by an *endorectal advancement flap* (see below). *Fibrin glue* and a variety of collagen-based plugs also have been used to treat persistent fistulas with variable results. A more recent technique, *ligation of the intersphincteric fistula tract (LIFT)*, also shows promise. In this procedure, the fistula is identified in the intersphincteric plane (usually by placement of a lacrimal probe), divided, and the two ends ligated. Early reports have shown success with this technique, but long-term outcome is not yet known.[103,104]

Rectovaginal Fistula

A rectovaginal fistula is a connection between the vagina and the rectum or anal canal proximal to the dentate line. Rectovaginal fistulas are classified as *low* (rectal opening close to the dentate line and vaginal opening in the fourchette), *middle* (vaginal opening between the fourchette and cervix), or *high* (vaginal opening near the cervix). Low rectovaginal fistulas are commonly caused by obstetric injuries or trauma from a foreign body. Mid-rectovaginal fistulas may result from more severe obstetric injury, but also occur after surgical resection of a mid-rectal neoplasm, radiation injury, or extension of an undrained abscess. High rectovaginal fistulas result from operative or radiation injury. Complicated diverticulitis may cause a colovaginal fistula. Crohn's disease can cause rectovaginal fistulas at all levels, as well as colovaginal and enterovaginal fistulas.

Diagnosis. Patients describe symptoms varying from the sensation of passing flatus from the vagina to the passage of solid stool from the vagina. Most patients experience some degree of fecal incontinence. Contamination may result in *vaginitis*. Large fistulas may be obvious on anoscopic and/or vaginal speculum examination, but smaller fistulas may be difficult to locate. Occasionally, a barium enema or vaginogram may identify these fistulas. Endorectal ultrasound may also be useful. With the patient in the prone position, installation of methylene blue into the rectum while a tampon is in the vagina may confirm the presence of a small fistula.

Treatment. The treatment of rectovaginal fistula depends on the size, location, etiology, and condition of surrounding tissues. Because up to 50% of fistulas caused by obstetric injury heal spontaneously, it is prudent to wait 3 to 6 months before embarking on surgical repair in these patients. If the fistula was caused by a cryptoglandular abscess, drainage of the abscess may allow spontaneous closure.

Low and mid-rectovaginal fistulas are usually best treated with an endorectal advancement flap. The principle of this procedure is based on the advancement of healthy mucosa, submucosa, and circular muscle over the rectal opening (the high-pressure side of the fistula) to promote healing (Fig. 29-41). If a sphincter injury is present, an overlapping sphincteroplasty should be performed concurrently. Fecal diversion is rarely required. High rectovaginal, colovaginal, and enterovaginal fistulas are usually best treated via a transabdominal approach. The diseased tissue, which caused the fistula (upper rectum, sigmoid colon, or small bowel), is resected and the hole in the vagina closed. Healthy tissue, such as omentum or muscle, frequently is interposed between the bowel anastomosis and the vagina to prevent recurrence.

Rectovaginal fistulas caused by Crohn's disease, radiation injury, or malignancy almost never heal spontaneously. In Crohn's disease, treatment is based on adequate drainage of perianal sepsis and nutritional support. An endorectal advancement flap may be performed if the rectum is spared from active Crohn's disease. Fistulas resulting from radiation damage are not amenable to local repair with an advancement flap because of damage to the surrounding rectal and vaginal tissues. Such mid- and high rectovaginal fistulas are occasionally repaired successfully with a transabdominal approach in which healthy tissue (omentum, muscle, or nonradiated bowel) is interposed between the damaged rectum and vagina. Fistulas caused by malignancy should be treated with resection of the tumor. Because differentiating radiation damage from malignancy can be extremely difficult, all fistulas resulting from radiation should be biopsied to rule out the presence of cancer.

Perianal Dermatitis

Pruritus Ani. Pruritus ani (severe perianal itching) is a common problem with a multitude of etiologies. Surgically correctable (anatomic) causes include prolapsing hemorrhoids, ectropion, fissure, fistula, and neoplasms. Perianal infection may also present with pruritus ani. Infections may be caused by fungus (*Candida* species and *Epidermophyton* organisms), parasites (*Enterobius vermicularis* [pinworms], *Pediculus pubis* [a louse], and *Sarcoptes scabiei* [scabies]), bacteria (*Corynebacterium minutissimum* [erythrasma] and *T. pallidum* [syphilis]), or viruses (HPV [condyloma acuminata]). Antibiotic use may also cause itching, usually by precipitating fungal infection. Noninfectious dermatologic causes include seborrhea, psoriasis, and contact dermatitis. Contact dermatitis can be particularly troublesome because many over-the-counter topical agents used by patients to relieve itching may exacerbate the problem. Occasionally, systemic diseases such as jaundice and diabetes may present with pruritus ani.

Despite the myriad of causes, the majority of pruritus ani is idiopathic and probably related to local hygiene, neurogenic, or

Figure 29-41. New York: Marcel Dekker, Inc.; 1999:412. Permission conveyed through Copyright Clearance Center, Inc.)*

psychogenic causes. Treatment focuses on removal of irritants, improving perianal hygiene, dietary adjustments, and avoiding scratching. Biopsy and/or culture may be required to rule out an infectious or dermatologic cause. Hydrocortisone ointment 0.5% to 1.0% can provide symptomatic relief but should not be used for prolonged periods of time because of the risk of dermal atrophy. Skin barriers such as Calmoseptine can also provide relief. Systemic antihistamines or tricyclic antidepressants have also been used with some success.

Nonpruritic Lesions. Several perianal skin conditions may present with perianal skin changes. Leprosy, amebiasis, actinomycosis, and lymphogranuloma venereum produce characteristic perianal lesions. Neoplasms such as squamous intraepithelial lesions, Paget's disease, and invasive carcinomas may also appear first in the perianal skin. Biopsy can usually distinguish these diagnoses.

Sexually Transmitted Diseases

Bacterial Infections. Proctitis is a common symptom of anorectal bacterial infection. *N. gonorrhoeae* is the most common bacterial cause of proctitis and causes pain, tenesmus, rectal bleeding, and mucus discharge. *Chlamydia trachomatis* infection may be asymptomatic or may produce similar symptoms. *T. pallidum*, the microbe causing syphilis, causes a chancre at the site of inoculation, which may be asymptomatic or may present as an atypical fissure (primary syphilis). Condyloma lata are characteristic of secondary syphilis. Chancroid, caused by *Haemophilus ducreyi*, is a disease manifested by multiple painful, bleeding lesions. Inguinal lymphadenopathy and fluctuant, draining lymph nodes are characteristic. *Donovania granulomatis* infection produces shiny, red masses on the perineum (granuloma inguinale). Diarrheal illnesses caused by organisms such as *Campylobacter* or *Shigella* may also be sexually transmitted.

Treatment consists of antimicrobial agents directed against the infecting organism.

Parasitic Infections. *Entamoeba histolytica* is an increasingly common sexually transmitted disease. Amebas produce ulcerations in the gastrointestinal mucosa and can infect any part of the gut. Symptoms include diarrhea, abdominal pain, and tenesmus. *Giardia lamblia* is also common and produces diarrhea, abdominal pain, and malaise.

Viral Infections

Herpes Simplex Virus. Herpes proctitis is extremely common. Proctitis is usually caused by type 2 herpes simplex virus and less commonly by type 1 herpes simplex virus. Patients complain of severe, intractable perianal pain and tenesmus. Pain often precedes the development of characteristic vesicles, and these patients may require an examination under anesthesia to exclude another diagnosis such as an intersphincteric abscess. Diagnosis is confirmed by viral culture of tissue or vesicular fluid.

Human Papillomavirus. HPV causes condyloma acuminata (anogenital warts) and is associated with squamous intraepithelial lesions and squamous cell carcinoma (see previous section, "Anal Canal and Perianal Tumors"). Condylomas occur in the perianal area or in the squamous epithelium of the anal canal. Occasionally, the mucosa of the lower rectum may be affected. There are approximately 30 serotypes of HPV. As previously mentioned, HPV types 16 and 18, in particular, appear to predispose to malignancy and often cause flat dysplasia in skin unaffected by warts. In contrast, HPV types 6 and 11 commonly cause warts, but do not appear to cause malignant degeneration.

Treatment of anal condyloma depends on the location and extent of disease. Small warts on the perianal skin and distal anal canal may be treated in the office with topical application of bichloracetic acid or podophyllin. Although 60% to 80% of patients will respond to these agents, recurrence and reinfection are common. Imiquimod (Aldara) is an immunomodulator that was recently introduced for topical treatment of several viral infections, including anogenital condyloma.[105] Initial reports suggest that this agent is highly effective in treating condyloma located on the perianal skin and distal anal canal. Larger and/or more numerous warts require excision and/or fulguration in the operating room. Excised warts should be sent for pathologic examination to rule out dysplasia or malignancy. It is important to note that prior use of podophyllin may induce histologic changes that mimic dysplasia. The recent introduction of a vaccine against HPV holds promise for preventing anogenital condylomas.

Human Immunodeficiency Virus. See later section, "The Immunocompromised Patient."

Pilonidal Disease

Pilonidal disease (cyst, infection) consists of a hair-containing sinus or abscess occurring in the intergluteal cleft. Although the etiology is unknown, it is speculated that the cleft creates a suction that draws hair into the midline pits when a patients sits. These ingrown hairs may then become infected and present acutely as an abscess in the sacrococcygeal region. Once an acute episode has resolved, recurrence is common.

An acute abscess should be incised and drained as soon as the diagnosis is made. Because these abscesses are usually very superficial, this procedure can often be performed in the office, clinic, or emergency room under local anesthetic. Because midline wounds in the region heal poorly, some surgeons recommend using an incision *lateral* to the intergluteal cleft. A number of procedures have been proposed to treat a chronic pilonidal sinus. The simplest method involves unroofing the tract, curetting the base, and marsupializing the wound. The wound must then be kept clean and free of hair until healing is complete (often requiring weekly office visits for wound care). Alternatively, a small lateral incision can be created and the pit excised. This method is effective for most primary pilonidal sinuses. In general, extensive resection should be avoided. Complex and/or recurrent sinus tracts may require more extensive resection and closure with a Z-plasty, advancement flap, or rotational flap.

Hidradenitis Suppurativa

Hidradenitis suppurativa is an infection of the cutaneous apocrine sweat glands. Infected glands rupture and form subcutaneous sinus tracts. The infection may mimic complex anal fistula disease, but stops at the anal verge because there are no apocrine glands in the anal canal. Treatment involves incision and drainage of acute abscesses and unroofing of all chronically inflamed fistulas and débridement of granulation tissue. Radical excision and skin grafting are almost never necessary.

TRAUMA

Penetrating Colorectal Injury

Colorectal injury is common following penetrating trauma to the abdomen and has historically been associated with high mortality. In the first half of the twentieth century, the mortality rate from colorectal injury was as high as 90%. The introduction of exteriorization of colonic injuries and fecal diversion during World War II dramatically decreased mortality, and this principle has governed the management of large bowel injury for over 50 years. Recently, however, this practice was challenged, and trauma surgeons are increasingly performing primary repairs in selected patients.

Management of colonic injury depends on the mechanism of injury, the delay between the injury and surgery, the overall condition and stability of the patient, the degree of peritoneal contamination, and the condition of the injured colon. A primary repair may be considered in hemodynamically stable patients with few additional injuries and minimal contamination if the colon appears otherwise healthy. Contraindications to primary repair include shock, injury to more than two other organs, mesenteric vascular damage, and extensive fecal contamination. A delay of greater than 6 hours between the injury and the operation also is associated with increased morbidity and mortality and is a relative contraindication to primary repair. Injuries caused by high-velocity gunshot wounds or blast injuries are often associated with multiple intra-abdominal injuries and tissue loss and therefore are usually treated by fecal diversion after débridement of all nonviable tissue. Patient factors, such as medical comorbidities, advanced age, and the presence of tumor or radiation injury, must also be considered (Table 29-6).

Like injuries to the intraperitoneal colon, penetrating trauma to the rectum traditionally has been associated with high morbidity and mortality. Primary repair of the rectum is more difficult than primary repair of the colon, however, and most rectal injuries are associated with significant contamination. For that reason, the majority of penetrating rectal injuries should be treated with proximal fecal diversion and copious irrigation of

Table 29-6

Criteria for use of an ostomy

Injuring agent factors
High-velocity bullet wounds
Shotgun wounds
Explosive blast wounds
Crush injury
Patient factors
Presence of tumor
Radiated tissue
Medical condition
Advanced age
Injury factors
Inflamed tissue
Advanced infection
Distal obstruction
Local foreign body
Impaired blood supply
Mesenteric vascular damage
Shock with blood pressure <80/60 mmHg
Hemorrhage >1000 mL
More than two organs (especially kidney) injured
Interval to operation >6 h (pancreatic, splenic, hepatic)
Extensive injury requiring resection
Major abdominal wall loss
Thoracoabdominal penetration

the rectum (distal rectal washout). Small, clean rectal injuries may be closed primarily without fecal diversion in an otherwise stable patient. Intractable rectal bleeding may require angiographic embolization. Very rarely, hemorrhage or extensive tissue loss (especially if the anal sphincter is severely damaged) may require an emergent APR. However, this operation should be avoided, if at all possible, because of the morbidity associated with an extensive pelvic dissection in a severely injured patient.

Blunt Colorectal Injury

Blunt injury to the colon and rectum is considerably less common than penetrating injury. Nevertheless, blunt trauma can cause colon perforation, and shear injury to the mesentery can devascularize the intestine. Management of these injuries should follow the same principles outlined for management of penetrating injuries. Small perforations with little contamination in a stable patient may be closed primarily; more extensive injury requires fecal diversion. A serosal hematoma alone does not mandate resection, but the bowel should be carefully inspected to ensure that there is not an associated perforation or significant bowel ischemia.

Blunt injury to the rectum may result from significant trauma, such as a pelvic crush injury, or may result from local trauma caused by an enema or foreign body. Crush injuries, especially with an associated pelvic fracture, are often associated with significant rectal damage and contamination. These patients require débridement of all nonviable tissue, proximal fecal diversion, and a distal rectal washout, with or without drain placement. Blunt trauma from an enema or foreign body may produce a mucosal hematoma, which requires no surgical treatment if the mucosa is intact. Small mucosal tears may be closed primarily if the bowel is relatively clean and there is little contamination.

Iatrogenic Injury

Intraoperative Injury. The colon and rectum are at risk for inadvertent injury during other procedures, especially during pelvic operations. The key to managing these injuries is *early recognition*. The vast majority of iatrogenic colorectal injuries may be closed primarily if there is little contamination and if the patient is otherwise stable. Delayed recognition of colorectal injuries may result in significant peritonitis and life-threatening sepsis. In these cases, fecal diversion is almost always required, and the patient may need repeated exploration for drainage of abscesses.

Injury from Barium Enema. Colorectal injury from a barium enema is an extremely rare complication associated with a high rate of morbidity and mortality. Perforation with spillage of barium, especially above the peritoneal reflection, may result in profound peritonitis, sepsis, and a systemic inflammatory response. If the perforation is recognized early, it may be closed primarily and the abdomen irrigated to remove stool and barium. However, if the patient has developed sepsis, fecal diversion (with or without bowel resection) is almost always required. Rarely, a small mucosal injury to the extraperitoneal rectum may be managed with bowel rest, broad-spectrum antibiotics, and close observation.

Colonoscopic Perforation. Perforation is the most common major complication after either diagnostic or therapeutic colonoscopy. Fortunately, this complication is rare and occurs in less than 1% of procedures. Perforation may result from trauma from the tip of the instrument, from shear forces related to the formation of a "loop" in the colonoscope, or from barotrauma from insufflation. Biopsy or fulguration can also cause perforation. Polypectomy using electrocautery may produce a full-thickness burn, resulting in *postpolypectomy syndrome* in which a patient develops abdominal pain, fever, and leukocytosis without evidence of diffuse peritonitis.

Management of colonoscopic perforation depends on the *size of the perforation*, the *duration of time* since the injury, the *overall condition of the patient,* and the *underlying diagnosis*. A large perforation recognized during the procedure requires surgical exploration. Because the bowel has almost always been prepared prior to the colonoscopy, there is usually little contamination associated with these injuries, and most can be repaired primarily. If there is significant contamination, if there has been a delay in diagnosis with resulting peritonitis, or if the patient is hemodynamically unstable, proximal diversion with or without resection is the safest approach. It is also important to know the indication for and findings at the time of colonoscopy. If the patient has an underlying neoplasm and is stable, definitive resection is best. Occasionally, a patient will develop abdominal pain and localized signs of perforation after what was thought to be an uneventful colonoscopy. Many of these patients will have a "microperforation," which will resolve with bowel rest, broad-spectrum antibiotics, and close observation. Evidence of peritonitis or any deterioration in clinical condition mandates exploration. Similarly, free retroperitoneal or intraperitoneal air may be discovered incidentally after colonoscopy.

In a completely asymptomatic patient, this finding is thought to result from barotrauma and dissection of air through tissue planes without a free perforation. Many of these patients can be successfully treated with bowel rest and broad-spectrum antibiotics. Surgical exploration is indicated if any clinical deterioration occurs.

Anal Sphincter Injury and Incontinence

The most common cause of anal sphincter injury is obstetric trauma during vaginal delivery. The risk of sphincter injury is increased by a laceration that extends into the rectum (fourth-degree tear), infection of an episiotomy or laceration repair, prolonged labor, and possibly by use of a midline episiotomy. Sphincter damage may also result from hemorrhoidectomy, sphincterotomy, abscess drainage, or fistulotomy. Patients with incontinence and a suspected sphincter injury can be evaluated with anal manometry, EMG, pudendal nerve motor latency, and endoanal ultrasound. Mild incontinence, even in the presence of a sphincter defect, may respond to dietary changes and/or biofeedback. More severe incontinence may require surgical repair.

The anal sphincter can also be injured by penetrating or blunt mechanisms (impalement, blast injury, crush injuries of the pelvis). Because damage to the anal sphincter is not life-threatening, definitive repair of the sphincter is often deferred until other injuries have been repaired and the patient's clinical condition is stable. Isolated sphincter injuries that do not involve the rectum may be repaired primarily. Rectal injury accompanied by sphincter injury should be treated with fecal diversion and distal rectal washout, with or without drain placement. Significant perineal tissue loss may require extensive débridement and a diverting colostomy.

Surgical Repairs. The most common method of repair of the anal sphincter is a *wrap-around sphincteroplasty* (Fig. 29-42).[106] The procedure involves mobilization of the divided sphincter muscle and reapproximation without tension. The internal and external sphincters may be overlapped together or separately. *Postanal intersphincteric levatorplasty* is less commonly used to repair sphincter defects but may be useful for incontinence caused by prolapse and/or loss of the anorectal angle (see "Continence"). The approach is via the intersphincteric plane posteriorly. It may be performed concomitantly with a perineal repair of rectal prolapse. The levator ani muscle is approximated to restore the anorectal angle, and the puborectalis and external sphincter muscle are tightened with sutures. These elective procedures usually do not require a diverting colostomy.

In cases where there has been significant loss of sphincter muscle or in which prior repairs have failed, more complex techniques, such as *gracilis muscle transposition* with or without chronic, low-frequency electrostimulation, have been used with some success.[107] In this procedure, the gracilis muscle is mobilized from the thigh, detached from its insertion on the tibial tuberosity, tunneled through the perineum, and wrapped around the anal canal. Another alternative in patients who have failed other repairs is the *artificial anal sphincter*. This device consists of an inflatable silastic cuff, a pressure-regulating balloon, and a control pump. Patients deflate the cuff manually to open the anal canal; the cuff then reinflates spontaneously to maintain closure of the anal canal. *Sacral nerve stimulation* via an implanted pulse generator is a technique used for neurogenic incontinence when the sphincter is intact.[16,27] In some patients, an end stoma provides the best relief for intractable incontinence.[108]

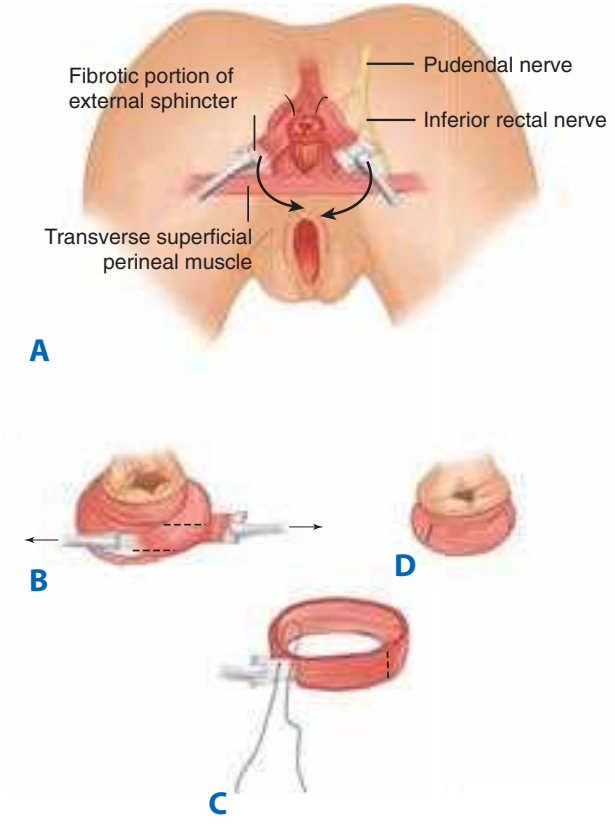

Figure 29-42. Overlapping sphincteroplasty for incontinence from sphincter disruption. **A.** The external sphincter muscle with scar at site of injury is mobilized. **B.** The muscle edges are aligned in an overlapping fashion. **C.** Mattress sutures are used to approximate the muscle. **D.** The completed operation.

Foreign Body

Foreign body entrapment in the rectum is not uncommon. Depending on the level of entrapment, a foreign body may cause damage to the rectum, rectosigmoid, or descending colon. Generalized abdominal pain suggests intraperitoneal perforation. Evaluation of the patient includes inspection of the perineum and a careful abdominal examination to detect any evidence of perforation. Plain films of the abdomen are mandatory to detect free intra-abdominal air.

Foreign bodies lodged low in the rectum may often be removed under conscious sedation with or without a local anesthetic block. Objects impacted higher in the rectum may require regional or general anesthesia for removal. Only rarely will a laparotomy be required to remove the object. After removal of the foreign body, it is crucial to evaluate the rectum and sigmoid colon for injury. Proctoscopy and/or flexible sigmoidoscopy should be performed. A hematoma without evidence of perforation requires no surgical treatment. Perforation of the rectum or sigmoid colon should be managed as described in the preceding sections.

THE IMMUNOCOMPROMISED PATIENT

Human Immunodeficiency Virus

Patients infected with HIV may present with a myriad of gastrointestinal symptoms. Diarrhea, in particular, is extremely common. The severity of gastrointestinal disease depends

in part on the degree of immunosuppression; however, both ordinary and opportunistic pathogens may affect patients at any stage of the disease. Opportunistic infections with bacteria (*Salmonella, Shigella, Campylobacter, Chlamydia*, and *Mycobacterium* species), fungi (histoplasmosis, coccidiosis, *Cryptococcus*), protozoa (toxoplasmosis, cryptosporidiosis, isosporiasis), and viruses (CMV, herpes simplex virus) can cause diarrhea, abdominal pain, and weight loss. *CMV* in particular may cause severe enterocolitis and is the most common infectious cause of emergency laparotomy in acquired immunodeficiency syndrome (AIDS) patients. *C. difficile colitis* is a major concern in these patients, especially because many patients are maintained on suppressive antibiotic therapy. The incidence of gastrointestinal malignancy is also increased in patients with HIV infection.[109] Kaposi's sarcoma is the most common malignancy in AIDS patients and can affect any part of the gastrointestinal tract. Patients may be asymptomatic or may develop bleeding or obstruction. Gastrointestinal lymphoma (usually non-Hodgkin's lymphoma) is also common. The incidence of colorectal carcinoma may also be increased in this population, although definitive data are lacking.

Perianal disease is extremely common in patients with HIV infection. Because HIV is sexually transmitted, it is common to find concomitant infection with other sexually transmitted diseases such as *Chlamydia, herpes simplex virus*, and *HPV* (anal condyloma). *Anal condyloma* in particular are very common, and the incidence of dysplasia (HSIL) is high in the HIV-infected population.[110] Abscesses and fistulas may be more difficult to diagnose in these patients and may be complex. Many patients require an examination under anesthesia with biopsy and cultures to determine the etiology of many of these perianal problems. The introduction of highly active antiretroviral therapy (HAART) has changed the natural history of HIV infection, but it remains to be seen how these medications will affect the incidence and outcome of colorectal disease in this patient population.

IMMUNOSUPPRESSION FOR TRANSPLANTATION

The gastrointestinal tract is a common site for posttransplantation complications that are responsible for significant morbidity and mortality. In these patients, infection and medication are the most common causes of diarrhea. Immunosuppressant medications, in particular, may cause diarrhea. CMV infection is common and may be severe. *C difficile* colitis also occurs commonly. Diverticulitis appears to be more common in some populations of transplant patients and may be more likely to present with abscess or free perforation. Elective resection after recovery from one episode of confirmed diverticulitis may be indicated in the transplant population. Graft-versus-host disease is unique to transplant patients and often requires endoscopy and biopsy to diagnose gastrointestinal involvement. Patients are subject to the same opportunistic infections outlined earlier; however, sexually transmitted infections and Kaposi's sarcoma are somewhat less prevalent. Perianal disease is somewhat less common in the transplant population than in patients infected with HIV; however, similar infections may occur, and immunosuppression often makes diagnosis and treatment challenging.

With increasing long-term survival among transplant recipients, the development of posttransplant malignancy has become a major concern. Posttransplant lymphoproliferative disease is increasingly common and may occur anywhere in the gastrointestinal tract. The risk of colorectal carcinoma is increased in patients with predisposing conditions such as ulcerative colitis. However, immunosuppression alone does not appear to increase the incidence of colorectal cancer, and current screening recommendations are similar to those for the average risk population. In contrast, the incidence of anal squamous cell carcinoma is dramatically increased in transplant patients, and patients with known HPV infection should undergo more vigorous screening.

THE NEUTROPENIC PATIENT

Neutropenic enterocolitis (typhlitis) is a life-threatening problem with a mortality rate of greater than 50%. This syndrome is characterized by abdominal pain and distention, fever, diarrhea (often bloody), nausea, and vomiting in a patient with fewer than 1000 neutrophils/μL blood from any cause (bone marrow transplantation, solid-organ transplantation, or chemotherapy). CT scan of the abdomen often shows a dilated cecum with pericolic stranding. However, a normal-appearing CT scan does not exclude the diagnosis. Some patients will respond to bowel rest, broad-spectrum antibiotics, parenteral nutrition, and granulocyte infusion or colony-stimulating factors. Evidence of perforation, generalized peritonitis, and deterioration in clinical condition are indications for operation.

Neutropenic patients often develop perianal pain, and diagnosis may be difficult because of a lack of inflammatory response to infection. While broad-spectrum antibiotics may cure some of these patients, an examination under anesthesia should not be delayed because of neutropenia. An increase in pain or fever and/or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.

chapter 30

The Appendix

Mike K. Liang, Roland E. Andersson, Bernard M. Jaffe, and David H. Berger

HISTORICAL BACKGROUND

Appendiceal disease is a frequent reason for emergency hospital admission, and appendectomy is one of the most common emergency procedures performed in contemporary medicine. Despite the prevalent role this organ plays in healthcare today, the human appendix was not noted until 1492. Leonardo da Vinci depicted the appendix in his anatomic drawings, but these were not published until the eighteenth century.[1] In 1521, Berengario Da Capri and, in 1543, Andreas Vesalius published drawings recognizing the appendix.[2]

Credit is given to Jean Fernel for first describing appendiceal disease in a paper published in 1544. He reported on a 7-year-old girl whose diarrhea he treated with doses of quince, an apple-like fruit used in folk remedies. She developed abdominal pain and died. At autopsy, the quince was found to have obstructed the lumen of the appendix, causing necrosis and perforation.[3] Lorenz Heister provided the first description of classic appendicitis in 1711.[1]

The first known appendectomy was performed in 1736 by Claudius Amyand in London. He operated on an 11-year-old boy with a scrotal hernia and a fecal fistula. Within the hernia sac, Amyand found a perforated appendix surrounded by omentum. The appendix and omentum were amputated. The patient was discharged a month later in good condition.[4]

It would be over a century later before appendicitis was widely recognized as a common cause of right lower quadrant pain and early appendectomy advocated as treatment. Throughout this period, there was extensive discussion of typhlitis and perityphlitis as the common etiologies of right lower quadrant pain. Only sporadic cases of right lower quadrant pain were treated with appendectomy. In 1886, Reginald H. Fitz presented his findings regarding appendicitis and recommended consideration for operative treatment. In 1889, Charles McBurney published his landmark paper in the *New York State Medical Journal* describing the indications for early laparotomy for the treatment of appendicitis.[5] During the following decade, the role of surgical treatment was discussed intensely between proponents of early appendectomy and of a more expectant management. It was recognized that most instances of appendicitis could resolve without surgical treatment; but, the problem was how to identify early the patients who had the progressive, often lethal form of the disease.[6] Eventually, early appendectomy became the accepted standard of care, with broad indications in order to prevent perforation. This change in practice resulted in an enormous increase in the number of appendectomies during the first decades of the twentieth century. However, this had almost no impact on the incidence of perforated appendicitis or on the mortality of appendicitis.[7] In the 1970s, the negative effects of the large number of appendectomies of uninflamed appendices were noted, and the focus gradually shifted toward a more conservative approach to exploration.[8]

EMBRYOLOGY, ANATOMY, AND PHYSIOLOGY

Embryology

In the sixth week of human embryonic development, the appendix and cecum appear as outpouchings from the caudal limb of the midgut. The appendiceal outpouching, initially noted in the eighth week, begins to elongate at about the fifth month to achieve a vermiform appearance.[9,10] The appendix maintains

Key Points

1. Appendicitis is one of the most common surgical emergencies in contemporary medicine, with a yearly incidence rate of about 100 per 100,000 inhabitants. Lifetime risk for appendicitis is 8.6% for males and 6.7% for females, with the highest incidence in the second decade of life.
2. The natural history of appendicitis is unclear, but it appears that progression to perforation is not predictable and that spontaneous resolution is common, suggesting that nonperforated and perforated appendicitis may, in fact, be different diseases.
3. Right lower quadrant pain, gastrointestinal symptoms starting after the onset of pain, and a systemic inflammatory response with leukocytosis and neutrophilia, increased C-reactive protein concentration, and fever are considered diagnostic of appendicitis. The Appendicitis Inflammatory Response Score or Alvarado score can help improve diagnostic accuracy.
4. Computed tomography scan has improved diagnostic accuracy in individual studies. However, in population-wide studies, the rate of misdiagnosis of appendicitis remains constant. Rates of misdiagnosis are highest in female patients of child-bearing age and patients on the extremes of age (i.e., very young and very old).
5. The role of nonoperative treatment for uncomplicated appendicitis remains controversial. Currently, appendectomy remains the standard of care. Laparoscopic appendectomy has a slight benefit over open appendectomy.
6. Perforated or complicated appendicitis is more common in the very young (age <5 years) and very old (age >65 years).
7. Complicated appendicitis without signs of sepsis or generalized peritonitis may benefit from nonoperative management. The role of interval appendectomy in these cases remains controversial.
8. Single-incision appendectomy provides no obvious advantage over standard laparoscopic appendectomy. Natural orifice transluminal endoscopic surgery remains an investigational procedure.
9. The incidence of fetal loss following normal appendectomy in pregnant patients is 4%, and the risk of premature delivery is 10%. The greatest opportunity to improve fetal outcomes may be through improving diagnostic accuracy and reducing the rate of negative appendectomy.
10. Antibiotic prophylaxis is effective in the prevention of postoperative surgical site infection. Postoperative antibiotics are unnecessary following uncomplicated appendicitis. For complicated appendicitis, a treatment duration of 4 to 7 days is recommended.
11. The role of incidental appendectomy is limited to patients at high risk for misdiagnosis of appendicitis (malrotation, patients unable to respond or react normally), patients at high risk for complications with appendicitis (children ready to undergo chemotherapy), and patients with limited access to modern healthcare.
12. The prevalence of appendiceal malignancy remains at or below 1% of appendectomies. Carcinoid and mucinous adenocarcinoma remain the most frequent histologic diagnosis.

its position at the tip of the cecum throughout development. The subsequent unequal growth of the lateral wall of the cecum causes the appendix to find its adult position on the posterior medial wall, just below the ileocecal valve. The base of the appendix can be located by following the longitudinally oriented taeniae coli to their confluence on the cecum. The tip of the appendix can be located anywhere in the right lower quadrant of the abdomen, pelvis, or retroperitoneum.

In patients with midgut malrotation and situs inversus, the cecum (and thus the appendix) will not reside in the usual right lower quadrant location. With midgut malrotation, the midgut (small bowel and proximal colon) incompletely rotates or fails to rotate around the axis of the superior mesenteric artery during fetal development. In this situation, the appendix will remain in the left upper quadrant of the abdomen. Situs inversus is a rare autosomal recessive congenital defect characterized by the transposition of abdominal and/or thoracic organs. In this situation, the appendix is found in the left lower quadrant of the abdomen.[11]

Anatomy

In the adult, the average length of the appendix is 6 to 9 cm; however, it can vary in length from <1 to >30 cm. The outer diameter varies between 3 and 8 mm, whereas the luminal diameter varies between 1 and 3 mm.[9]

The appendix receives its arterial supply from the appendicular branch of the ileocolic artery. This artery originates posterior to the terminal ileum, entering the mesoappendix close to the base of the appendix.[12] The lymphatic drainage of the appendix flows into lymph nodes that lie along the ileocolic artery. Innervation of the appendix is derived from sympathetic elements contributed by the superior mesenteric plexus (T10-L1) and afferents from the parasympathetic elements via the vagus nerves.[12]

The histologic features of the appendix are contained within the three following layers: the outer serosa, which is an extension of the peritoneum; the muscularis layer, which is not well defined and may be absent in certain locations; and finally, the submucosa and mucosa. Lymphoid aggregates occur in the submucosal layer and may extend into the muscularis mucosa. Lymphatic channels are prominent in regions underlying these lymphoid aggregates. The mucosa is like that of the large intestine, except for the density of the lymphoid follicles. The crypts are irregularly sized and shaped, in contrast to the more uniform appearance of the crypts in the colon. Neuroendocrine complexes composed of ganglion cells, Schwann cells, neural fibers, and neurosecretory cells are positioned just below the crypts.[13,14]

Physiology

For many years, the appendix was erroneously believed to be a vestigial organ with no known function. It is now well recognized that the appendix is an immunologic organ that actively participates in the secretion of immunoglobulins, particularly immunoglobulin A.

Although there is no clear role for the appendix in the development of human disease, an inverse association between appendectomy and the development of ulcerative colitis has been reported, suggesting a protecting effect of the appendectomy. However, this association is only seen in patients treated with appendectomy for appendicitis before age 20.[15-17]

The association between Crohn's disease and appendectomy is less clear. Although earlier studies suggested that appendectomy increases the risk of developing Crohn's disease, more recent studies that carefully assessed the timing of appendectomy in relationship to the onset of Crohn's disease demonstrated no correlation.[17] A recent meta-analysis demonstrated a significant risk of Crohn's disease early following appendicitis.[18] This risk diminishes later, which suggests that a diagnostic (misidentifying Crohn's disease as appendicitis) rather than a physiologic relationship exists between appendectomy and Crohn's disease.

The appendix may function as a reservoir to recolonize the colon with healthy bacteria. One retrospective study demonstrated that prior appendectomy may have an inverse relationship to recurrent *Clostridium difficile* infections.[19] However, in another retrospective study, prior appendectomy did not affect the rate of *C. difficile* infections.[20] The role of the appendix in recolonizing the colon remains to be elucidated.

ACUTE APPENDICITIS

Epidemiology

The lifetime risk of developing appendicitis is 8.6% for males and 6.7% for females, with the highest incidence in the second and third decades.[21] The rate of appendectomy for appendicitis has been decreasing since the 1950s in most countries. In the United States, it reached its lowest incidence rate of about 15 per 10,000 inhabitants in the 1990s.[22] Since then, there has been an increase in the incidence rate of nonperforated appendicitis. The reason for this is not clear, but it has been proposed that the increased use of diagnostic imaging has led to a higher detection rate of mild appendicitis that would otherwise resolve undetected.

Etiology and Pathogenesis

The etiology and pathogenesis of appendicitis are not completely understood. Obstruction of the lumen due to fecaliths or hypertrophy of lymphoid tissue is proposed as the main etiologic factor in acute appendicitis. The frequency of obstruction rises with the severity of the inflammatory process. Fecaliths and calculi are found in 40% of cases of simple acute appendicitis,[23] in 65% of cases of gangrenous appendicitis without rupture, and in nearly 90% of cases of gangrenous appendicitis with rupture.[24]

Traditionally, the belief has been that there is a predictable sequence of events leading to eventual appendiceal rupture. The proximal obstruction of the appendiceal lumen produces a closed-loop obstruction, and continuing normal secretion by the appendiceal mucosa rapidly produces distension. Distension of the appendix stimulates the nerve endings of visceral afferent stretch fibers, producing vague, dull, diffuse pain in the mid-abdomen or lower epigastrium. Distension increases from continued mucosal secretion and from rapid multiplication of the resident bacteria of the appendix. This causes reflex nausea and vomiting, and the visceral pain increases. As pressure in the organ increases, venous pressure is exceeded. Capillaries and venules are occluded but arterial inflow continues, resulting in engorgement and vascular congestion. The inflammatory process soon involves the serosa of the appendix and in turn the parietal peritoneum. This produces the characteristic shift in pain to the right lower quadrant.

The mucosa of the appendix is susceptible to impairment of blood supply; thus, its integrity is compromised early in the process, which allows bacterial invasion. The area with the poorest blood supply suffers the most: ellipsoidal infarcts develop in the antimesenteric border. As distension, bacterial invasion, compromise of the vascular supply, and infarction progress, perforation occurs, usually on the antimesenteric border just beyond the point of obstruction. This sequence is not inevitable, however, and some episodes of acute appendicitis may resolve spontaneously.

Microbiology

Appendicitis may occur in clusters, suggesting an infectious genesis. However, an association with various contagious bacteria and viruses has only been found in a small proportion of appendicitis patients.[25] The flora of the inflamed appendix differs from that of the normal appendix. About 60% of aspirates of inflamed appendices have anaerobes compared to 25% of aspirates from normal appendices.[26] Tissue specimens from the inflamed appendix wall (not luminal aspirates) virtually all grow *Escherichia coli* and *Bacteroides* species on culture.[27,28] *Fusobacterium nucleatum/necrophorum*, which is not present in the normal cecal flora, has been identified in 62% of inflamed appendices.[29] In addition to the other usual species (*Peptostreptococcus*, *Pseudomonas*, *Bacteroides splanchnicus*, *Bacteroides intermedius*, *Lactobacillus*), previously unreported fastidious gram-negative anaerobic bacilli have been encountered. Patients with gangrene or perforated appendicitis appear to have more tissue invasion by *Bacteroides*.

Natural History

Because of the current predilection for surgical treatment, the natural history of appendicitis has not been well described. An increasing amount of circumstantial evidence suggests that not all patients with appendicitis will progress to perforation and that resolution may be a common event.[30] Among the strongest evidence are two randomized trials comparing early laparoscopy with conservative management of patients with acute abdominal pain. These studies found three to five times more patients with appendicitis in the group of patients who were randomized to laparoscopy.[31,32] Based on epidemiologic differences, it has been proposed that nonperforated and perforated appendicitis may, in fact, be different diseases.[22]

Clinical Presentation

The inflammatory process in the appendix presents as pain, which initially is of a diffuse visceral type and later becomes more localized as the peritoneal lining gets irritated (Table 30-1).[33]

Symptoms. Appendicitis usually starts with periumbilical and diffuse pain that eventually localizes to the right lower quadrant (sensitivity, 81%; specificity, 53%).[34] Although right lower quadrant pain is one of the most sensitive signs of appendicitis, pain in an atypical location or minimal pain will often be the initial presentation. Variations in the anatomic location of the appendix may account for the differing presentations of the somatic phase of pain.

Appendicitis is also associated with gastrointestinal symptoms like nausea (sensitivity, 58%; specificity, 36%), vomiting (sensitivity, 51%; specificity, 45%), and anorexia (sensitivity,

Conclusions: Individually, disease history, clinical findings, and laboratory tests are weak. But, when combined, they yield high discriminatory power.

68%; specificity, 36%). Gastrointestinal symptoms that develop before the onset of pain suggest a different etiology such as gastroenteritis.[34] Many patients complain of a sensation of obstipation prior to the onset of pain and feel that defecation will relieve their abdominal pain. Diarrhea may occur in association with perforation, especially in children.

Signs. Early in presentation, vital signs may be minimally altered. The body temperature and pulse rate may be normal or slightly elevated. Changes of greater magnitude may indicate that a complication has occurred or that another diagnosis should be considered.[35]

Physical findings are determined by the presence of peritoneal irritation and are influenced by whether the organ has already ruptured when the patient is first examined. Patients with appendicitis usually move slowly and prefer to lie supine due to the peritoneal irritation. On abdominal palpation, there is tenderness with a maximum at or near McBurney's point (Fig. 30-1).[5] On deep palpation, one can often feel a muscular resistance (guarding) in the right iliac fossa, which may be more evident when compared to the left side. When the pressure of the examining hand is quickly relieved, the patient feels a sudden pain, the so-called rebound tenderness. Indirect tenderness (Rovsing's sign) and indirect rebound tenderness (i.e., pain in the right lower quadrant when the left lower quadrant is palpated) are strong indicators of peritoneal irritation. Rebound tenderness can be very sharp and uncomfortable for the patient. It is therefore recommended to start with testing for indirect rebound tenderness and direct percussion tenderness.

Anatomic variations in the position of the inflamed appendix lead to deviations in the usual physical findings. With a retrocecal appendix, the abdominal findings are less striking, and tenderness may be most marked in the flank. When the appendix hangs into the pelvis, abdominal findings may be entirely absent, and the diagnosis may be missed. Right-sided rectal tenderness is said to help in this situation, but the diagnostic value is low. Pain with extension of the right leg (psoas sign) indicates a focus of irritation in the proximity of the right psoas muscle. Similarly, stretching of the obturator internus through internal rotation of a flexed thigh (obturator sign) suggests inflammation near the muscle.

Laboratory Findings. Appendicitis is associated with an inflammatory response that is strongly related to the severity of

Figure 30-1. McBurney's point (1 = anterior superior iliac spine; 2 = umbilicus; x = McBurney's point).

the disease. Laboratory examinations are therefore an important part of the diagnosis. Mild leukocytosis is often present in patients with acute, uncomplicated appendicitis and is usually accompanied by a polymorphonuclear prominence. It is unusual for the white blood cell count to be >18,000 cells/mm^3 in uncomplicated appendicitis. Counts above this level raise the possibility of a perforated appendix with or without an abscess. An increased C-reactive protein (CRP) concentration is a strong indicator of appendicitis, especially for complicated appendicitis.[36]

White blood cell counts can be low due to lymphopenia or septic reaction, but in this situation, the proportion of neutrophils is usually very high. Therefore, all inflammatory variables should be viewed together. Appendicitis is very unlikely if the white blood cell count, proportion of neutrophils, and CRP are all normal. The inflammatory response in acute appendicitis is a dynamic process. Early in the process, the inflammatory response can be weak. CRP elevation, in particular, can have up to a 12-hour delay. A decreasing inflammatory response may indicate spontaneous resolution.

Urinalysis can be useful to rule out the urinary tract as the source of infection; however, several white or red blood cells can be present from irritation of the ureter or bladder. Bacteriuria is generally not seen.

Clinical Scoring Systems. The clinical diagnosis of appendicitis is a subjective estimate of the probability of appendicitis based on multiple variables that individually are weak discriminators; however, used in conjunction, they possess a high predictive value. This process can be made more objective by the use of clinical scoring systems, which are based on variables with proven discriminating power and assigned a proper weight. The Alvarado score is the most widespread scoring system. It is especially useful for ruling out appendicitis and selecting patients for further diagnostic workup.[37] The Appendicitis Inflammatory Response Score resembles the Alvarado score but uses more graded variables and includes CRP (Table 30-2).[38,39] Studies have shown it to perform better than the Alvarado score in accurately predicting appendicitis.[38,39] However, clinical scoring systems have not gained widespread acceptance in making the diagnosis of appendicitis.

3▶

Imaging Studies. Plain films of the abdomen can show the presence of a fecalith and fecal loading in the cecum associated with appendicitis but are rarely helpful in diagnosing acute appendicitis[40]; however, they may be of benefit in ruling out other pathology. A chest radiograph is helpful to rule out referred pain from a right lower lobe pneumonic process. If the appendix fills on barium enema, appendicitis is unlikely[41]; however, this test is not indicated in the acute setting. Technetium-99m–labeled

leukocyte scan has been reported for use in diagnosing appendicitis with good results but has not gained widespread use due to its relative unavailability and impracticality in daily use.[42]

Ultrasonography and computed tomography (CT) scan are the most commonly used imaging tests in patients with abdominal pain, particularly in evaluation of possible appendicitis. Multiple meta-analyses have been performed comparing the two imaging modalities (Table 30-3).[43-47] Overall, CT scan is more sensitive and specific than ultrasonography in diagnosing appendicitis.

Graded compression ultrasonography is inexpensive, can be performed rapidly, does not require a contrast medium, and can be used in pregnant patients. Sonographically, the appendix is identified as a blind-ending, nonperistaltic bowel loop originating from the cecum. With maximal compression, the diameter of the appendix is measured in the anterior-posterior direction. Thickening of the appendiceal wall and the presence of periappendiceal fluid are highly suggestive of appendicitis. Demonstration of an easily compressible appendix measuring <5 mm in diameter excludes the diagnosis of appendicitis. The sonographic diagnosis of acute appendicitis has a reported sensitivity of 55% to 96% and a specificity of 85% to 98%. Ultrasonography is similarly effective in children and pregnant women, although its application is limited in late pregnancy. Ultrasonography has its limitations, particularly the operator-dependent nature of results. In the adult population, ultrasonography remains limited in its use.

With high-resolution helical CT, the inflamed appendix appears dilated (>5 mm), and the wall is thickened. There is often evidence of inflammation, which can include periappendiceal fat stranding, thickened mesoappendix, periappendiceal phlegmon, and free fluid. Fecaliths can be often visualized; however, their presence is not pathognomonic of appendicitis. CT scanning is also an excellent technique for identifying other inflammatory processes masquerading as appendicitis. Several CT techniques have been used, including focused and nonfocused CT scans and contrast and noncontrast scans. Surprisingly, all of these techniques have yielded essentially identical rates of diagnostic accuracy: 92% to 97% sensitivity, 85% to 94% specificity, 90% to 98% accuracy, 75% to 95% positive predictive value, and 95% to 99% negative predictive value. The additional use of rectal contrast does not improve the results of CT scanning.

A number of studies have documented improvement in diagnostic accuracy with the liberal use of CT scanning in the workup of suspected appendicitis. CT lowered the rate of negative appendectomies from 19% to 12% in one study[48] and the incidence of negative appendectomies in women from 24% to 5% in another study.[49] Use of CT altered the care of 24% of patients studied and provided an alternative diagnosis in half of the patients with normal appendices on CT scan.

Despite the potential usefulness of CT, there are significant disadvantages. CT scanning is expensive, exposes the patient to significant radiation, and has limited use during pregnancy. Allergy to iodine or contrast limits the administration of contrast agents in some patients, and others cannot tolerate the oral ingestion of luminal dye.

The role of CT scanning in patients who present with right lower quadrant pain is unclear. One rationale is universal CT scanning. There is, however, an argument that indiscriminate diagnostic imaging can increase the detection of clinically nonsignificant appendicitis that would resolve without treatment. Alternatively, selective CT scanning based on the likelihood of appendicitis takes advantage of the clinical skills of the surgeon and, when indicated, adds the expertise of the radiologist.

Despite the increased use of ultrasonography and CT, the rate of misdiagnosis of appendicitis has remained constant (15%). The percentage of misdiagnosed cases of appendicitis is significantly higher among women than men (22% vs. 9.3%).[50,51] The negative appendectomy rate is highest in women of reproductive age.

Differential Diagnosis

The differential diagnosis of acute appendicitis is essentially the diagnosis of acute abdomen. An identical clinical picture can result from a wide variety of acute processes within the peritoneal cavity that produce the same physiologic alterations as acute appendicitis.

The accuracy of preoperative diagnosis should be higher than 85%. If it is consistently less, it is likely that unnecessary operations are being performed and a more rigorous preoperative differential diagnosis is needed.

The most common findings in the case of an erroneous preoperative diagnosis of appendicitis—together accounting for more than 75% of cases—are, in descending order of frequency, acute mesenteric adenitis, no organic pathologic condition, acute pelvic inflammatory disease, twisted ovarian cyst or ruptured graafian follicle, and acute gastroenteritis.

The differential diagnosis of acute appendicitis depends on four major factors: the anatomic location of the inflamed appendix; the stage of the process (uncomplicated or complicated); the patient's age; and the patient's gender.[52-56]

Pediatric Patient. Acute mesenteric adenitis is the disease most often confused with acute appendicitis in children. Almost invariably, an upper respiratory tract infection is present or has recently subsided. The pain usually is diffuse, and tenderness is not as sharply localized as in appendicitis. Voluntary guarding is sometimes present, but true rigidity is rare. Generalized lymphadenopathy may be noted. Laboratory procedures are of little help in arriving at the correct diagnosis, although a relative lymphocytosis, when present, suggests mesenteric adenitis. Observation for several hours is appropriate if the diagnosis of mesenteric adenitis is suspected, as it is a self-limited disease.

Elderly Patient. Diverticulitis or perforating carcinoma of the cecum or of a portion of the sigmoid that overlies the right lower abdomen may be impossible to distinguish from appendicitis. These entities should be considered, particularly in older patients. CT scanning is often helpful in making a diagnosis in older patients with right lower quadrant pain and atypical clinical presentations. In patients successfully managed conservatively, interval surveillance of the colon (colonoscopy or barium enema) may be warranted.

Female Patient. Diseases of the female internal reproductive organs that may erroneously be diagnosed as appendicitis are, in approximate descending order of frequency, pelvic inflammatory disease, ruptured graafian follicle, twisted ovarian cyst or tumor, endometriosis, and ruptured ectopic pregnancy. As a result, the rate of misdiagnosis remains higher among female patients.

In pelvic inflammatory disease, the infection is usually bilateral but, if confined to the right tube, may mimic acute appendicitis. Nausea and vomiting are present in patients with appendicitis but in only approximately 50% of those with pelvic

inflammatory disease. Pain and tenderness are usually lower, and motion of the cervix is exquisitely painful. Intracellular diplococci may be demonstrable on smear of the purulent vaginal discharge. The ratio of cases of appendicitis to cases of pelvic inflammatory disease is low in females in the early phase of the menstrual cycle and high during the luteal phase. The careful clinical use of these features has reduced the incidence of negative findings on laparoscopy in young women to 15%.

Ovulation commonly results in the spillage of sufficient amounts of blood and follicular fluid to produce brief, mild lower abdominal pain. If the amount of fluid is unusually copious and is from the right ovary, appendicitis may be simulated. Pain and tenderness may be rather diffuse, and leukocytosis and fever minimal or absent. Because this pain occurs at the midpoint of the menstrual cycle, it is often called *mittelschmerz*.

Serous cysts of the ovary are common and generally remain asymptomatic. When right-sided cysts rupture or undergo torsion, the manifestations are similar to those of appendicitis. Patients develop right lower quadrant pain, tenderness, rebound, fever, and leukocytosis. Both transvaginal ultrasonography and CT scanning can be diagnostic.

Torsion requires emergent operative treatment. If the torsion is complete or longstanding, the pedicle undergoes thrombosis, and the ovary and tube become gangrenous and require resection. However, simple detorsion, fenestration of the cyst, and fixation of the ovary as a primary intervention, followed by a laparoscopy a few days later, can be recommended because it is often difficult to preoperatively determine the viability of the ovary.

Blastocysts may implant in the fallopian tube (usually the ampullary portion) and in the ovary. Rupture of right tubal or ovarian pregnancies can mimic appendicitis. Patients may give a history of abnormal menses, either missing one or two periods or noting only slight vaginal bleeding. Unfortunately, patients do not always realize they are pregnant. The development of right lower quadrant or pelvic pain may be the first symptom. The diagnosis of ruptured ectopic pregnancy should be relatively easy. The presence of a pelvic mass and elevated levels of human chorionic gonadotropin are characteristic. Although the leukocyte count rises slightly, the hematocrit level falls as a consequence of the intra-abdominal hemorrhage. Vaginal examination reveals cervical motion and adnexal tenderness, and a more definitive diagnosis can be established by culdocentesis. The presence of blood and particularly decidual tissue is pathognomonic. The treatment of ruptured ectopic pregnancy is emergency surgery.

Immunosuppressed Patient. The incidence of acute appendicitis in patients infected with human immunodeficiency virus (HIV) is reported to be 0.5%. This is higher than the 0.1% to 0.2% incidence reported for the general population.[57] The presentation of acute appendicitis in HIV-infected patients is similar to that in noninfected patients. The majority of HIV-infected patients with appendicitis have fever, periumbilical pain radiating to the right lower quadrant (91%), right lower quadrant tenderness (91%), and rebound tenderness (74%). HIV-infected patients do not manifest an absolute leukocytosis; however, if a baseline leukocyte count is available, nearly all HIV-infected patients with appendicitis demonstrate a relative leukocytosis.[57]

The risk of appendiceal rupture appears to be increased in HIV-infected patients. In one large series of HIV-infected patients who underwent appendectomy for presumed appendicitis, 43% of patients were found to have perforated appendicitis at laparotomy.[58] The increased risk of appendiceal rupture may be related to the delay in presentation seen in this patient population.[57,58] A low CD4 count is also associated with an increased incidence of appendiceal rupture.[57]

The differential diagnosis of right lower quadrant pain is expanded in HIV-infected patients compared with the general population. In addition to the conditions discussed elsewhere in this chapter, opportunistic infections should be considered as a possible cause of right lower quadrant pain.[57,58] Neutropenic enterocolitis (typhlitis) should also be considered in the differential diagnosis of right lower quadrant pain in HIV-infected patients.[57,58]

Initial Management

Uncomplicated Appendicitis

Operative versus Nonoperative Management of Uncomplicated Appendicitis In patients with uncomplicated appendicitis, surgical treatment has been the standard of treatment since McBurney reported his experiences. The concept of nonoperative treatment for uncomplicated appendicitis developed from two lines of observations. First, for patients in an environment where surgical treatment is not available (e.g., submarines, expeditions in remote areas), treatment with antibiotics alone was noted to be effective. Second, many patients with signs and symptoms consistent with appendicitis who did not pursue medical treatment would occasionally have spontaneous resolution of their illness.

A handful of observational studies and controlled trials have reported the outcomes of nonoperative versus operative treatment of presumed uncomplicated appendicitis (Table 30-4).[59-64] Overall, there is a reported 9% short-term (<30 days) failure rate with nonoperative management of appendicitis (13% if evaluated per protocol). In patients in whom nonoperative treatment fails, nearly half of patients have complicated (perforated or gangrenous) appendicitis. After 1 month, about 1% of patients in the trials underwent an interval appendectomy, and 13% of patients who initially were successfully treated with nonoperative measures developed recurrent appendicitis, with an 18% rate of complicated appendicitis. Follow-up was not longer than 1 year in any study. In addition, one-third of patients declined or dropped out from nonoperative management of appendicitis.

In comparison, operative appendectomy demonstrated a relatively low dropout rate (2%), lower proportion of complicated appendicitis (25%), small proportion of a normal appendix (5%), and low rates of superficial surgical site infection (3.7%) and intra-abdominal abscess (1.3%).

The results in these studies must viewed with caution due to unclear selection of patients, incomplete diagnostic workup in the nonoperated patients, unclear gold standard for the operated patients, and high rates of crossover between the treatment arms. The consequences in terms of use of hospital beds, length of hospital stay, morbidity of delayed surgical treatment after failed nonsurgical treatment, delayed diagnosis for patients with an underlying cancer in the appendix or cecum, and risk of increased antibiotic resistance need to be further investigated. Thus, operative treatment of presumed uncomplicated appendicitis still remains the standard of care. Certain subgroups with uncomplicated appendicitis may do well with nonoperative therapy. Patients pursuing nonoperative management should be carefully counseled regarding the risks of treatment failure and recurrent appendicitis.

[a]Although 123 patients were randomized to nonoperative management and 3 patients dropped out, only 120 patients were included in the intent-to-treat analysis.
[b]Standard deviation.
[c]Standard error of the mean.
[d]Study only reported pathology results based on the per-protocol group and not the intent-to-treat group.
[e]Study did not report the meaning of these values.
[f]Study did not report the intent-to-treat values; instead, at one institution, 79 of 104 patients declined to be included in the trial.
[g]These patients declined to be included in the study and opted for surgical management.
NA = not applicable; NR = not reported; PCT = prospective controlled trial; PRCT = prospective randomized controlled trial; RT = retrospective trial; SSI = surgical site infection.

Urgent versus Emergent Appendectomy for Uncomplicated Appendicitis Traditionally, appendicitis has been considered a surgical emergency. Once diagnosed, a patient was emergently taken to the operating room for surgical treatment. However, delays in diagnosis, lack of access to available operating suites, and nonoperative management of appendicitis have challenged the notion that uncomplicated appendicitis is a surgical emergency.

Three retrospective studies have evaluated the role of emergent or urgent surgery for uncomplicated appendicitis; the emergent group had a time from presentation to the operating room of <12 hours, whereas the urgent group had a time from presentation to the operating room of 12 to 24 hours (Table 30-5).[65-67] There was no statistically significant increase in the number of complicated appendicitis cases in the urgent group when compared to the emergent group. Similarly, rates of surgical site infection, intra-abdominal abscesses, conversion to an open procedure, or operative time showed no difference between the two groups. While length of stay was longer for the urgent group, it was not statistically or clinically different from the emergent group. Important caveats in consideration of urgent as opposed to emergent surgical care include the patient's clinical examination, time of presentation from onset of symptoms, and duration of "delay" in surgery. Patients with clinical signs of perforation, patients with delayed presentation of greater than 48 hours from onset of symptoms, and patients whose definitive therapy may be delayed for more than 12 hours were beyond the scope of these studies.

Emergent versus urgent operation for uncomplicated appendicitis is dependent on each institution and surgeon. Institutions without readily available operating rooms and staff may consider performing appendectomy in an urgent fashion as opposed to emergently.

Complicated Appendicitis. Complicated appendicitis typically refers to perforated appendicitis commonly associated with an abscess or phlegmon. The yearly incidence rate of perforated appendicitis is about 2 per 10,000 persons and has remarkable little variance over time, geographic region, and age.[51,68,69] The proportion of perforated appendicitis, commonly around 25%, is often used as an indicator of quality of care. Differences in this proportion are almost entirely related to differences in the incidence of nonperforated appendicitis. A low proportion of perforations may therefore be the consequence of a higher rate of detection and treatment of early or resolving appendicitis.

Children less than 5 years of age and patients more than 65 years of age have the highest rates of perforation (45% and 51%, respectively). The proportion of perforation increases with increasing duration of symptoms. There is, however, no association of in-hospital delay with perforation. This suggests that most perforations occur early, before the patient arrives to hospital. It has also been proposed that the increasing proportion of perforations with time is explained by selection due to spontaneous resolution of noncomplicated appendicitis.

6▶

Perforated appendicitis has been suggested to increase the risk of female infertility due to impaired tubal function, but this has not been shown in epidemiologic studies.[70]

Rupture should be suspected in the presence of generalized peritonitis and a strong inflammatory response. In many cases, rupture is contained and patients display localized peritonitis. In 2% to 6% of cases, a palpable mass is detected on physical examination. This could represent a phlegmon, which consists

of matted loops of bowel adherent to the adjacent inflamed appendix or a periappendiceal abscess. Patients who present with a mass have experienced symptoms for a longer duration, usually 5 to 7 days. Distinguishing acute, uncomplicated appendicitis from acute appendicitis with perforation based on clinical findings is often difficult, but it is important to make the distinction because the treatments may differ. CT scan may be beneficial in establishing a diagnosis and guiding therapy.

Operative versus Nonoperative Management of Complicated Appendicitis Patients who present with signs of sepsis and generalized peritonitis should be taken to the operating room immediately with concurrent resuscitation. The surgical approach is based on the surgeon's level of comfort; however, open appendectomy through a lower midline incision may be necessary to treat these complicated cases.

In patients with complicated appendicits and a contained abscess or phlegmon but limited peritonitis (focal right lower quadrant pain), the treatment options become more complicated. Often, these patients will require a challenging procedure with a high risk for development of a postoperative intra-abdominal abscess. Options include operative management versus conservative management (antibiotics, bowel rest, fluids, and possible percutaneous drainage).

There have been no prospective randomized controlled studies comparing operative versus conservative management of complicated appendicitis in adults; all studies have been retrospective cohort studies. Two meta-analyses have been performed. In Andersson and Petzold's 2007 analysis of 61 studies evaluating this issue, they noted that initial nonoperative management had superior outcomes.[70] Nonoperative management included intravenous fluids, minimizing gastrointestinal stimulation, parenteral antibiotics, and percutaneous drainage where deemed appropriate. The morbidity of immediate operative treatment was 36.5%, whereas the morbidity of conservative management was 11%. Of patients undergoing conservative treatment, 7.6% failed conservative treatment and underwent operative management. This subgroup had an overall complication rate of 13.5%. The recurrence rate was 7.4%, which does not necessitate interval appendectomy. The authors concluded that conservative treatment was favored over early operation in complicated appendicitis.[30]

Simillis and colleagues performed a meta-analysis of 17 studies.[71] They noted that conservative treatment was associated with fewer overall complications (odds ratio, 0.24; 95% confidence interval [CI], 0.13 to 0.44), intra-abdominal abscesses (odds ratio, 0.19; 95% CI, 0.07 to 0.58), bowel obstructions (odds ratio, 0.35; 95% CI, 0.17 to 0.71), and reoperations (odds ratio, 0.17; 95% CI, 0.04 to 0.75).[71] The authors concluded that conservative treatment was favored over early operation in complicated appendicitis.

7▶

In the pediatric literature, there have been two prospective randomized controlled trials[72,73] demonstrating that early operative intervention had equivalent or superior outcomes to conservative management, but these studies included interval appendectomy for all patients in their calculations. St. Peter and colleagues[72] demonstrated that 20% of patients failed conservative treatment. Early surgical intervention had equivalent results to interval appendectomy. Alternatively, Blakely and colleagues[73] noted that interval appendectomy, versus early appendectomy, had a higher incidence of adverse events (50% vs. 30%, $P = .003$), intra-abdominal abscesses (37% vs. 19%, $P = .02$), small bowel obstruction (10.4% vs. 0%, $P = .01$), and readmissions (31% vs. 8%, $P = .06$). In addition, Blakely and colleagues noted that 9% of the group treated conservatively developed recurrent appendicitis. The authors concluded that immediate surgical treatment was superior to conservative treatment with interval appendectomy.

Interval Appendectomy Following Nonoperative Management of Complicated Appendicitis Interval appendectomy is defined as performing an appendectomy following initial successful nonoperative management in patients with no further symptoms. The major argument against interval appendectomy is that many patients treated conservatively never develop manifestations of appendicitis, and those who do generally can be treated without additional morbidity. The major argument for interval appendectomy is to prevent future attacks of appendicitis or to identify other disease, such as appendiceal malignancy.

There has only been one small prospective randomized controlled trial (n = 40) investigating this subject. The literature is largely populated with small case series and retrospective cohort studies; there is no meta-analysis evaluating the subject (Table 30-6).[74-81] Of the 1434 patients who had presumed complicated appendicitis and were successfully treated conservatively, 8.8% developed recurrent appendicitis with a median follow-up of 35 months. The incidence of complicated appendicitis following recurrence was low (2.4%). Malignancy was noted in 1.3% of cases where pathology was reported. Many of the patients were excluded from these studies due to persistent symptoms, persistent infections, or note of malignancy on screening colonoscopy.

Alternatively, of the 344 patients who had presumed complicated appendicitis, were successfully treated conservatively, and subsequently underwent interval appendectomy, surgical complications occurred in 9.4% of the patients. Most patients underwent interval appendectomy 2 to 4 months after their acute presentation. Although operative and pathologic details were not uniformly reported in these patients, many continued to have evidence of appendicitis or abscess at the time of interval appendectomy; 3.6% of patients had malignancy in cases where pathology was reported.

The role of interval appendectomy following successful management of conservative treatment of complicated appendicitis is unclear. Close clinical follow-up, a complete history searching for persistent symptoms, and screening colonoscopy (when age appropriate) should all be used to help guide the discussion with the patient on the role of interval appendectomy following conservative management of complicated appendicitis.

OPERATIVE INTERVENTIONS FOR THE APPENDIX

Open Appendectomy

Typically performed with a patient under general anesthesia, the patient is placed in supine position. The entire abdomen should be prepped and draped in case a larger incision is needed. For early nonperforated appendicitis, a right lower quadrant incision at McBurney's point (one-third of the distance from the anterior superior iliac spine to the umbilicus) is commonly used. A McBurney (oblique) or Rocky-Davis (transverse) right lower quadrant muscle splitting incision is made. If perforated appendicitis is suspected or the diagnosis is in doubt, a lower midline laparotomy can be considered. Although it has been reported that the position of the base of the appendix can change with pregnancy, prospective studies have demonstrated that pregnancy does not change the proportion of patients with the appendiceal base within 2 cm of McBurney's point.[82]

CS = case series; NR = not reported; PCT = prospective controlled trial; PRCT = prospective randomized controlled trial; RT = retrospective trial.

Following entry into the abdomen, the patient should be placed in slight Trendelenburg position with rotation of the bed to the patient's left. If the appendix is not easily identified, the cecum should be located. Tracing the taenia libera (anterior taenia), the most visible of the three taeniae coli, distally, the base of the appendix can be identified.

The appendix will often have attachments to the lateral wall or pelvis that can be dissected free. Dividing the mesentery of the appendix first will often allow improved exposure of the base of the appendix. The appendiceal stump can be managed by simple ligation or by ligation and inversion. As long as the stump is clearly visible and the base of the cecum is not involved with the inflammatory process, the stump can be safely ligated. Obliteration of the mucosa with electrocautery with the intention to obviate the development of a mucocele is recommended by some surgeons; however, no data have evaluated the risk or benefit of this surgical maneuver. Inversion of the stump with plication of the cecum has also been described. Placement of surgical drains for both uncomplicated[83] and complicated appendicitis,[84-87] practiced by many surgeons, has not been supported in clinical trials. Pus in the abdomen should be aspirated, but irrigation in complicated appendicitis is not recommended.[88] The skin can also be closed primarily in patients with perforated appendicitis.

If appendicitis is not found, a methodical search must be made for an alternative diagnosis. The cecum and mesentery should be inspected. The small bowel should be evaluated in a retrograde fashion beginning at the ileocecal valve. Concerns for Crohn's disease or Meckel's diverticulum should be of priority. In female patients, the reproductive organs should be closely inspected. If purulent or bilious fluid is encountered, it is imperative that the source be identified. For example, Valentino's appendicitis, or a perforated duodenal ulcer presenting as appendicitis, should be excluded in such cases. A medial extension of the incision (Fowler-Weir) or superior extension of the lateral incision is appropriate if further evaluation of the lower abdomen or right colon is warranted. Selective laparoscopy through a right lower quadrant incision has also been described.[89] If upper abdominal pathology is encountered, a midline incision should be made.

Laparoscopic Appendectomy

The first reported laparoscopic appendectomy was performed in 1983 by Semm; however, the laparoscopic approach did

not come into widespread use until much later, following the success of laparoscopic cholecystectomy. This may be due to the small incision already commonly used with open appendectomy.

Laparoscopic appendectomy is performed under general anesthesia. An oro- or nasogastric tube and urinary catheter are placed. The patient should be placed supine with his or her left arm tucked and securely strapped to the operating table. Both surgeon and assistant should be standing on the patient's left facing the appendix. The laparoscopic screens should be positioned on the patient's right or at the foot of the bed. Standard laparoscopic appendectomy typically uses three ports. Typically, a 10- or 12-mm port is placed at the umbilicus, whereas two 5-mm ports are placed suprapubic and in the left lower quadrant. The patient should be placed in Trendelenburg and tilted to the left (Fig. 30-2).

The appendix should be identified similarly as in open surgery by tracking the taenia libera/coli to the appendiceal base. Through the suprapubic port, the appendix should be grasped securely and elevated to the 10 o'clock position. An "appendiceal critical view" should be obtained where the taenia libera is at the 3 o'clock position, the terminal ileum at the 6 o'clock position, and the retracted appendix at the 10 o'clock position to allow proper identification of the base of the appendix (Fig. 30-3).[90] Through the infraumbilical port, the mesentery should be gently dissected from the base of the appendix and a window created. Typically the base of the appendix is stapled, followed by stapling of the mesentery. Alternatively, the mesentery may be divided by an energy device or clipped and the base of the appendix secured with an Endoloop. The stump should be carefully examined to ensure hemostasis, complete transection, and ensure that no stump is left behind. The appendix is removed through the infraumbilical trocar in a retrieval bag.

Laparoscopic versus Open Appendectomy

There have been multiple prospective, randomized controlled trials comparing laparoscopic and open appendectomy outcomes. A number of meta-analyses have been performed evaluating the cumulative outcomes (Table 30-7).[91-99]

Laparoscopic appendectomy is associated with fewer incisional surgical site infections compared to open appendectomy. However, laparoscopic appendectomy may be associated with increased risk of intra-abdominal abscess compared to open appendectomy. There is less pain, shorter length of stay, and

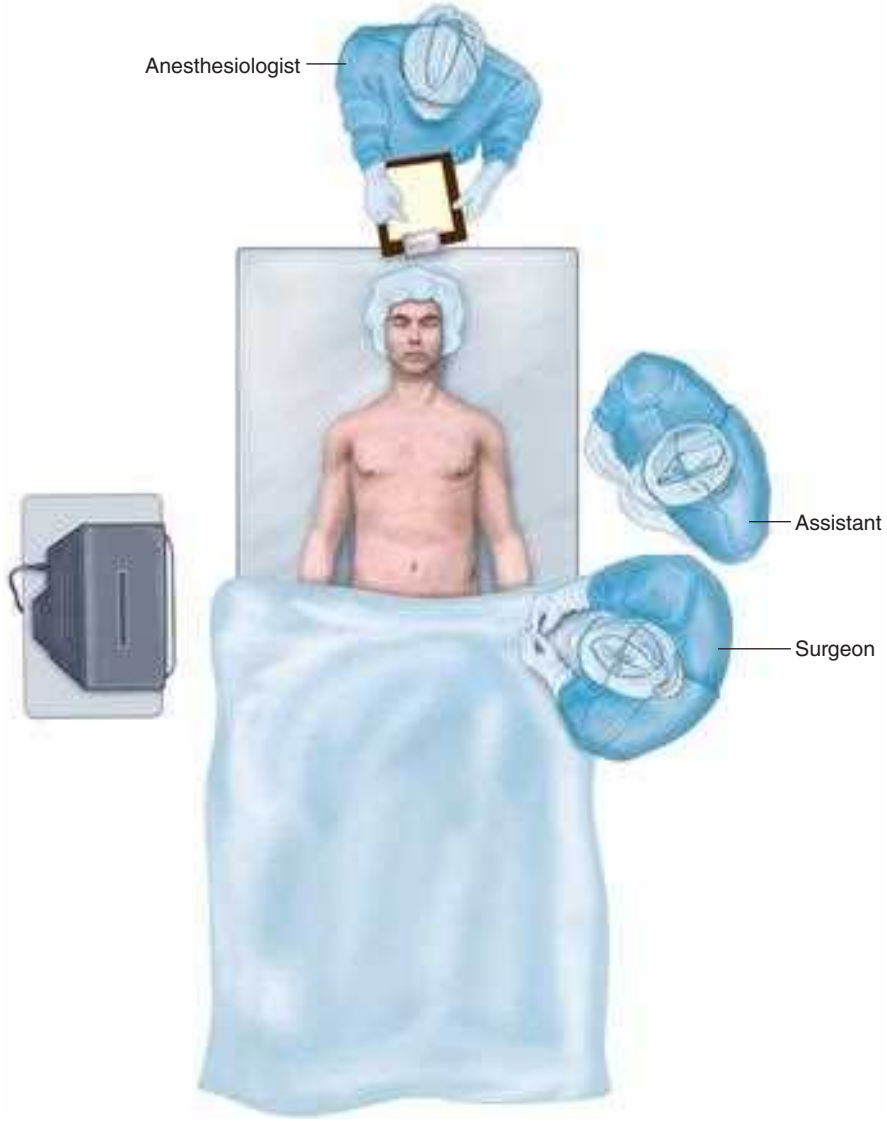

Figure 30-2. Operating room setup.

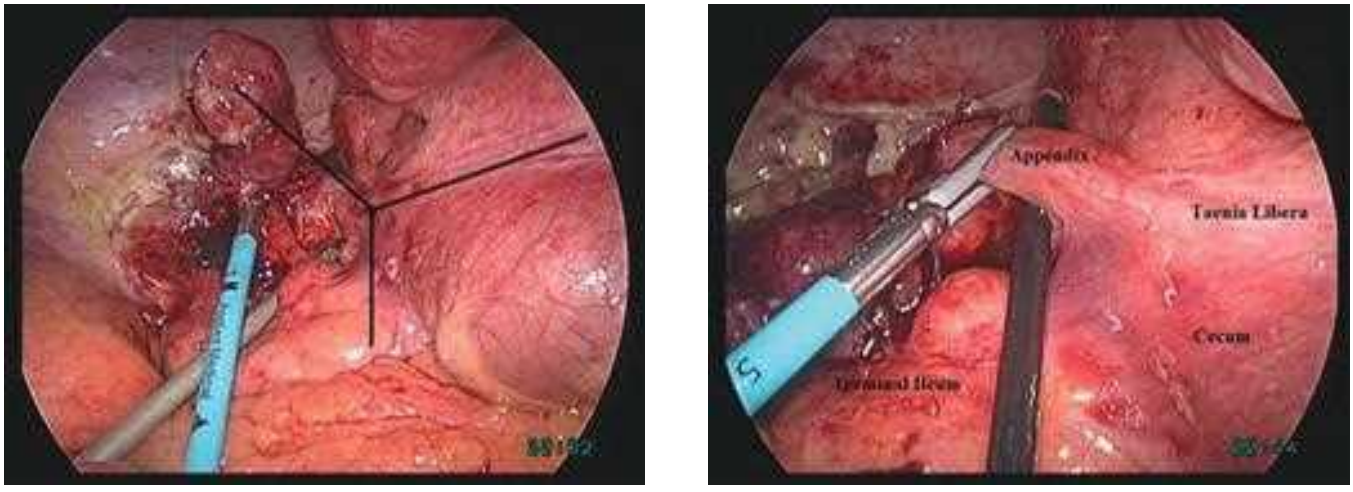

Figure 30-3. A and B. Appendiceal critical view.

quicker return to normal activity with laparoscopic appendectomy when compared to open appendectomy. Laparoscopic appendectomy is associated with increased operative duration and increased operating rooms costs; however, overall costs are likely similar when compared to open appendectomy. Patients tend to have improved satisfaction scores with laparoscopic appendectomy. Many of the differences, while statistically significant, have nominal clinical difference, such as length of stay where differences are measured in hours.[91-99]

In addition, laparoscopic appendectomy may provide a benefit when the diagnosis is in question, such as in female patients of reproductive age, older patients in whom malignancy is suspected, and morbidly obese patients for whom larger open appendectomy incisions may be required.

Laparoscopic Single-Incision Appendectomy

There has been growing interest in laparoscopic single-incision appendectomy. Instead of two or three incisions, a single incision is made, typically periumbilical. The first published laparoscopic-assisted, single-incision appendectomy was reported by Inoue in 1994, where the appendix was identified laparoscopically and grasped and pulled through the laparoscopic incision and the appendectomy completed in an open manner. The first reports of a pure laparoscopic single-incision appendectomy were described in 2009 by multiple surgical groups. By this time, industry had designed multiple options for true single-port access as opposed to makeshift single-incision access.

With laparoscopic single-incision appendectomy, the patient is prepared similarly to laparoscopic appendectomy. Under general anesthesia, the patient is secured in a supine position with the left arm tucked. The surgeon and assistant stand on the left side facing the appendix and the screen. When performing laparoscopic single-incision appendectomy, the surgeon's hands perform the opposite function that they would normally in standard laparoscopic surgery. The surgeon's right hand will grasp the appendix and retract it to the right lower quadrant at the 10 o'clock position.[90] The surgeon's left hand will dissect the mesenteric window and, upon identifying the appendiceal critical view, staple across the base of the appendix and mesentery. If the base of the appendix cannot be definitively identified or the appendiceal critical view cannot be obtained, additional ports can be placed to perform a "plus one" or even standard laparoscopic appendectomy. The appendix may be placed in a retrieval bag or removed through the single incision.

There have been multiple small trials evaluating the efficacy of laparoscopic single-incision appendectomy compared to standard appendectomy; however, there has only been one prospective randomized study (in the pediatric population) and one meta-analysis. Gill and colleagues, in 2012, reviewed nine studies for a total of 275 laparoscopic single-incision appendectomies and 348 standard laparoscopic appendectomy procedures. In this meta-analysis, there was no difference in operative time (57 ± 10 vs. 55 ± 13 minutes), complications (11% vs. 8.3%), incisional surgical site infections (5.6% vs. 4.9%), intra-abdominal abscesses (1.8% vs. 1.4%), or length of stay (3 ± 2 vs. 4 ± 1 days). Cases were converted to open or additional ports were placed in 4% of laparoscopic single-incision appendectomies and 0.9% of standard laparoscopic procedures. There was no difference in return to bowel function, postoperative pain, or return to normal activity. There was no difference in overall cost. The incidence of hernia formation following the laparoscopic single-incision appendectomy procedure compared to standard laparoscopy has not been reported.[100]

Although further study is needed, it appears that in laparoscopic appendectomy, laparoscopic single-incision appendectomy conveys no discernible advantage or disadvantage with short-term outcomes. Late outcomes and patient quality-of-life outcomes remain to be investigated.

Natural Orifice Transluminal Endoscopic Surgery

Natural orifice transluminal endoscopic surgery (NOTES) is a new surgical procedure using flexible endoscopes in the abdominal cavity. In this procedure, access is gained by way of organs that are reached through a natural, already-existing external orifice. The hoped-for advantages associated with this method include the reduction of postoperative wound pain, shorter convalescence, avoidance of wound infection and abdominal wall hernias, and the absence of scars.

One hundred thirteen NOTES appendectomies in human patients have been reported in the medical literature. Eighty-seven were performed transvaginally, and 26 were performed transgastrically.[101] The vast majority of these cases are hybrid procedures (NOTES plus laparoscopic assist port) with only 14 cases of pure NOTES appendectomies (three transvaginal

and 11 transgastric). Although reported complication rates appear low, conversion rates (to hybrid procedures) remain high.

The main concern with NOTES has been complications with closure of the enterotomy. To date, there is no reliable method of closure of the gastrotomy site, and there has been significant morbidity reported with this approach.

Although the transvaginal approach appears to be more promising, in women surveyed on their perception of NOTES, three-quarters were either neutral or unhappy about the prospects of NOTES.[102]

Much work remains to demonstrate whether NOTES is able to provide the theoretical benefits purported. Great care must be taken to prevent significant morbidity or mortality en route to studying these procedures.

SPECIAL CIRCUMSTANCES

Acute Appendicitis in the Young

The establishment of a diagnosis of acute appendicitis is more difficult in young children than in the adult. The inability of young children to give an accurate history, diagnostic delays by both parents and physicians, and the frequency of gastrointestinal distress in children are all contributing factors to the misdiagnosis and delay in diagnosis.[103] In children, the physical examination findings of maximal tenderness in the right lower quadrant, the inability to walk or walking with a limp, and pain with percussion, coughing, and hopping were found to have the highest sensitivity for appendicitis.[104]

The more rapid progression to rupture and the inability of the underdeveloped greater omentum to contain a rupture lead to significant morbidity rates in children. Children <5 years of age have a negative appendectomy rate of 25% and an appendiceal perforation rate of 45%. These rates may be compared with a negative appendectomy rate of <10% and a perforated appendix rate of 20% in children 5 to 12 years of age.[50,51] The incidence of major complications after appendectomy in children is correlated with appendiceal rupture. The wound infection rate after the treatment of nonperforated appendicitis in children is 2.8%, compared with a rate of 11% after the treatment of perforated appendicitis. The incidence of intra-abdominal abscess also is higher after the treatment of perforated appendicitis than after nonperforated appendicitis (6% vs. 3%).[105] The treatment regimen for perforated appendicitis generally includes immediate appendectomy. Antibiotic coverage is limited to 24 to 48 hours in cases of nonperforated appendicitis. For perforated appendicitis, intravenous antibiotics usually are given until the white blood cell count is normal and the patient is afebrile for 24 hours. Laparoscopic appendectomy has been shown to be safe and effective for the treatment of appendicitis in children.[106]

Acute Appendicitis in the Elderly

Compared with younger adults, elderly patients with appendicitis often pose a more difficult diagnostic problem because of the atypical presentation, expanded differential diagnosis, and communication difficulty. These factors may be responsible for the disproportionately high perforation rate seen in the elderly. In the general population, perforation rates range from 20% to 30%, compared with 50% to 70% in the elderly.[107] In addition, the perforation rate appears to increase with age greater than 80 years.[108]

Elderly patients usually present with lower abdominal pain, but on clinical examination, localized right lower quadrant tenderness is not as common as in younger patients. A history of periumbilical pain migrating to the right lower quadrant is reported infrequently. Although currently there are no criteria that definitively identify elderly patients with acute appendicitis who are at risk of rupture, prioritization should be given to patients with a temperature of greater than 38°C (100.4°F) and a shift to the left in leukocyte count of more than 76%, especially if they are male, are anorexic, or have had pain of long duration before admission.[65]

As a result of increased comorbidities and an increased rate of perforation, postoperative morbidity, mortality, and hospital length of stay are increased in the elderly compared with younger populations with appendicitis. Although no randomized trials have been conducted, it appears that elderly patients benefit from a laparoscopic approach to treatment of appendicitis. The use of laparoscopy in the elderly has significantly increased in recent years. In general, laparoscopic appendectomy offers elderly patients with appendicitis a shorter length of hospital stay, a reduction in complication and mortality rates, and a greater chance of discharge to home (independent of further nursing care or rehabilitation).[109]

Acute Appendicitis during Pregnancy

Appendectomy for presumed appendicitis is the most common surgical emergency during pregnancy. The incidence is approximately 1 in 766 births. Acute appendicitis can occur at any time during pregnancy but is rare in the third trimester.[110] The overall negative appendectomy rate during pregnancy is approximately 25% and appears to be higher than the rate seen in nonpregnant women.[110,111] A higher rate of negative appendectomy is seen in the second trimester, whereas the lowest rate is in the third trimester. The diversity of clinical presentations and the difficulty in making the diagnosis of acute appendicitis in pregnant women are well established. This is particularly true in the late second trimester and the third trimester, when many abdominal symptoms may be considered pregnancy related. In addition, during pregnancy, there are anatomic changes in the appendix and increased abdominal laxity that may further complicate clinical evaluation.

Appendicitis in pregnancy should be suspected when a pregnant woman complains of abdominal pain of new onset. The most consistent sign encountered in acute appendicitis during pregnancy is pain in the right side of the abdomen. Seventy-four percent of patients report pain located in the right lower abdominal quadrant, with no difference between early and late pregnancy. Only 57% of patients present with the classic history of diffuse periumbilical pain migrating to the right lower quadrant. Laboratory evaluation is not helpful in establishing the diagnosis of acute appendicitis during pregnancy. The physiologic leukocytosis of pregnancy has been defined as high as 16,000 cells/mm^3. In one series, only 38% of patients with appendicitis had a white blood cell count of more than 16,000 cells/mm^3.[110] Recent data suggest that the incidence of perforated or complex appendicitis is not increased in pregnant patients.[111]

When the diagnosis is in doubt, abdominal ultrasound may be beneficial. Another option is magnetic resonance imaging, which has no known deleterious effects on the fetus. The American College of Radiology recommends the use of nonionizing radiation techniques for front-line imaging in

pregnant women.[70] Laparoscopy has been advocated in equivocal cases, especially early in pregnancy; however, laparoscopic appendectomy may be associated with an increase in pregnancy-related complications. In an analysis of outcomes in California using administrative databases, laparoscopy was found to be associated with a 2.31 times increased risk of fetal loss compared with open surgery.[111]

The overall incidence of fetal loss after appendectomy is 4%, and the risk of early delivery is 7%. Rates of fetal loss are considerably higher in women with complicated appendicitis than in those with a negative appendectomy or with simple appendicitis. It is important to note that a negative appendectomy is not a benign procedure. Removing a normal appendix is associated with a 4% risk of fetal loss and 10% risk of early delivery.

9▶ Maternal mortality after appendectomy is extremely rare (0.03%). Because the incidence of complicated appendix is similar in pregnant and nonpregnant women and because maternal mortality is so low, it appears that the greatest opportunity to improve fetal outcomes is by improving diagnostic accuracy and reducing the rate of negative appendectomy.[110-113]

POSTOPERATIVE CARE AND COMPLICATIONS

Following uncomplicated appendectomy, complication rates are low,[114] and most patients can quickly be started on a diet and discharged home the same day or the following day.[115] Postoperative antibiotic therapy is unnecessary.[116]

Alternatively, with complicated appendectomy, complication rates are increased compared to uncomplicated appendicitis.[114] Patients should be continued on broad-spectrum

10▶ antibiotics for 4 to 7 days.[117,118] Postoperative ileus may occur, so diet should be started based on daily clinical evaluation. These patients are at increased risk for surgical site infections.

Surgical Site Infection

In patients with incisional (superficial or deep) surgical site infection, treatment should be opening of the incision and obtaining a culture. Following laparoscopic appendectomy, the extraction port site is the most common site of surgical site infection. Patients with cellulitis can be started on antibiotics. The cultured organisms are typically bowel flora, as opposed to skin flora.[119]

Patients with postoperative intra-abdominal abscesses can present in a variety of ways. Although fever, leukocytosis, and abdominal pain are common presentations, patients with ileus, bowel obstruction, diarrhea, and tenesmus may also harbor intra-abdominal abscesses. Small abscesses can be simply treated with antibiotics; however, larger abscesses require drainage. Most commonly, percutaneous drainage with CT or ultrasound guidance is effective. For abscesses not amenable to percutaneous drainage, laparoscopic abscess drainage is a viable option.

Stump Appendicitis

Incomplete appendectomy represents a failure of removing the entire appendix on the initial procedure. A review of literature has revealed only 60 reports of this phenomenon. Likely, incomplete appendectomy is underreported, and the true prevalence is much higher. Reported as "stump appendicitis," patients typically present with recurrent symptoms of appendicitis approximately 9 years after their initial surgery. There was no difference in initial surgery between laparoscopic and open procedures. However, there were more complicated appendectomies on initial surgery. Patients presenting with stump appendicitis are more likely to have complicated appendicitis, have an open procedure, and undergo colectomy.

The key to avoiding stump appendicitis is prevention. Use of the "appendiceal critical view" (appendix placed at 10 o'clock, taenia coli/libera at 3 o'clock, and terminal ileum at 6 o'clock) and identification of where the taeniae coli merge and disappear is paramount to identifying and ligating the base of the appendix during the initial operation. The remaining stump should be no longer than 0.5 cm, as stump appendicitis has only been noted in stumps ≥0.5 cm in the literature.

In patients who have had prior appendectomy, a low index of suspicion is important to prevent delay in diagnosis and complications. Prior appendectomy should not be an absolute criterion in ruling out acute appendicitis.

INCIDENTAL APPENDECTOMY

Decisions regarding the efficacy of incidental appendectomy should be based on the epidemiology of appendicitis. The best data were published by the Centers for Disease Control and Prevention based on the period from 1979 to 1984.[120] During this period, an average of 250,000 cases of appendicitis and 310,000 incidental appendectomies occurred annually in the United States. It was estimated that 36 incidental appendectomies had to be performed to prevent one patient from developing appendicitis.[121] In view of the added costs and risk of morbidity for each extension of a surgical intervention, this does not seem to justify incidental appendectomy.

The financial aspects of the decision to perform incidental appendectomy were assessed.[122] For open appendectomy, there was a financial disincentive to perform incidental appendectomy. On an annual basis, $20,000,000 had to be spent to save the $6,000,000 cost of appendicitis. With the laparoscopic approach, it was cost-effective to perform incidental appendectomy only in patients less than 25 years of age and only if the reimbursement for surgeons was 10% of the usual and customary charges. At a higher rate of reimbursement, incidental appendectomy was not cost-effective in any age group.

Although incidental appendectomy is generally neither clinically nor economically appropriate, there are some special patient groups in whom it should be performed during laparotomy or laparoscopy for other indications. These include children about to undergo chemotherapy, the disabled who cannot describe symptoms or react normally to abdominal pain, patients with Crohn's disease in whom the cecum is free of macroscopic disease, and

11▶ individuals who are about to travel to remote places where there is no access to medical or surgical care.[123]

Appendectomy is routinely carried out during the performance of Ladd's procedure for malrotation because displacement of the cecum into the left upper quadrant would complicate the diagnosis of subsequent appendicitis.

NEOPLASMS OF THE APPENDIX

Prevalence of Neoplasms

Multiple studies have evaluated the prevalence of mass lesions present in appendectomy specimens (Table 30-8).[124-132] The prevalence of identifying a mass within the appendix is less than 1%. Appendiceal carcinoid and appendiceal adenomas are the

12▶ most common lesions identified. There is no clear age relationship associated with the identification of these masses.

Table 30-8

Prevalence of malignancy associated with appendix specimens

AUTHOR	NO.	MALE GENDER	AGE (MEAN)	AGE (RANGE)	ADENOMA	CARCINOID	OTHER	OVERALL
Ozer	2376	22 (81.5%)	26.7	NR	NR	27 (1.13%)	NR	27 (1.13%)
Lee	3744	NR	NR	NR	14 (0.35%)	9 (0.24%)	5 (0.12%)	28 (0.7%)
Sieren	141	6 (60%)	47	NR	NR	NR	NR	10 (7.1%)
Debnath	1941	11 (69%)	41.8	NR	NR	16 (0.82%)	NR	16 (0.82%)
In't Hof	1485	4 (57%)	32.7	20–59	NR	7 (0.47%)	NR	7 (0.47%)
Smeenk	167,744	608 (41%)	61	7–93	NR	NR	NR	1482 (0.9%)
O'Donnel	2154	8 (36%)	30	14–83	NR	11 (0.5%)	11 (0.5%)	22 (1.02%)
Marudanayagam	2660	NR	NR	NR	16 (0.6%)	14 (0.52%)	10 (0.39%)	40 (1.50%)
Overall	184,118				30 (0.47%)	57 (0.54%)	26 (0.30%)	1558 (0.89%)
Lai[a]	1873	11 (69%)	69	42–89	NR	NR	16 (0.85%)	16 (0.85%)

[a]Lai reported only the incidence of colon cancer presenting as appendicitis.
NR = not reported.

In older patients, the prevalence of identifying colon cancer appearing as appendicitis has been reported in a single study with a prevalence of less than 1%. The mean age in this case series was 69 years (range, 42 to 89 years).

Carcinoid

The finding of a firm, yellow, bulbar mass in the appendix should raise the suspicion of an appendiceal carcinoid. The appendix is the most common site of gastrointestinal carcinoid, followed by the small bowel and rectum. Carcinoid syndrome is rarely associated with appendiceal carcinoid unless widespread metastases are present, which occur in 2.9% of cases. Symptoms attributable directly to the carcinoid are rare, although the tumor can occasionally obstruct the appendiceal lumen much like a fecalith and result in acute appendicitis.[131,133,134]

The majority of carcinoids are located in the tip of the appendix. Malignant potential is related to size, with tumors <1 cm rarely resulting in extension outside of the appendix or adjacent to the mass. The mean tumor size for carcinoids is 2.5 cm.[133] Carcinoid tumors usually present with localized disease (64%). Treatment for tumors ≤1 cm is appendectomy. For tumors larger than 1 to 2 cm located at the base, involving the mesentery, or with lymph node metastases, right hemicolectomy is indicated. Despite these recommendations, surveillance, epidemiology, and end results data indicate that proper surgery for carcinoids is not performed at least 28% of the time.[133]

Adenocarcinoma

Primary adenocarcinoma of the appendix is a rare neoplasm with three major histologic subtypes: mucinous adenocarcinoma, colonic adenocarcinoma, and adenocarcinoid.[135] The most common mode of presentation for appendiceal carcinoma is that of acute appendicitis. Patients also may present with ascites or a palpable mass, or the neoplasm may be discovered during an operative procedure for an unrelated cause. The recommended treatment for all patients with adenocarcinoma of the appendix is a formal right hemicolectomy. Appendiceal adenocarcinomas have a propensity for early perforation, although they are not clearly associated with a worsened prognosis.[134] Overall 5-year survival is 55% and varies with stage and grade. Patients with appendiceal adenocarcinoma are at significant risk for both synchronous and metachronous neoplasms, approximately half of which will originate from the gastrointestinal tract.[135]

Mucocele

A mucocele of the appendix is an obstructive dilatation by intraluminal accumulation of mucoid material. Mucoceles may be caused by one of four processes: retention cysts, mucosal hyperplasia, cystadenomas, and cystadenocarcinomas. The clinical presentation of a mucocele is nonspecific, and often it is an incidental finding at operation for acute appendicitis. An intact mucocele presents no future risk for the patient; however, the opposite is true if the mucocele has ruptured and epithelial cells have escaped into the peritoneal cavity. As a result, when a mucocele is visualized at the time of laparoscopic examination, conversion to open laparotomy is recommended. Conversion from a laparoscopic approach to a laparotomy ensures that a benign process will not be converted to a malignant one through mucocele rupture. In addition, laparotomy allows for thorough abdominal exploration to rule out the presence of mucoid fluid accumulations.[135]

The presence of a mucocele of the appendix does not mandate performance of a right hemicolectomy. The principles of surgery include resection of the appendix, wide resection of the mesoappendix to include all the appendiceal lymph nodes, collection and cytologic examination of all intraperitoneal mucus, and careful inspection of the base of the appendix. Right hemicolectomy or, preferably, ileocecectomy is reserved for patients with a positive margin at the base of the appendix or positive periappendiceal lymph nodes. Recently, a more aggressive approach to ruptured appendiceal neoplasms has been advocated. This approach includes a thorough but minimally aggressive approach at initial laparotomy, as described earlier, with subsequent referral to a specialized center for consideration of reexploration and hyperthermic intraperitoneal chemotherapy.[134]

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a rare condition in which diffuse collections of gelatinous fluid are associated with mucinous

implants on peritoneal surfaces and omentum. Pseudomyxoma is two to three times more common in females than in males. Recent immunocytologic and molecular studies suggest that the appendix is the site of origin for the overwhelming majority of cases of pseudomyxoma. Pseudomyxoma is invariably caused by neoplastic mucus-secreting cells within the peritoneum. These cells may be difficult to classify as malignant because they may be sparse, widely scattered, and have a low-grade cytologic appearance. Patients with pseudomyxoma usually present with abdominal pain, distention, or a mass. Primary pseudomyxoma usually does not cause abdominal organ dysfunction. However, ureteral obstruction and obstruction of venous return can be seen.[136] Pseudomyxoma is a disease that progresses slowly and in which recurrences may take years to develop or become symptomatic.[136] In a series from the Mayo Clinic, 76% of patients developed recurrences within the abdomen.[137] Lymph node metastasis and distant metastasis are uncommon.

The use of imaging before surgery is advantageous to plan surgery. CT scanning is the preferred imaging modality. At surgery, a variable volume of mucinous ascites is found together with tumor deposits involving the right hemidiaphragm, right retrohepatic space, left paracolic gutter, ligament of Treitz, and the ovaries in women. Peritoneal surfaces of the bowel are usually free of tumor. Thorough surgical debulking is the mainstay of treatment. All gross disease and the omentum should be removed. If not done previously, appendectomy is routinely performed. Hysterectomy with bilateral salpingo-oophorectomy is performed in women. Survival is better in patients who undergo R0 or R1 resection than in patients who undergo R2 resection (visible gross disease remaining).[138] Because 5-year survival of mucinous appendiceal neoplasms is only 30%, adjuvant intraperitoneal hyperthermic chemotherapy is advocated as a standard adjunct to radical cytoreductive surgery.[139] Cytoreductive surgery with intraperitoneal hyperthermic chemotherapy is a long, tedious procedure with operative times of 300 to 1020 minutes reported. In addition, morbidity (38%) and mortality (6%) are high. Cytoreductive surgery with intraperitoneal hyperthermic chemotherapy is associated with a 5-year survival rate of 53% to 78%. Survival is associated with initial patient performance status.[138-140]

Any recurrence should be investigated completely. Recurrences are usually treated by additional surgery. It is important to note that surgery for recurrent disease is usually difficult and is associated with an increased incidence of enterotomies, anastomotic leaks, and fistulas.[136,137]

Lymphoma

Lymphoma of the appendix is extremely uncommon. The gastrointestinal tract is the most frequently involved extranodal site for non-Hodgkin's lymphoma.[141] Other types of appendiceal lymphoma, such as Burkitt's lymphoma, as well as leukemia, have also been reported.[142] Primary lymphoma of the appendix accounts for 1% to 3% of gastrointestinal lymphomas. Appendiceal lymphoma usually presents as acute appendicitis and is rarely suspected preoperatively. Findings on CT scan of an appendiceal diameter ≥2.5 cm or surrounding soft tissue thickening should prompt suspicion of an appendiceal lymphoma. The management of appendiceal lymphoma confined to the appendix is appendectomy. Right hemicolectomy is indicated if tumor extends beyond the appendix onto the cecum or mesentery. A postoperative staging workup is indicated before initiating adjuvant therapy. Adjuvant therapy is not indicated for lymphoma confined to the appendix.[142,143]

chapter 31

Liver

Elaine Y. Cheng, Ali Zarrinpar, David A. Geller, John A. Goss, and Ronald W. Busuttil

Key Points

1. When operating on the liver, gallbladder, pancreas, or adjacent organs, recognition of the normal or variant vascular and biliary anatomy is essential to avoiding surgical complications.
2. The liver is the largest gland in the body and performs a diverse spectrum of functions.
3. Computed tomography and magnetic resonance imaging with contrast enhancement constitute the mainstays for the radiologic evaluation of the liver.
4. Acute liver failure rapidly progresses to hepatic coma and death even with maximal medical therapy. The only definitive treatment is orthotopic liver transplantation.
5. Cirrhosis is the end result of chronic hepatic insult, and further deterioration can lead to the development of end-stage liver disease, which carries a high mortality rate.
6. Acute variceal bleeding should be managed with aggressive resuscitation and prompt endoscopic diagnosis with hemorrhage control. The transjugular intrahepatic portosystemic shunt procedure can be considered for cases refractory to medical treatment.
7. Common benign lesions of the liver include cysts, hemangiomas, focal nodular hyperplasia, and hepatocellular adenomas. In most instances, these lesions can be reliably diagnosed by their characteristic features on imaging.
8. Many options exist for the treatment of hepatocellular carcinomas, and these cases are best managed by a multidisciplinary liver transplant team.
9. Surgical resection is the treatment of choice for hilar cholangiocarcinoma. Under a protocol with strict eligibility criteria, patients with unresectable tumors can be considered for liver transplantation following neoadjuvant chemoradiation, with survival rates that compare favorably with the rates for resection.
10. The resectability of colorectal cancer metastases to the liver is primarily determined by the volume of the future liver remnant and the health of the background liver and not actual tumor number.
11. Laparoscopic liver resections can be performed safely by experienced surgeons in selected patients and have been shown to produce comparable morbidity and mortality rates to open resections.

HISTORY OF LIVER SURGERY

The ancient Greek myth of Prometheus reminds us that the liver is the only organ that regenerates. According to Greek mythology, Zeus was furious with the Titan Prometheus because he gave fire to mortals. In return, Zeus chained Prometheus to Mount Caucasus and sent his giant eagle to eat his liver during the day, only to have it regenerate at night. Although this is folklore, the principles are correct that after hepatic resection, the remnant liver will hypertrophy over weeks to months to regain most of its original liver mass. It is interesting to note that the ancient Greeks seem to have been aware of this fact, because the Greek word for the liver, *hēpar,* derives from the verb *hēpaomai,* which means "mend" or "repair." Hence *hēpar* roughly translates as "repairable."[1] The importance of the liver dates back to even biblical times, for the Babylonians (c. 2000 B.C.) considered the liver to be the seat of the soul. There are scattered reports of liver surgery for battlefield injuries, but the first recorded elective hepatic resection was done in 1888 in Germany by Langenbuch. There followed reports of liver resections in the United States (Tiffany, 1890) and Europe (Lucke, 1891), as well as the first large series of hepatic resections by Keen in 1899.[2,3] In 1908, Pringle described in *Annals of Surgery* the "arrest of hepatic hemorrhage due to trauma" by compression of the porta hepatis, a maneuver that now bears his name.[4] Possibly due to the potential for massive hemorrhage during liver surgery, very little progress in surgical techniques was recorded for the next half-century. Work by Rex, Cantlie, and others laid the groundwork for experimental and clinical reports in the 1950s by Couinaud, Hjortsjo, Healey, Lortat-Jacob, and Starzl.[5,6] These seminal contributions paved the way for the modern era of hepatic resection surgery.

LIVER ANATOMY

The liver is the largest organ in the body, weighing approximately 1500 g. It resides in the right upper abdominal cavity beneath the diaphragm and is protected by the rib cage. It is reddish brown and is surrounded by a fibrous sheath known as *Glisson's capsule.* The liver is held in place by several ligaments (Fig. 31-1). The round ligament is the remnant of the obliterated umbilical vein and enters the left liver hilum at the front edge of the falciform ligament. The falciform ligament separates the left lateral and left medial segments along the umbilical fissure and anchors the liver to the anterior abdominal wall. Deep in the plane between the caudate lobe and the left lateral segment is the fibrous ligamentum venosum (Arantius' ligament), which is the obliterated ductus venosus and is covered by the plate of Arantius. The left and right triangular ligaments secure the two sides of the liver to the diaphragm. Extending from the triangular ligaments anteriorly on the liver are the coronary ligaments. The right coronary ligament also extends from the right undersurface of the liver to the peritoneum overlying the right kidney, thereby anchoring the liver to the right retroperitoneum. These ligaments (round, falciform, triangular, and coronary) can be divided in a bloodless plane to fully mobilize the liver to facilitate hepatic resection. Centrally and just to the left of the gallbladder fossa, the liver attaches via the hepatoduodenal and the gastrohepatic ligaments (Fig. 31-2). The hepatoduodenal ligament is known as the *porta hepatis* and contains the common bile duct, the hepatic artery, and the portal vein. From the right side and deep (dorsal) to the porta hepatis is the foramen of Winslow, also known as the *epiploic foramen* (see Fig. 31-2). This passage connects directly to the lesser sac and allows complete vascular inflow control to the liver when the hepatoduodenal ligament is clamped using the Pringle maneuver.

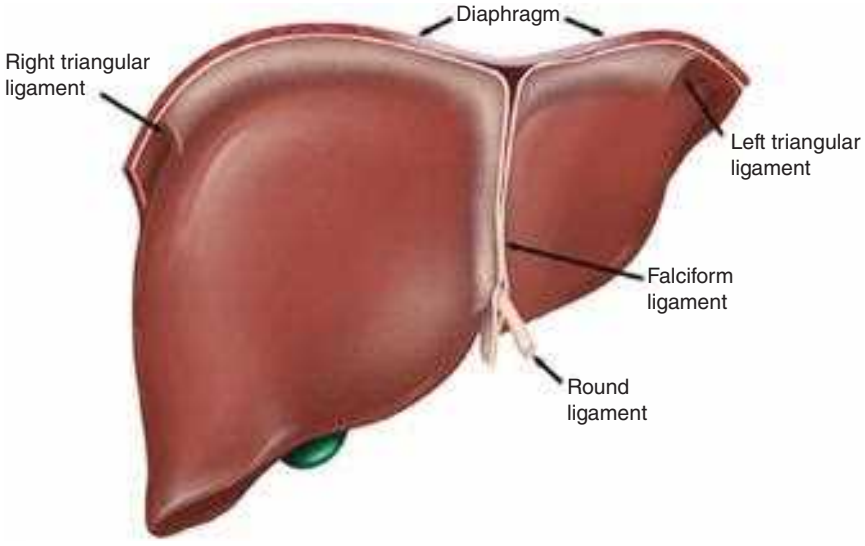

Figure 31-1. Hepatic ligaments suspending the liver to the diaphragm and anterior abdominal wall.

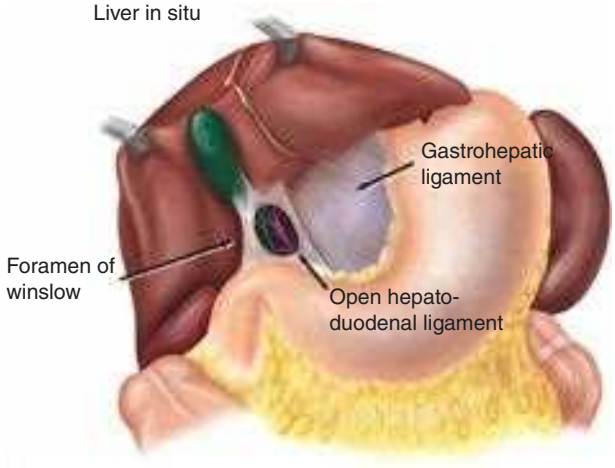

Figure 31-2. In situ liver hilar anatomy with hepatoduodenal and gastrohepatic ligaments. Foramen of Winslow is depicted.

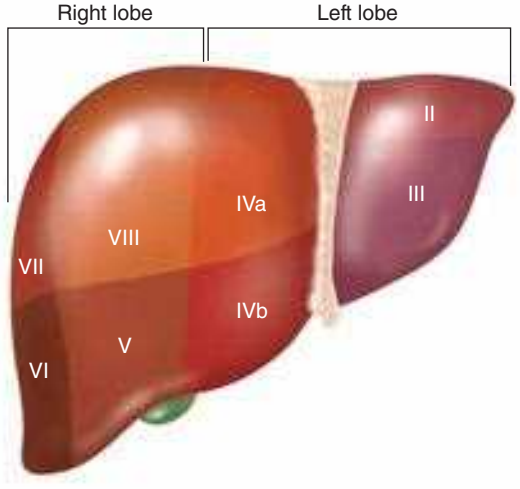
Segmental Anatomy

The liver is grossly separated into the right and left lobes by the plane from the gallbladder fossa to the inferior vena cava (IVC), known as *Cantlie's line*.[5] The right lobe typically accounts for 60% to 70% of the liver mass, with the left lobe (and caudate lobe) making up the remainder. The caudate lobe lies to the left and anterior of the IVC and contains three subsegments: the Spiegel lobe, the paracaval portion, and the caudate process.[7] The falciform ligament does not separate the right and left lobes, but rather it divides the left lateral segment from the left medial segment. The left lateral and left medial segments also are referred to as *sections* as defined in the Brisbane 2000 terminology, which is outlined later in the section titled "Hepatic Resection." A significant advance in our understanding of liver anatomy came from the cast work studies of the French surgeon and anatomist Couinaud in the early 1950s. Couinaud divided the liver into eight segments, numbering them in a clockwise direction beginning with the caudate lobe as segment I.[6] Segments II and III comprise the left lateral segment, and segment IV is the left medial segment (Fig. 31-3). Thus, the left lobe is made up of the left lateral segment (Couinaud's segments II and III) and the left medial segment (segment IV). Segment IV can be subdivided into segment IVA and segment IVB. Segment IVA is cephalad and just below the diaphragm, spanning from segment VIII to the falciform ligament adjacent to segment II. Segment IVB is caudad and adjacent to the gallbladder fossa. Many anatomy textbooks also refer to segment IV as the *quadrate lobe. Quadrate lobe* is an outdated term, and the preferred term is *segment IV* or *left medial segment.* Most surgeons still refer to segment I as the *caudate lobe,* rather than segment I. The right lobe is comprised of segments V, VI, VII, and



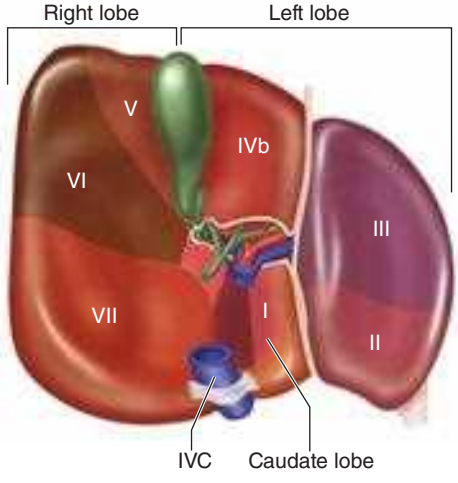


Figure 31-3. Couinaud's liver segments (I through VIII) numbered in a clockwise manner. The left lobe includes segments II to IV, the right lobe includes segments V to VIII, and the caudate lobe is segment I. IVC = inferior vena cava.

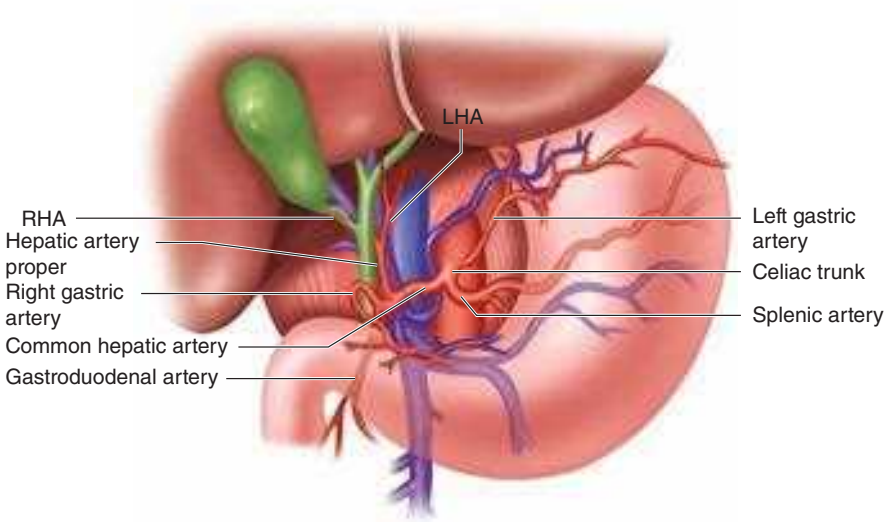

Figure 31-4. Arterial anatomy of the upper abdomen and liver, including the celiac trunk and hepatic artery branches. a. = artery; LHA = left hepatic artery; RHA = right hepatic artery.

VIII, with segments V and VIII making up the right anterior lobe, and segments VI and VII the right posterior lobe.

Additional functional anatomy was highlighted by Bismuth based on the distribution of the hepatic veins. The three hepatic veins run in corresponding scissura (fissures) and divide the liver into four sectors.[8] The right hepatic vein runs along the right scissura and separates the right posterolateral sector from the right anterolateral sector. The main scissura contains the middle hepatic vein and separates the right and left livers. The left scissura contains the course of the left hepatic vein and separates the left posterior and left anterior sectors.

Hepatic Artery

The liver has a dual blood supply consisting of the hepatic artery and the portal vein. The hepatic artery delivers approximately 25% of the blood supply, and the portal vein approximately 75%. The hepatic artery arises from the celiac axis (trunk), which gives off the left gastric, splenic, and common hepatic arteries (Fig. 31-4). The common hepatic artery then divides into the gastroduodenal artery and the hepatic artery proper. The right gastric artery typically originates off of the hepatic artery proper, but this is variable. The hepatic artery proper divides into the right and left hepatic arteries. This "classic" or standard arterial anatomy is present in only approximately 76% of cases, with the remaining 24% having variable anatomy. It is critical to 1▶ understand the arterial (and biliary) anatomic variants to avoid surgical complications when operating on the liver, gallbladder, pancreas, or adjacent organs.

The most common hepatic arterial variants are shown (Fig. 31-5). Approximately 10% to 15% of the time, there is a

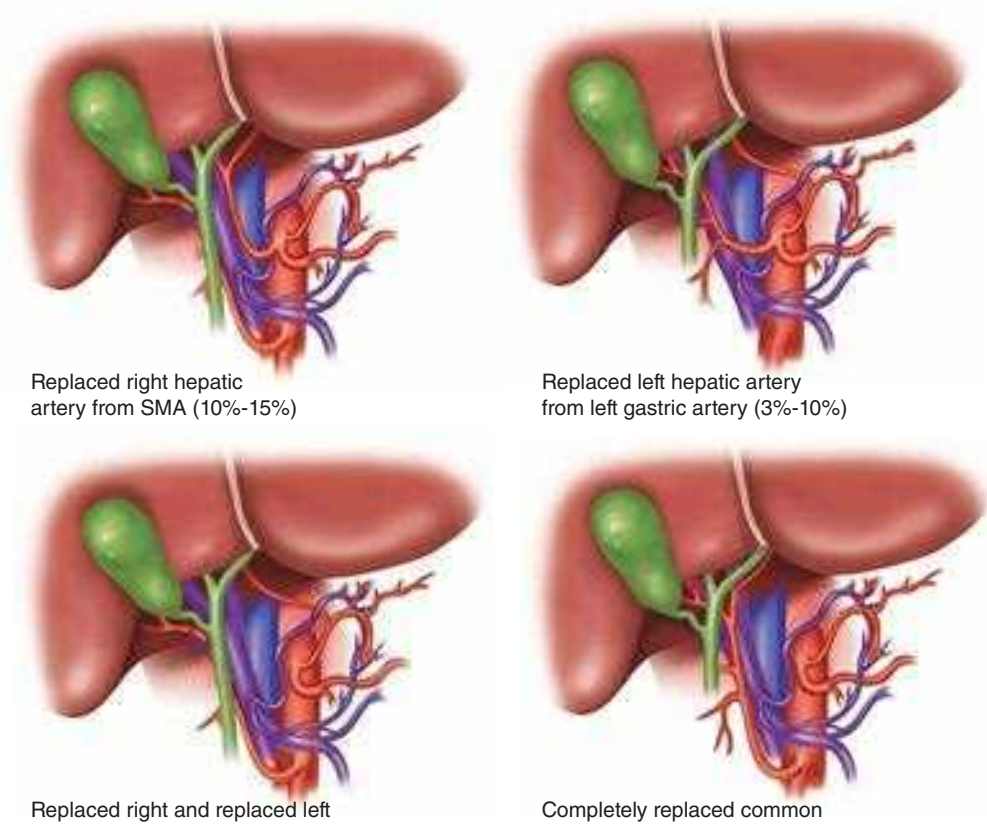

Figure 31-5. Common hepatic artery anatomic variants. SMA = superior mesenteric artery.

replaced or accessory right hepatic artery arising from the superior mesenteric artery (SMA). When there is a replacement or accessory right hepatic artery, it travels posterior to the portal vein and then takes up a right lateral position before diving into the liver parenchyma. This can be recognized visually on a preoperative computed tomography (CT) or magnetic resonance imaging (MRI) scan, and confirmed by palpation in the hilum where a separate right posterior pulsation is felt distinct from that of the hepatic artery proper that lies anteriorly in the hepatoduodenal ligament to the left of the common bile duct. In approximately 3% to 10% of cases, there exists a replacement (or accessory) left hepatic artery coming off of the left gastric artery and running obliquely in the gastrohepatic ligament anterior to the caudate lobe before entering the hilar plate at the base of the umbilical fissure. Other less common variants (approximately 1% to 2% each) are the presence of both replaced right and replaced left hepatic arteries, as well as a completely replaced common hepatic artery coming off the SMA (see Fig. 31-5). Although not well demonstrated in the illustration, the clue for a completely replaced common hepatic artery coming off the SMA is the presence of a strong arterial pulsation to the right of and posterior to the common bile duct, rather than the left side and anterior, in the porta hepatis. Another important point is that the right hepatic artery passes deep and posterior to the common bile duct approximately 88% of the time but crosses anterior to the common bile duct in approximately 12% of cases. The cystic artery feeding the gallbladder usually arises from the right hepatic artery in Calot's triangle.

Portal Vein

The portal vein is formed by the confluence of the splenic vein and the superior mesenteric vein. The inferior mesenteric vein usually drains into the splenic vein upstream from the confluence (Fig. 31-6). The main portal vein traverses the porta hepatis before dividing into the left and right portal vein branches. The left portal vein typically branches from the main portal vein outside of the liver with a sharp bend to the left and consists of the transverse portion followed by a 90° turn at the base of the umbilical fissure to become the umbilical portion before entering the liver parenchyma (Fig. 31-7). The left portal vein then

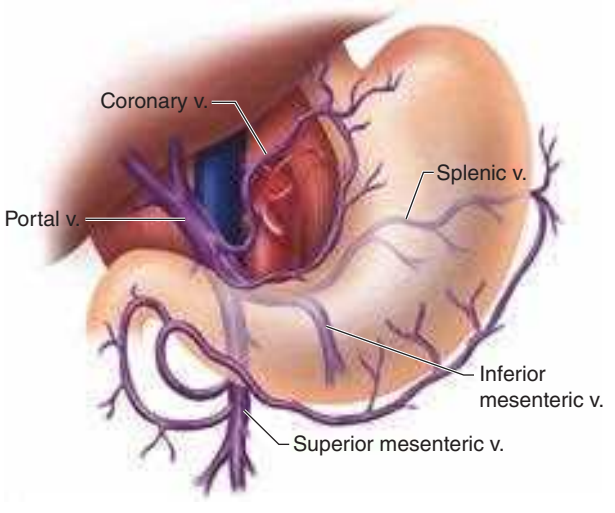

Figure 31-6. Portal vein anatomy. The portal vein is formed by the confluence of the splenic and superior mesenteric veins. The inferior mesenteric vein drains into the splenic vein. The coronary (left gastric) vein drains into the portal vein in the vicinity of the confluence. v. = vein.

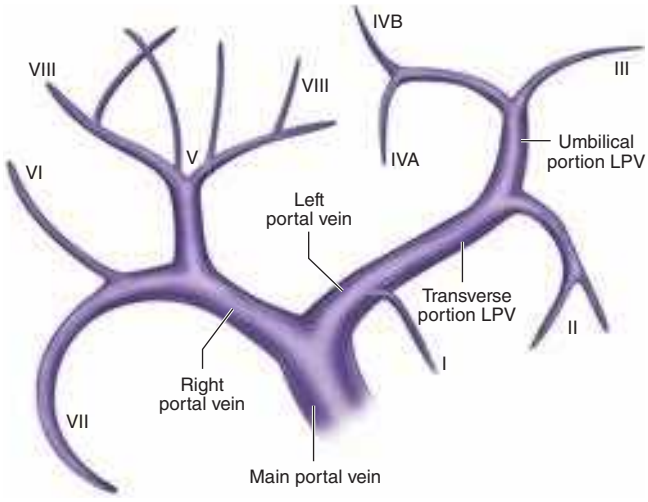

Figure 31-7. Anatomy of the left portal vein (LPV). Cadaver cast shows the transverse and umbilical portions of the LPV.

divides to give off the segment II and III branches to the left lateral segment, as well as the segment IV branches that supply the left medial segment. The left portal vein also provides the dominant inflow branch to the caudate lobe (although branches can arise from the main and right portal veins also), usually close to the bend between the transverse and umbilical portions. The division of the right portal vein is usually higher in the hilum and may be close to (or inside) the liver parenchyma at the hilar plate. Twenty percent to thirty-five percent of individuals have aberrant portal venous anatomy, with portal vein trifurcation or an aberrant branch from the left portal vein supplying the right anterior lobe being the most frequent.

The portal vein drains the splanchnic blood from the stomach, pancreas, spleen, small intestine, and majority of the colon to the liver before returning to the systemic circulation. The portal vein pressure in an individual with normal physiology is low at 3 to 5 mmHg. The portal vein is valveless, however, and in the setting of portal hypertension, the pressure can be quite high (20 to 30 mmHg). This results in decompression of the systemic circulation through portocaval anastomoses, most commonly via the coronary (left gastric) vein, which produces esophageal and gastric varices with a propensity for major hemorrhage. Another branch of the main portal vein is the superior pancreaticoduodenal vein (which comes off low in an anterior lateral position and is divided during pancreaticoduodenectomy). Closer to the liver, the main portal vein typically gives off a short branch (posterior lateral) to the caudate process on the right side. It is important to identify this branch and ligate it during hilar dissection for anatomic right hemihepatectomy to avoid avulsion.

Hepatic Veins and Inferior Vena Cava

There are three hepatic veins (right, middle, and left) that pass obliquely through the liver to drain the blood to the suprahepatic IVC and eventually the right atrium (Fig. 31-8). The right hepatic vein drains segments V through VIII; the middle hepatic vein drains segment IV as well as segments V and VIII; and the left hepatic vein drains segments II and III. The caudate lobe is unique because its venous drainage feeds directly into the IVC. In addition, the liver usually has a few small, variable short hepatic veins that directly enter the IVC from the undersurface of the liver. The left and middle hepatic veins form a common trunk approximately 95% of the time before entering the IVC, whereas the right hepatic vein inserts separately (in an oblique orientation) into the IVC.

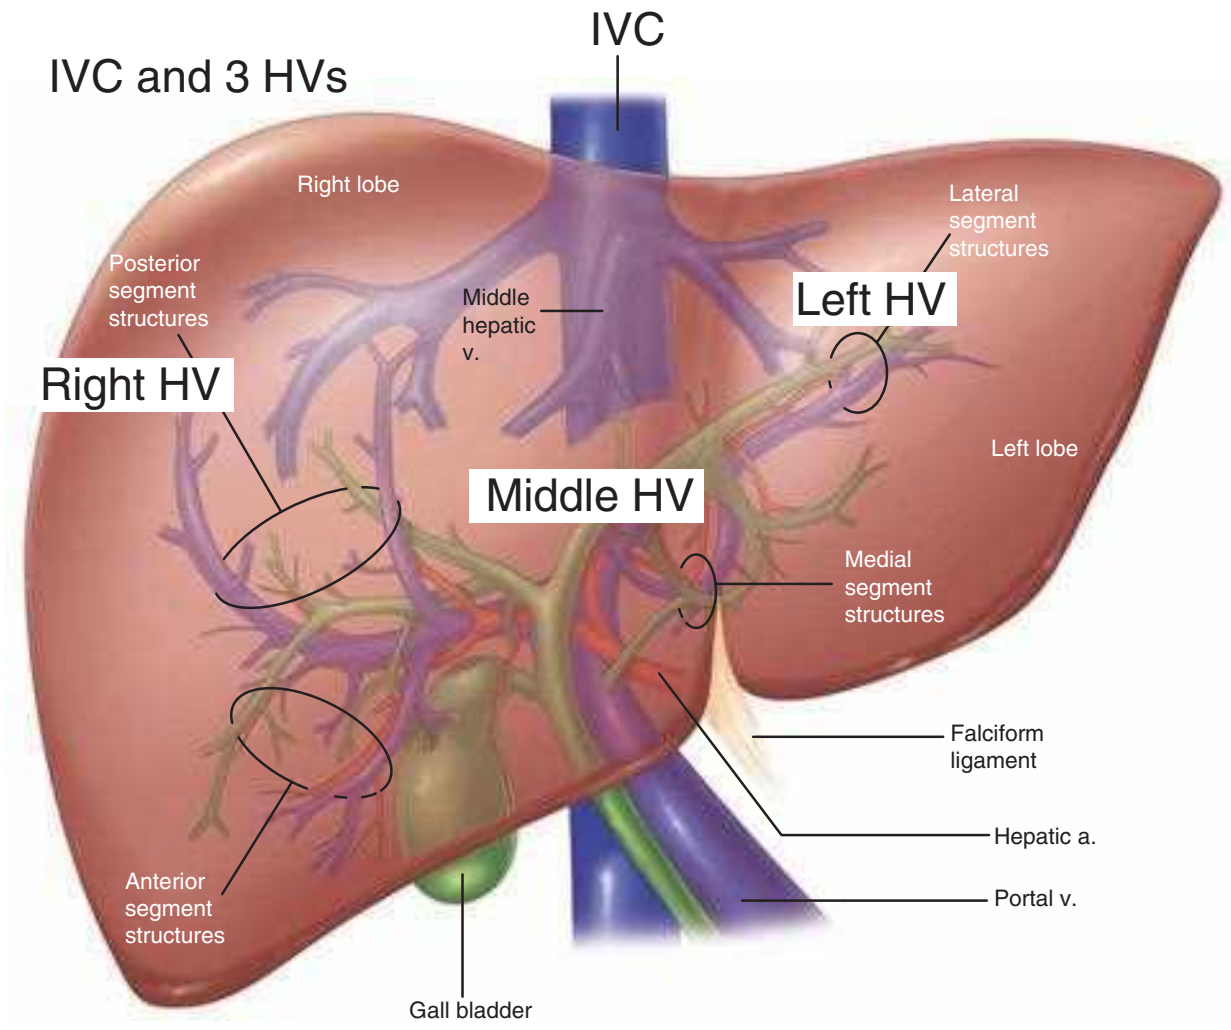

Figure 31-8. Confluence of the three hepatic veins (HVs) and the inferior vena cava (IVC). Note that the middle and left HVs drain into a common trunk before entering the IVC. a. = artery; v. = vein. *(Adapted with permission from Cameron JL, ed.* Atlas of Surgery. Vol. I, Gallbladder and Biliary Tract, the Liver, Portasystemic Shunts, the Pancreas. *Toronto: BC Decker; 1990:153.)*

There is a large inferior accessory right hepatic vein in 15% to 20% of cases that runs in the hepatocaval ligament. This can be a source of torrential bleeding if control of it is lost during right hepatectomy. The hepatic vein branches bisect the portal branches inside the liver parenchyma (i.e., the right hepatic vein runs between the right anterior and posterior portal veins; the middle hepatic vein passes between the right anterior and left portal vein; and the left hepatic vein crosses between the segment II and III branches of the left portal vein).

Bile Duct and Hepatic Ducts

Within the hepatoduodenal ligament, the common bile duct lies anteriorly and to the right. It gives off the cystic duct to the gallbladder and becomes the common hepatic duct before dividing into the right and left hepatic ducts. In general, the hepatic ducts follow the arterial branching pattern inside the liver. The right anterior hepatic duct usually enters the liver above the hilar plate, whereas the right posterior duct dives behind the right portal vein and can be found on the surface of the caudate process before entering the liver. The left hepatic duct typically has a longer extrahepatic course before giving off segmental branches behind the left portal vein at the base of the umbilical fissure. Considerable variation exists, and in 30% to 40% of cases, there is a nonstandard hepatic duct confluence with accessory or aberrant ducts (Fig. 31-9). The cystic duct itself also has a variable pattern of drainage into the common bile duct. This can lead to potential injury or postoperative bile leakage during cholecystectomy or hepatic resection, and the surgeon needs to expect these variants. The gallbladder sits adherent to hepatic segments IVB (left lobe) and V (right lobe).

Neural Innervation and Lymphatic Drainage

The parasympathetic innervation of the liver comes from the left vagus, which gives off the anterior hepatic branch, and the right vagus, which gives off the posterior hepatic branch. The sympathetic innervation involves the greater thoracic splanchnic nerves and the celiac ganglia, although the function of these nerves is poorly understood. The denervated liver after hepatic transplantation seems to function with normal capacity. A common source of referred pain to the right shoulder and scapula as well as the right side or back is the right phrenic nerve, which is stimulated by tumors that stretch Glisson's capsule or by diaphragmatic irritation.

Lymph is produced within the liver and drains via the perisinusoidal space of Disse and periportal clefts of Mall to larger lymphatics that drain to the hilar cystic duct lymph node

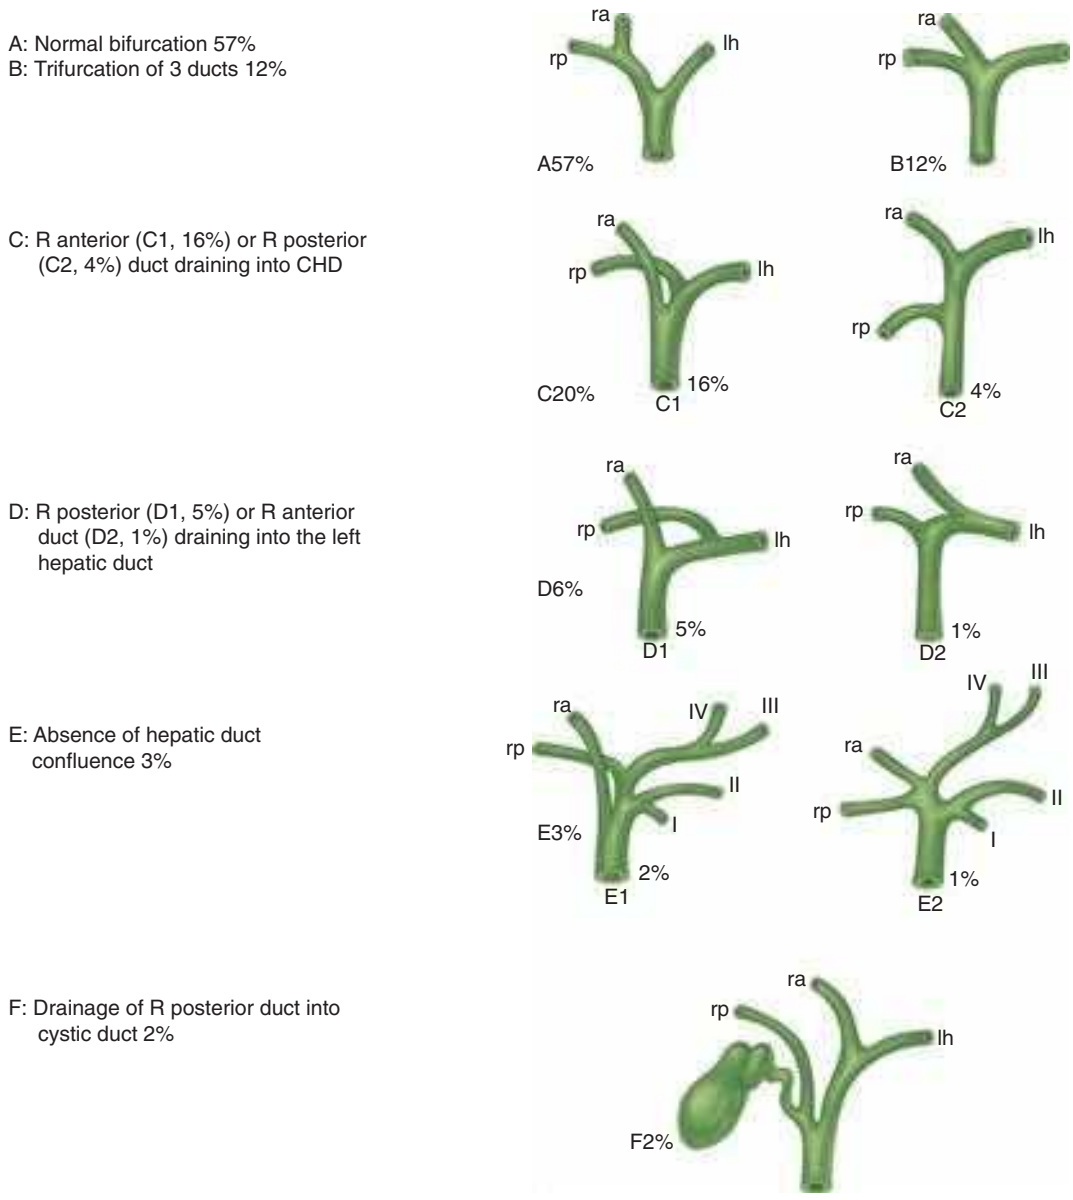

Figure 31-9. Main variations of hepatic duct confluence. As described by Couinaud in 1957, the bifurcation of the hepatic ducts has a variable pattern in approximately 40% of cases. CHD = common hepatic duct; lh = left hepatic; R = right; ra = right anterior; rp = right posterior. *(Reproduced with permission from Blumgart LH, Fong Y, eds.* Surgery of the Liver and Biliary Tract. *3rd ed, Vol. I. London: Elsevier Science; 2000. Copyright © Elsevier Science.)*

(Calot's triangle node), as well as the common bile duct, hepatic artery, and retropancreatic and celiac lymph nodes. This is particularly important for resection of hilar cholangiocarcinoma, which has a high incidence of lymph node metastases. The hepatic lymph also drains cephalad to the cardiophrenic lymph nodes, and the latter can be pathologically identified on a staging CT or MRI scan.

LIVER PHYSIOLOGY

The liver is the largest gland in the body and has an extraordinary spectrum of functions. These include processes such as storage, metabolism, production, and secretion. One crucial role is the processing of absorbed nutrients through the metabolism of glucose, lipids, and proteins. The liver maintains glucose concentrations in a normal range over both short and long periods by performing several important roles in carbohydrate metabolism. In the fasting state, the liver ensures a sufficient supply of glucose to the central nervous system. The liver can produce glucose by breaking down glycogen through glycogenolysis and by de novo synthesis of glucose through gluconeogenesis from noncarbohydrate precursors such as lactate, amino acids, and glycerol. In the postprandial state, excess circulating glucose is removed by glycogen synthesis or glycolysis and lipogenesis. The liver also plays a central role in lipid metabolism through the formation of bile and the production of cholesterol and fatty acids. Protein metabolism occurs in the liver through amino acid deamination, resulting in the production of ammonia as well as the production of a variety of amino acids. In addition to metabolism, the liver also is responsible for the synthesis of most circulating plasma proteins. Among these proteins are albumin, factors of the coagulation and fibrinolytic systems, and compounds of the complement cascade. Furthermore, the detoxification of many substances through drug metabolism occurs in the

2▶

liver, as do immunologic responses through the many immune cells found in its reticuloendothelial system.[9]

Bilirubin Metabolism

Bilirubin is the breakdown product of normal heme catabolism. Bilirubin is bound to albumin in the circulation and sent to the liver. In the liver, it is conjugated to glucuronic acid to form bilirubin diglucuronide in a reaction catalyzed by the enzyme glucuronyl transferase, making it water soluble. This glucuronide is then excreted into the bile canaliculi. A small amount dissolves in the blood and is then excreted in the urine. The majority of conjugated bilirubin is excreted in the intestine as waste, because the intestinal mucosa is relatively impermeable to conjugated bilirubin. However, it is permeable to unconjugated bilirubin and urobilinogens, a series of bilirubin derivatives formed by the action of bacteria. Thus, some of the bilirubin and urobilinogens are reabsorbed in the portal circulation; they are again excreted by the liver or enter the circulation and are excreted in the urine.[10]

Formation of Bile

Bile is a complex fluid containing organic and inorganic substances dissolved in an alkaline solution that flows from the liver through the biliary system and into the small intestine. The main components of bile are water, electrolytes, and a variety of organic molecules including bile pigments, bile salts, phospholipids (e.g., lecithin), and cholesterol. The two fundamental roles of bile are to aid in the digestion and absorption of lipids and lipid-soluble vitamins and to eliminate waste products (bilirubin and cholesterol) through secretion into bile and elimination in feces. Bile is produced by hepatocytes and secreted through the biliary system. In between meals, bile is stored in the gallbladder and concentrated through the absorption of water and electrolytes. Upon entry of food into the duodenum, bile is released from the gallbladder to aid in digestion. The human liver can produce about 1 L of bile daily.

Bile salts, in conjunction with phospholipids, are responsible for the digestion and absorption of lipids in the small intestine. Bile salts are sodium and potassium salts of bile acids conjugated to amino acids. The bile acids are derivatives of cholesterol synthesized in hepatocytes. Cholesterol, ingested from the diet or derived from hepatic synthesis, is converted into the bile acids cholic acid and chenodeoxycholic acid. These bile acids are conjugated to either glycine or taurine before secretion into the biliary system. Bacteria in the intestine can remove glycine and taurine from bile salts. They can also convert some of the primary bile acids into secondary bile acids by removing a hydroxyl group, producing deoxycholic acid from cholic acid and lithocholic acid from chenodeoxycholic acid.

Bile salts secreted into the intestine are efficiently reabsorbed and reused. Approximately 90% to 95% of the bile salts are absorbed from the small intestine at the terminal ileum. The remaining 5% to 10% enter the colon and are converted to the secondary salts, deoxycholic acid and lithocholic acid. The mixture of primary and secondary bile salts and bile acids is absorbed primarily by active transport in the terminal ileum. The absorbed bile salts are transported back to the liver in the portal vein and re-excreted in the bile. Those lost in the stool are replaced by synthesis in the liver. The continuous process of secretion of bile salts in the bile, their passage through the intestine, and their subsequent return to the liver is termed the *enterohepatic circulation.*[10]

Drug Metabolism

The liver plays an important role in providing mechanisms for ridding the body of foreign molecules (xenobiotics) that are absorbed from the environment. In most cases, a drug is relatively lipophilic to ensure good absorption. The liver participates in the elimination of these lipid-soluble drugs by transforming them into more readily excreted hydrophilic products. There are two main reactions important for drug metabolism. Phase I reactions include oxidation, reduction, and hydrolysis of molecules. These result in metabolites that are more hydrophilic than the original chemicals. The cytochrome P450 system is a family of hemoproteins important for oxidative reactions involving drugs and toxic substances. Phase II reactions, also known as *conjugation reactions,* are synthetic reactions that involve addition of subgroups to the drug molecule. These subgroups include glucuronate, acetate, glutathione, glycine, sulfate, and methyl groups. These drug reactions occur mainly in the smooth endoplasmic reticulum of hepatocytes.

Many factors can affect drug metabolism in the liver. When the rate of metabolism of a drug is increased (i.e., enzyme induction), the duration of the drug action will decrease. However, when the metabolism of a drug is decreased (i.e., enzyme inhibition), then the drug will circulate for a longer period of time. It is important to note that some drugs may be converted to active products by metabolism in the liver. An example is acetaminophen when taken in larger doses. Normally, acetaminophen is conjugated by the liver to harmless glucuronide and sulfate metabolites that are water soluble and eliminated in the urine. During an overdose, the normal metabolic pathways are overwhelmed, and some of the drug is converted to a reactive and toxic intermediate by the cytochrome P450 system. Glutathione normally reacts with this intermediate, leading to the production and subsequent excretion of a harmless product. However, as glutathione stores are diminished, the reactive intermediate cannot be detoxified and it combines with lipid membranes of hepatocytes, which results in cellular necrosis. Thus, treatment of acetaminophen overdoses consists of replenishing glutathione stores by supplementing with sulfhydryl compounds such as acetylcysteine.

Liver Function Tests

Liver function tests is a term frequently used to refer to measurement of the levels of a group of serum markers for evaluation of liver dysfunction. Most commonly, levels of aspartate transaminase (AST), alanine transaminase (ALT), alkaline phosphatase (AP), γ-glutamyltranspeptidase (GGT), and bilirubin are included in this panel. This term is a misnomer, however, because most of these tests measure not liver function but rather cell damage. More accurate measurement of the liver's synthetic function is provided by serum albumin levels and prothrombin time (PT). Although measuring liver enzyme levels is important in the assessment of a patient's liver disease, these test results can be nonspecific. Thus, evaluation of patients with suspected liver disease should always involve careful interpretation of abnormalities in these liver test results in the context of a thorough history and physical examination. The approach to evaluating abnormal laboratory values also can be simplified by categorizing the type of abnormality that predominates (hepatocellular damage, abnormal synthetic function, or cholestasis).

Hepatocellular Injury

Hepatocellular injury of the liver is usually indicated by abnormalities in levels of the liver aminotransferases AST and ALT.

These enzymes participate in gluconeogenesis by catalyzing the transfer of amino groups from aspartic acid or alanine to ketoglutaric acid to produce oxaloacetic acid and pyruvic acid, respectively (these enzymes are also referred to as *serum glutamic-oxaloacetic transaminase [SGOT]* and *serum glutamic-pyruvic transaminase [SGPT]*). AST is found in liver, cardiac muscle, skeletal muscle, kidney, brain, pancreas, lungs, and red blood cells and thus is less specific for disorders of the liver. ALT is predominately found in the liver and thus is more specific for liver disease. Hepatocellular injury is the trigger for release of these enzymes into the circulation. Common causes of elevated aminotransferase levels include viral hepatitis, alcohol abuse, medications, genetic disorders (Wilson's disease, hemochromatosis, α_1-antitrypsin deficiency), and autoimmune diseases.

The extent of serum aminotransferase elevations can suggest certain etiologies of the liver injury. However, the levels of the enzymes in these tests correlate poorly with the severity of hepatocellular necrosis, because they may not be significantly elevated in conditions of hepatic fibrosis or cirrhosis. In alcoholic liver disease, an AST:ALT ratio of >2:1 is common. Mild elevations of transaminase levels can be found in nonalcoholic fatty liver disease, chronic viral infection, or medication-induced injury. Moderate increases in the levels of these enzymes are common in acute viral hepatitis. In conditions of ischemic insults, toxin ingestions (i.e., acetaminophen), and fulminant hepatitis, AST and ALT levels can be elevated to the thousands.

Abnormal Synthetic Function

Albumin synthesis is an important function of the liver and thus can be measured to evaluate the liver's synthetic function. The liver produces approximately 10 g of albumin per day. However, albumin levels are dependent on a number of factors such as nutritional status, renal dysfunction, protein-losing enteropathies, and hormonal disturbances. In addition, level of albumin is not a marker of acute hepatic dysfunction due to albumin's long half-life of 15 to 20 days.

Most clotting factors (except factor VIII) are synthesized exclusively in the liver, and thus their levels can also be used as a measure of hepatic synthetic function. Measurements of the prothrombin time (PT) and international normalized ratio (INR) are some of the best tests of hepatic synthetic function. PT measures the rate of conversion of prothrombin to thrombin. To standardize the reporting of PT and avoid interlaboratory variability, the INR was developed. The INR is the ratio of the patient's PT to the mean control PT. Because vitamin K is involved in the γ-carboxylation of factors used to measure PT (factors II, VII, IX, and X), values also may be prolonged in other conditions such as vitamin K deficiency and warfarin therapy.

Cholestasis

Cholestasis is a condition in which bile flow from the liver to the duodenum is impaired. Disturbances in bile flow may be due to intrahepatic causes (hepatocellular dysfunction) or extrahepatic causes (biliary tree obstruction). Cholestasis often results in the release of certain enzymes and thus can be detected by measuring the serum levels of bilirubin, AP, and GGT. Bilirubin is a breakdown product of hemoglobin metabolism. Unconjugated bilirubin is insoluble and thus is transported to the liver bound to albumin. In the liver, it is conjugated to allow excretion in bile. Measured total bilirubin levels can be normal or high in patients with significant liver disease because of the liver's ability to conjugate significant amounts of bilirubin. Thus, to help aid in the diagnosis of hyperbilirubinemia, fractionation of total bilirubin is usually performed to distinguish between conjugated (direct) and unconjugated (indirect) bilirubin. *Indirect bilirubin* is a term frequently used to refer to unconjugated bilirubin in the circulation because the addition of another chemical is necessary to differentiate this fraction from the whole. Normally, >90% of serum bilirubin is unconjugated. The testing process for conjugated bilirubin, in contrast, is direct without the addition of other agents. The direct bilirubin test measures the levels of conjugated bilirubin and δ bilirubin (conjugated bilirubin bound to albumin).

The patterns of elevation of the different fractions of bilirubin provide important diagnostic clues as to the cause of cholestasis. In general, an elevated indirect bilirubin level suggests intrahepatic cholestasis, and an elevated direct bilirubin level suggests extrahepatic obstruction. Mechanisms that can result in increases in unconjugated bilirubin levels include increased bilirubin production (hemolytic disorders and resorption of hematomas) or defects (inherited or acquired) in hepatic uptake or conjugation. The rate-limiting step in bilirubin metabolism is the excretion of bilirubin from hepatocytes, so conjugated hyperbilirubinemia can be seen in inherited or acquired disorders of intrahepatic excretion or extrahepatic obstruction. Conjugated bilirubin that cannot be excreted accumulates in hepatocytes, which results in its secretion into the circulation. Because conjugated bilirubin is water soluble, it can be found in the urine of patients with jaundice.

AP is an enzyme with a wide tissue distribution but is found primarily in the liver and bones. In the liver, it is expressed by the bile duct epithelium. In conditions of biliary obstruction, levels rise as a result of increased synthesis and release into the serum. Because the half-life of serum AP is approximately 7 days, it may take several days for levels to normalize even after resolution of the biliary obstruction.

GGT is another enzyme found in hepatocytes and released from the bile duct epithelium. Elevation of GGT is an early marker and also a sensitive test for hepatobiliary disease. Like AP elevation, however, it is nonspecific and can be produced by a variety of disorders in the absence of liver disease. Increased levels of GGT can be induced by certain medications, alcohol abuse, pancreatic disease, myocardial infarction, renal failure, and obstructive pulmonary disease. For this reason, elevated GGT levels are often interpreted in conjunction with other enzyme abnormalities. For example, a raised GGT level with increased AP level supports a liver source.

Jaundice

Jaundice refers to the yellowish staining of the skin, sclera, and mucous membranes with the pigment bilirubin. Hyperbilirubinemia usually is detectable as jaundice when blood levels rise above 2.5 to 3 mg/dL. Jaundice can be caused by a wide range of benign and malignant disorders. However, when present, it may indicate a serious condition, and thus knowledge of the differential diagnosis of jaundice and a systematic approach to the workup of the patient is necessary. Workup of a patient with jaundice is simplified by organizing the possible causes of the disorder into groups based on the location of bilirubin metabolism. As mentioned previously, bilirubin metabolism can take place in three phases: prehepatic, intrahepatic, and posthepatic.

The prehepatic phase includes the production of bilirubin from the breakdown of heme products and its transport to the liver. The majority of the heme results from red blood cell metabolism and the rest from other heme-containing organic compounds such as myoglobin and cytochromes. In the liver, the insoluble unconjugated bilirubin is then conjugated to glucuronic acid to allow for solubility in bile and excretion. The posthepatic phase of bilirubin metabolism consists of excretion of soluble bilirubin through the biliary system into the duodenum. Dysfunction in any of these phases can lead to jaundice.[10]

Prehepatic. Jaundice as a result of elevated levels of unconjugated bilirubin occurs from faulty prehepatic metabolism and usually arises from conditions that interfere with proper conjugation of bilirubin in the hepatocyte. Insufficient conjugation is often seen in processes that result in excessive heme metabolism. Subsequently, the conjugation system is overwhelmed, which results in unconjugated hyperbilirubinemia. Causes of hemolysis include inherited and acquired hemolytic anemias. Inherited hemolytic anemias include genetic disorders of the red blood cell membrane (hereditary spherocytosis and eliptocytosis), enzyme defects (glucose-6-phosphate dehydrogenase deficiency), and defects in hemoglobin structure (sickle cell anemia and thalassemias). Hemolytic anemias can also be acquired, and these can be further divided into those with immune-mediated and those with non–immune-mediated causes. Immune-mediated hemolytic anemias result in a positive finding on a direct Coombs' test and have a variety of autoimmune and drug-induced causes. In contrast, direct Coombs' test results are negative in nonimmune hemolytic anemias. The causes in this latter category are varied and include drugs and toxins that directly damage red blood cells, mechanical trauma (heart valves), microangiopathy, and infections. Prehepatic dysfunction of bilirubin metabolism also can result from failure in the transport of unconjugated bilirubin to the liver by albumin in any condition that leads to plasma protein loss. A poor nutritional state or excess protein loss as seen in burn patients can lead to elevated levels of unconjugated bilirubin in the circulation and jaundice.

Intrahepatic. Intrahepatic causes of jaundice involve the intracellular mechanisms for conjugation and excretion of bile from the hepatocyte. The enzymatic processes in hepatocytes can be affected by any condition that impairs hepatic blood flow and subsequent function of the liver (ischemic or hypoxic events). Furthermore, there are multiple inherited disorders of enzyme metabolism that can result in either unconjugated or conjugated hyperbilirubinemia. Gilbert's syndrome is a genetic variant characterized by diminished activity of the enzyme glucuronyltransferase, which results in decreased conjugation of bilirubin to glucuronide. It is a benign condition that affects approximately 4% to 7% of the population. Typically, the disease results in transient mild increases in unconjugated bilirubin levels and jaundice during episodes of fasting, stress, or illness. These episodes are self-limited and usually do not require further treatment. Another inherited disorder of bilirubin conjugation is Crigler-Najjar syndrome. It is a rare disease found in neonates and can result in neurotoxic sequelae from bilirubin encephalopathy.

In addition to defects in conjugation, disorders in bilirubin excretion in hepatocytes can also lead to jaundice. Rotor's syndrome and Dubin-Johnson syndrome are two uncommon genetic disorders that disrupt secretion of conjugated bilirubin from the hepatocyte into the bile and result in conjugated hyperbilirubinemia. There are also multiple acquired conditions that result in inflammation and intrahepatic cholestasis by affecting hepatocyte mechanisms for conjugation and excretion of bile. Viruses, alcohol abuse, sepsis, and autoimmune disorders all can result in inflammation in the liver with subsequent disruption of bilirubin transport in the liver. In addition, jaundice can also occur from the cytotoxic effects of many medications, including acetaminophen, oral contraceptives, and anabolic steroids.

Posthepatic. Posthepatic causes of jaundice are usually the result of intrinsic or extrinsic obstruction of the biliary duct system that prevents the flow of bile into the duodenum. There is a wide spectrum of pathologies that may present with obstructive jaundice. Intrinsic obstruction can occur from biliary diseases, including cholelithiasis, choledocholithiasis, benign and malignant biliary strictures, cholangiocarcinoma, cholangitis, and disorders of the papilla of Vater. Extrinsic compression of the biliary tree is commonly due to pancreatic disorders. Patients with pancreatitis, pseudocysts, and malignancies can present with jaundice due to external compression of the biliary system. Finally, with the growing armamentarium of endoscopic tools and minimally invasive surgical approaches, surgical complications are becoming more frequent causes of extrahepatic cholestasis. Misadventures with surgical clips, retained stones, and inadvertent ischemic insults to the biliary system can result in obstructive jaundice recognized at any time from immediately postoperatively to many years later.

RADIOLOGIC EVALUATION OF THE LIVER

Ultrasound

Abdominal ultrasound is a commonly applied imaging modality used to evaluate abdominal symptoms. Ultrasound technology is based on the pulse-echo principle. The ultrasound transducer converts electrical energy to high-frequency sound energy that is transmitted into tissue. Although some of the ultrasound waves are transmitted through the tissue, some are reflected back, and the ultrasound image is produced when the ultrasound receiver detects those reflected waves. This real-time gray scale (B-mode) imaging is augmented by Doppler flow imaging. Doppler ultrasound not only can detect the presence of blood vessels but also can determine the direction and velocity of blood flow. Ultrasonography is a useful initial imaging test of the liver because it is inexpensive, widely available, involves no radiation exposure, and is well tolerated by patients. It is excellent for diagnosing biliary pathology and focal liver lesions. In addition, liver injury can be evaluated in trauma patients using the focused abdominal sonography for trauma examination. Limitations of ultrasound include incomplete imaging of the liver, most often at the dome or beneath ribs on the surface, and incomplete visualization of lesion boundaries. Moreover, obesity and overlying bowel gas also can interfere with image quality. Thus, ultrasonographically detected masses usually require further evaluation by other imaging modalities due to the lower sensitivity and specificity of ultrasound compared with CT and MRI.

The advent of contrast-enhanced ultrasound has improved the ability of this modality to differentiate among benign and malignant lesions. The injection of gas microbubble agents can increase the sensitivity and specificity of ultrasound in detecting and diagnosing liver lesions. Microbubbles are <10 μm

and, when given intravenously, allow for more effective echo enhancement. Contrast-enhanced ultrasound imaging of the liver improves delineation of liver lesions through identification of dynamic enhancement patterns and the vascular morphology of the lesion. In addition, some agents exhibit a late liver-specific phase in which the bubbles are taken up by cells in the reticuloendothelial system and accumulate in normal liver parenchyma after the vascular enhancement has faded.

The use of intraoperative ultrasound of the liver has rapidly expanded over the years with the increasing number and complexity of hepatic resections being performed.[11] It has the ability to provide the surgeon with real-time accurate information useful for surgical planning. Intraoperative ultrasound is considered the gold standard for detecting liver lesions, and studies have shown that it can identify 20% to 30% more lesions than other preoperative imaging modalities. Importantly, it has been shown to influence surgical management in almost 50% of planned liver resections for malignancies. Applications for intraoperative ultrasound of the liver include tumor staging, visualization of intrahepatic vascular structures (Fig. 31-10), and guidance of resection plane by assessment of the relationship of a mass to the vessels. In addition, biopsy of lesions and ablation of tumors can be guided by intraoperative ultrasound.

Ultrasound elastography, also referred to as transient elastography, can be used to assess the degree of fibrosis or cirrhosis in the liver. Low-frequency vibrations transmitted through the liver induce an elastic shear wave that is detected by pulse-echo ultrasonography as the wave propagates through the liver. The velocity of the wave correlates with the stiffness of the organ—the wave travels faster through fibrotic or cirrhotic tissues. Ultrasound elastography has been found in large cohorts of individuals to have a sensitivity of 87% and a specificity of 91% for the diagnosis of cirrhosis when compared with liver biopsy.[12] Unlike liver biopsy, ultrasound elastography is non-invasive and can be repeated often without additional risk to the patient. Furthermore, this rapid test can acquire information from a larger area of the tissue relative to needle biopsy, providing a better understanding of the entire hepatic parenchyma and reducing sampling error.

Computed Tomography

CT produces a digitally processed cross-sectional image of the body from a large series of x-ray images. The introduction of helical (spiral) CT has improved the imaging capabilities of this technique compared to earlier conventional axial CT by combining a continuous patient-table motion with continuous rotation of the CT gantry and allowing rapid acquisition of a volume of data within a single breath hold. With the recent advent of multi-detector row CT scanners, high-resolution images can be obtained in submillimeter section thickness within a short scan time, with virtually no penalty in increased radiation dose. Together, these technologic advances have led to reduced motion artifacts due to variations in inspiration, facilitated optimal contrast delivery, and allowed for the capability to generate high-resolution reformations in any desired plane. In a single examination, modern-day CT scans provide detailed morphologic information on the number, size, distribution, and vascularity of liver lesions, all of which are vital in guiding the clinical management and therapeutic plan.

Contrast medium is routinely used in CT evaluation of the liver because of the similar densities of most pathologic liver masses and normal hepatic parenchyma. A CT scan with a dual- or triple-phase bolus of intravenous contrast agent is performed to achieve the greatest enhancement of contrast between normal and pathologic tissues.[13] Ideally, contrast media should be selectively delivered to either the tumor or the liver, but not both. Radiologists use the dual blood supply of the liver and the hemodynamics of hepatic tumors to achieve this goal. The liver is unique in that it has a dual blood supply. As previously noted, the portal vein supplies approximately 75% of the blood flow and the hepatic artery the remaining 25%. However, many liver tumors receive the majority of their blood supply from the hepatic artery. After injection of the contrast agent, the rapid

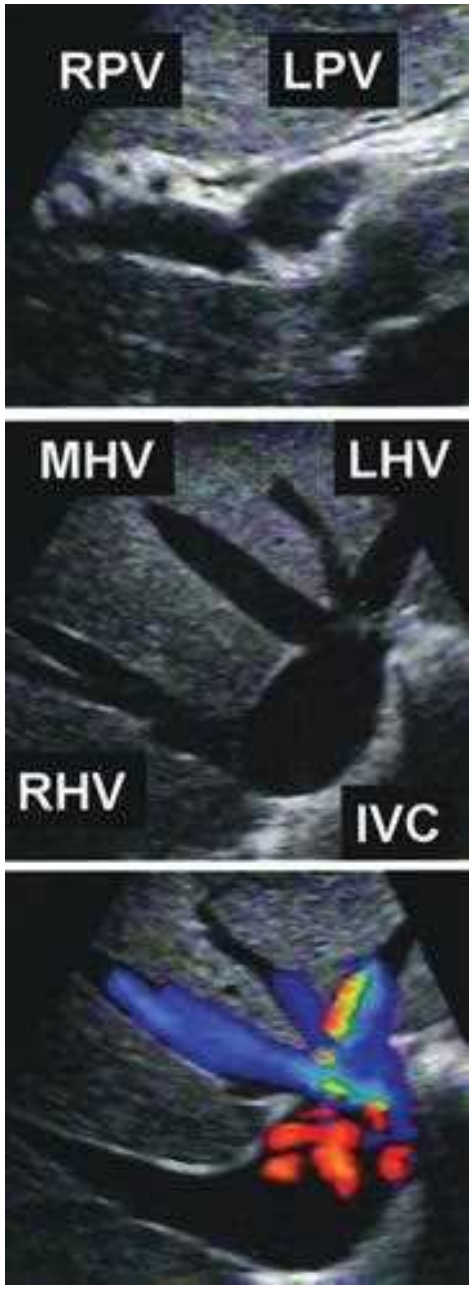

Figure 31-10. Intraoperative liver ultrasound images of the portal veins, hepatic veins, and inferior vena cava (IVC). *Upper panel* shows the portal vein bifurcation with echogenic Glissonian sheath. The confluence of the three hepatic veins (right hepatic vein [RHV], middle hepatic vein [MHV], and left hepatic vein [LHV]) and the IVC is shown in the *middle panel*. An accessory LHV is present in this patient. *Lower panel* is a color Doppler image showing flow.

scan time of helical CT allows for CT sections through the liver in both the arterial dominant phase (20 to 30 seconds after the beginning of contrast delivery) and venous or portal dominant phase (60 to 70 seconds after contrast injection) (Fig. 31-11). Thus, many hepatic tumors that derive the majority of their blood supply from the hepatic artery as well as other hypervascular lesions are well delineated in the arterial phase. On the other hand, the portal phase provides optimal enhancement of the normal liver parenchyma because the majority of its blood supply is derived from the portal vein. This allows for detection of hypovascular lesions because they will appear hypoattenuated in relation to the brighter normal liver parenchyma.[3] Furthermore, the arterial and portal phase images allow for noninvasive mapping of the hepatic arterial and venous anatomy, information that is crucial in the preoperative planning for patients undergoing liver surgery.

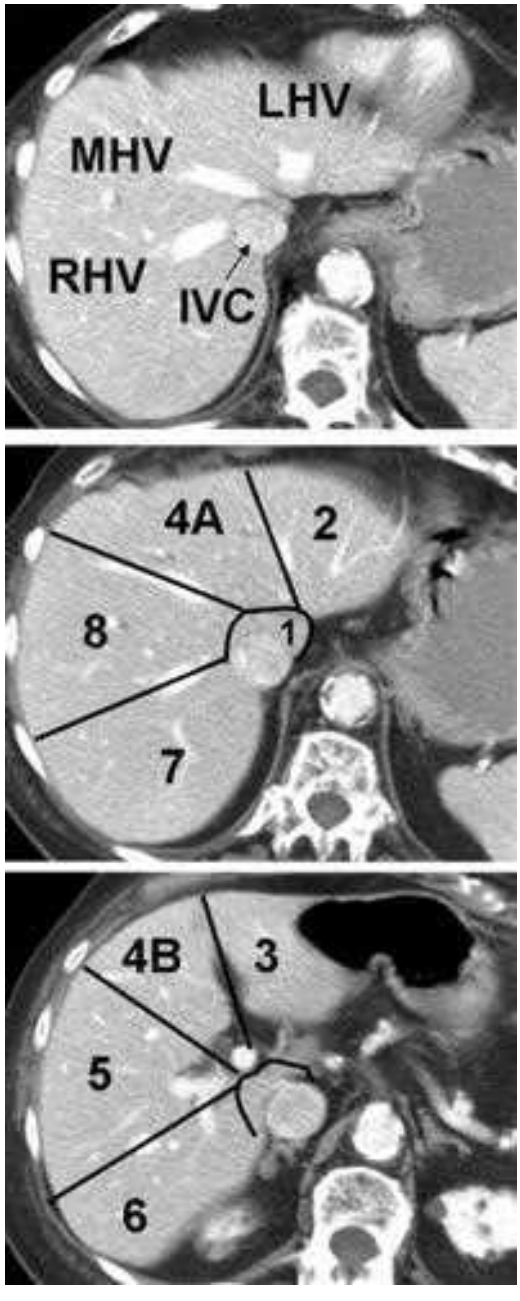

Figure 31-11. Computed tomographic (CT) images of hepatic veins and Couinaud's liver segments. The images show the three hepatic veins and inferior vena cava (IVC) (*upper panel*), as well as Couinaud's liver segments (*lower panels*). LHV = left hepatic vein; MHV = middle hepatic vein; RHV = right hepatic vein.

CT cholangiography has emerged as a new imaging modality for biliary disease. This technique usually involves the use of contrast agents, which are excreted by hepatocytes into the bile ducts. CT cholangiography, therefore, provides information on hepatocyte function and bile flow, in addition to high-resolution depiction of the biliary tree. It has compared well to endoscopic retrograde cholangiopancreatography (ERCP) in identifying obstructive biliary disease.[14] One of the major advantages of CT cholangiography over other imaging modalities is the ability to depict small nondilated peripheral biliary radicals. This technique may be useful in the context of live liver donation or complex biliary surgery to aid in the preoperative depiction of biliary anatomy. It also may be applicable in the postoperative setting for the detection of biliary leakage or obstruction. A limitation of CT cholangiography is that the biliary tree may not be well visualized in patients with excessively dilated bile ducts or in those with hyperbilirubinemia, as bilirubin excretion is impaired in these cases.

Magnetic Resonance Imaging

MRI is a technique that produces images based on magnetic fields and radio waves. The MRI scanner creates a powerful magnetic field that aligns the hydrogen atoms in the body, and radio waves are used to alter the alignment of this magnetization. Different tissues absorb and release radio wave energy at different rates, and this information is used to construct an image of the body. Most tissues can be differentiated by differences in their characteristic T1 and T2 relaxation times. T1 is a measure of how quickly a tissue can become magnetized, and T2 measures how quickly it loses its magnetization. As with CT technology, advances in MRI now provide the opportunity to perform single-breath T1-weighted imaging and respiration-triggered T2-weighted imaging. The development of breath-hold imaging techniques has eliminated many of the motion artifacts that previously limited the sensitivity and application of MRI for imaging of the liver. Compared with CT scanning, the major advantages of MRI pertain to higher soft tissue contrast resolution and excellent depiction of fluid-containing structures, while obviating the need for ionizing radiation.

As with the iodinated contrast media use in CT scanning, multiple contrast agents have been developed for MRI to increase the difference in signal intensity between normal liver and pathologic lesions. Various gadolinium-based compounds have been used as MRI contrast agents that behave in a manner very similar to iodine in CT. Liver-specific MRI contrast agents also have been developed that rely either on excretion by Kupffer cells, such as ferumoxide (Feridex, Advanced Magnetics, Cambridge, MA), or on secretion in bile by hepatocytes, including gadoxetate (Eovist or Primovist, Bayer-Schering, Berlin, Germany). These agents combine the information obtained during a standard MRI with additional functional data, which in turn yields improved detection and characterization of lesions within the liver.[15]

3▶

Just as ultrasound elastography is useful in the diagnosis of hepatic fibrosis and cirrhosis, magnetic resonance (MR) elastography appears promising as an imaging modality in reducing the need for liver biopsy. In this technique, a vibration device is used to induce a shear wave in the liver. A modified MRI machine detects the shear wave, then generates a color-coded image that

depicts the wave velocity, and hence stiffness, throughout the organ. Although preliminary studies have shown that MR elastography can detect cirrhosis with a high degree of accuracy, the clinical utility of this modality, especially given its relatively high cost, remains to be determined.

Magnetic resonance cholangiopancreatography (MRCP) enables rapid, noninvasive depiction of both the biliary tree and the pancreatic duct without the use of ionizing radiation or intravenous contrast media. One of the most common clinical indications for MRCP is biliary obstruction. MRCP provides visualization of dilated bile ducts, and the high spatial and contrast resolution often enables accurate assessment of the level of occlusion in the biliary tree. MRCP also can be enhanced with liver-specific MRI contrast agents that are actively secreted into the bile, but the clinical indications for such studies are still a matter of intensive investigation.[16]

Positron Emission Tomography

Positron emission tomography (PET) is a nuclear medicine test that produces images of metabolic activity in tissues by detecting gamma rays emitted by a radioisotope incorporated into a metabolically active molecule. Fluorodeoxyglucose (FDG) is the most common metabolic molecule used in PET imaging. Although traditional imaging such as CT, ultrasound, and MRI provide anatomic information, PET offers functional imaging of tissues with high metabolic activity, including most types of metastatic tumors. PET imaging increasingly is used as a tool in the diagnostic evaluation of a patient with potentially resectable hepatic disease. In nonrandomized trials, PET demonstrated better sensitivity and specificity than CT scanning for the detection of both intrahepatic and extrahepatic disease.[17] Integrated PET/CT improves diagnostic accuracy over standard PET or CT alone and has been shown to be sensitive in the detection of liver metastases derived from a wide range of cancers, including colorectal (Fig. 31-12), breast, or lung primaries.[17]

More than 20% of patients with colorectal cancer initially present with hepatic metastasis, and a large percentage of patients undergoing resection for their primary colorectal cancer eventually experience disease recurrence in the liver. The role of FDG-PET/CT in colorectal cancers lies predominantly in tumor staging and follow-up, particularly in the detection of occult intrahepatic metastases or extrahepatic disease. Although hepatic resection of colorectal metastases provides survival rates nearing 50%, the presence of extrahepatic disease is a poor prognosticator and usually precludes aggressive surgical intervention. Thus, accurate information regarding the extent of the disease is necessary for management of patients with colorectal metastases. PET/CT has also been shown to be more accurate than contrast-enhanced CT in tumor surveillance after radiofrequency ablation.[18] The sensitivity of FDG-PET, however, is lowered by neoadjuvant chemotherapy, most likely secondary to reduced metabolic activity within the tumor.

Although the role of PET/CT in the clinical management of liver metastases has been well-established, its utility in the diagnostic workup of primary liver tumors is still debated. In hepatocellular carcinoma (HCC), FDG uptake correlates with the degree of differentiation—high-grade HCC lesions have increased FDG uptake compared to low-grade HCCs. As a result, the overall sensitivity of FDG-PET/CT in the detection of HCCs is reported to be only 50% to 65%, rendering this modality insufficient when used alone in the diagnosis of primary HCCs. For this reason, dual-tracer PET has been introduced to improve sensitivity in detecting all HCC. This modality combines the use of FDG, which accumulates in poorly differentiated tumors, with ^{11}C-acetate, a tracer preferentially accumulated by well-differentiated HCC lesions. Although the clinical benefits of dual-tracer PET/CT have yet to be fully established, this combined modality has the potential to become a valuable tool in the diagnosis and staging of HCC. In cholangiocarcinoma tumors, FDG avidity depends on the morphologic characteristics and location of the lesion. Therefore, FDG-PET and FDG-PET/CT have not been shown to be highly beneficial in the diagnosis of primary cholangiocarcinoma, but they may be beneficial in the detection of regional and distal metastases, which can affect clinical decision making and patient management.

ACUTE LIVER FAILURE

Acute liver failure (ALF) occurs when the rate and extent of hepatocyte death exceeds the liver's regenerative capabilities. It was initially described as a specific disease entity in the 1950s. It also has been referred to as *fulminant hepatic failure.* ALF is a rare disorder affecting approximately 2000 patients annually in the United States. ALF is defined by the development of hepatic encephalopathy occurring within 26 weeks of severe liver injury in a patient without a history of previous liver disease or portal

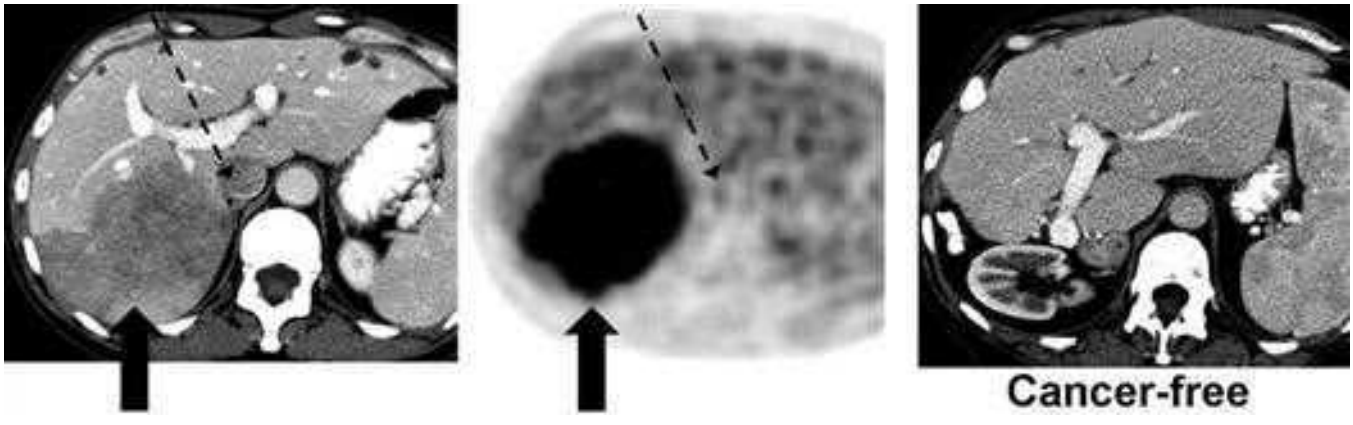

Figure 31-12. Computed tomography (CT)–positron emission tomography (PET) scans before and after resection of liver metastasis from colorectal cancer in a 54-year-old patient. CT scan shows large 10-cm right lobe liver metastasis (*left panel*), and PET scan findings are strongly positive (*middle panel*). Two years after right hepatectomy, the patient has no evidence of recurrence and significant hypertrophy of the left lobe (*right panel*).

hypertension.[19] The manifestations of ALF may include cerebral edema, hemodynamic instability, increased susceptibility to bacterial and fungal infections, renal failure, coagulopathy, and metabolic disturbances. Even with current medical care, ALF can progress rapidly to hepatic coma and death. The most common cause of death is intracranial hypertension due to cerebral edema, followed by sepsis and multisystem organ failure. The causes of ALF, which are the most important variables in determining outcome, are numerous and can include viral infection as well as drug overdose, reaction, and toxicity. It has been determined that the etiologic factor leading to ALF varies according to geographic location.[20] Before the introduction of orthotopic liver transplantation (OLT), the chance for survival was <20%. Currently, most series report 5-year survival rates of >70% for affected patients.[21]

4▶

Etiology

Differences in etiology, management, and patient outcomes have been described for various regions of the globe. In the East and developing portions of the world, the most common causes of ALF are viral infections, primarily hepatitis B, A, and E.[20] In these areas, there are a relatively small number of drug-induced cases. In contrast, 65% of cases of ALF in the West are thought to be due to drugs and toxins, with acetaminophen (paracetamol) being the most common etiologic agent in the United States, Australia, United Kingdom, and most of Europe. In France and Spain, where acetaminophen sales are restricted, the rate of acetaminophen-induced ALF is quite low.[22] Acetaminophen-induced ALF is also uncommon in South America. The U.S. Acute Liver Failure Study Group identified several other causes of ALF, including autoimmune hepatitis, hypoperfusion of the liver (in cardiomyopathy or cardiogenic shock), pregnancy-related conditions, and Wilson's disease.[23] Even with exhaustive efforts to identify a cause, approximately 20% of all cases of ALF remain indeterminate in origin.

Clinical Presentation

In a multicenter study involving 17 tertiary care centers and 308 patients in the United States, 73% of all patients with ALF were female, with a median age of 38 years.[24] The most common ethnic group affected was whites (74%), followed by Hispanics (9%) and African Americans (3%). Patients were ill for a median of 6 days before the onset of encephalopathy and had a median of 2 days between the onset of jaundice and the development of encephalopathy. Hepatic coma grade at presentation was approximately equally distributed across grades I to IV. Eighty-four percent of the patients in the study were referred from outside hospitals, 40% had a serum creatinine level exceeding 2.0 mg/dL, and 14% had an arterial pH of <7.30. In addition, 44% of the patients acquired a culture-proven infection.

Diagnosis and Clinical Management

When the medical history is obtained, it is important to address the possibility of exposure to viral infections, medications, and other possible toxins. The possibility of previous liver disease needs to be explored. The physical examination must assess and document the patient's mental status as well as attempt to identify findings of chronic liver disease. The initial laboratory examination must evaluate the severity of the ALF as well as attempt to identify the cause (Table 31-1). A liver biopsy should be performed if certain disease entities such as autoimmune hepatitis or lymphoma are a possibility. Because of the associated coagulopathy, if a liver biopsy is needed, it is usually safest to obtain the tissue via a transjugular approach. Patients with ALF should be admitted to the hospital and monitored frequently. Due to the rapidity with which this disease process may progress, a liver transplant center should be contacted and the affected patient transferred to the center early in the evaluation period.

Pregnancy test (females)

HIV = human immunodeficiency virus.

If acetaminophen overdose is suspected to have occurred within a few hours of presentation, administration of activated charcoal may be useful to reduce the volume of acetaminophen present in the gastrointestinal (GI) tract. *N*-acetylcysteine (NAC), the clinically effective antidote for acetaminophen overdose, should be administered as early as possible to any patient with suspected acetaminophen-associated ALF.[25] NAC also should be administered to patients with ALF of unclear etiology, because replenishing glutathione may be beneficial in this patient population as well.[26] NAC can be administered either orally (140 mg/kg initial dose, followed by 70 mg/kg every 4 hours × 17 doses) or via the intravenous route (loading dose of 150 mg/kg, followed by a maintenance dose of 50 mg/kg every 4 hours × 12 doses). For patients who are suspected of having drug-induced hepatotoxicity, it is important to obtain details regarding all prescription and nonprescription drugs, herbs, and dietary supplements that may have been taken in the previous year. Most instances of drug-induced hepatotoxicity occur in the first 6 months after drug initiation. Any suspected offending agent must be discontinued, and an attempt should be made to administer only essential medications.

The majority of patients with ALF need to be monitored in the intensive care unit (ICU) setting, and specific attention needs to be given to fluid management, ulcer prophylaxis, hemodynamic monitoring, electrolyte management, and surveillance for and treatment of infection. Surveillance cultures should be performed to identify bacterial and fungal infections as early as possible. Serum phosphorus levels need to be monitored. Hypophosphatemia, a sign of hepatic regeneration, may indicate a higher likelihood of spontaneous recovery and needs to be corrected via intravenous (IV) administration of phosphate. Sedation should be avoided, and the head of the bed should be elevated at least 30°. Neurologic examinations

should be performed frequently. Intracranial pressure monitoring is reserved for patients in whom a neurologic examination is no longer reliable. CT scans of the head should be performed to rule out mass lesion or hemorrhage, but they provide only limited information regarding increased intracranial pressure. The administration of blood products for thrombocytopenia and prolonged PT is recommended only in the setting of hemorrhage or before invasive procedures. Acute renal failure is a frequent complication in patients with ALF, and efforts should be made to protect renal function by maintaining sufficient perfusion and avoiding nephrotoxic medications. Should renal replacement therapy become necessary, continuous venovenous hemodialysis should be used rather than intermittent hemodialysis, because continuous venovenous hemodialysis provides better hemodynamic and intracranial pressure stability. The most severely affected patients have a poor prognosis with medical management alone and require liver transplantation. Identifying these patients early in the clinical course is important both to maximize the time available to obtain a donor liver allograft for those in need and to avoid transplant in those who will recover without it.

Prognosis

Accurate identification of ALF patients who will recover spontaneously is important because of the severe shortage of donor liver allografts and the potential complications of lifelong nonspecific immunosuppression. The most widely applied prognostic scoring system is the King's College Hospital ALF criteria.[27] This scoring system has separate criteria predicting a poor medical management outcome for acetaminophen-related and non–acetaminophen-related forms of ALF (Table 31-2). Many other prognostic models exist such as the Acute Physiology and Chronic Health Evaluation II (APACHE II) score, the Clichy criteria,[28] and actin-free Gc-globulin serum concentration.[29] Overall, prognostic scoring systems have proven to have acceptable specificity but low sensitivity in determining patient outcome and therefore should not replace the judgment of an experienced clinician.[30]

Table 31-2

King's College selection criteria for liver transplantation in acute liver failure

CAUSE	SELECTION CRITERIA
Acetaminophen	Arterial pH <7.30 irrespective of hepatic coma grade *Or* Prothrombin time >100 s + serum creatinine level >3.4 mg/dL + grade III or IV hepatic coma
Not acetaminophen	Prothrombin time >100 s irrespective of hepatic coma grade *Or* Any three of the following, irrespective of hepatic coma grade: Cryptogenic or drug-induced hepatitis Jaundice to coma interval >7 d Prothrombin time >50 s Serum bilirubin level >17.5 mg/dL Age <10 y or >40 y

Liver Transplantation

Despite advances in medical management, OLT remains the only definitive therapy for patients unable to regenerate sufficient hepatocyte mass in a timely manner. The advent of OLT has coincided with a rise in overall ALF survival rates from approximately 20% in the pretransplantation era to >70% at the present time. One-year posttransplantation survival for patients with ALF has been reported to be as high as 80% to 90%.[21] Although these improvements in survival rates are impressive, it should be noted that 10% of patients still die while awaiting OLT, which confirms that the potential for improved patient outcome still has not been realized because of the ongoing liver allograft shortage.

Emerging Technologies

As mentioned earlier, patient survival could be improved if additional time could be gained for the patient while awaiting liver replacement or hepatocyte regeneration. The development of a support device to replace the acutely failing liver has been a highly sought after (and elusive) goal. Several systems have been tested without definitive evidence of efficacy. Transient improvement in hepatic encephalopathy has been observed in several trials, but improvement in hepatocyte function and long-term benefit have not been realized.[31] Liver support trials are difficult to perform due to access to liver replacement, the rarity of affected patients, and the heterogeneous causes and varying levels of disease severity. Therefore, additional data are necessary, and liver support systems should be used only as part of an approved clinical trial. Focus has now shifted toward xenotransplantation,[32] organ engineering, and cell transplantation.[33] In the meantime, living donation and auxiliary liver transplantation can help overcome the organ shortage.[34]

CIRRHOSIS AND PORTAL HYPERTENSION

Cirrhosis, the final sequela of chronic hepatic insult, is characterized by the presence of fibrous septa throughout the liver subdividing the parenchyma into hepatocellular nodules (Fig. 31-13).[35] Cirrhosis is the consequence of sustained wound healing in response to chronic liver injury. Approximately 40% of cirrhotic patients are asymptomatic, but progressive deterioration leading to the need for liver transplantation or death is typical after the development of end-stage liver disease (ESLD). The complications of ESLD include progressive hyperbilirubinemia, malnutrition, decreased synthetic function of the liver, coagulopathy, portal hypertension (i.e., ascites and variceal bleeding), hepatic encephalopathy, and life-limiting fatigue. ESLD carries a 5-year mortality of 50%, with 70% of deaths due to liver failure.[36] In the United States, cirrhosis accounts for 30,000 deaths per year and 5▶ is the most common nonneoplastic cause of death among patients with hepatobiliary and digestive diseases. An additional 10,000 to 12,000 deaths occur annually due to HCC, the most rapidly increasing neoplasm in the United States.[36].

Morphologic Classification of Cirrhosis

Morphologically, cirrhosis can be described as micronodular, macronodular, or mixed. Micronodular cirrhosis is characterized by thick regular septa, small uniform regenerative nodules, and involvement of virtually every hepatic lobule. Macronodular cirrhosis frequently has septa and regenerative nodules of

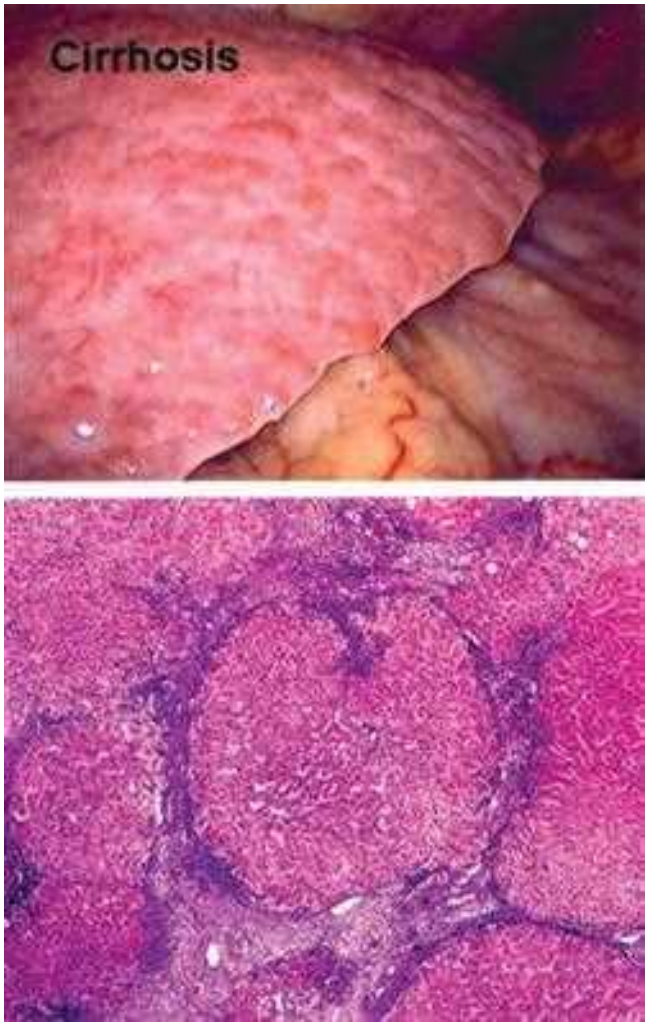

Figure 31-13. Histology of cirrhotic liver with regenerating macronodules. *Upper panel:* Grossly cirrhotic liver. *Lower panel:* Regenerative nodules and bridging fibrosis representative of cirrhosis seen on standard light microscopy (hematoxylin and eosin stain).

varying sizes. The regenerative nodules consist of irregularly sized hepatocytes with large nuclei and cell plates of varying thickness. Mixed cirrhosis is present when regeneration is occurring in a micronodular liver and over time converts to a macronodular pattern. This morphologic categorization is limited, and cirrhosis is a dynamic process in which nodule size varies over time. The three patterns correlate poorly with etiology, and the same pattern can result from a variety of disease processes. Conversely, a single disease process can demonstrate several morphologic patterns. Irrespective of etiology and morphologic pattern, the cirrhotic liver frequently demonstrates right hepatic lobe atrophy, caudate lobe and left lateral segment hypertrophy, recanalization of the umbilical vein, a nodular surface contour, dilatation of the portal vein, gastroesophageal varices, and splenomegaly on radiographic evaluation.

Etiology of Cirrhosis

Cirrhosis can result from a wide range of disease processes, including viral, autoimmune, drug-induced, cholestatic, and metabolic diseases (Table 31-3). In the diagnosis of alcoholic liver disease, documentation of chronic alcohol abuse is imperative. Liver biopsy will reveal the typical findings of alcoholic hepatitis, including hepatocyte necrosis, Mallory bodies, neutrophil infiltration, and perivenular inflammation. Patients with nonalcoholic steatohepatitis (NASH) often endorse a history of diabetes mellitus or metabolic syndrome. The diagnosis of NASH requires the demonstration of steatohepatitis on biopsy, the lack of a history of significant alcohol consumption, and exclusion of other causes of hepatic steatosis. Although cryptogenic cirrhosis, or cirrhosis without an apparent cause, accounted for a third of all cases in the past, this proportion has declined over time as it becomes increasingly apparent that many of such patients may actually have unrecognized NASH.

Table 31-3

Etiology of cirrhosis

Viral hepatitis (hepatitis B, C, and D)
Cryptogenic
Alcohol abuse
Metabolic abnormalities
Iron overload (hemochromatosis)
Copper overload (Wilson's disease)
α_1-Antitrypsin deficiency
Glycogen storage disease (types IA, III, and IV)
Tyrosinemia
Galactosemia
Cholestatic liver disease
Hepatic vein outflow abnormalities
Budd-Chiari syndrome
Cardiac failure
Autoimmune hepatitis
Toxins and drugs

Chronic hepatitis C infection is the most common cause of chronic liver disease and the most frequent indication for liver transplantation in the United States. The identification of chronic hepatitis C infection is facilitated by serologic assays that detect antibody to hepatitis C and molecular assays that quantify hepatitis C viral RNA. Chronic hepatitis B, on the other hand, can be diagnosed based on the detection of hepatitis B surface antigen (HBsAg) more than 4 to 6 months after initial infection. Additional tests of hepatitis B viral replication, such as the hepatitis B e antigen (HBeAg) and hepatitis B viral DNA, can be used to confirm ongoing infection and to guide appropriate antiviral therapy.

Autoimmune causes of cirrhosis include primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune hepatitis. Patients with primary biliary cirrhosis may be asymptomatic or may present with a history of fatigue, pruritus, and skin hyperpigmentation that is not related to jaundice. Antimitochondrial antibodies will test positive in the vast majority of cases. Affected patients also may have marked elevations in serum cholesterol, while hyperbilirubinemia is seen late in the course of the disease. Primary sclerosing cholangitis is a chronic cholestatic disease of the liver associated with ulcerative colitis and Crohn's disease. The clinical presentation can include pruritus, steatorrhea, fat-soluble vitamin deficiencies, and metabolic bone disease. The diagnosis is often established by imaging of the biliary tree, which reveals a characteristic picture of diffuse, multifocal strictures with focal dilation of the bile ducts resulting in a beaded appearance. Complications are common and can include biliary strictures, cholangitis, cholelithiasis, and

cholangiocarcinoma. Autoimmune hepatitis is often accompanied by an elevation in serum globulins, particularly gamma globulins. Liver biopsy will show nonspecific changes such as a portal mononuclear cell infiltrate with the characteristic presence of plasma cells. Many patients with autoimmune hepatitis will respond to treatment with prednisone with or without azathioprine.

Hereditary hemochromatosis is the most common metabolic disorder causing cirrhosis. This entity should be suspected if the patient's clinical presentation includes skin hyperpigmentation, diabetes mellitus, pseudogout, cardiomyopathy, or a family history of cirrhosis. Elevated plasma ferritin and increased iron saturation levels suggest the presence of iron overload, but these findings also can be seen in other diseases of the liver. Confirmatory testing can be achieved by means of genetic testing, liver biopsy, or by assessing the response to phlebotomy. Other uncommon metabolic disorders leading to cirrhosis include Wilson's disease and α_1-antitrypsin deficiency.

Clinical Manifestations of Cirrhosis

The clinical history associated with cirrhosis can include fatigue, anorexia, weight loss, jaundice, abdominal pain, peripheral edema, ascites, GI bleeding, and hepatic encephalopathy. On physical examination, a number of findings have been described in patients with cirrhosis. Spider angiomata and palmar erythema are believed to be caused by alterations in sex hormone metabolism. Finger clubbing may be a consequence of hypoalbuminemia, while the pathogenesis of white nail beds and Dupuytren's contractures are less well understood. Males may develop features of feminization such as gynecomastia, loss of chest and axillary hair, and testicular atrophy. Splenomegaly is common, whereas the cirrhotic liver itself may be enlarged, normal sized, or small. Ascites and pleural effusion can be seen with fluid accumulation. Portal hypertension can manifest as caput medusae and/or the presence of the Cruveilhier-Baumgarten murmur, a venous hum that can be auscultated in the epigastrium resulting from collaterals between the portal system and the remnant of the umbilical vein. Jaundice usually does not appear until the bilirubin rises above 2 to 3 mg/dL. Asterixis can be detected in patients with hepatic encephalopathy. Other manifestations include fetor hepaticus, as well as features suggestive of malnutrition such as weakness, weight loss, and temporal muscle wasting.

Although fat stores and muscle mass are reduced, resting energy expenditure is increased. Muscle cramps occur frequently in the cirrhotic patient and are felt to correlate with ascites, low mean arterial pressure, and plasma renin activity. Abdominal hernias are common with ascites and should be electively repaired only in patients with well-compensated cirrhosis; otherwise, the hernia should be repaired at the time of or after hepatic transplantation. HCC can occur in all forms of cirrhosis, and every cirrhotic patient should undergo screening for the development of HCC every 6 months via imaging and measurement of a serum α-fetoprotein (AFP) level. Cirrhosis is associated with increased cardiac output and heart rate as well as decreased systemic vascular resistance and blood pressure. Patients with cirrhosis are more prone to infections due to impaired phagocytic activity of the reticuloendothelial system. Bacterial infections, often of intestinal origin, are common and must be suspected in a patient with unexplained pyrexia or clinical deterioration. Spontaneous bacterial peritonitis also is seen in cases of cirrhosis with ascites. Intrinsic drug metabolism is reduced in the cirrhotic liver, and this fact needs to be recognized when prescribing medications.

Laboratory Findings Associated with Cirrhosis

Laboratory findings vary in the cirrhotic patient depending on the degree of compensation; however, in general, a number of trends are seen. The cirrhotic patient usually has a mild normocytic normochromic anemia. The white blood cell and platelet counts are reduced, and the bone marrow is macronormoblastic. The PT is prolonged and does not respond to vitamin K therapy, and the serum albumin level is depressed. Urobilinogen is present and urinary sodium excretion is diminished in the presence of ascites. The serum levels of bilirubin, transaminases, and alkaline phosphatase may all be elevated. However, normal liver function test results do not eliminate the possibility of cirrhosis.

Liver Biopsy

The diagnosis of cirrhosis can be made in many cases from a constellation of clinical features, laboratory values, and radiographic findings. Histopathologic examination of liver tissue is occasionally needed to confirm the diagnosis of cirrhosis and in determining disease etiology, activity, and progression. Liver biopsy can be performed via a percutaneous, transjugular, or laparoscopic approach. If needed, ultrasound or CT guidance can be helpful in obtaining an adequate sample and avoiding other viscera.

Various serologic markers of hepatic fibrosis are currently being investigated to help predict the presence of cirrhosis without the need for liver biopsy. However, no currently available marker is sufficiently accurate for clinical use. Ultrasound elastography, which measures the stiffness of the liver by inducing an elastic shear wave that propagates through the tissue, shows promise as a noninvasive test in identifying patients with advanced fibrosis and cirrhosis. (See earlier section, "Radiologic Evaluation of the Liver.")

Hepatic Reserve and Assessment of Surgical Risk in the Cirrhotic Patient

Assessing the hepatic reserve of the cirrhotic patient is important, because cirrhosis and portal hypertension can have a negative impact on the outcome of nontransplant surgical procedures. Patients with liver disease undergoing surgery are at increased risk for surgical and anesthesia-related complications. The actual risk depends on the type of anesthetic used, the specific surgical procedure performed, and the severity of liver disease. Previous studies have demonstrated that emergency operations, cardiac surgery, hepatic resections, and abdominal surgery, particularly cholecystectomy, gastric resection, and colectomy, generate the highest operative risk among cirrhotic patients. Additionally, preoperative patient characteristics such as anemia, ascites, encephalopathy, malnutrition, hypoalbuminemia, hypoxemia, infection, jaundice, portal hypertension, and prolonged PT have also been associated with inferior outcomes after surgery. Nontransplant surgical procedures are contraindicated in patients with acute fulminant hepatitis and those with severe decompensated chronic hepatitis.

A number of laboratory tests have been used to assess hepatic reserve in patients with cirrhosis. Tests of indocyanine green, sorbitol, and galactose elimination capacity as well as the carbon-13 galactose breath test and carbon-13 aminopyrine breath test have all been disappointing clinically due to their

dependence on flow to the liver as well as the unavailability and complexity of the tests. The monoethylglycinexylidide (MEGX) test, which measures MEGX formation after the administration of lidocaine, has been shown to be approximately 80% sensitive and specific in diagnosing cirrhosis. However, this test loses both sensitivity and specificity as the serum bilirubin level rises and interferes with the fluorescent readout system.

Child-Turcotte-Pugh Score

The Child-Turcotte-Pugh (CTP) score was originally developed to evaluate the risk of portocaval shunt procedures performed for portal hypertension and subsequently has been shown to be useful in predicting surgical risks of other intra-abdominal operations on cirrhotic patients (Table 31-4). Numerous studies have demonstrated overall surgical mortality rates of 10% for patients with class A cirrhosis, 30% for those with class B cirrhosis, and 75% to 80% for those with class C cirrhosis.[37] The CTP score is derived from five variables as shown in Table 31-4. The problems with the CTP score are the presence of subjective variables (encephalopathy and ascites), its narrow range (5 to 15 points), and the equal weighting given to each variable. Multiple retrospective studies have demonstrated that perioperative mortality and morbidity rates correlate well with the CTP score, and for over 30 years, this measure had been used as the principal predictor of operative risk.

Model for End-Stage Liver Disease Scoring System

The Model for End-Stage Liver Disease (MELD) is a linear regression model based on objective laboratory values (INR, bilirubin level, and creatinine level). It was originally developed as a tool to predict mortality after transjugular intrahepatic portosystemic shunt (TIPS) but has been validated and used as the sole method of liver transplant allocation in the United States since 2002. The MELD formula is as follows:

$$\text{MELD Score} = 9.57\,\text{Ln(SCr)} + 3.78\,\text{Ln(Tbil)} + 11.2\,\text{Ln(INR)} + 6.43$$

where Ln represents natural logarithm, SCr is serum creatinine level (in milligrams per deciliter), and Tbil is serum bilirubin level (in milligrams per deciliter).

A number of studies have examined the relative values of MELD and CTP scores in predicting postoperative mortality in cirrhotic patients undergoing nontransplant surgical procedures. Northup and colleagues demonstrated that MELD score was the only statistically significant predictor of 30-day mortality.[38] In this study, mortality increased by approximately 1% for each MELD point up to a score of 20 and by 2% for each MELD point above 20. A comparison of the MELD model with the CTP classification showed good correlation between the two measures in predicting mortality, especially in the setting of emergency surgery.[39] In these studies, the relative risk of mortality increased by 14% for each 1-point increase in MELD score. As a result, it has been proposed that patients with a MELD score below 10 can safely undergo elective surgery, those with MELD between 10 and 15 may undergo surgery with caution, while those with MELD scores in excess of 15 should not be subjected to elective surgical procedures.[40]

Table 31-4

Child-Turcotte-Pugh (CTP) score

VARIABLE	1 POINT	2 POINTS	3 POINTS
Bilirubin level	<2 mg/dL	2–3 mg/dL	>3 mg/dL
Albumin level	>3.5 g/dL	2.8–3.5 g/dL	<2.8 g/dL
International normalized ratio	<1.7	1.7–2.2	>2.2
Encephalopathy	None	Controlled	Uncontrolled
Ascites	None	Controlled	Uncontrolled
Child-Turcotte-Pugh class			
Class A = 5–6 points			
Class B = 7–9 points			
Class C = 10–15 points			

Portal Hypertension

The portal venous system contributes approximately 75% of the blood and 72% of the oxygen supplied to the liver. In the average adult, 1000 to 1500 mL/min of portal venous blood is supplied to the liver. However, this amount can be significantly increased in the cirrhotic patient. The portal venous system is without valves and drains blood from the spleen, pancreas, gallbladder, and abdominal portion of the alimentary tract into the liver. Tributaries of the portal vein communicate with veins draining directly into the systemic circulation. These collateral communications occur at the gastroesophageal junction, anal canal, falciform ligament, splenic venous bed and left renal vein, and retroperitoneum (Fig. 31-14). The normal portal venous pressure is 5 to 10 mmHg, and at this pressure, very little blood is shunted from the portal venous system into the systemic circulation. As portal venous pressure increases, however, the collateral communications with the systemic circulation dilate, and a large amount of blood may be shunted around the liver and into the systemic circulation.

Imaging of the Portal Venous System and Measurement of Portal Venous Pressure

The patency of the portal vein and the nature of the collateral circulation should be established. An understanding of portal vein patency and anatomy is crucial before undertaking portosystemic shunts, hepatic resection, or hepatic transplantation. The simplest initial investigation is abdominal ultrasonography. A large portal vein suggests portal hypertension but is not diagnostic. Doppler ultrasound is capable of outlining the anatomy of the portal vein, excluding the presence of thrombosis, and identifying the direction of portal venous blood flow. Doppler ultrasound also is useful in evaluating blood flow through surgical shunts and TIPS. Abdominal CT and magnetic resonance angiography both are capable of revealing portal vein anatomy as well as patency. Visceral angiography and portal venography are reserved for cases that cannot be evaluated satisfactorily by noninvasive methods and require further clarification of portal patency or anatomy.

The most accurate method of determining portal hypertension is hepatic venography. The most commonly used procedure involves placing a balloon catheter directly into the hepatic vein and measuring the free hepatic venous pressure (FHVP) with the balloon deflated and the wedged hepatic venous pressure (WHVP) with the balloon inflated to occlude the hepatic vein. The hepatic venous pressure gradient (HVPG) is then calculated by subtracting the free from the wedged venous pressure

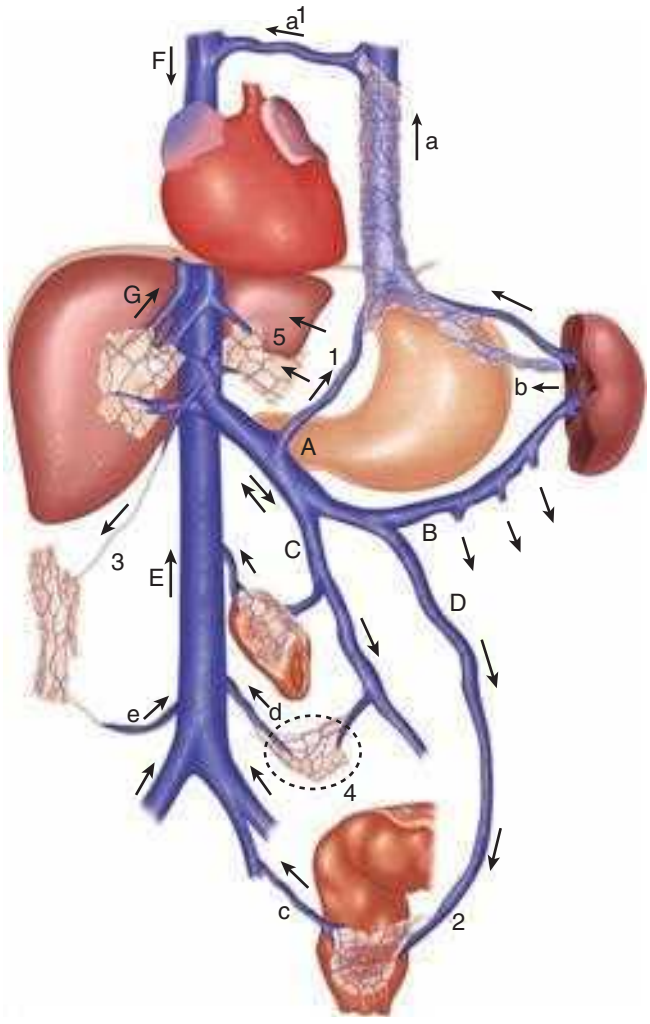

Figure 31-14. Intra-abdominal venous flow pathways leading to engorged veins (varices) from portal hypertension. *1*, Coronary vein; *2*, superior hemorrhoidal veins; *3*, paraumbilical veins; *4*, Retzius' veins; *5*, veins of Sappey; *A*, portal vein; *B*, splenic vein; *C*, superior mesenteric vein; *D*, inferior mesenteric vein; *E*, inferior vena cava; F, superior vena cava; *G*, hepatic veins; *a*, esophageal veins; a^1, azygos system; *b*, vasa brevia; *c*, middle and inferior hemorrhoidal veins; *d*, intestinal; *e*, epigastric veins.

(HVPG = WHVP – FHVP). The HVPG represents the pressure in the hepatic sinusoids and portal vein and is a measure of portal venous pressure. Clinically significant portal hypertension is evident when HVPG exceeds 10 mmHg.

Etiology and Clinical Features of Portal Hypertension

The causes of portal hypertension can be divided into three major groups: presinusoidal, sinusoidal, and postsinusoidal.[41] Although multiple disease processes can result in portal hypertension (Table 31-5), in the United States, the most common cause of portal hypertension is usually an intrahepatic one, namely, cirrhosis. The most significant clinical finding associated with portal hypertension is the development of gastroesophageal varices, which are mainly supplied by the anterior branch of the left gastric (coronary) vein.

Portal hypertension also results in splenomegaly with enlarged, tortuous, and even aneurysmal splenic vessels. Splenomegaly is frequently associated with functional hypersplenism, causing leukopenia, thrombocytopenia, and anemia. Ascites occurs in the setting of severe portal hypertension in combination with hepatocyte dysfunction. The umbilical vein may recannulate and dilate, leading to visible collaterals on the abdominal wall. Anorectal varices are present in approximately 45% of cirrhotic patients and must be distinguished from hemorrhoids, which do not communicate with the portal system and are not present at increased incidence in patients with portal hypertension. Large spontaneous venous shunts may form between the portal venous system and the left renal vein or the IVC, but these shunts are ineffective in reducing portal venous pressures and preventing bleeding from gastroesophageal varices.

Table 31-5

Etiology of portal hypertension

Management of Gastroesophageal Varices

The most significant manifestation and the leading cause of morbidity and mortality related to portal hypertension is variceal bleeding. Approximately 30% of patients with compensated cirrhosis and 60% of patients with decompensated cirrhosis have esophageal varices. One third of all patients with varices will experience variceal bleeding. Each episode of bleeding is associated with a 20% to 30% risk of mortality. If left untreated, 70% of patients who survive the initial bleed will experience recurrent variceal hemorrhage within 2 years of the index hemorrhage.

Prevention of Variceal Bleeding

Current measures aimed at preventing variceal bleeding include the administration of nonselective β-blockers and prophylactic

endoscopic surveillance with variceal band ligation. Meta-analyses have demonstrated that nonselective β-blockers such as propranolol and nadolol reduce the index variceal bleed by approximately 45% and decrease bleeding mortality by 50%.[42] However, approximately 20% of patients do not respond to β-blockade, and another 20% cannot tolerate β-blockade due to medication side effects. Endoscopic surveillance with prophylactic variceal band ligation has been associated with a lower incidence of a first variceal bleed.[43] Variceal band ligation is recommended for patients with medium to large varices, performed every 1 to 2 weeks until obliteration, followed by esophagogastroduodenoscopy (EGD) 1 to 3 months later and surveillance EGD every 6 months to monitor for recurrence of varices.

Management of Acute Variceal Hemorrhage

Patients with acute variceal hemorrhage should be admitted to an ICU for resuscitation and management. Blood resuscitation should be performed carefully to reach a hemoglobin level of approximately 8 g/dL. Overzealous replacement of blood products and administration of saline can lead to both rebleeding and increased mortality. Administration of fresh frozen plasma and platelets can be considered in patients with severe coagulopathy. Use of recombinant factor VIIa has not been shown to be more beneficial than standard therapy and therefore is not recommended at this time. Cirrhotic patients with variceal bleeding have a high risk of developing bacterial infections, which are associated with increased risks of rebleeding and mortality. Spontaneous bacterial peritonitis accounts for approximately half of these infections, with urinary tract infections and pneumonias comprising the remainder. The use of short-term prophylactic antibiotics (e.g., ceftriaxone 1 g/d intravenously) has been shown both to decrease the rate of bacterial infections and to increase survival.

Vasoactive medications decrease blood flow to the gastroesophageal varices and can be initiated as soon as the diagnosis of variceal bleeding is made. Although vasopressin is the most potent available vasoconstrictor, its use is limited by its systemic vasoconstrictive effects that can produce hypertension, myocardial ischemia, arrhythmias, ischemic abdominal pain, and limb gangrene. Octreotide, a somatostatin analog, has the advantage that it can be administered for 5 days or longer, and it is currently the preferred pharmacologic agent for initial management of acute variceal bleeding. In addition to pharmacologic therapy, endoscopy with variceal band ligation should be carried out as soon as possible. This combination of pharmacologic and endoscopic therapy has been shown both to improve the initial control of bleeding and to increase the 5-day hemostasis rate.[43]

6▶

Luminal Tamponade

When medical and endoscopic measures fail to control variceal hemorrhage, balloon tamponade using a Sengstaken-Blakemore tube will control refractory bleeding in up to 90% of patients. However, its application is limited due to the potential for complications, which include aspiration, airway obstruction, and esophageal perforation due to overinflation or pressure necrosis. Therefore, the use of a Sengstaken-Blakemore tube should not exceed 36 hours to avoid tissue necrosis, and this treatment modality should only be considered a temporary bridge to more definitive measures of variceal hemorrhage control.

Transjugular Intrahepatic Portosystemic Shunt

The TIPS procedure involves implantation of a metallic stent between an intrahepatic branch of the portal vein and a hepatic vein radicle. The needle track is dilated until a portal pressure gradient of ≤12 mmHg is achieved. TIPS can be performed in 95% of patients by an experienced interventional radiologist, controls variceal bleeding in >90% of cases refractory to medical treatment, and should not affect subsequent hepatic transplantation. Possible complications include bleeding either intra-abdominally or via the biliary tree, infections, renal failure, decreased hepatic function, and hepatic encephalopathy, which occur in 25% to 30% of patients after the TIPS procedure. A high rate of thrombosis is seen and can be attributed to intimal hyperplasia of the metallic stent. Frequent follow-up with repeated interventions such as dilation or restenting often are needed to maintain TIPS patency.

Balloon-Occluded Retrograde Transvenous Obliteration

The balloon-occluded retrograde transvenous obliteration (BRTO) procedure has been used for the specific management of bleeding gastric varices in patients with spontaneous gastrorenal or splenorenal shunts shown on contrast-enhanced cross-sectional imaging. Using a transjugular or transfemoral approach, a balloon-occlusion catheter is directed through the left renal vein into the spontaneous shunt, which is then obliterated with the use of a sclerosing agent. BRTO effectively controls hemorrhage from gastric varices and preserves portal flow to the liver, thereby reducing the risk of hepatic encephalopathy relative to TIPS. The occlusion of spontaneous shunts, however, can theoretically exacerbate portal hypertension, precipitate hemorrhage from esophageal varices, and exacerbate the accumulation of ascites.

Surgical Shunting

The need for surgical shunts has been reduced since the introduction of the TIPS procedure and hepatic transplantation. At this time, the recommendation is that surgical shunts be considered only in patients who have MELD scores of <15, who are not candidates for hepatic transplantation, or who have limited access to TIPS therapy and the necessary follow-up. The aim of the surgical shunt is to reduce portal venous pressure, maintain total hepatic and portal blood flow, and avoid the high incidence of complicating hepatic encephalopathy. Patient survival is determined by hepatic reserve.

The portacaval shunt, as first described by Eck in 1877, either joins the portal vein to the IVC in an end-to-side fashion and completely disrupts portal vein flow to the liver, or joins it in a side-to-side fashion and thereby maintains partial portal venous flow to the liver. Currently this shunt is rarely performed due to the high incidence of hepatic encephalopathy and decreased liver function resulting from the reduction of portal perfusion. The Eck fistula also makes subsequent hepatic transplantation much more technically difficult.

The mesocaval shunt uses an 8- or 10-mm polytetrafluoroethylene (PTFE) graft to connect the superior mesenteric vein to the IVC. The mesocaval shunt is technically easier to perform and can be easily ligated during subsequent hepatic transplantation. The smaller caliber of the shunt avoids the deleterious effects of portal blood flow deprivation on hepatic function. Small-diameter portosystemic shunts have been reported to reduce the incidence of encephalopathy but at the expense of increased risks of shunt thrombosis and rebleeding.

The surgical shunt currently used most often is the distal splenorenal or Warren shunt (Fig. 31-15). This shunt is technically

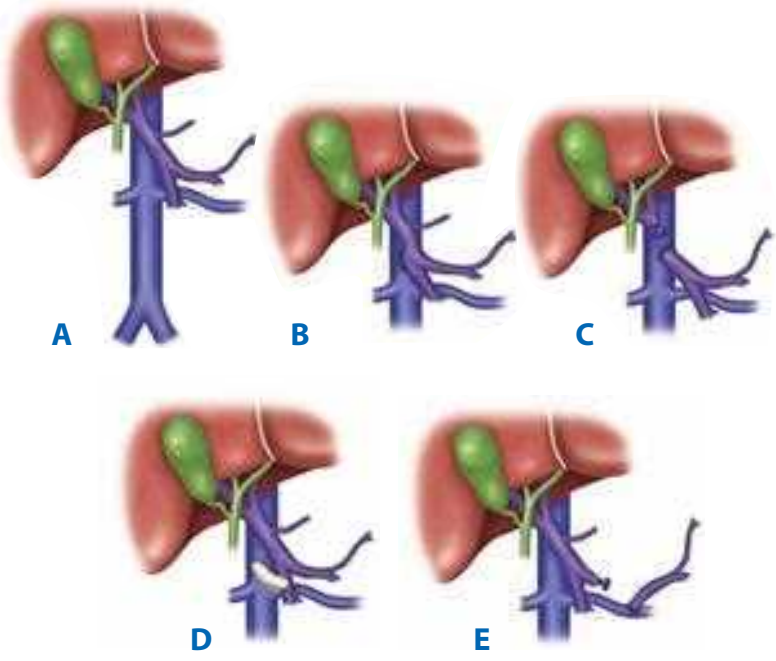

Figure 31-15. Surgical shunts for portal hypertension. Types of portacaval anastomoses. **A.** Normal anatomy. **B.** Side-to-side portacaval shunt. **C.** End-to-side portacaval shunt. **D.** Mesocaval shunt. **E.** Distal splenorenal (Warren) shunt. *(Reproduced with permission from Doherty GM, Way LW, eds.* Current Surgical Diagnosis and Treatment. *12th ed. New York: McGraw-Hill; 2006). Copyright © The McGraw-Hill Companies, Inc.*

the most difficult to perform. It requires division of the gastroesophageal collaterals and allows venous drainage of the stomach and lower esophagus through the short gastrosplenic veins into the spleen, and ultimately decompresses the left upper quadrant by allowing the splenic vein to drain directly into the left renal vein via an end-to-side splenic to left renal vein anastomosis. This shunt has the advantages of being associated with a lower rate of hepatic encephalopathy and decompensation and not interfering with subsequent liver transplantation.

Nonshunt Surgical Management of Refractory Variceal Bleeding

In the patient with extrahepatic portal vein thrombosis and refractory variceal bleeding, the Sugiura procedure may be considered. The Sugiura procedure consists of extensive devascularization of the stomach and distal esophagus along with transection of the esophagus, splenectomy, truncal vagotomy, and pyloroplasty. As with performance of surgical shunts, patient survival is dependent on hepatic reserve at the time of the surgical procedure. Experience in Western countries is somewhat limited, and a number of modifications have been made to the original Sugiura procedure over time.

Hepatic Transplantation

Patients with cirrhosis, portal hypertension, and variceal bleeding usually die as a result of hepatic failure and not acute blood loss. Therefore, hepatic transplantation must be considered in the patient with ESLD, because it represents the patient's only chance for definitive therapy and long-term survival. Hepatic transplantation also can be considered for the patient with variceal bleeding refractory to all other forms of management. Survival after hepatic transplantation is not affected adversely by the previous performance of endoscopic variceal band ligation, TIPS, or splenorenal or mesocaval shunts. Previous creation of an Eck fistula, however, does make hepatic transplantation much more technically difficult, and therefore this procedure should be avoided in the transplant candidate. In addition to saving the patient's life, hepatic transplantation reverses most of the hemodynamic and humoral changes associated with cirrhosis.

Budd-Chiari Syndrome

Budd-Chiari syndrome (BCS) is an uncommon congestive hepatopathy characterized by the obstruction of hepatic venous outflow. The incidence of BCS is 1 in 100,000 of the general population worldwide.[44] Patients may present with acute signs and symptoms of abdominal pain, ascites, and hepatomegaly or more chronic symptoms related to long-standing portal hypertension. BCS is defined as primary when the obstructive process involves an endoluminal venous thrombosis. BCS is considered as a secondary process when the veins are compressed or invaded by a neighboring lesion originating outside the vein.

A thorough evaluation demonstrates one or more thrombotic risk factors in approximately 75% to 90% of patients with primary BCS.[44] Primary myeloproliferative disorders, such as essential thrombocythemia or polycythemia rubra, account for approximately 35% to 50% of the primary cases of BCS. All known inherited thrombophilias also have been implicated in the development of BCS. Activated protein C resistance, generally related to factor V Leiden mutation, is present in approximately 25% of patients. Anticardiolipin antibodies, hyperhomocysteinemia, and oral contraceptive use all have been shown to be risk factors for BCS.[44]

Clinically significant BCS is usually the result of obstruction of two or more of the major hepatic veins. The obstruction results in hepatomegaly, liver congestion, and right upper quadrant pain. In addition, liver perfusion via the portal vein may be decreased, and 70% of affected patients have noninflammatory centrilobular necrosis on biopsy. Although ALF is rare, most patients will go on to develop chronic portal hypertension and ascites. Caudate lobe hypertrophy occurs in approximately 50% of cases and is due to the fact that the caudate lobe has direct venous drainage into the IVC. This caudate lobe hypertrophy, in turn, can result in further obstruction of the IVC.

Abdominal ultrasonography is the initial investigation of choice and can demonstrate the absence of hepatic vein flow, spider web hepatic veins, and collateral hepatic veins.[45] CT or MRI of the abdomen also is capable of demonstrating hepatic vein thrombosis and evaluating the IVC but is limited in that it cannot show direction of blood flow. The definitive radiographic study to evaluate BCS is hepatic venography to determine the presence and extent of hepatic vein thrombus as well as measure IVC pressures.

Initial treatment consists of diagnosing and medically managing the underlying disease process and preventing extension of the hepatic vein thrombosis through systemic anticoagulation. The BCS-associated portal hypertension and ascites can be medically managed in a manner similar to that in most cirrhotic patients. Radiologic and surgical intervention should be reserved for patients whose condition is nonresponsive to medical therapy. Percutaneous angioplasty and TIPS, in combination with thrombolytic therapy, are the preferred strategies to restore the outflow of blood from the liver. Thrombolytic therapy alone may be attempted for acute thrombosis. Surgical shunting, namely with the side-to-side portacaval shunt, essentially turns the portal vein into a hepatic outflow tract. Most patients with a portacaval shunt show improvement in hepatic function and fibrosis at 1 year without significant hepatic encephalopathy.[45] However, the enthusiasm for this procedure has been curbed due to the relatively high rate of operative mortality and shunt dysfunction. Patients with progressive BCS and manifestations of ESLD will ultimately require hepatic transplantation.

INFECTIONS OF THE LIVER

The liver contains the largest portion of the reticuloendothelial system in the human body and is therefore able to handle the continuous low-level exposure to enteric bacteria that it receives through the portal venous system. Due to the high level of reticuloendothelial cells in the liver, nonviral infections are unusual.

Pyogenic Liver Abscesses

Pyogenic liver abscesses are the most common liver abscesses seen in the United States. They may be single or multiple and are more frequently found in the right lobe of the liver.[46] The abscess cavities are variable in size and, when multiple, may coalesce to give a honeycomb appearance. Approximately 40% of abscesses are monomicrobial, an additional 40% are polymicrobial, and 20% are culture-negative. The most common infecting agents are gram-negative bacteria; *Escherichia coli* is found in two thirds of cases, and other common organisms include *Streptococcus faecalis, Klebsiella,* and *Proteus vulgaris*. Anaerobic organisms such as *Bacteroides fragilis* also are seen frequently. In patients with endocarditis and infected indwelling catheters, *Staphylococcus* and *Streptococcus* species are more commonly found.

In the past, pyogenic liver abscesses often resulted from infections of the intestinal tract such as acute appendicitis and diverticulitis, which then spread to the liver via the portal circulation. With improved imaging modalities and earlier diagnosis of these intra-abdominal infections, this particular etiology of pyogenic liver abscesses has become less common. Pyogenic liver abscesses also occur as a result of impaired biliary drainage, subacute bacterial endocarditis, infected indwelling catheters, dental work, or the direct extension of infections such as diverticulitis or Crohn's disease into the liver. There appears to be an increasing incidence due to infection by opportunistic organisms among immunosuppressed patients, including transplant and chemotherapy recipients as well as patients with acquired immunodeficiency syndrome (AIDS).

Patients commonly present with right upper quadrant pain and fever. Jaundice occurs in up to one third of affected patients. A thorough history and physical examination are usually helpful in identifying the underlying cause of the liver abscess. Leukocytosis, an elevated sedimentation rate, and an elevated AP level are the most common laboratory findings. Significant abnormalities in the results of the remaining liver function tests are unusual. Blood cultures will only reveal the causative organism in approximately 50% of cases. Ultrasound examination of the liver reveals pyogenic abscesses as round or oval hypoechoic lesions with well-defined borders and a variable number of internal echoes. CT scan is highly sensitive in the localization of pyogenic liver abscesses, which appear hypodense with peripheral enhancement and may contain air-fluid levels indicating a gas-producing infectious organism (Fig. 31-16). MRI of the abdomen can also detect pyogenic abscesses with a high level of sensitivity but plays a limited role because of its inability to be used for image-guided diagnosis and therapy.

The current cornerstones of treatment include correction of the underlying cause and IV antibiotic therapy. Empiric antibiotic therapy should cover gram-negative and anaerobic organisms; percutaneous needle aspiration and culture of the aspirate may be useful in guiding subsequent antibiotic therapy. IV antibiotic therapy should be continued for at least 8 weeks and can be expected to be effective in 80% to 90% of patients. Placement of a percutaneous drainage catheter is beneficial only for a minority of patients, as most pyogenic abscesses are quite viscous and catheter drainage is often ineffective.

Surgical drainage either via the laparoscopic or open approach may become necessary if initial therapies fail. Anatomic surgical resection can be performed in patients with recalcitrant abscesses. It must be kept in mind throughout the evaluation and treatment of the presumed pyogenic abscess that a necrotic hepatic malignancy must not be mistaken for a hepatic abscess. Therefore, early diagnosis and progression to

Figure 31-16. Computed tomographic scan of pyogenic liver abscesses. Multiple hepatic abscesses are seen in a patient after an episode of diverticulitis. Note the loculated large central abscess as well as the left lateral segment abscess.

surgical resection should be advocated for patients who do not respond to initial antibiotic therapy.

Amebic Abscesses

Entamoeba histolytica is a parasite that is endemic worldwide, infecting approximately 10% of the world's population. Amebiasis is most common in subtropical climates, especially in areas with poor sanitation. *E. histolytica* exists as cysts in a vegetative form that are capable of surviving outside the human body. The cystic form passes through the stomach and small bowel unharmed and then transforms into a trophozoite in the colon. Here it invades the colonic mucosa forming typical flask-shaped ulcers, enters the portal venous system, and is carried to the liver. Occasionally, the trophozoite will pass through the hepatic sinusoid and into the systemic circulation, which results in lung and brain abscesses.

Amebae multiply and block small intrahepatic portal radicles with consequent focal infarction of hepatocytes. They contain a proteolytic enzyme that also destroys liver parenchyma. The abscesses formed are variable in size and can be single or multiple. The amebic abscess is most commonly located in the superior-anterior aspect of the right lobe of the liver near the diaphragm and has a necrotic central portion that contains a thick, reddish brown, pus-like material. This material has been likened to anchovy paste or chocolate sauce. Amebic abscesses are the most common type of liver abscesses worldwide.

Amebiasis should be considered in patients who have traveled to an endemic area and present with right upper quadrant pain, fever, hepatomegaly, and hepatic abscess.[46] Leukocytosis is common, whereas elevated transaminase levels and jaundice are unusual. The most common biochemical abnormality is a mildly elevated AP level. Even though this disease process is secondary to a colonic infection, the presence of diarrhea is unusual. Most patients have a positive fluorescent antibody test for *E. histolytica*, and test results can remain positive for some time after a clinical cure. This serologic test has a high sensitivity, and therefore amebiasis is unlikely if the test results are negative.

Ultrasound and CT scanning of the abdomen are both very sensitive but nonspecific for the detection of amebic abscesses.[46] Amebic abscesses usually appear on CT as well-defined low-density round lesions that have enhancement of the wall, somewhat ragged in appearance with a peripheral zone of edema. The central cavity may have septations as well as fluid levels. CT scanning is also useful in the detection of extrahepatic involvement.

Metronidazole 750 mg three times a day for 7 to 10 days is the treatment of choice and is successful in 95% of cases. Defervescence usually occurs in 3 to 5 days, but the time necessary for the abscess to resolve depends on the initial size at presentation and varies from 30 to 300 days.[46] Both ultrasound and CT of the liver can be used as follow-up after the initiation of medical therapy. Aspiration of the abscess rarely is needed and should be reserved for patients with large abscesses, those who do not respond to medical therapy, or those who appear to be superinfected. Furthermore, abscesses of the left lobe of the liver at risk for rupture into the pericardium should be treated with aspiration and drainage.

Hydatid Disease

Hydatid disease is due to infection by the tapeworm *Echinococcus granulosus* in its larval or cyst stage.[47] The tapeworm lives in canids, which are infected by eating the viscera of sheep that contain hydatid cysts. Scolices, contained in the cysts, adhere to the small intestine of dogs and become adult taenia, which attach to the intestinal wall. Each worm sheds approximately 500 ova into the bowel. The infected ova-containing feces of dogs contaminate grass and farmland, and the ova are ingested by intermediate hosts such as sheep, cattle, pigs, and humans. The ova have chitinous envelopes that are dissolved by gastric juice. The liberated ovum then burrows through the intestinal mucosa and is carried by the portal vein to the liver, where it develops into an adult cyst. Most cysts are caught in the hepatic sinusoids, and therefore 70% of hydatid cysts form in the liver. A few ova pass through the liver and are held up in the pulmonary capillary bed or enter the systemic circulation, forming cysts in the lung, spleen, brain, or bones.

Hydatid disease is most common in sheep-raising areas, where dogs have access to infected offal. These include South Australia, New Zealand, Africa, Greece, Spain, and the Middle East. Hydatid cysts commonly involve the right lobe of the liver, usually the anterior-inferior or posterior-inferior segments. The uncomplicated cyst may be silent and found only incidentally or at autopsy. Occasionally, the affected patient presents with symptoms such as dull right upper quadrant pain or abdominal distention. Cysts may become secondarily infected, involve other organs, or even rupture, which leads to an allergic or anaphylactic reaction.

The diagnosis of hydatid disease is based on the findings of an enzyme-linked immunosorbent assay (ELISA) for echinococcal antigens, and results are positive in approximately 85% of infected patients.[47] The ELISA results may be negative in an infected patient if the cyst has not leaked or does not contain scolices or if the parasite is no longer viable. Eosinophilia is seen in approximately 30% of infected patients. Ultrasonography and CT scanning of the abdomen are both quite sensitive for detecting hydatid cysts. The appearance of the cysts on images depends on the stage of cyst development. Typically, hydatid cysts are well-defined hypodense lesions with a distinct wall. Ring-like calcifications of the pericysts are present in 20% to 30% of cases. As healing occurs, the entire cyst calcifies densely, and a lesion with this appearance is usually dead or inactive. Daughter cysts generally occur in a peripheral location within the main cyst and are typically slightly hypodense compared with the mother cyst. MRI of the abdomen may be useful to evaluate the pericyst, cyst matrix, and daughter cyst characteristics.

Unless the cysts are small or the patient is not a suitable candidate for surgical resection, the treatment of hydatid disease is surgically based because of the high risk of secondary infection and rupture. Medical treatment with albendazole relies on drug diffusion through the cyst membrane. The concentration of drug achieved in the cyst is uncertain but is better than that of mebendazole, and albendazole can be used as initial treatment for small, asymptomatic cysts. For most cysts, surgical resection involving laparoscopic or open complete cyst removal with instillation of a scolicidal agent is preferred and usually is curative. If complete cystectomy is not possible, then formal anatomic liver resection can be undertaken. During surgical resection, caution must be exercised to avoid rupture of the cyst with release of protoscolices into the peritoneal cavity. Peritoneal contamination can result in an acute anaphylactic reaction or peritoneal implantation of scolices with daughter cyst formation and inevitable recurrence.

Echinococcus multilocularis occurs in the Northern Hemisphere and can infect the liver in a fashion similar to that described earlier, although the cysts are multilocular. Infection of the lung also is common (alveolar echinococcosis). Canine species such as wolves, foxes, and dogs ingest infected viscera of an intermediate host (e.g., rodents, moose) and become infected; humans become infected incidentally by ingesting contaminated food or water. Treatment consists of albendazole; however, infection in the lung produces a more generalized granulomatous reaction, can present in a manner similar to that of a malignancy, and often requires resection.

Ascariasis

Ascaris infection is particularly common in the Far East, India, and South Africa. Ova of the roundworm *Ascaris lumbricoides* arrive in the liver by retrograde locomotion in the bile ducts from the GI tract. The adult worm is 10 to 20 cm long and may lodge in the common bile duct, causing partial bile duct obstruction and secondary cholangitic abscesses. The *Ascaris* may serve as a nidus for the development of intrahepatic gallstones. The clinical presentation in an affected patient may include biliary colic, acute cholecystitis, acute pancreatitis, or hepatic abscesses.[48] Plain abdominal radiographs, abdominal ultrasound, and ERCP can demonstrate the *Ascaris* as linear filling defects within the bile ducts. Occasionally, worms can be seen moving into and out of the biliary tree from the duodenum. Treatment consists of the administration of piperazine citrate, mebendazole, or albendazole in combination with endoscopic extraction of the worms. Surgical intervention may become necessary if the *Ascaris* cannot be removed via ERCP.

Schistosomiasis

Schistosomiasis affects >200 million people in 74 countries. Hepatic schistosomiasis occurs when emboli of the ova in the intestines reach the liver via the mesenteric venous system. Eggs excreted in the feces hatch in water to release free-swimming embryos, which enter snails and develop into fork-tailed cercariae. They then re-enter human skin during contact with infected water. They burrow down to the capillary bed and enter the bloodstream, leading to widespread hematogenous dissemination. Those entering the intrahepatic portal system grow rapidly, resulting in a granulomatous reaction. The degree of consequent portal fibrosis is related to the adult worm load.

Schistosomiasis has three stages of clinical symptomatology: the first includes itching after the entry of cercariae through the skin; the second includes fever, urticaria, and eosinophilia; and the third involves hepatic fibrosis followed by presinusoidal portal hypertension. During this third phase, the liver shrinks, the spleen enlarges, and the patient may develop complications of portal hypertension while hepatic function is maintained. Active infection is detected by stool examination. Serologic tests indicate past exposure but do not provide information regarding the timing of infection. A negative serologic test result excludes the presence of schistosomal infection. Serum levels of transaminases are usually normal, but the AP level may be mildly elevated. A decreased serum albumin level is usually the result of frequent GI bleeds and malnutrition.

Medical treatment of schistosomiasis includes education on hygiene and the avoidance of infected water. Treatment with praziquantel 40 to 75 mg/kg as a single dose is the treatment of choice for all forms of schistosomiasis and produces few side effects. GI bleeding usually is controlled by endoscopic variceal ligation. However, in a patient with refractory GI portal hypertensive bleeding, distal splenorenal shunt or gastric devascularization and splenectomy may be considered.

Viral Hepatitis

The role of the surgeon in the management of viral hepatitis is somewhat limited. However, the disease entities of hepatitis A, B, and C need to be kept in mind during any evaluation for liver disease. Hepatitis A usually results in an acute self-limited illness and only rarely leads to fulminant hepatic failure. Patients can present with fatigue, malaise, nausea, vomiting, anorexic fever, and right upper quadrant abdominal pain. The most common physical findings are jaundice and hepatomegaly. Because the disease is self-limited, the treatment is usually supportive. Patients who develop fulminant infection require aggressive therapy and should be transferred to a center capable of performing liver transplantation.

Hepatitis B and C, on the other hand, can both lead to chronic liver disease, cirrhosis, and HCC. The prevalence of chronic hepatitis B infection in the U.S. population is estimated to be 0.27%, but hepatitis B remains a major burden in resource-limited countries, accounting for 30% of cirrhosis and 53% of HCC cases. The ultimate goal of treatment for chronic hepatitis B is viral suppression, thereby preventing the development of clinical outcomes such as cirrhosis, liver failure, and HCC. The cornerstone of current antiviral therapy includes pegylated interferon and nucleoside analogs such as tenofovir or entecavir.[49] These agents have been proven to reduce complications of cirrhosis and HCC and perhaps reverse previous damage to the liver. Interferon therapy produces various side effects including fatigue, flu-like symptoms, mood changes, bone marrow suppression, and stimulation of autoimmunity. On the other hand, the nucleoside analogs are generally well-tolerated by patients. Compared with lamivudine, the nucleoside analogs are less likely to produce resistance and are more likely to be clinically effective. Despite its high rate of viral resistance, lamivudine may be the preferred treatment in some countries because of its relatively low cost.

Acute hepatitis C viral (HCV) infection typically develops 2 to 26 weeks after exposure to the virus, and presenting symptoms can include jaundice, nausea, dark urine, and right upper quadrant abdominal pain. Diagnosis is confirmed by testing for the presence of HCV RNA and anti-HCV antibodies in the serum; viral RNA is first detectable in the serum by polymerase chain reaction (PCR) within days to weeks following the exposure, whereas antibodies will not appear until 2 to 6 months after. If the diagnosis of acute hepatitis is established and the virus is not spontaneously cleared within 12 weeks, patients should generally be treated with pegylated interferon monotherapy. High rates of sustained viral response, in excess of 80%, have been achieved with the early treatment of acute HCV infection.[50] Unfortunately patients with acute HCV infection are typically asymptomatic, and the vast majority of cases go undetected. Untreated, most of these patients will eventually develop chronic infection.

Chronic HCV infection often follows a progressive course over many years and can ultimately result in cirrhosis, HCC, and the need for liver transplantation. Cirrhosis secondary to hepatitis C remains the leading indication for liver transplantation in the United States, Europe, and Japan. The decision to treat a patient with chronic HCV infection is complex and involves consideration of multiple factors including the natural history of

the disease, stage of fibrosis, and the efficacy and adverse effects related to the treatment regimen. Patients with genotype 1 are now treated with triple-agent therapy including pegylated interferon, ribavirin, and a protease inhibitor. The protease inhibitors telaprevir and boceprevir were recently approved for the treatment of chronic HCV genotype 1 infection, and their addition to the treatment regimen has been shown to increase the rate of sustained viral response from 40% to 70%. These protease inhibitors do no exhibit significant antiviral activity against other HCV genotypes, and therefore genotypes 2, 3, and 4 are treated with interferon and ribavirin alone. Genotypes 2 and 3 are generally more responsive to treatment than genotypes 1 and 4, but the therapeutic response also is dependent on other factors such as baseline viral load, ethnicity, and the patient's genetic background and compliance with the regimen.

EVALUATION OF AN INCIDENTAL LIVER MASS

A liver mass often is identified incidentally during a radiologic imaging procedure performed for another indication. For example, a liver mass may be discovered during evaluation for gallbladder disease or kidney stones. In addition, with advances in imaging technology, previously undetected lesions not infrequently are now identified. Although many of these lesions are benign and will require no further treatment, the concern for malignancy requires a thorough evaluation. Thus, an orderly approach should be taken to the workup of an incidental liver lesion to minimize unnecessary testing.[51]

The evaluation of an incidental liver mass begins with a history and physical examination (Fig. 31-17). The patient should be asked about abdominal pain, weight loss, previous liver disease, cirrhosis, alcohol use, viral hepatitis, blood transfusions, tattoos, oral contraceptive use (in women), and personal or family history of cancer. On physical examination, jaundice, scleral icterus, hepatomegaly, splenomegaly, palpable mass, or stigmata of portal hypertension should be noted. After completion of the history and physical examination, blood work should be performed, including complete blood count; platelet count; measurement of levels of electrolytes, blood urea nitrogen, creatinine, glucose, and albumin; liver function tests; serum ammonia level; coagulation studies; hepatitis screen; and measurement of levels of the

The differential diagnosis for an incidental liver mass includes cysts, benign solid lesions, and primary or metastatic cancers (Table 31-6). Ultrasound or CT is commonly performed to evaluate respiratory or abdominal symptoms, and these imaging studies usually lead to the discovery of an incidental liver lesion. Further radiologic evaluation by dual- or triple-phase CT scan or MRI is often necessary to fully characterize the extent and nature of the lesion. Different types of liver masses have distinct appearances and patterns of contrast enhancement on these studies, facilitating the clinician in the diagnosis and formulation of the treatment plan. The use of liver-specific contrast agents in MRI provides information on hepatocyte function in combination with the structural data obtained during a standard MRI, and yields improved detection and characterization of liver lesions. CT cholangiography or MRCP can be obtained, particularly when visualization of the biliary tract is desired. These modalities may be useful in the depiction of benign or malignant strictures resulting in biliary obstruction. In the evaluation of metastases to the liver from a variety of primary cancers, FDG-PET/CT has emerged as an indispensable tool in disease staging and in the follow-up after treatment. The techniques available for imaging of liver lesions are described in detail earlier in the section "Radiologic Evaluation of the Liver."

Liver biopsy is indicated when biochemical analysis and diagnostic imaging fail to lead to a definitive diagnosis. Percutaneous liver biopsy with ultrasound or CT guidance is the simplest, fastest, and most commonly performed approach to obtain hepatic tissue for histologic examination. Absolute contraindications to percutaneous liver biopsy include significant coagulopathy (as in patients with decompensated cirrhosis), biliary dilatation, and suspicion for hemangioma or echinococcal cyst. Obesity and the presence of ascites are relative contraindications that can present a challenge to the percutaneous approach. In these patients, laparoscopic liver biopsy can be considered. The laparoscopic technique is likely to have a higher diagnostic yield in cirrhotic patients with ascites and/or coagulopathy, in whom bleeding risk is excessive by the percutaneous route. Laparoscopy also offers the opportunity to stage the extent of disease in patients with various intra-abdominal malignancies.

HEPATIC CYSTS

Congenital Cysts

The majority of hepatic cysts are asymptomatic. Hepatic cysts are usually identified incidentally and can occur at any time throughout life. The most common benign lesion found in the liver is the congenital or simple cyst. The exact prevalence of simple hepatic cysts in the U.S. population is not known, but the female:male ratio is approximately 4:1, and the prevalence is approximately 2.8% to 3.6%.[52] Simple cysts are the result of excluded hyperplastic bile duct rests. Simple cysts usually are identified in hepatic imaging studies as thin-walled, homogeneous, fluid-filled structures with few to no septations. The cyst epithelium is cuboidal and secretes a clear nonbilious serous fluid. With the exception of large cysts, simple cysts are usually asymptomatic. Large simple cysts may cause abdominal pain, epigastric fullness, and early satiety. Occasionally the affected patient presents with an abdominal mass.

Asymptomatic simple cysts are best managed conservatively. The preferred treatment for symptomatic cysts is ultrasound- or CT-guided percutaneous cyst aspiration followed by sclerotherapy. This approach is approximately 90% effective in controlling symptoms and ablating the cyst cavity. If percutaneous treatment is unavailable or ineffective, treatment may include either laparoscopic or open surgical cyst fenestration. The laparoscopic approach is being used more frequently and is 90% effective. The excised cyst wall is sent for pathologic analysis to exclude the presence of carcinoma, and the remaining cyst wall must be carefully inspected for evidence of neoplastic change. If such change is present, complete resection is required, either by enucleation or formal hepatic resection.

Biliary Cystadenoma

Biliary cystadenomas are slow-growing, unusual, benign lesions that most commonly present as large lesions in the right lobe of the liver. Although these lesions are usually benign, they can undergo malignant transformation. Patients with biliary cystadenomas commonly present with abdominal pain. An abdominal mass occasionally can be identified on physical examination. In contrast to simple cysts, biliary cystadenomas have walls that appear thicker with soft tissue nodules and septations that usually enhance. The protein content of the fluid can be variable and can affect the radiographic images on CT and MRI. Surgical resection is the preferred mode of treatment.

Polycystic Liver Disease

Adult polycystic liver disease (PCLD) occurs as an autosomal dominant disease and usually presents in the third decade of life. Approximately 44% to 76% of affected families are found to have mutations of *PKD1*, and approximately 75% have mutations of *PKD2*.[53] The prevalence and number of hepatic cysts are higher in females and increase with advancing age and with increasing severity of renal cystic disease and renal dysfunction. Patients with a small number of cysts or with small cysts (<2 cm) usually remain asymptomatic. In contrast, patients who develop many or large cysts, with a cyst-to-parenchymal volume ratio of >1, usually develop clinical symptoms, including abdominal pain, distension, shortness of breath, and early satiety. Disease progression often results in renal failure and the need for hemodialysis. In most patients, the liver parenchymal volume and synthetic function are preserved despite extensive cystic disease. Hepatic decompensation, variceal hemorrhage, ascites,

and encephalopathy develop rarely in patients with PCLD and only in those with massive cystic disease. The most common liver-specific complications associated with PCLD are intracystic hemorrhage, infection, and posttraumatic rupture. The most common abnormal biochemical test finding is a modestly elevated γ-glutamyltransferase level, and the most useful imaging tests are CT or MRI of the abdomen, which will demonstrate the characteristic polycystic appearance. Other conditions that may be associated with PCLD include cerebral aneurysm, diverticulosis, mitral valve prolapse, and inguinal hernia.

The principal aim of treatment for PCLD is to ameliorate symptoms by decreasing liver volume. Medical therapy options for PCLD remain experimental at this time. Somatostatin analogs such as octreotide and lanreotide have been shown to modestly reduce liver volume and are generally well tolerated. Sirolimus and other mammalian target of rapamycin (mTOR) inhibitors possess antiproliferative effects and thus have been postulated to slow disease progression. The effectiveness of these medical measures in relieving symptoms among patients with PCLD, however, remains to be proven.[54]

Cyst aspiration and sclerotherapy entail puncture of a cyst with an aspiration needle followed by injection of a sclerosing agent that causes destruction of the epithelial lining thereby inhibiting fluid production. Common agents used for sclerosis include ethanol, minocycline, and tetracycline. This technique may be considered if the patient has one or a few dominant cysts, each measuring over 5 cm. Appropriate candidates for sclerotherapy can experience a complete resolution of symptoms, but patients with numerous cysts often do not improve when this technique is used. This procedure is generally well tolerated, with the most common complication being pain from the instillation of ethanol.

Cyst fenestration, or surgical unroofing of the cyst, can be performed via an open or laparoscopic approach in symptomatic patients.[55] This approach allows multiple cysts to be treated during a single procedure, but carries the risk of potential surgical complications, including ascites, pleural effusion, hemorrhage, and biliary leakage. Immediate symptom relief can be achieved in up to 92% of cases, but 22% of patients eventually develop recurrence of their symptoms.

Hepatic resection can be considered for PCLD patients with massive hepatomegaly, when fenestration alone is unlikely to significantly reduce liver volume. Appropriate candidates are those with portions of liver that harbor numerous cysts, but have at least one spared segment with predominantly normal liver parenchyma. Because the intrahepatic vascular and biliary anatomy can be distorted by the cysts, PCLD patients undergoing hepatic resection are at increased risk for hemorrhagic and biliary complications. Furthermore, adhesion formation after liver resection can increase the technical complexity of future OLT. Significant symptom relief has been reported in up to 86% of PCLD patients following hepatic resection.

OLT represents the only definitive therapy for patients with symptomatic PCLD. This therapeutic option is indicated in patients with severely disabling symptoms that lead to a poor quality of life or in those who have developed untreatable complications such as portal hypertension and nutritional deprivation. If the patient has severe renal insufficiency from polycystic kidney disease, consideration should be given to combined liver-kidney transplantation. Because of the genetic basis of PCLD, living-donor transplantation should be considered only if the presence of PCLD in the donor can be ruled out.

Caroli's Disease

Caroli's disease is a syndrome of congenital ductal plate malformations of the intrahepatic bile ducts and is characterized by segmental cystic dilatation of the intrahepatic biliary radicals.[56] Caroli's disease also is associated with an increased incidence of biliary lithiasis, cholangitis, and biliary abscess formation. Caroli's disease usually occurs in the absence of cirrhosis and is associated with cystic renal disease.[56] The most common presenting symptoms include fever, chills, and abdominal pain. Most patients present by the age of 30 years, and males and females are affected equally. Rarely, patients can present later in life with complications secondary to portal hypertension. Approximately 33% of affected patients develop biliary lithiasis and 7% develop cholangiocarcinoma. The diagnosis of Caroli's disease is made based on imaging studies. Magnetic resonance cholangiopancreatography, ERCP, and percutaneous transhepatic cholangiography provide more detailed imaging of the biliary tree and confirm communication of the intrahepatic cysts with the biliary tree, which is necessary to solidify the diagnosis. Treatment consists of biliary drainage, with ERCP and percutaneous transhepatic cholangiography serving as first-line therapeutic modalities. If the disease is limited to a single lobe of the liver, hepatic resection can be beneficial. Liver resection can be considered in the patient with hepatic decompensation or unresponsive recurrent cholangitis and possibly in the patient with a small (T1 or T2) cholangiocarcinoma.

BENIGN LIVER LESIONS

The liver is an organ that is commonly involved either primarily or secondarily with vascular, metabolic, infectious, and malignant processes. Many classification schemes are used to help narrow the differential diagnosis of liver lesions: solid or cystic, single or multiple, cell of origin (hepatocellular, cholangiocellular, or mesenchymal), and benign or malignant. Benign liver lesions occur in up to 20% of the general population and are much more common than malignant tumors. The most common benign lesions are cysts, hemangiomas, focal nodular hyperplasia (FNH), and hepatocellular adenomas (see Table 31-6). Many of these lesions have typical features in imaging studies that help confirm the diagnosis.

7▶

Cyst

Hepatic cysts are the most frequently encountered liver lesion overall and are described in detail in the section "Hepatic Cysts." Cystic lesions of the liver can arise primarily (congenital) or secondarily from trauma (seroma or biloma), infection (pyogenic or parasitic), or neoplastic disease. Congenital cysts are usually simple cysts containing thin serous fluid and are reported to occur in 5% to 14% of the population, with higher prevalence in women. In most cases, congenital cysts are differentiated from secondary cysts (infectious or neoplastic origin) in that they have a well-defined thin wall and no solid component and are filled with homogeneous, clear fluid. For benign solid liver lesions, the differential diagnosis includes hemangioma, adenoma, FNH, and bile duct hamartoma.

Hemangioma

Hemangiomas (also referred to as *hemangiomata*) are the most common solid benign masses that occur in the liver. They consist of large endothelial-lined vascular spaces and represent

congenital vascular lesions that contain fibrous tissue and small blood vessels that eventually grow. They are predominantly seen in women and occur in 2% to 20% of the population. They can range from small (≤1 cm) to giant cavernous hemangiomas (10 to 25 cm). Most hemangiomas are discovered incidentally with little clinical consequence. However, large lesions can cause symptoms as a result of compression of adjacent organs or intermittent thrombosis, which in turn results in further expansion of the lesion. Spontaneous rupture (bleeding) is rare, but surgical resection can be considered if the patient is symptomatic. Resection can be accomplished by enucleation or formal hepatic resection, depending on the location and involvement of intrahepatic vascular structures and hepatic ducts.

The majority of hemangiomas can be diagnosed by liver imaging studies. On biphasic contrast CT scan, large hemangiomas show asymmetrical nodular peripheral enhancement that is isodense with large vessels and exhibit progressive centripetal enhancement fill-in over time (Fig. 31-18). On MRI, hemangiomas are hypointense on T1-weighted images and hyperintense on T2-weighted images.[57] With gadolinium enhancement, hemangiomas show a pattern of peripheral nodular enhancement similar to that seen on contrast CT scans. Caution should be exercised in ordering a liver biopsy if the suspected diagnosis is hemangioma because of the risk of bleeding from the biopsy site, especially if the lesion is at the edge of the liver.

Adenoma

Hepatic adenomas are benign solid neoplasms of the liver. They are most commonly seen in premenopausal women older than 30 years of age and are typically solitary, although multiple adenomas also can occur. Prior or current use of estrogens (oral contraceptives) is a clear risk factor for development of liver adenomas, although they can occur even in the absence of oral contraceptive use. On gross examination, they appear soft and encapsulated and are tan to light brown. Histologically, adenomas lack bile duct glands and Kupffer cells, have no true lobules, and contain hepatocytes that appear congested or vacuolated due to glycogen deposition. On CT scan, adenomas usually have sharply defined borders and can be confused with metastatic tumors. With venous phase contrast, they can look hypodense or isodense in comparison with background liver, whereas on arterial phase contrast, subtle hypervascular enhancement often is seen (see Fig. 31-18). On MRI scans, adenomas are hyperintense on T1-weighted images and enhance early after gadolinium injection. With the use of liver-specific MRI contrast agents such as gadoxetate (Eovist or Primovist, Bayer-Schering, Berlin, Germany), hepatic adenomas can be

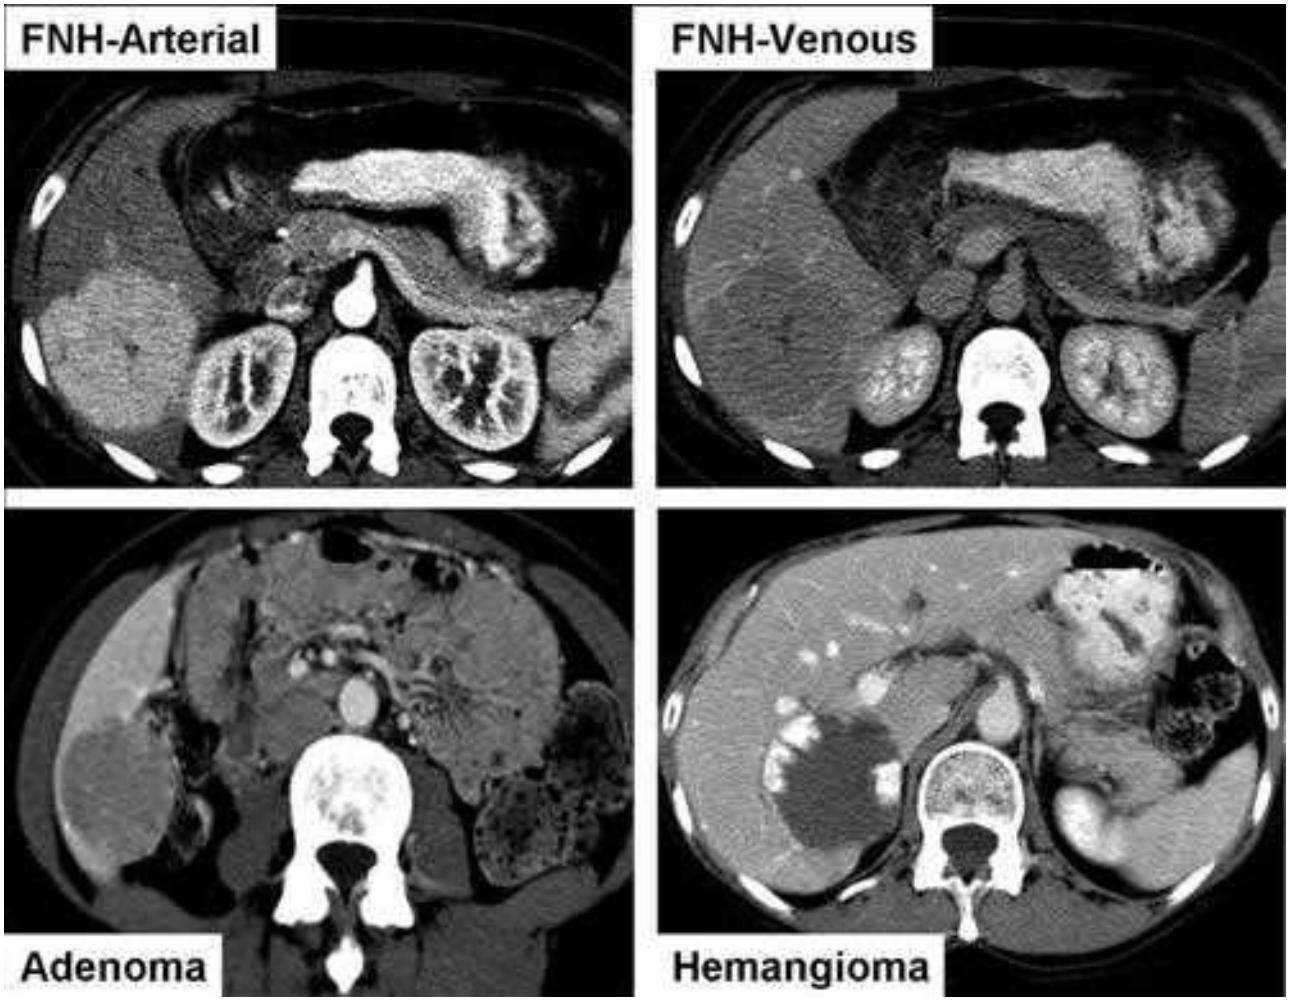

Figure 31-18. Computed tomographic scans showing classic appearance of benign liver lesions. Focal nodular hyperplasia (FNH) is hypervascular on arterial phase, isodense to liver on venous phase, and has a central scar (*upper panels*). Adenoma is hypovascular (*lower left panel*). Hemangioma shows asymmetrical peripheral enhancement (*lower right panel*).

better distinguished from FNH by their enhancement characteristics during the hepatobiliary phase of imaging. The new MRI contrast agent, gadobenate dimeglumine (MultiHance, Bracco Diagnostics, Milan, Italy), is eliminated through both renal and biliary excretion. Therefore, liver lesions that contain hepatocytes with intact biliary excretion mechanism will take up this contrast agent and be easily distinguished from lesions that do not. This contrast agent has improved our ability to differentiate hepatic adenoma from FNH with a high degree of accuracy.

Hepatic adenomas carry a significant risk of spontaneous rupture with intraperitoneal bleeding. The clinical presentation may be abdominal pain, and in 10% to 25% of cases, hepatic adenomas present with spontaneous intraperitoneal hemorrhage. Hepatic adenomas also have a risk of malignant transformation to a well-differentiated HCC. Therefore, it usually is recommended that a hepatic adenoma (once diagnosed) be surgically resected.

Focal Nodular Hyperplasia

FNH is a solid, benign lesion of the liver believed to be a hyperplastic response to an anomalous artery. Similar to adenomas, they are more common in women of childbearing age, although the link to oral contraceptive use is not as clear as with adenomas. A good-quality biphasic CT scan usually is diagnostic of FNH, on which such lesions appear well circumscribed with a typical central scar (see Fig. 31-18). They show intense homogeneous enhancement on arterial phase contrast images and are often isodense or invisible compared with background liver on the venous phase. On MRI scans, FNH lesions are hypointense on T1-weighted images and isointense to hyperintense on T2-weighted images. After gadolinium administration, lesions are hyperintense but become isointense on delayed images. The fibrous septa extending from the central scar are also more readily seen with MRI. Unlike adenomas, FNH lesions usually do not rupture spontaneously and have no significant risk of malignant transformation. Therefore, the management of FNH is usually reassurance and prospective observation irrespective of size. Surgical resection can be recommended, however, when patients are symptomatic or when hepatic adenoma or HCC cannot be definitively excluded. Oral contraceptive or estrogen use should be stopped when either FNH or adenoma is diagnosed.

Bile Duct Hamartoma

Bile duct hamartomas are typically small liver lesions, 2 to 4 mm in size, visualized on the surface of the liver at laparotomy. They are firm, smooth, and whitish yellow in appearance. They can be difficult to differentiate from small metastatic lesions, and excisional biopsy often is required to establish the diagnosis.

MALIGNANT LIVER TUMORS

Malignant tumors in the liver can be classified as primary (cancers that originate in the liver) or metastatic (cancers that spread to the liver from an extrahepatic primary site) (see Table 31-6). Primary cancers in the liver that originate from hepatocytes are known as *hepatocellular carcinomas* (HCCs or hepatomas), whereas cancers arising in the bile ducts are known as *cholangiocarcinomas.*

In the United States, approximately 150,000 new cases of colorectal cancer are diagnosed each year, and the majority of patients (approximately 60%) will develop hepatic metastases over their lifetime. Hence, the most common tumor seen in the liver is metastatic colorectal cancer. This compares with approximately 18,000 new cases of HCC diagnosed annually in the United States. Interestingly, in a Western series of 1000 consecutive new liver cancer patients seen at a university medical center, 47% had HCC, 17% had colorectal cancer metastases, 11% had cholangiocarcinomas, 7% had neuroendocrine metastases, and 18% had other tumors.[58] Although these figures do not reflect the incidence or prevalence of these liver cancers, they are indicative of referral patterns in a tertiary academic medical center with a large liver transplantation team and active hepatology clinic.

Hepatocellular Carcinoma

HCC is the fifth most common malignancy worldwide, with an estimated 750,000 new cases diagnosed annually. Because of its high fatality, it is the third most common cause of cancer death worldwide.[59] Major risk factors are viral hepatitis (B or C), alcoholic cirrhosis, hemochromatosis, and NASH. In Asia, the risk is as high as 35 to 117 per 100,000 persons per year, whereas in the United States, the risk is only 7 per 100,000 persons per year.[59] Although cirrhosis is not present in all cases, it has been estimated to be present 70% to 90% of the time. In a person with cirrhosis, the annual conversion rate to HCC is 2% to 6%.[60] In patients with chronic HCV infection, cirrhosis usually is present before the HCC develops; however, in cases of hepatitis B virus infection, HCC tumors can occur before the onset of cirrhosis. HCCs are typically hypervascular with blood supplied predominantly from the hepatic artery. Thus, the lesion often appears hypervascular during the arterial phase of CT studies (Fig. 31-19) and relatively hypodense during the delayed phases due to early washout of the contrast medium by the arterial blood. MRI imaging also is effective in characterizing HCC. HCC is variable on T1-weighted images and usually hyperintense on T2-weighted images. As with contrast CT, HCC enhances in the arterial phase after gadolinium injection because of its hypervascularity and becomes hypointense in the delayed phases due to contrast washout. HCC has a tendency to invade the portal vein, and the presence of an enhancing portal vein thrombus is highly suggestive of HCC.

The treatment of HCC is complex and is best managed by a multidisciplinary liver transplant team. A complete algorithm for the evaluation and management of HCC is shown (Fig. 31-20). For patients without cirrhosis who develop HCC, resection is the treatment of choice. For patients with Child's class A cirrhosis with preserved liver function and no portal hypertension, resection also is considered. If resection is not possible because of poor liver function and the HCC meets transplant criteria (discussed later), liver transplantation is the treatment of choice.[61,62]

The Barcelona-Clinic Liver Cancer Group has refined its HCC management strategy and has developed the American Association for the Study of Liver Diseases Practice Guidelines.[63] Management guidelines vary slightly in Asia, Europe, the United States, and other countries based in part on availability of organ donors for liver transplantation. Living donor liver transplantation also is an alternative for patients with HCC awaiting transplantation to avoid dropout as a candidate for cadaveric donor liver transplantation due to tumor progression.[62] Specific treatment options are described in the next section.

Cholangiocarcinoma

Cholangiocarcinoma, or bile duct cancer, is the second most common primary malignancy of the liver. Cholangiocarcinoma is an adenocarcinoma of the bile ducts; it forms in the biliary epithelial cells and can be subclassified into peripheral

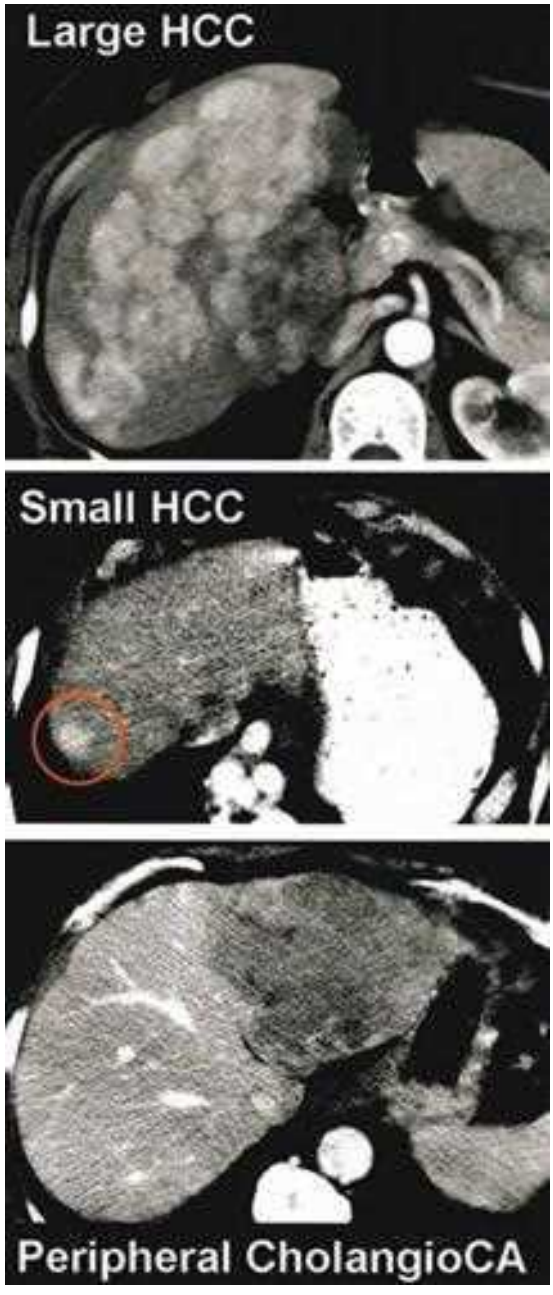

Figure 31-19. Computed tomographic (CT) images of hepatocellular carcinoma (HCC) and peripheral cholangiocarcinoma. CT scans reveal a large (*upper panel*) and small (*middle panel*) hypervascular HCC. A hypovascular left lobe peripheral cholangiocarcinoma (CholangioCA) is also shown (*lower panel*).

(intrahepatic) bile duct cancer and central (extrahepatic) bile duct cancer. Extrahepatic bile duct cancer can be located distally or proximally. When proximal, it is referred to as a *hilar cholangiocarcinoma* (Klatskin's tumor). Hilar cholangiocarcinoma originates in the wall of the bile duct at the hepatic duct confluence and usually presents with obstructive jaundice rather than an actual liver mass. In contrast, a peripheral (or intrahepatic) cholangiocarcinoma represents a tumor mass within a hepatic lobe or at the periphery of the liver. A biopsy specimen from the cholangiocarcinoma will show adenocarcinoma, but pathologists are often unable to differentiate metastatic adenocarcinoma to the liver from primary bile duct adenocarcinoma. Therefore, a search for a primary site should be undertaken in cases in which an incidentally discovered liver lesion is proven to be an adenocarcinoma on biopsy.

Hilar cholangiocarcinoma is difficult to diagnose and typically presents as a stricture of the proximal hepatic duct causing painless jaundice. It preferentially grows along the length of the bile ducts, often involving the periductal lymphatics with frequent lymph node metastases. Surgical resection offers the only chance for cure of cholangiocarcinoma.[64] The location and extent of tumor dictate the operative approach. In one series of 225 patients with hilar cholangiocarcinoma, 65 (29%) were deemed to have unresectable tumors by initial imaging.[65] Of the remaining 160 patients who underwent exploratory surgery with curative intent, 80 (50%) were found to have inoperable tumors. Histologically negative margins, concomitant hepatic resection, and well-differentiated tumor histology were associated with improved outcome after resection. In another series of 61 patients undergoing surgical exploration for hilar cholangiocarcinoma, the 5-year actuarial survival rates for an R0 or R1 resection were 45% and 26%, respectively.[66] In a large series reported by Nagino and colleagues, 132 patients with hilar cholangiocarcinoma underwent extended hepatectomy with resection of the caudate lobe and extrahepatic bile duct, and/or portal vein resection (n = 63) after portal vein embolization.[67] The 3- and 5-year survival rates were 41.7% and 26.8%, respectively.

In the absence of associated primary sclerosing cholangitis (PSC), surgical resection is the treatment of choice for hilar cholangiocarcinoma. However, approximately 10% of patients with cholangiocarcinoma have PSC.[68] Furthermore, cholangiocarcinoma in the setting of PSC is frequently multicentric and often is associated with underlying liver disease, with eventual cirrhosis and portal hypertension. As a result, experience has shown that resection of cholangiocarcinoma in patients with PSC yields dismal results. This led transplant centers to consider OLT for patients with hilar cholangiocarcinoma. The initial results of transplantation were disappointing, however, with high recurrence and overall 3-year survival rates of <30%.[69]

Because the growth of hilar cholangiocarcinoma indicates that this disease spreads in a locoregional manner, a rationale for the use of neoadjuvant chemoradiation was developed by the transplant team at the University of Nebraska in the late 1980s. This was adapted in 1993 by the transplant team at the Mayo Clinic, which led to the current Mayo Clinic protocol.[70] The pretransplant Mayo protocol consists of external-beam radiation therapy plus a protracted course of intravenous 5-fluorouracil followed by iridium-192 brachytherapy.[71] Patients then undergo an abdominal exploration with staging. If findings are negative, patients are given capecitabine for 2 of every 3 weeks until transplantation. Even after restaging with CT/MRI and endoscopic ultrasonography, approximately 15% to 20% of patients will have positive findings for tumor on abdominal exploration.[68,71] The 5-year survival rate for those undergoing transplantation for cholangiocarcinoma at the Mayo Clinic is approximately 70% and compares favorably with the rate for resection.[68,71] Current eligibility criteria for this Mayo Clinic protocol include unresectable hilar cholangiocarcinoma or hilar cholangiocarcinoma with PSC. The tumor must have a radial dimension of ≤3 cm with no intrahepatic or extrahepatic metastases, and the patient must not have undergone prior radiation therapy or transperitoneal biopsy.[71] Many centers have adopted similar protocols with comparable results.[72]

9▶

Peripheral, or intrahepatic, cholangiocarcinoma is less common than hilar cholangiocarcinoma. In a series of 53 patients

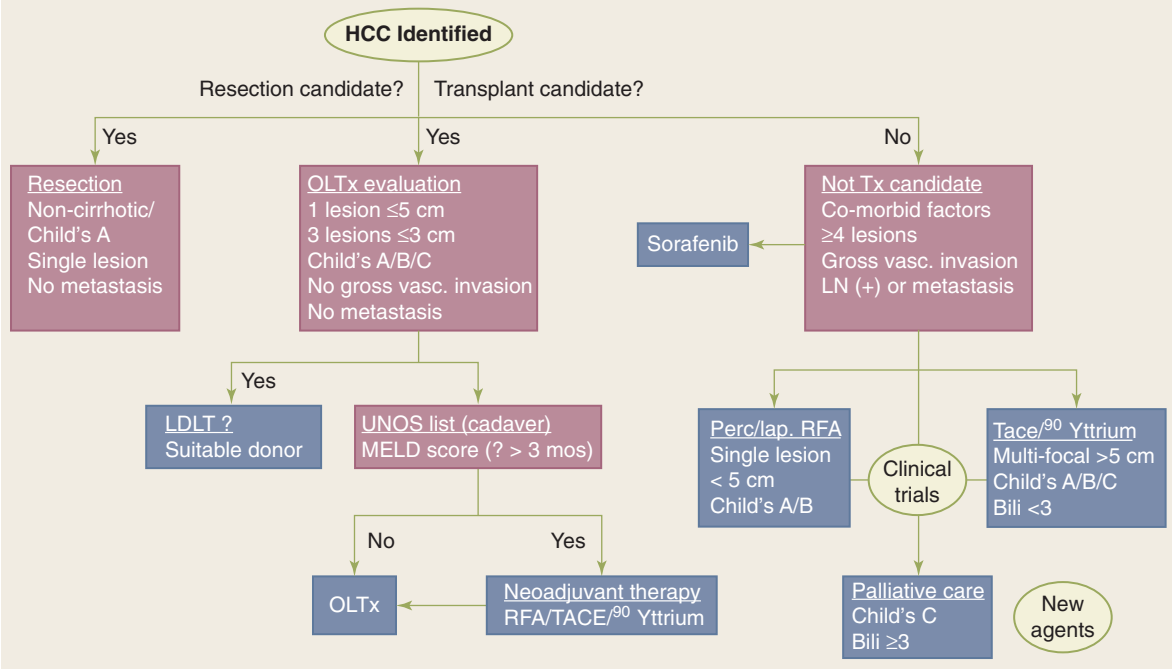

Figure 31-20. Algorithm for the management of hepatocellular carcinoma (HCC). The treatment algorithm for HCC begins with determining whether the patient is a resection candidate or liver transplant candidate. Bili = bilirubin level (in milligrams per deciliter); Child's = Child-Turcotte-Pugh class; lap = laparoscopic; LDLT = living-donor liver transplantation; LN = lymph node; MELD = Model for End-Stage Liver Disease; OLTx = orthotopic liver transplantation; Perc = percutaneous; RFA = radiofrequency ablation; TACE = transarterial chemoembolization; Tx = transplantation; UNOS = United Network for Organ Sharing; vasc. = vascular.

at Memorial Sloan-Kettering Cancer Center who underwent surgical exploration for a diagnosis of intrahepatic cholangiocarcinoma, 33 (62%) were found to have resectable tumors.[73] Actuarial 3-year survival for patients undergoing resection was 55%. Factors predictive of poor survival included vascular invasion, histologically positive margins, and multiple tumors. In a large series in Taiwan, 373 patients with peripheral cholangiocarcinoma underwent surgical treatment from 1977 to 2001. Absence of mucobilia, nonpapillary tumor type, tumor of advanced stage, nonhepatectomy, and lack of postoperative chemotherapy were five independent prognostic factors that adversely affected overall survival.[74] Liver transplantation has been performed for peripheral cholangiocarcinoma[75]; however, currently all but one center in the United States have eschewed this approach because of organ shortages and relatively high recurrence rates.

Gallbladder Cancer

Gallbladder cancer is a rare aggressive tumor with a very poor prognosis. Over 90% of patients have associated cholelithiasis. In one study examining the mode of presentation over a 10-year period from 1990 to 2000 in 44 patients diagnosed with gallbladder cancer, the diagnosis was found to be made preoperatively in 57%, intraoperatively in 11%, and incidentally after cholecystectomy in 32%.[76] Surgical approaches can be classified into (a) reoperation for an incidental finding of gallbladder cancer after cholecystectomy, and (b) radical resection in patients with advanced disease. The results are dismal for radical resection in patients with advanced disease and positive hilar lymph nodes.[77,78] For incidental gallbladder cancer beyond stage T1, reoperation with central liver resection, hilar lymphadenectomy, and evaluation of cystic duct stump is most commonly performed.[79,80] The role of formal lobectomy or extended lobectomy as well as common bile duct resection is more controversial. In a single-center study of 23 patients undergoing attempted curative treatment by surgical resection, survival was 85% at 1 year, 63% at 2 years, and 55% at 3 years.[80] In a multicenter study encompassing 115 patients with incidentally discovered gallbladder cancer who underwent re-resection,[79] residual disease in the liver was identified in 46% of patients (0% of those with stage T1 disease, 10% of those with T2 tumors, and 36% of those with T3 disease). T stage also was associated with the risk of metastasis to locoregional lymph nodes (lymph node metastasis for T1 of 13%; for T2, 31%; and for T3, 46%). In another study, a German registry of incidental gallbladder cancer identified 439 patients. Patients with tumors staged as T2 or T3 after cholecystectomy had better survival if they underwent reoperation than if they were managed with observation.[81] Hence, reoperation should be considered for all patients who have T2 or T3 tumors or for whom the accuracy of staging is in question.

Metastatic Colorectal Cancer

Over 50% to 60% of patients diagnosed with colorectal cancer will develop hepatic metastases during their lifetime. Resection for hepatic metastases has been a routine part of treatment for colorectal cancer since the publication of a large single-center experience demonstrating its safety and efficacy.[82] Predictors of poor outcome in that study included node-positive primary, disease-free interval <12 months, more than one tumor, tumor size >5 cm, and carcinoembryonic antigen level >200 ng/mL. Traditional teaching suggested that hepatic resection for metastatic colorectal cancer to the liver, if technically feasible, should be performed only for fewer than four metastases.[83] However, later studies challenged this paradigm. In a series of 235 patients who underwent hepatic resection for metastatic colorectal cancer, the 10-year survival rate of patients with four or more nodules was 29%, nearly comparable to the 32% survival rate of patients

with only a solitary tumor metastasis.[84] In the Memorial Sloan-Kettering Cancer Center series of 98 patients with four or more colorectal hepatic metastases who underwent resection between 1998 and 2002, the 5-year actuarial survival was 33%.[85] Furthermore, improved chemotherapeutic regimens and surgical techniques have produced aggressive strategies for the management of this disease. Many groups now consider volume of future liver remnant and the health of the background liver, and not actual tumor number, as the primary determinants in selection for an operative approach.[86,87] Hence, resectability is no longer defined by what is actually removed, but indications for hepatic resection now center on what will remain after resection.[88] Use of neoadjuvant chemotherapy, portal vein embolization, two-stage hepatectomy, simultaneous ablation, and resection of extrahepatic tumor in select patients have increased the number of patients eligible for a surgical approach.[89,90]

10▸

Neuroendocrine Tumors

Hepatic metastases from neuroendocrine tumors have a protracted natural history and commonly are associated with debilitating endocrinopathies. Several groups have advocated an aggressive surgical approach of debulking surgery, both to control symptoms and to extend survival.[91,92] In a series of 170 patients undergoing resection of hepatic metastases from neuroendocrine tumors between 1977 and 1998 at the Mayo Clinic, overall survival was 61% and 35% at 5 and 10 years, respectively.[93] There was no difference in survival between patients with carcinoid tumors and those with islet cell tumors. Major hepatectomy was performed in 91 patients (54%), and recurrence rate was 84% at 5 years. Belghiti's group has described a two-stage strategy used in 41 patients with a primary neuroendocrine tumor and synchronous bilobar liver metastases.[94] In the first stage, the primary tumor is resected and limited resection of metastases in the left hemiliver, combined with right portal vein ligation, is performed. After 8 weeks of hypertrophy, a right hepatectomy or extended right hepatectomy (also referred to as a right trisectionectomy; resection of Couinaud's segments IV, V, VI, VII, and VIII of the liver) is performed.[94] In patients treated using this strategy, the 2-, 5-, and 8-year Kaplan-Meier overall survival rates were 94%, 94%, and 79%, respectively, and disease-free survival rates were 85%, 50%, and 26%, respectively. Because systemic therapy has had little success in the treatment of advanced tumors, a broader approach using multimodal therapy has been used to increase survival and improve hormone-related symptoms. These therapies include radiofrequency or microwave ablation and intra-arterial therapy with chemoembolization or radioembolization (yttrium-90). Some centers perform liver transplantation for selected patients (carcinoid histology; primary tumor removed with curative resection; primary tumor drained by portal system; ≤50% hepatic parenchyma involved; good response or stable disease for at least 6 months during pretransplantation period; and age 55 years or younger), although this is not routine.[95]

Other Metastatic Tumors

Nearly every cancer has the propensity to metastasize to the liver. Historically, enthusiasm was low for resecting metastases other than those from a colorectal cancer primary. This was due in part to the recognition that many other primary cancers (such as breast cancer) represent a systemic disease when liver metastases are present. However, more recent studies have shown acceptable 5-year survival rates in the 20% to 40% range for resection of hepatic metastases from breast, renal, and other GI tumors.[96,97] In a large study of hepatic resection for noncolorectal, nonendocrine liver metastases in 1452 patients, negative prognostic factors were nonbreast origin, age >60 years, disease-free interval of <12 months, need for major hepatectomy, performance of R2 resection, and presence of extrahepatic metastases.[96]

TREATMENT OPTIONS FOR LIVER CANCER

In general, the major treatment options for liver cancer can be categorized as shown in Table 31-7. The decision making for any given patient is complex and is best managed by a multidisciplinary liver tumor board. The treatments listed in Table 31-7 are not mutually exclusive; the important point is to select the most appropriate initial treatment after a complete evaluation. In general, surveillance imaging (CT or MRI) is performed every 3 to 4 months during the first year after diagnosis to observe for response, progression, or recurrence. The treatment plan is individualized and modified according to the response of the patient.

Hepatic Resection

For primary liver cancers or hepatic metastases, hepatic resection is the gold standard and treatment of choice. Although there are anecdotal reports of long-term survival after ablation and other regional liver therapies, liver resection remains the only real option for cure. For HCC in the setting of cirrhosis, liver transplantation also offers the potential for long-term survival, albeit with the consequences of immunosuppression. Hepatic resection also has been advocated for HCC in select patients with cirrhosis before secondary liver transplantation, although not without some controversy.[98] Many large series of patients undergoing major hepatectomy now report mortality rates of <5%.[99-102] Previously, a 1-cm tumor margin was considered desirable; however, recent studies have reported comparable survival rates with smaller margins.[103-105] Technical innovation in liver surgery and a better understanding of perioperative care have even allowed surgeons to perform resections in cases with IVC involvement

with extracorporeal liver surgery.[106] The technical aspects of anatomic hepatic lobectomies are described later.

Liver Transplantation

The rationale supporting OLT for HCC includes the fact that most HCCs (>80%) arise in the setting of cirrhosis.[69,107] The cirrhotic liver often does not have enough reserve to tolerate a formal resection. Also, HCC tumors are commonly multifocal and are underestimated by current CT or MRI imaging.[108] Furthermore, recurrence rates are high at 5 years after resection (>50%). Hence, OLT is an appealing treatment, because it removes both the cancer and the cirrhotic liver that leads to cancer. More than 6000 liver transplantations are performed each year in the United States, with 1-year survival rates approaching 90%. In June 2013, approximately 15,800 patients were on the waiting list for liver transplantation.[109]

Initial series of OLT for HCC reported in the 1990s included advanced cases of HCC, and the 5-year survival rates were only 20% to 50%.[69] This compared poorly with overall 5-year survival rates of 70% to 75% for OLT in the Organ Procurement and Transplantation Network/United Network for Organ Sharing (OPTN/UNOS) database. Mazzaferro and colleagues at Milan subsequently showed that survival rates were markedly improved when OLT was limited to patients with early-stage HCC (stage I or stage II) with one tumor ≤5 cm, or up to three tumors no larger than 3 cm, along with the absence of gross vascular invasion or extrahepatic spread.[110] Multiple studies have validated these findings, and many groups have proposed an expansion of the Milan criteria.[62]

As noted previously, the 6- to 40-point MELD score was adopted by OPTN/UNOS in 2002 for allocation of deceased donor liver organs in the United States. In an attempt to prioritize patients with preserved liver function and progressive HCC, patients with stage I or stage II HCC are allocated exception points (currently 22 MELD points, increasing every 3 months as long as they continue to meet transplant criteria). This allocation has had a positive effect for HCC liver transplant candidates, leading to decreased waiting list dropout and increased transplant rates with excellent long-term outcomes.[111] The goal is to better equate death rates on the liver transplant waiting list for patients with stage I or stage II HCC with rates for patients with chronic liver disease without HCC. Although indications for liver transplantation have increased, the supply of donor livers has failed to keep pace with the numbers of potential recipients. A partial solution has been the use of living donor grafts. This is especially true in Asia where the incidence of HCC is high and the rate of cadaveric donation is low. Living donor grafts include right and left lobes, as well as dual grafts from separate donors to provide adequate hepatic mass to the recipient. The use of living donor grafts also allows for transplant programs to push the boundaries by accepting patients beyond the Milan criteria with good results.[112]

Radiofrequency Ablation

In 1891, d'Arsonval discovered that radiofrequency (RF) waves delivered as an alternating electric current (>10 kHz) could pass through living tissue without causing pain or neuromuscular excitation. The resistance of the tissue to the rapidly alternating current produced heat. This discovery contributed to the development of the surgical application of electrocautery. In 1908, Beer used RF coagulation to destroy urinary bladder tumors. Cushing and Bovie later applied RF ablation to intracranial tumors. In 1961, Lounsberry studied the histologic changes of the liver after RF ablation (RFA) in animal models. He found that RF caused local tissue destruction with uniform necrosis. In the early 1990s, two groups proposed that RFA can be an effective method for destroying unresectable malignant liver tumors.[113,114] Both groups found that RFA produced lesions with well-demarcated areas of necrosis without viable tumor cells present. Clinical reports after short-term follow-up suggested that RFA was safe and effective in the treatment of liver tumors.[115-117] However, Abdalla and colleagues examined data for 358 consecutive patients with colorectal liver metastases treated with curative intent over a 10-year period (1992 to 2002).[118] Liver-only recurrence after RFA was four times the rate after resection (44% vs. 11% of patients), and RFA alone or in combination with resection did not provide survival rates comparable to those with resection alone. Other studies have corroborated this trend.[119] Nonetheless, RFA remains a common procedure that can be performed by a percutaneous, minimally invasive laparoscopic, or open approach.[120,121] It also has been used successfully to ablate small HCCs as a bridge to liver transplantation.[122] Recently, results were reported for the first randomized clinical trial involving RFA treatment for HCC in 291 Chinese patients with three or fewer HCC tumors ranging in size from 3 to 7.5 cm.[123] Patients were randomly assigned to treatment arms of RFA alone (n = 100), transarterial chemoembolization (TACE) alone (n = 95), or combined TACE plus RFA (n = 96). At a median follow-up of 28.5 months, median survival was 22 months in the RFA group, 24 months in the TACE group, and 37 months in the TACE plus RFA group. Patients treated with TACE plus RFA had significantly better overall survival than those treated with TACE alone ($P < .001$) or RFA alone ($P < .001$).

Ethanol Ablation, Cryosurgery, and Microwave Ablation

Percutaneous ethanol injection has been shown to be a safe and effective treatment for small HCCs.[107] The ethanol usually is delivered by percutaneous injection under ultrasound or CT guidance. Percutaneous ethanol injection also is used to treat small HCC tumors as a bridge to liver transplantation in some centers to avoid patient dropout.[61] Although cryosurgery was used in the late 1980s and 1990s for ablation of liver tumors, many have abandoned this approach in favor of RFA because of the latter's fewer side effects and ease of use. Microwave ablation is a thermal ablative technique used in the management of unresectable liver tumors to produce a coagulation necrosis. In a multicenter phase II U.S. trial using a 915-MHz microwave generator, 87 patients underwent 94 ablation procedures for 224 hepatic tumors.[124] Forty-five percent of the procedures were performed using an open approach, 7% laparoscopically, and 48% percutaneously. The average tumor size was 3.6 cm (range, 0.5 to 9.0 cm). At a mean follow-up of 19 months, 47% of the patients were alive with no evidence of disease. Local recurrence at the ablation site occurred in 2.7% of tumors, and regional recurrence occurred in 43% of patients. There were no procedure-related deaths. Further studies are required to define the role of this technology in relation to the other ablation options available.

Chemoembolization and Hepatic Artery Pump Chemoperfusion

Chemoembolization is the process of injecting chemotherapeutic drugs combined with embolization particles into the hepatic artery that supplies the liver tumor using a percutaneous, transfemoral approach. It is most commonly used for treatment of unresectable HCC. Three randomized trials and a meta-analysis

have shown a survival benefit with chemoembolization.[125-128] In a study by Lo and colleagues, 80 Asian patients were randomly assigned to receive either chemoembolization with cisplatin in lipiodol or symptomatic treatment only.[125] Chemoembolization resulted in a marked tumor response, and the actuarial survival was significantly better in the chemoembolization group (1- and 3-year survival of 57% and 26%, respectively) than in the control group (1- and 3-year survival of 32% and 3%, respectively). In another randomized trial, a Barcelona group compared chemoembolization with doxorubicin versus supportive care and showed that chemoembolization significantly improved survival.[126] Finally, in a large prospective cohort study of 8510 patients with unresectable HCC in Japan who received transcatheter arterial lipiodol chemoembolization, the 5-year survival rate was 26% and median survival time was 34 months.[127] The TACE-related mortality rate after the initial therapy was 0.5%. Complications of TACE include liver dysfunction or liver failure, hepatic abscess, and hepatic artery thrombosis. Multiple studies also have shown promising results for chemoembolization with drug-eluting beads in treatment of HCC.[129]

In the 1990s, hepatic artery pump chemoperfusion with floxuridine for colorectal cancer metastases to the liver was used both for treatment of inoperable disease and in the adjuvant setting.[130] However, in the modern era of improved chemotherapeutic options, this treatment modality is seldom used outside of a clinical trial.

Yttrium-90 Microspheres

Selective internal radioembolization or transarterial radioembolization (TARE) is a promising new treatment modality for patients with inoperable primary or metastatic liver tumors. The treatment is a minimally invasive transcatheter therapy in which radioactive microspheres are infused into the hepatic arteries via a transfemoral percutaneous approach. The yttrium-90 microspheres are directly injected into the hepatic artery branches that supply the tumor. Once infused, the microspheres deliver doses of high-energy, low-penetration radiation selectively to the tumor. The main indications are inoperable HCC[131] and colorectal cancer hepatic metastases for which systemic chemotherapy has failed.[132,133] In a recent study involving 137 patients with unresectable chemorefractory liver metastases treated with radioembolization, there was a response rate of 42.8% (2.1% complete response, 40.7% partial response) according to World Health Organization criteria.[133] One-year survival rate was 47.8%, and 2-year survival rate was 30.9%. Median survival was 457 days for patients with colorectal tumor metastases, 776 days for those with neuroendocrine tumor metastases, and 207 days for those with noncolorectal, nonneuroendocrine tumor metastases. The two products available in the United States are SIR-Spheres (Sirtex, Sydney, Australia) and TheraSphere (Nordian, Ottawa, Canada).

Stereotactic Radiosurgery and Intensity-Modulated Radiation Therapy

Although stereotactic radiosurgery (with CyberKnife and other systems) is in widespread use for brain and spinal tumors, body application to HCC or metastatic liver tumors has only recently occurred. In a phase I study, 31 patients with unresectable HCCs and 10 with unresectable cholangiocarcinomas completed a six-fraction course of stereotactic body radiotherapy.[134] The treatment was well tolerated, and median survival was 11.7 and 15.0 months for the two groups, respectively. A similar safety profile was observed in a study in the Netherlands.[135] Further clinical trials are required to define the future role of stereotactic radiosurgery in treatment of HCC and metastatic tumors. Intensity-modulated radiation therapy (IMRT) is another technologic advancement that facilitates the targeted delivery of external-beam radiation. Early clinical data suggested favorable outcomes with IMRT for the treatment of patients with unresectable HCC, and ongoing trials are further examining the role of IMRT for these locally advanced tumors.

Downstaging

In more advanced-stage patients not eligible for MELD exception points, hepatic-directed therapy including TACE and tumor ablation with radiofrequency, microwave, and ethanol ablation have been found to be effective in shrinking tumors to meet Milan criteria (downstaging). Multiple centers have used downstaging to allow for OLT in patients whose tumors responded and shrank to meet eligibility criteria.[136,137]

Systemic Chemotherapy

Chemotherapy has not demonstrated great efficacy in patients with HCC, especially in patients with significant cirrhosis. For treatment of HCC, the multikinase inhibitor sorafenib has shown some efficacy in a phase III randomized international multicenter trial. The SHARP trial (Sorafenib HCC Assessment Randomized Protocol) enrolled 602 patients with Child's class A cirrhosis and inoperable HCC. At interim analysis, the trial was discontinued because a survival benefit was found in the treatment group. The median overall survival for patients receiving sorafenib was 10.7 months versus 7.9 months for patients in the control arm. Based on these findings, sorafenib received accelerated Food and Drug Administration approval for the treatment of advanced unresectable HCC.[138] Future studies will likely examine the role of other molecularly targeted agents and combinations of sorafenib with other treatment modalities.

HEPATIC RESECTION SURGICAL TECHNIQUES

Nomenclature

Due to the confusion in language with regard to anatomic descriptions of hepatic resections, a common nomenclature was introduced at the International Hepato-Pancreato-Biliary Association meeting in Brisbane, Australia, in 2000 (Table 31-8).[139,140] The goal was to provide universal terminology for liver anatomy and hepatic resections, because there was much overlap among the designations for hepatic lobes, sections, sectors, and segments used by surgeons worldwide (Fig. 31-21). The most common or prevailing anatomic pattern was used as the basis for naming liver anatomy, and the surgical procedure nomenclature adopted for hepatic resections was based on the assigned anatomic terminology.[141] Adoption of a common language should enable hepatic surgeons to better understand and interpret liver surgery publications from different continents and disseminate their knowledge to the next generation of hepatobiliary surgeons. Nonetheless, even today, the literature is full of both old and new liver resection terminology, so the surgeon in training must be familiar with all the various classifications.

Techniques and Devices for Dividing the Hepatic Parenchyma

Hepatic resection surgery has evolved over the past 50 years. A better understanding of liver anatomy and physiology, coupled with improved anesthesia techniques and widespread use of

Table 31-8

Brisbane 2000 liver terminology

OLDER HEPATIC RESECTION TERMINOLOGY	BRISBANE 2000 HEPATIC RESECTION TERMINOLOGY
Right hepatic lobectomy	Right hepatectomy or right hemihepatectomy (V, VI, VII, VIII)
Left hepatic lobectomy	Left hepatectomy or left hemihepatectomy (II, III, IV)
Right hepatic trisegmentectomy	Right trisectionectomy or extended right hepatectomy (or hemihepatectomy, IV, V, VI, VII, VIII)
Left hepatic trisegmentectomy	Left trisectionectomy or extended left hepatectomy (or hemihepatectomy, II, III, IV, V, VIII)
Left lateral segmentectomy	Left lateral sectionectomy or bisegmentectomy (II, III)
Right posterior lobectomy	Right posterior sectionectomy (VI, VII)
Caudate lobectomy	Caudate lobectomy or segmentectomy (I)
	ALTERNATIVE "SECTOR" TERMINOLOGY
	Right anterior sectorectomy
	Right posterior sectorectomy or right lateral sectorectomy
	Left medial sectorectomy or left paramedian sectorectomy (bisegmentectomy, III, IV)
	Left lateral sectorectomy (segmentectomy, II)

intraoperative ultrasound, has led to virtually "bloodless" liver surgery in the modern era (the year 2000 to the present). Innovations in technology have expanded the list of liver parenchymal transection devices[142-144] and hemostatic agents (Table 31-9). Use of each device or agent has a learning curve, and undoubtedly every experienced hepatic surgeon has his or her personal preferences.

One major trend has been the application of vascular stapling devices for division of the hepatic and portal veins.[145-147] Based on early reports of successful stapling of extrahepatic vessels, stapling devices are now being used in the parenchymal transection phase, which remains a source of potential blood loss due to back bleeding from the middle hepatic vein.[148,149] One advantage of the stapling technique is the speed with which the transection can be performed, which minimizes surface bleeding and period of ischemia for the remnant liver.

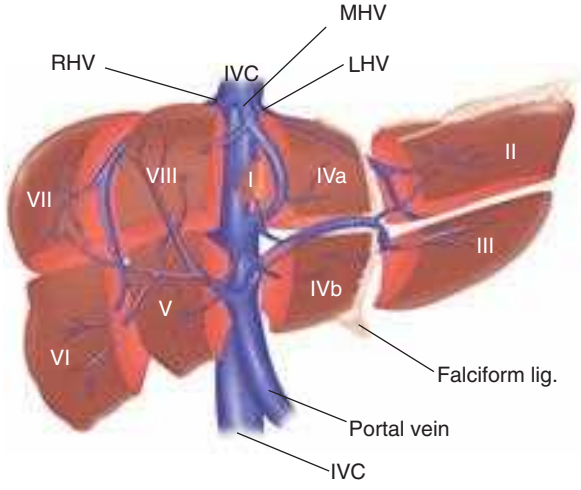

Figure 31-21. Hepatic anatomy. Hepatic segments removed in the formal major hepatic resections are indicated. IVC = inferior vena cava; LHV = left hepatic vein; MHV = middle hepatic vein; RHV = right hepatic vein.

Table 31-9

Endovascular staplers
TissueLink sealing devices
Habib 4X Laparoscopic sealer
InLine bipolar linear coagulator
Topical agents (fibrin glues, Surgicel, Gelfoam, Avitene, Tisseel, Floseal, Crosseal)

However, a major disadvantage of the stapling technique is the cost of multiple stapler cartridges. This is balanced by the decreased expenses reported with avoidance of ICU admission and blood transfusion, as well as shortened operating room time. Another consideration in the use of staplers for parenchymal transection is the potential for bile leaks. However, in a large series of 101 consecutive right hemihepatectomies performed using the stapling technique, there was only one reported bile leak (1%), which sealed after ERCP.[149]

Steps in Commonly Performed Hepatic Resections

A fundamental understanding of hepatic anatomy is vital for any surgeon with the desire to perform hepatobiliary surgery. Each hepatic resection surgery can be broken down into a

series of orderly steps. The key to being a proficient hepatic surgeon is not to operate swiftly but rather to accomplish the operation by completing the steps in an orchestrated fashion. Mastery of the operative steps coupled with knowledge of liver anatomy and the common anatomic variants provides the foundation for safe hepatic surgery. There are many different techniques and sequences for accomplishing each of the anatomic (and nonanatomic) hepatic operations. The authors present their preferred approach in a stepwise fashion for right hepatic lobectomy (right hemihepatectomy), left hepatic lobectomy (left hemihepatectomy), and left lateral segmentectomy (left lateral sectionectomy). Provision of a detailed approach for every type of liver resection is beyond the scope of this chapter, and readers are referred to several excellent descriptions.[150]

Steps Common to All Open Major Hepatic Resections

1. Make the skin incision—right subcostal with or without a partial or complete left subcostal extension across the midline, depending on the patient's habitus and liver/tumor anatomy.
2. Open and explore the abdomen, and place a fixed table retractor (e.g., Thompson or Bookwalter).
3. Examine the liver with bimanual palpation. Perform liver ultrasound, and confirm the operation to be performed.
4. Take down the round and falciform ligaments, and expose the anterior surface of the hepatic veins.
5. For a left hepatectomy, divide the left triangular ligament; for a right hepatectomy, mobilize the right lobe from the right coronary and triangular ligaments.
6. Open the gastrohepatic ligament, palpate the porta hepatis, and assess for accessory or replaced hepatic arteries.
7. Perform a cholecystectomy; leave the gallbladder with the cystic duct intact if the gallbladder is involved by the tumor.

Right Hepatic Lobectomy (Right Hepatectomy or Hemihepatectomy)

8. Mobilize the liver from the anterior aspect of the IVC in "piggyback" fashion; ligate the short hepatic veins up to the right hepatic vein (RHV).
9. Perform a right hilar dissection—gently lower the hilar plate, then doubly ligate and divide the right hepatic artery (RHA), superior to the right side of the common bile duct.
10. Doubly ligate and divide a replaced or accessory RHA if present.
11. Expose the portal vein, identifying its right and left branches. There is a small lateral portal vein branch off the right portal vein (RPV) to the caudate lobe that should be controlled and ligated to allow the exposure of additional length on the RPV. Divide the RPV either with a vascular stapler or between vascular clamps.
12. Dissect the avascular tissue along the suprahepatic vena cava between the right and middle hepatic veins. Pass a silastic tube of a Jackson-Pratt drain through this gap.
13. Notch or divide the caudate process crossing to the right hepatic lobe, and bring the drain up and through this notch.
14. Hang the liver over the drain by pulling up as you divide through the liver parenchyma.
15. Repeat ultrasound and confirm the transection plane, staying just to the right of the middle hepatic vein (MHV) unless the tumor extends over it.
16. Cauterize approximately 1 cm into the liver parenchyma, then switch to a hydro-jet dissection device in combination with Bovie electrocautery and suture ligation.
17. Continue parenchymal division until the RHV is encountered. During this division, identification, control, ligation, and transection of the right hepatic duct (RHD) are obtained late in the parenchymal transection process.
18. Divide the RHV between vascular clamps and suture ligate the RHV.
19. Examine the transected liver edge for bleeding; place a figure-of-eight ligating vascular suture if bleeding is encountered.
20. Ensure hemostasis of the transected liver edge with an argon beam coagulator and suture ligation.
21. Inspect the transection surface for bile leaks. These should be clipped or suture ligated. Applying a dilute solution of hydrogen peroxide can facilitate the visualization of bile leaks.
22. Inspect the IVC and right retroperitoneal space for hemostasis.
23. Perform completion ultrasound to confirm left portal vein (LPV) inflow and outflow in the remaining hepatic veins.
24. Fix the proximal falciform ligament back to the diaphragm side with figure-of-eight sutures.
25. Apply tissue sealant to the cut surface of the liver, and place a Jackson-Pratt drain in the right subphrenic space and close the abdomen (Fig. 31-22).

Comments Although some liver surgeons advocate a one-step division of the entire intrahepatic Glissonian pedicle as described by Launois and Jamieson,[151] it is the authors' preference to divide the RHA, RHD, and RPV in an extrahepatic fashion. As for the transection plane, the key is to perform

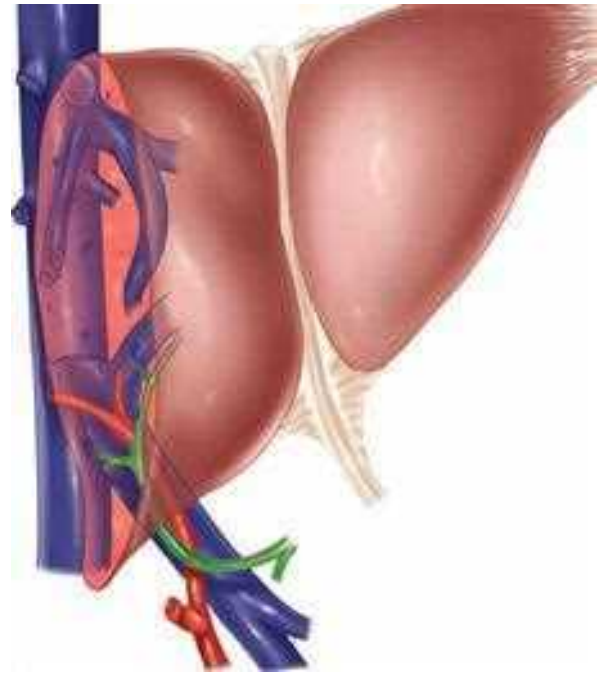

Figure 31-22. Completed right hepatic lobectomy (right hepatectomy) with the right portal vein, right hepatic artery, and right bile duct ligated and divided. The right hepatic vein is ligated and divided. Middle hepatic vein branches inside the liver are divided.

accurate ultrasound visualization and mapping of the MHV and to stay just to the right of it. Weaving in and out or bisecting the MHV can leading to torrential back bleeding. Also, for bulky right lobe tumors adherent to the diaphragm or retroperitoneum, an anterior approach with division of the parenchyma can be performed before right lobe mobilization.[152,153]

Left Hepatic Lobectomy (Left Hepatectomy or Hemihepatectomy)

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory left hepatic artery (LHA) if present.
10. Clamp the round ligament (ligament teres) and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Dissect the left hilum at the base of the umbilical fissure and lower the hilar plate anterior to the left portal pedicle.
13. Incise the peritoneum overlying the hilum from the left side, and doubly ligate the LHA (after test clamping and confirming a palpable pulse in the RHA).
14. Dissect the portal vein at the base of the umbilical fissure (it will take a nearly 90° bend from the transverse to the umbilical portion).
15. Expose the portal vein, identifying the right and left branches. Control the small portal vein branch off the LPV to the caudate lobe to allow the exposure of additional length. Divide the LPV either with a vascular stapler or between vascular clamps.
16. Ligate and divide the ligamentum venosum caudally.
17. Identify the long extrahepatic course of the left hepatic duct (LHD) behind the portal vein. Ligate and divide the LHD at the umbilical fissure.
18. Fold the left lateral segment up and back to the right, exposing the window at the base of the left hepatic vein (LHV) as it enters the IVC. This is facilitated by dividing any loose areolar tissue overlying the ligamentum venosum, which is divided proximally.
19. Pass a large, blunt right-angle clamp in the window between the RHV and the MHV, and hug the back of the MHV, aiming for the deep edge of the LHV. *Do not force it or perforate the IVC or MHV.*
20. Pass the silastic tube of a Jackson-Pratt drain through this window.
21. Notch or divide the caudate process crossing to the left hepatic lobe and bring the drain up and through this notch.
22. Hang the liver over the drain by pulling up as you divide through the liver parenchyma.
23. Repeat ultrasound and confirm the transection plane on the anterior surface, staying close to the demarcated line. Do not bisect the MHV as it passes tangentially from the left to the right lobe.
24. Cauterize down approximately 1 cm in the liver parenchyma, then switch to a hydro-jet dissection device in combination with Bovie electrocautery and suture ligation.
25. Continue parenchymal division until the left/middle hepatic veins are encountered.
26. Divide the LHV and MHV between vascular clamps and suture the ligate the LHV/MHV.

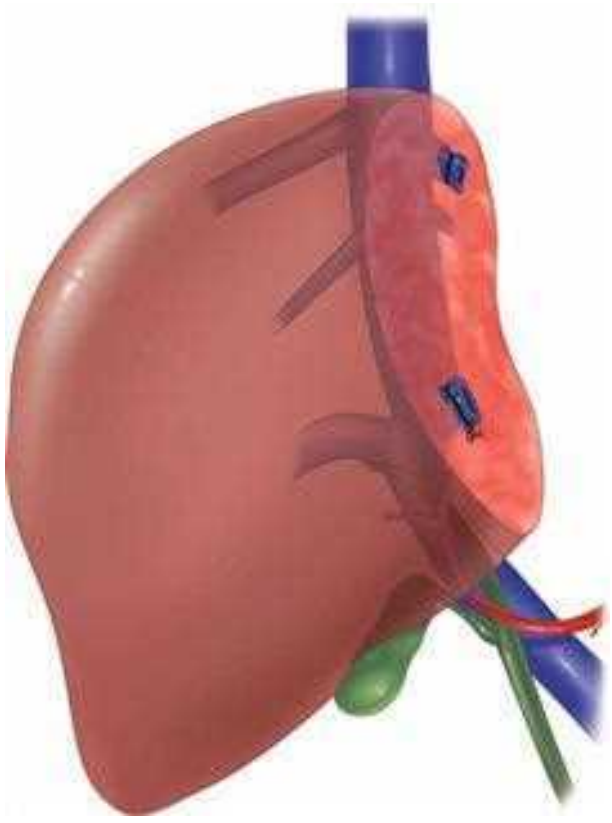

Figure 31-23. Completed left hepatic lobectomy (left hepatectomy) resecting segments II, III, and IV.

27. Check the transected edge of the liver for surgical bleeding; ensure hemostasis of the transected edge with an argon beam coagulator and suture ligation.
28. Inspect the transection surface for bile leaks. These should be clipped or suture ligated. Apply dilute solution of hydrogen peroxide to facilitate the visualization of bile leaks.
29. Perform completion ultrasound to confirm RPV inflow and RHV outflow.
30. Apply tissue sealant to the transected surface of the liver. Place a Jackson-Pratt drain in the left subphrenic space and close the abdomen (Fig. 31-23).

Comments Because the right posterior duct arises from the left hepatic duct (LHD) in approximately 20% of cases (see Fig. 31-9) and the right anterior duct comes off the LHD in approximately 5% of cases,[6] it is vital to divide the LHD at the base of the umbilical fissure and not more centrally in the hilum as it bifurcates. If the LHD were divided as it appears to bifurcate from the right hepatic duct, then approximately 20% to 25% of the time, either the right posterior or right anterior duct would be transected. After the LHD is divided as described earlier (Step 17), the liver parenchyma is scored and divided horizontally approximately 1 cm above the left hilum; the surgeon thus assumes that an aberrant right anterior or posterior duct is coming off the LHD in the hilum and preserves it. Then as the parenchymal transection reaches the left side of the gallbladder fossa, the transection plane turns vertical to run parallel to Cantlie's line (or the left edge of the gallbladder bed). The left lobe of the liver will be well demarcated at this point (after the vascular inflow has been divided), which guides the transection plane on the anterior surface. In general, the transection plane should be close to the demarcation line to minimize the amount

of devascularized liver remaining. When dividing the LHV and MHV, the surgeon should keep in mind that they have a common trunk approximately 90% of the time. If it is not easy to open the window deep to the MHV and LHV, then division of the MHV and LHV can be accomplished after the parenchymal transection.

Left Lateral Segmentectomy (Left Lateral Sectionectomy)

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory LHA if present.
10. Clamp the round ligament and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Carry the dissection down from the end of the round ligament, and the segment III pedicle will be encountered.
13. Incise the peritoneal reflection on the left side of the round ligament as it inserts into the umbilical fissure. This will facilitate encircling the segment III and II pedicles, which can be divided separately. When encircling the segment II pedicle, take care to avoid injury to the caudate inflow vessels coming off the LPV.
14. Divide the liver parenchyma, staying flush on the left side of the falciform ligament using Bovie electrocautery.
15. Divide the LHV as the parenchymal transection is complete.
16. A Pringle maneuver usually is not required for a left lateral sectionectomy because complete devascularization occurs before transection and little back bleeding is encountered.

Comments If the segment III and II LHA branches are large, they can be individually ligated in the left hilum before the pedicles (with portal vein and hepatic duct branches) are taken. If the tumor is more peripheral in the left lateral segment, then the segment III and II pedicles can be divided with a vascular stapler inside the liver during the parenchymal transection.

Pringle and Ischemic Preconditioning

Pringle described clamping of the portal triad a century ago in the landmark paper "Notes on the Arrest of Hepatic Hemorrhage Due to Trauma."[4] Although the Pringle maneuver was initially described for controlling bleeding due to traumatic liver injury, it is commonly used during elective hepatic resections.[154,155] The goal is to minimize blood loss and hypotension, which add significant morbidity to the operation. Furthermore, intraoperative blood transfusion has been shown to be an independent risk factor for increased postoperative infection as well as worse patient survival in some studies. Therefore, all efforts should be made to minimize blood loss during hepatic resection.

Although the liver has been shown to tolerate up to 1 hour of warm ischemia, some technical variations of the Pringle maneuver include intermittent vascular occlusion with cycles of approximately 15 minutes on and 5 minutes off. Experimental and clinical studies have demonstrated the efficacy of intermittent vascular occlusion in decreasing ischemia/reperfusion injury compared with continuous vascular occlusion, with less elevation of postoperative liver enzyme levels.[156] Another variation is selective hemihepatic vascular occlusion, which can reduce the severity of visceral congestion and total liver ischemia. In one prospective trial of total versus selective portal triad clamping, both techniques of inflow clamping were found to be equally effective for patients with normal livers, but greater liver damage was observed with total inflow occlusion in patients with cirrhotic livers.[157]

In an attempt to decrease the ischemic damage associated with inflow occlusion, some hepatic surgeons have advocated the use of ischemic preconditioning.[158] *Ischemic preconditioning* refers to the brief interruption of blood flow to an organ, followed by a short reperfusion period, and then a more prolonged period of ischemia. In a randomized clinical trial involving 100 patients undergoing major hepatic resection, Clavien and colleagues reported significantly less liver injury in the group who received ischemic preconditioning with a 10-minute clamp, a 10-minute reperfusion, and then a 30-minute clamp than in those who received a 30-minute clamp alone.[159] Patients with steatosis also were especially protected by ischemic preconditioning, and the mechanism was shown to be related in part to preservation of the adenosine triphosphate content of liver tissue.

Preoperative Portal Vein Embolization

The observation that tumor thrombosis of a major portal vein branch induced ipsilateral lobar atrophy and contralateral lobe hypertrophy led to the concept of intentional preoperative portal vein embolization (PVE) to induce compensatory hypertrophy of the remnant liver. This procedure was first described in the 1980s and is accomplished via a percutaneous, transhepatic route.[160,161] Numerous studies have subsequently confirmed that PVE is effective in inducing hypertrophy of nonembolized hepatic segments.[67,162] PVE usually is performed in the setting of a planned right trisectionectomy or extended left hepatectomy (also referred to as a left trisectionectomy; resection of Couinaud's segments II, III, IV, V, and VIII of the liver) or extended hepatic lobectomy when it is thought that the patient's remnant liver will be too small to support liver function. The future liver remnant volume (e.g., the volume of segments II, III, and I) in a patient undergoing a planned right trisectionectomy can be directly measured by helical CT and then divided by the total estimated liver volume to calculate the percentage of the future liver remnant. If the future liver remnant is thought to be too small, then PVE should be considered to increase the size of the future liver remnant.[163] In general, surgery is planned approximately 4 weeks after PVE to allow adequate time for hypertrophy.

There is no universal agreement on what constitutes a future liver remnant adequate to avoid postoperative liver failure. It is thought that 25% to 30% of the total liver volume is adequate in patients with a normal liver.[164] Vauthey and associates reported that major postoperative complications were increased when the estimated future liver remnant was <25%.[165] Farges and colleagues conducted a prospective study to assess the benefits of PVE before right hepatectomy. They demonstrated that PVE had no beneficial effect on the postoperative course in patients with normal livers but significantly reduced postoperative complications in patients with chronic liver diseases.[166] A larger remnant may be necessary even in patients with normal livers when a complex hepatectomy is planned or when the background liver is steatotic.[167] This is especially relevant with the increased incidence of fatty liver disease. A larger remnant may also be needed when patients have received preoperative chemotherapy. Some have suggested that 40% of the total hepatic volume should remain to minimize postoperative complications in patients who have underlying liver disease or who have received preoperative chemotherapy for colorectal cancer metastases.[168,169] In a recent study encompassing

112 patients who underwent PVE, major complications, hepatic insufficiency, length of hospital stay, and 90-day mortality rate were significantly greater in patients with a standardized future liver remnant of ≤20% or a degree of hypertrophy of <5% than in patients with higher values.[170] In another study, the authors performed PVE during neoadjuvant chemotherapy for colorectal cancer metastases. After a median wait of 30 days after PVE, patients receiving neoadjuvant chemotherapy showed median liver growth of 22% in the contralateral (nonembolized) lobe compared with 26% for those not receiving chemotherapy (not a statistically significant difference), which indicated that liver growth occurs after PVE even when cytotoxic chemotherapy is administered.[171] PVE-related complications occur at a relatively low rate and include bleeding, hemobilia, liver abscess, incomplete embolization, and small bowel obstruction. To augment the ability to increase liver function reserve in patients who have undergone PVE, some groups have added ipsilateral hepatic artery embolization and ipsilateral hepatic vein embolization.[172]

Staged Hepatectomy and Repeat Hepatic Resection for Recurrent Liver Cancer

A two-stage hepatectomy is a sequential resection strategy to remove all metastatic liver tumors when it is impossible to resect all disease in a single operative procedure. The first-stage hepatectomy usually consists of clearance of the left hemiliver by nonanatomic resection, followed by right portal vein ligation or embolization to induce left lobe hypertrophy.[173,174] This is followed by a second-stage major right hepatectomy or extended right hepatectomy to resect the right liver metastases. This approach is most commonly used in cases of initially unresectable colorectal hepatic metastases and has yielded very good results.[174] Another possibility is to potentiate the effect of PVE on increasing future liver remnant by performing an in situ liver transection along the future line of resection leaving the arterial and hepatic vein branches intact.[175]

The majority of patients undergoing hepatic resection for colorectal cancer metastases experience a recurrence. For those with limited disease recurrence confined to the liver, repeat hepatectomy is a reasonable option and can be performed with low morbidity and mortality in experienced hands.[176] In one study, 126 patients who underwent a second liver resection for colorectal cancer metastases had 1-, 3-, and 5-year survival rates of 86%, 51%, and 34%, respectively. By multivariate analysis, the presence of more than one lesion and a tumor size of >5 cm were independent prognostic indicators of reduced survival.[177] In another study, 40 patients underwent a second hepatectomy for liver metastases from colorectal cancer and experienced a survival benefit similar to that from the first hepatectomy; however, the results suggested that this approach should be limited to those patients who do not have extrahepatic disease and for whom >1 year has elapsed since the first operation.[178] A meta-analysis of 21 studies examining clinical outcomes after first and second liver resections for colorectal cancer metastases showed that repeat hepatectomy was safe and provided a survival benefit equal to that from the first liver resection.[179]

Repeat hepatectomy also has been performed in patients with HCC. Nakajima and colleagues reported on follow-up of 94 patients who underwent curative liver resection for HCC from 1991 to 1996.[180] Of these, 57 patients had isolated recurrent disease in the liver. Twelve of these 57 patients underwent repeat hepatic resection, whereas the other 45 patients received ablation therapy. The overall survival rate in those undergoing a second hepatectomy was 90% at 2 years; however, the disease-free survival rate was only 31% at 2 years, significantly lower than the 62% rate after initial hepatectomy. Likewise, in another group of 84 patients who underwent second hepatectomy for recurrent HCC, the overall 5-year survival rate was 50%, but the recurrence-free survival rate was only 10%.[181] In a report of 67 patients undergoing a second resection for HCC, overall 1-, 3-, and 5-year survival rates were 93%, 70%, and 56%, respectively.[182] Multivariate analysis showed that absence of portal invasion at the second resection, single HCC at primary hepatectomy, and disease-free interval of ≥1 year after primary hepatectomy were independent prognostic factors after the second resection.

LAPAROSCOPIC LIVER RESECTION

Cherqui and colleagues first reported in 2000 that laparoscopic hepatic surgery was feasible.[183] Since this initial report, laparoscopic liver surgery has expanded from the simple unroofing of hepatic cysts to resection of peripheral benign lesions to formal anatomic lobectomies for malignancy and laparoscopic hepatectomy for living donor liver transplantation. While minimally invasive approaches have been widely adopted in other areas of abdominal surgery, there was initial apprehension regarding laparoscopic liver resection (LLR), hampering its widespread adoption.[184] First, the elementary maneuvers of open hepatic surgery, such as manual palpation, organ mobilization, vascular control, and parenchymal transection, were thought to be difficult to reproduce laparoscopically. Second, there was concern that hemorrhage may be more difficult to control laparoscopically and that the risk of gas embolism may be increased by the use of pneumoperitoneum. Third, there was apprehension concerning the possibility of oncologic inadequacy and tumor seeding, but data regarding long-term oncologic outcomes were lacking at the time.

Because of the increased technical demands in LLR, stringent criteria based on surgeon experience and lesion size and location must be used. Surgeons should have an advanced understanding of liver anatomy, extensive experience in open liver surgery, and the technical skills to control major vascular and biliary structures laparoscopically before embarking on LLR. Familiarity with laparoscopic ultrasonography is needed to help confirm the number and size of lesions, demarcate transection planes, and define relationships to major intrahepatic and extrahepatic structures intraoperatively. Smaller, more peripheral lesions, particularly those located in the anterolateral segments (segments II to VI) are most amenable to LLR. Several centers have reported large series consisting of laparoscopic resections of the left lateral and anterior hepatic segments. Laparoscopic major hepatectomy, such as lobectomies, trisegmentectomies, and the resection of difficult posterior segments, has been described and can be performed by expert centers, but should not be considered standard practice at the current time.

As in open hepatic resections, various different technical approaches for performing major laparoscopic liver resection have been described. Hepatic resection can be achieved using either electrosurgical devices to transect the parenchyma, reserving staplers for larger vascular and biliary structures, or staplers alone to divide parenchyma and major structures without the aid of portal triad clamping. As in open liver surgery, no single method of parenchymal transection has been shown to be superior.

Three general techniques have been used for laparoscopic hepatectomy. The pure laparoscopic method is suitable for experienced surgeons to achieve better cosmetic outcomes, whereas the hand-assisted method has been associated with a reduced conversion rate to open procedures. The addition of the assisting hand allows for tactile feedback while palpating the liver and may help in abdominal exploration, parenchymal transection, mobilization of the liver, and providing gentle retraction. Additionally, in cases when significant bleeding is encountered, hand compression allows for easier hemostasis. The specimen is then removed from the hand-port incision. Hand assistance allows the laparoscopic approach to be extended to lesions in posterosuperior segments. Finally, the laparoscopic-assisted method, or the hybrid procedure, is used by surgeons for difficult or unique resections such as resection in cirrhotic livers, laparoscopic resection of tumors in unfavorable locations, and living donor hepatectomies.[185] With the hybrid procedure, the liver is first mobilized laparoscopically, and the hilar dissection and parenchymal transection are then carried out under direct vision through an 8- to 12-cm midline or subcostal incision, through which the specimen is removed.

Results with laparoscopic liver resections have been excellent. Advantages of laparoscopic liver resection include reduced operative blood loss and need for portal triad clamping, decreased postoperative pain and narcotic requirements, faster return of bowel function, and shorter length of hospital stay.[186] The actual occurrence of gas embolism in clinical practice has proven to be extremely low. Carbon dioxide pneumoperitoneum minimizes the risk of gas embolism as compared to air, and lowered pneumoperitoneum pressures further reduce its incidence. The occurrence of gas embolism has been also related to argon beam coagulation, which increases intra-abdominal pressure, leading to an increased risk of gas embolism.

Comparative studies between open resection and LLR for malignant lesions have revealed no difference in overall or disease-free survival after short- and medium-term follow-up, and no difference in the width of resection margins. Some series have even reported fewer positive resection margins with LLR compared to open resection for malignant lesions.[187] No port site recurrences or tumor seeding has been reported to date after LLR. It has been proposed that LLR may allow for more timely start of adjuvant chemotherapy because of a quicker postoperative recovery and fewer wound-related complications.

In particular to LLR for HCC, hypothesized advantages include avoidance of collateral vessel ligation, resulting in reduced portal hypertension, decreased need for intravenous fluids, and improved reabsorption of ascites. The reduced occurrence of postoperative ascites and hepatic insufficiency in cirrhotic patients has led to decreased morbidity in these high-risk patients operated through a laparoscopic approach. The persisting underlying liver disease in these patients, however, dictates that HCC will recur in 40% to 90% of this population after resection, necessitating salvage liver transplantation.[188] Laurent and colleagues[189] reported that prior LLR for HCC compared to open resection facilitated subsequent salvage liver transplantation with decreased morbidity. In this study, patients with previous LLR had shorter hepatectomy and total operative times, less blood loss, and reduced need for blood transfusions after liver transplantation, possibly due to less arduous adhesiolysis.

Zhou and colleagues[190] published a meta-analysis of 10 nonrandomized controlled studies to compare surgical and oncologic outcomes following LLR or open resection for HCC. Compared with perioperative results of open liver resection, reports of LLR demonstrate advantageous outcomes related to blood loss, transfusion requirements, postoperative morbidity, and hospital length of stay. There were significantly lower rates of cirrhotic decompensation and ascites, as well as a trend toward lower rates of postoperative liver failure following LLR. There were no differences in operative time or postoperative mortality. With regard to specific oncologic outcomes, there were no differences in pathologic resection margin or in 3- and 5-year overall and disease-free survival. There were no reported cases of port site recurrences or peritoneal dissemination. This meta-analysis suggests that LLR is comparable, and in some parameters superior, to open resection for HCC.

Regarding LLR for metastatic colorectal cancer, multiple retrospective series have reported the safety, feasibility, and oncologic integrity of the laparoscopic approach. Castaing and colleagues[191] reported a matched prospective comparison in patients undergoing resection of colorectal cancer liver metastases via laparoscopic and open approaches. There were no differences in resection margins, whereas the incidence of positive margins was greater in the open group. There were no differences in 1- or 3-year overall, recurrence-free, and disease-free survival, indicating that equivalent oncologic outcomes can be achieved with LLR in selected patients.

Initial experience with laparoscopic living-donor hepatectomy for transplantation was with left lateral segmentectomy during liver allograft procurement for pediatric transplants. With continued advances in laparoscopic liver surgery, this approach has been applied to adult-to-adult donor right hepatectomy using the hybrid procedure. Complication rates are comparable to those reported for open living-donor hepatectomies.

Laparoscopic liver resection can now be performed safely by experienced surgeons in selected patients. Benefits of the laparoscopic approach include less operative blood loss, reduced postoperative pain and narcotic requirements, a shorter length of hospital stay, and comparable postoperative morbidity and mortality rates to open liver resection. Although small peripheral lesions in anterolateral segments are most amenable to laparoscopic resection, surgeons with extensive experience can embark on major hepatic resections using the laparoscopic approach. Comparative studies have identified similar oncologic outcomes for laparoscopic and open resections for malignant lesions such as HCC and colorectal liver metastases.

chapter 32

Gallbladder and the Extrahepatic Biliary System

Thai H. Pham and John G. Hunter

ANATOMY

Gallbladder

The gallbladder is a pear-shaped sac, about 7 to 10 cm long, with an average capacity of 30 to 50 mL. When obstructed, the gallbladder can distend markedly and contain up to 300 mL.[1] The gallbladder is located in a fossa on the inferior surface of the liver. A line from this fossa to the inferior vena cava divides the liver into right and left liver lobes. The gallbladder is divided into four anatomic areas: the fundus, the corpus (body), the infundibulum, and the neck. The fundus is the rounded, blind end that normally extends 1 to 2 cm beyond the liver's margin. It contains most of the smooth muscles of the organ, in contrast to the body, which is the main storage area and contains most of the elastic tissue. The body extends from the fundus and tapers into the neck, a funnel-shaped area that connects with the cystic duct. The neck usually follows a gentle curve, the convexity of which may be enlarged to form the infundibulum or Hartmann's pouch. The neck lies in the deepest part of the gallbladder fossa and extends into the free portion of the hepatoduodenal ligament (Fig. 32-1).

The same peritoneal lining that covers the liver covers the fundus and the inferior surface of the gallbladder. Occasionally, the gallbladder has a complete peritoneal covering and is suspended in a mesentery off the inferior surface of the liver, and rarely, it is embedded deep inside the liver parenchyma (an intrahepatic gallbladder).

The gallbladder is lined by a single, highly folded, tall columnar epithelium that contains cholesterol and fat globules. The mucus secreted into the gallbladder originates in the tubuloalveolar glands found in the mucosa lining the infundibulum and neck of the gallbladder, but are absent from the body and fundus. The epithelial lining of the gallbladder is supported by a lamina propria. The muscle layer has circular longitudinal and oblique fibers, but without well-developed layers. The perimuscular subserosa contains connective tissue, nerves, vessels, lymphatics, and adipocytes. It is covered by the serosa except where the gallbladder is embedded in the liver. The gallbladder differs histologically from the rest of the gastrointestinal (GI) tract in that it lacks a muscularis mucosa and submucosa.

The cystic artery that supplies the gallbladder is usually a branch of the right hepatic artery (>90% of the time). The course of the cystic artery may vary, but it nearly always is found within the hepatocystic triangle, the area bound by the cystic duct, common hepatic duct, and the liver margin (triangle of Calot). When the cystic artery reaches the neck of the gallbladder, it divides into anterior and posterior divisions. Venous return is carried either through small veins that enter directly into the liver or, rarely, to a large cystic vein that carries blood back to the portal vein. Gallbladder lymphatics drain into nodes at the neck of the gallbladder. Frequently, a visible lymph node overlies the insertion of the cystic artery into the gallbladder wall. The nerves of the gallbladder arise from the vagus and from sympathetic branches that pass through the celiac plexus.

Key Points

1. The physiology of the gallbladder and sphincter of Oddi is regulated by a complex interplay of hormones and neuronal inputs designed to coordinate bile release with food consumption. Dysfunctions related to this activity are linked to the development of gallbladder pathologies described in this chapter.
2. In Western countries, the most common type of gallstones are cholesterol stones. The pathogenesis of these stones relates to supersaturation of bile with cholesterol and subsequent precipitation.
3. Laparoscopic cholecystectomy has been demonstrated to be a safe and effective alternative to open cholecystectomy and has become the treatment of choice for symptomatic gallstones. Knowledge of the various anatomic anomalies of the cystic duct and artery is helpful in guiding the dissection of these structures as well as avoiding injury to the common bile duct during cholecystectomy.
4. Common bile duct injuries, although uncommon, can be devastating to patients. Proper exposure of Calot's triangle and careful identification of the anatomic structures are keys to avoiding these injuries. Once a bile duct injury is diagnosed, the best outcomes are seen at large referral centers with experienced biliary surgeons.
5. The main risk factor for gallbladder disease in Western countries is cholelithiasis. The main complications include cholecystitis, choledocholithiasis, cholangitis, and biliary pancreatitis. In addition, cholelithiasis plays the role as the major risk factor for the development of gallbladder cancer.
6. Carcinoma of the gallbladder and bile duct generally have a poor prognosis because patients usually present late in the disease process and have poor response to chemotherapy and radiation therapy. Surgery offers the best chance for survival and has good long-term survival in patients with early-stage disease.

The preganglionic sympathetic level is T8 and T9. Impulses from the liver, gallbladder, and the bile ducts pass by means of sympathetic afferent fibers through the splanchnic nerves and mediate the pain of biliary colic. The hepatic branch of the vagus nerve supplies cholinergic fibers to the gallbladder, bile ducts, and liver. The vagal branches also have peptide-containing nerves containing agents such as substance P, somatostatin, enkephalins, and vasoactive intestinal polypeptide.[2]

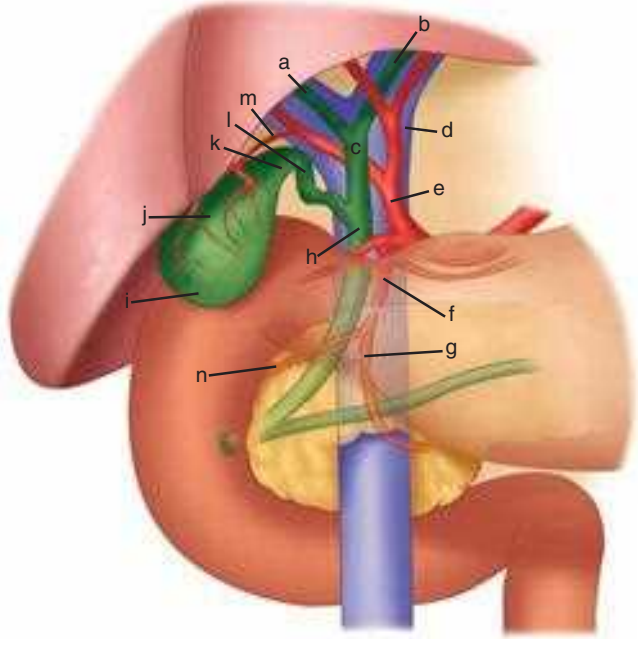

Figure 32-1. Anterior aspect of the biliary anatomy. a = right hepatic duct; b = left hepatic duct; c = common hepatic duct; d = portal vein; e = hepatic artery; f = gastroduodenal artery; g = left gastric artery; h = common bile duct; i = fundus of the gallbladder; j = body of gallbladder; k = infundibulum; l = cystic duct; m = cystic artery; n = superior pancreaticoduodenal artery. Note the situation of the hepatic bile duct confluence anterior to the right branch of the portal vein, and the posterior course of the right hepatic artery behind the common hepatic duct.

Bile Ducts

The extrahepatic bile ducts consist of the right and left hepatic ducts, the common hepatic duct, the cystic duct, and the common bile duct or choledochus. The common bile duct enters the second portion of the duodenum through a muscular structure, the sphincter of Oddi.[3]

The left hepatic duct is longer than the right and has a greater propensity for dilatation as a consequence of distal obstruction. The two ducts join to form a common hepatic duct, close to their emergence from the liver. The common hepatic duct is 1 to 4 cm in length and has a diameter of approximately 4 mm. It lies in front of the portal vein and to the right of the hepatic artery. The common hepatic duct is joined at an acute angle by the cystic duct to form the common bile duct.

The length of the cystic duct is quite variable. It may be short or absent and have a high union with the hepatic duct, or long and run parallel, behind, or spiral to the main hepatic duct before joining it, sometimes as far as at the duodenum. Variations of the cystic duct and its point of union with the common hepatic duct are surgically important (Fig. 32-2). The segment of the cystic duct adjacent to the gallbladder neck bears a variable number of mucosal folds called the *spiral valves of Heister*. They do not have any valvular function but may make cannulation of the cystic duct difficult.

The common bile duct is about 7 to 11 cm in length and 5 to 10 mm in diameter. The upper third (supraduodenal portion) passes downward in the free edge of the hepatoduodenal ligament, to the right of the hepatic artery and anterior to the portal vein. The middle third (retroduodenal portion) of the common bile duct curves behind the first portion of the duodenum and diverges laterally from the portal vein and the hepatic arteries. The lower third (pancreatic portion) curves behind the head of the pancreas in a groove, or traverses through it and enters the second part of the duodenum. There, the pancreatic duct frequently joins it. The common bile duct runs obliquely downward

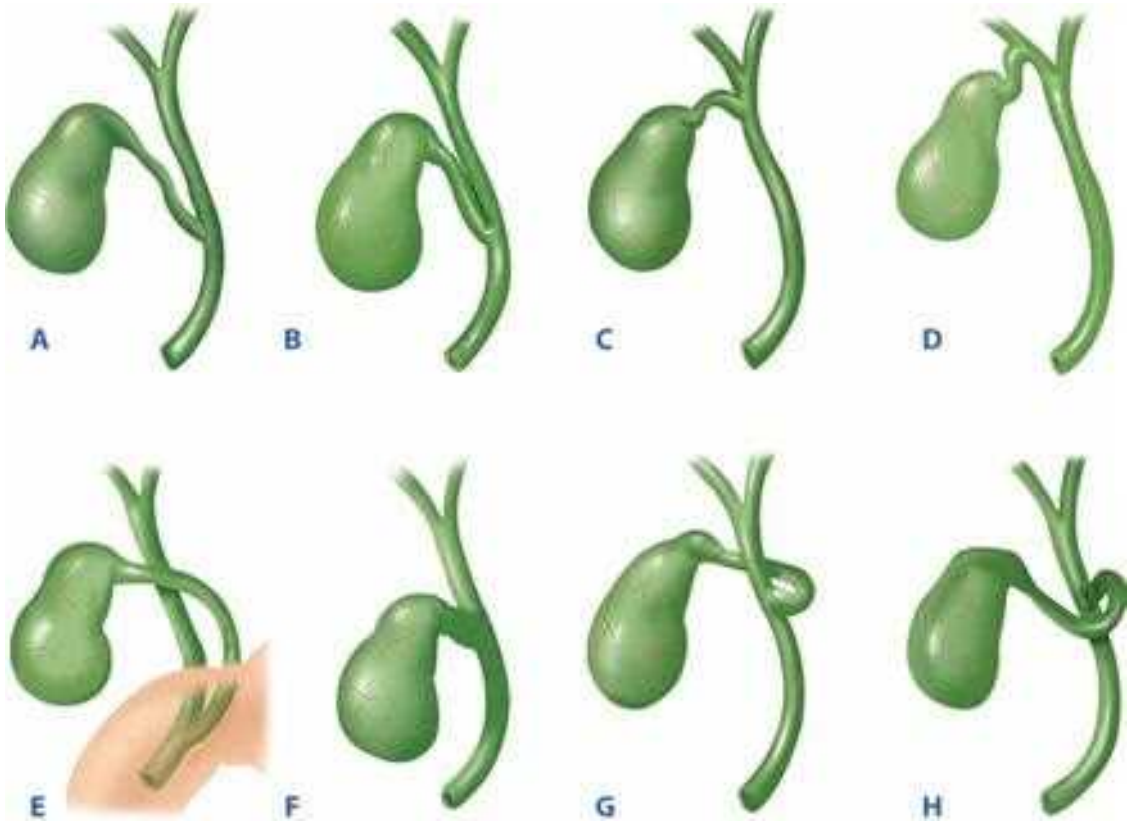

Figure 32-2. Variations of the cystic duct anatomy. **A.** Low junction between the cystic duct and common hepatic duct. **B.** Cystic duct adherent to the common hepatic duct. **C.** High junction between the cystic and the common hepatic duct. **D.** Cystic duct drains into right hepatic duct. **E.** Long cystic duct that joins common hepatic duct behind the duodenum. **F.** Absence of cystic duct. **G.** Cystic duct crosses posterior to common hepatic duct and joins it anteriorly. **H.** Cystic duct courses anterior to common hepatic duct and joins it posteriorly.

within the wall of the duodenum for 1 to 2 cm before opening on a papilla of mucous membrane (ampulla of Vater), about 10 cm distal to the pylorus. The union of the common bile duct and the main pancreatic duct follows one of three configurations. In about 70% of people, these ducts unite outside the duodenal wall and traverse the duodenal wall as a single duct. In about 20%, they join within the duodenal wall and have a short or no common duct, but open through the same opening into the duodenum. In about 10%, they exit via separate openings into the duodenum. The sphincter of Oddi, a thick coat of circular smooth muscle, surrounds the common bile duct at the ampulla of Vater (Fig. 32-3). It controls the flow of bile, and in some cases pancreatic juice, into the duodenum.

The extrahepatic bile ducts are lined by a columnar mucosa with numerous mucous glands in the common bile duct. A fibroareolar tissue containing scant smooth muscle cells surrounds the mucosa. A distinct muscle layer is not present in the human common bile duct. The arterial supply to the bile ducts is derived from the gastroduodenal and the right hepatic arteries, with major trunks running along the medial and lateral walls of the common duct (sometimes referred to as 3 o'clock and 9 o'clock). These arteries anastomose freely within the duct walls. The density of nerve fibers and ganglia increases near the sphincter of Oddi, but the nerve supply to the common bile duct and the sphincter of Oddi is the same as for the gallbladder.[1,2]

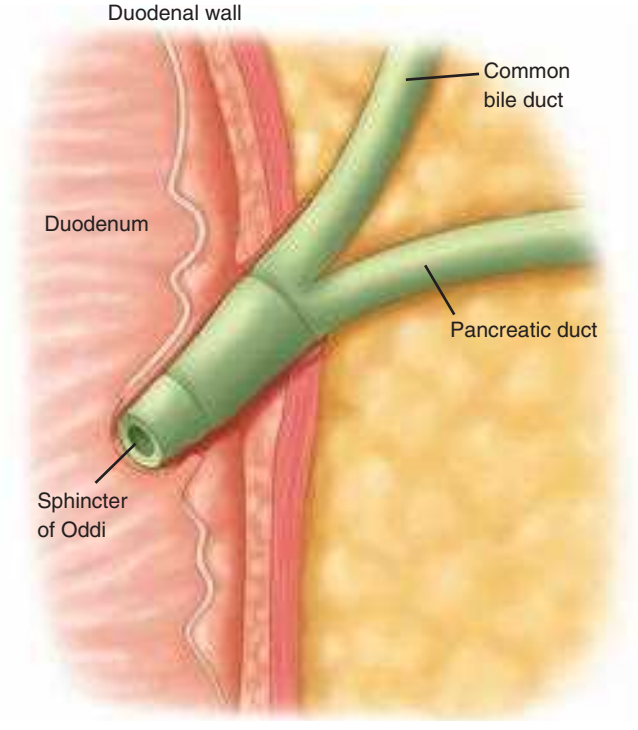

Figure 32-3. The sphincter of Oddi.

Anomalies

The classic description of the extrahepatic biliary tree and its arteries applies only in about one third of patients.[4] The gallbladder may have abnormal positions, be intrahepatic, be rudimentary, have anomalous forms, or be duplicated. Isolated congenital absence of the gallbladder is very rare, with a reported incidence of 0.03%. Before the diagnosis is made, the presence of an intrahepatic bladder or anomalous position must be ruled out. Duplication of the gallbladder with two separate cavities and two separate cystic ducts has an incidence of about one in every 4000 persons. This occurs in two major varieties: the more common form in which each gallbladder has its own cystic duct that empties independently into the same or different parts of the extrahepatic biliary tree, and as two cystic ducts that merge before they enter the common bile duct. Duplication is only clinically important when some pathologic processes affect one or both organs. A left-sided gallbladder with a cystic duct emptying into the left hepatic duct or the common bile duct and a retrodisplacement of the gallbladder are both extremely rare. A partial or totally intrahepatic gallbladder is associated with an increased incidence of cholelithiasis.

Small ducts (of Luschka) may drain directly from the liver into the body of the gallbladder. If present, but not recognized at the time of a cholecystectomy, a bile leak with the accumulation of bile (biloma) may occur in the abdomen. An accessory right hepatic duct occurs in about 5% of cases. Variations of how the common bile duct enters the duodenum are described in earlier, in the Bile Ducts section.

Anomalies of the hepatic artery and the cystic artery are quite common, occurring in as many as 50% of cases.[5] In about 5% of cases, there are two right hepatic arteries, one from the common hepatic artery and the other from the superior mesenteric artery. In about 20% of patients, the right hepatic artery comes off the superior mesenteric artery. The right hepatic artery may course anterior to the common duct. The right hepatic artery may be vulnerable during surgical procedures, in particular when it runs parallel to the cystic duct or in the mesentery of the gallbladder. The cystic artery arises from the right hepatic artery in about 90% of cases, but may arise from the left hepatic, common hepatic, gastroduodenal, or superior mesenteric arteries (Fig. 32-4).

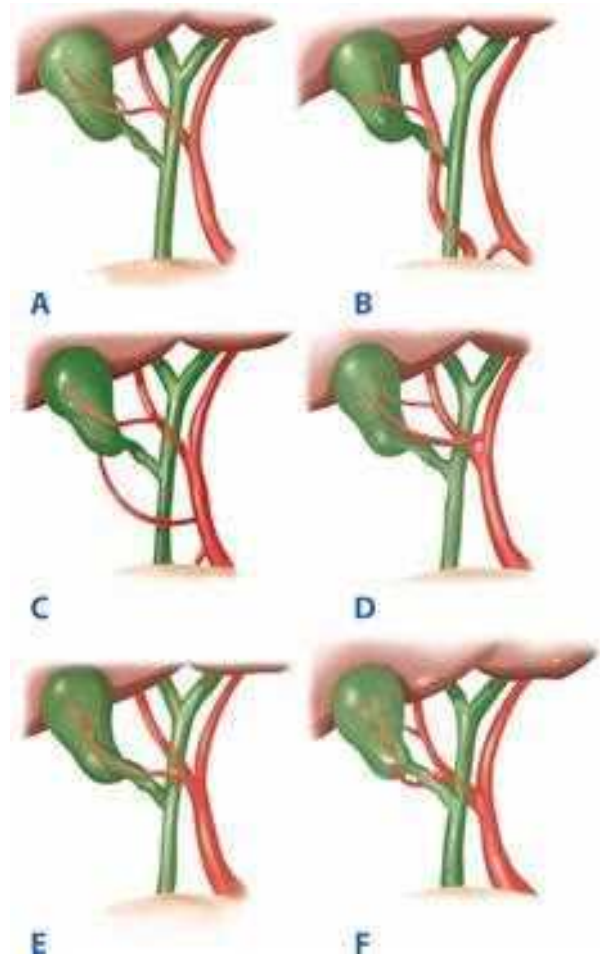

Figure 32-4. Variations in the arterial supply to the gallbladder. **A.** Cystic artery from right hepatic artery, about 80% to 90%. **B.** Cystic artery from right hepatic artery (accessory or replaced) from superior mesenteric artery, about 10%. **C.** Two cystic arteries, one from the right hepatic, the other from the common hepatic artery, rare. **D.** Two cystic arteries, one from the right hepatic, the other from the left hepatic artery, rare. **E.** The cystic artery branching from the right hepatic artery and running anterior to the common hepatic duct, rare. **F.** Two cystic arteries arising from the right hepatic artery, rare.

PHYSIOLOGY

Bile Formation and Composition

The liver produces bile continuously and excretes it into the bile canaliculi. The normal adult consuming an average diet produces within the liver 500 to 1000 mL of bile a day. The secretion of bile is responsive to neurogenic, humoral, and chemical stimuli. Vagal stimulation increases secretion of bile, whereas splanchnic nerve stimulation results in decreased bile flow. Hydrochloric acid, partly digested proteins, and fatty acids in the duodenum stimulate the release of secretin from the duodenum that, in turn, increases bile production and bile flow. Bile flows from the liver through to the hepatic ducts, into the common hepatic duct, through the common bile duct, and finally into the duodenum. With an intact sphincter of Oddi, bile flow is directed into the gallbladder.

Bile is mainly composed of water, electrolytes, bile salts, proteins, lipids, and bile pigments. Sodium, potassium, calcium, and chlorine have the same concentration in bile as in plasma or extracellular fluid. The pH of hepatic bile is usually neutral or slightly alkaline, but varies with diet; an increase in protein shifts the bile to a more acidic pH. The primary bile salts, cholate and chenodeoxycholate, are synthesized in the liver from cholesterol. They are conjugated there with taurine and glycine and act within the bile as anions (bile acids) that are balanced by sodium. Bile salts are excreted into the bile by the hepatocyte and aid in the digestion and absorption of fats in the intestines.[6] In the intestines, about 80% of the conjugated bile acids are absorbed in the terminal ileum. The remainder is dehydroxylated (deconjugated) by gut bacteria, forming secondary bile acids deoxycholate and lithocholate. These are absorbed in the colon, transported to the liver, conjugated, and secreted into the bile. Eventually, about 95% of the bile acid pool is reabsorbed and returned via the portal venous system to the liver, the so-called *enterohepatic circulation*. Five percent is excreted in the stool, leaving the relatively small amount of bile acids to have maximum effect.

Cholesterol and phospholipids synthesized in the liver are the principal lipids found in bile. The synthesis of phospholipids and cholesterol by the liver is, in part, regulated by bile acids. The color of the bile is due to the presence of the pigment bilirubin diglucuronide, which is the metabolic product from the breakdown of hemoglobin and is present in bile in concentrations 100 times greater than in plasma. Once in the intestine, bacteria convert it into urobilinogen, a small fraction of which is absorbed and secreted into the bile.

Gallbladder Function

The gallbladder, the bile ducts, and the sphincter of Oddi act together to store and regulate the flow of bile. The main function of the gallbladder is to concentrate and store hepatic bile and to deliver bile into the duodenum in response to a meal.

Absorption and Secretion. In the fasting state, approximately 80% of the bile secreted by the liver is stored in the gallbladder. This storage is made possible because of the remarkable absorptive capacity of the gallbladder, as the gallbladder mucosa has the greatest absorptive power per unit area of any structure in the body. It rapidly absorbs sodium, chloride, and water against significant concentration gradients, concentrating the bile as much as 10-fold and leading to a marked change in bile composition. This rapid absorption is one of the mechanisms that prevent a rise in pressure within the biliary system under normal circumstances. Gradual relaxation as well as emptying of the gallbladder during the fasting period also plays a role in maintaining a relatively low intraluminal pressure in the biliary tree.

The epithelial cells of the gallbladder secrete at least two important products into the gallbladder lumen: glycoproteins and hydrogen ions. The mucosal glands in the infundibulum and the neck of the gallbladder secrete mucus glycoproteins that are believed to protect the mucosa from the lytic action of bile and to facilitate the passage of bile through the cystic duct. This mucus makes up the colorless "white bile" seen in hydrops of the gallbladder resulting from cystic duct obstruction. The transport of hydrogen ions by the gallbladder epithelium leads to a decrease in the gallbladder bile pH. The acidification promotes calcium solubility, thereby preventing its precipitation as calcium salts.[6]

Motor Activity. Gallbladder filling is facilitated by tonic contraction of the sphincter of Oddi, which creates a pressure gradient between the bile ducts and the gallbladder. During fasting, the gallbladder does not simply fill passively. In association with phase II of the interdigestive migrating myenteric motor complex in the gut, the gallbladder repeatedly empties small volumes of bile into the duodenum. This process is mediated at least in part by the hormone motilin. In response to a meal, the gallbladder empties by a coordinated motor response of gallbladder contraction and sphincter of Oddi relaxation. One of the main stimuli to gallbladder emptying is the hormone cholecystokinin (CCK). CCK is released endogenously from the duodenal mucosa in response to a meal.[7] When stimulated by eating, the gallbladder empties 50% to 70% of its contents within 30 to 40 minutes. Over the following 60 to 90 minutes, the gallbladder gradually refills. This is correlated with a reduced CCK level. Other hormonal and neural pathways also are involved in the coordinated action of the gallbladder and the sphincter of Oddi. Defects in the motor activity of the gallbladder are thought to play a role in cholesterol nucleation and gallstone formation.[8]

Neurohormonal Regulation. The vagus nerve stimulates contraction of the gallbladder, and splanchnic sympathetic stimulation is inhibitory to its motor activity. Parasympathomimetic drugs contract the gallbladder, whereas atropine leads to relaxation. Neurally mediated reflexes link the sphincter of Oddi with the gallbladder, stomach, and duodenum to coordinate the flow of bile into the duodenum. Antral distention of the stomach causes both gallbladder contraction and relaxation of the sphincter of Oddi.

Hormonal receptors are located on the smooth muscles, vessels, nerves, and epithelium of the gallbladder. CCK is a peptide that comes from epithelial cells of the upper GI tract and is found in the highest concentrations in the duodenum. CCK is released into the bloodstream by acid, fat, and amino acids in the duodenum.[9] CCK has a plasma half-life of 2 to 3 minutes and is metabolized by both the liver and the kidneys. CCK acts directly on smooth muscle receptors of the gallbladder and stimulates gallbladder contraction. It also relaxes the terminal bile duct, the sphincter of Oddi, and the duodenum. CCK stimulation of the gallbladder and the biliary tree also is mediated by cholinergic vagal neurons. In patients who have had a vagotomy, the response to CCK stimulation is diminished and the size and the volume of the gallbladder are increased.

Vasoactive intestinal polypeptide inhibits contraction and causes gallbladder relaxation. Somatostatin and its analogues are potent inhibitors of gallbladder contraction. Patients treated with somatostatin analogues and those with somatostatinoma have a high incidence of gallstones, presumably due to the inhibition of gallbladder contraction and emptying. Other hormones such as substance P and enkephalin affect gallbladder motility, but the physiologic role is unclear.[7]

Sphincter of Oddi

The sphincter of Oddi regulates flow of bile (and pancreatic juice) into the duodenum, prevents the regurgitation of duodenal contents into the biliary tree, and diverts bile into the gallbladder. It is a complex structure that is functionally independent from the duodenal musculature and creates a high-pressure zone between the bile duct and the duodenum. The sphincter of Oddi is about 4 to 6 mm in length and has a basal resting pressure of about 13 mmHg above the duodenal pressure. On manometry, the sphincter shows phasic contractions with a frequency of about four per minute and an amplitude of 12 to 140 mmHg.[8] The spontaneous motility of the sphincter of Oddi is regulated by the interstitial cells of Cajal through intrinsic and extrinsic inputs from hormones and neurons acting on the smooth muscle cells.[10] Relaxation occurs with a rise in CCK, leading to diminished amplitude of phasic contractions and reduced basal pressure, allowing increased flow of bile into the duodenum (Fig. 32-5). During fasting, the sphincter of Oddi activity is coordinated with the periodic partial gallbladder emptying and an increase in bile flow that occurs during phase II of the migrating myoelectric motor complexes.[11]

DIAGNOSTIC STUDIES

A variety of diagnostic modalities are available for the patient with suspected disease of the gallbladder and the bile ducts. In 1924, the diagnosis of gallstones was improved significantly by the introduction of oral cholecystography by Graham and Cole. For decades, it was the mainstay of investigation for gallstones. In the 1950s, biliary scintigraphy was developed, as well as intrahepatic and endoscopic retrograde cholangiography (ERC), allowing imaging of the biliary tract. Later ultrasonography,

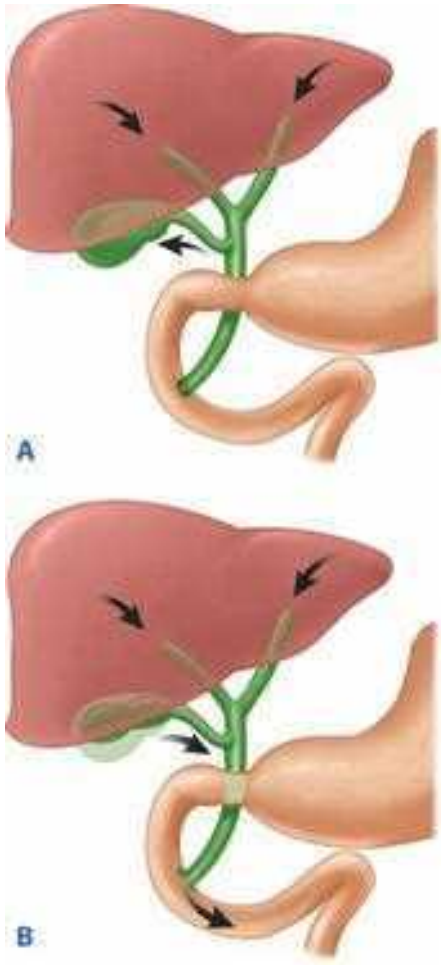

Figure 32-5. The effect of cholecystokinin on the gallbladder and the sphincter of Oddi. **A.** During fasting, with the sphincter of Oddi contracted and the gallbladder filling. **B.** In response to a meal, the sphincter of Oddi relaxed and the gallbladder emptying.

computed tomography (CT), and magnetic resonance imaging (MRI) vastly improved the ability to image the biliary tract.[12]

Blood Tests

When patients with suspected diseases of the gallbladder or the extrahepatic biliary tree are evaluated, a complete blood count and liver function tests are routinely requested. An elevated white blood cell (WBC) count may indicate or raise suspicion of cholecystitis. If associated with an elevation of bilirubin, alkaline phosphatase, and aminotransferase, cholangitis should be suspected. Cholestasis, an obstruction to bile flow, is characterized by an elevation of bilirubin (i.e., the conjugated form) and a rise in alkaline phosphatase. Serum aminotransferases may be normal or mildly elevated. In patients with biliary colic or chronic cholecystitis, blood tests will typically be normal.

Ultrasonography

An ultrasound is the initial investigation of any patient suspected of disease of the biliary tree.[13] It is noninvasive, painless, does not submit the patient to radiation, and can be performed on critically ill patients. It is dependent upon the skills and the experience of the operator, and it is dynamic (i.e., static images do not give the same information as those obtained during the ultrasound investigation itself). Adjacent organs can frequently be examined at the same time. Obese patients, patients with ascites, and patients with distended bowel may be difficult to examine satisfactorily with an ultrasound.

Figure 32-6. An ultrasonography of the gallbladder. *Arrows* indicate the acoustic shadows from stones in the gallbladder.

Ultrasound will show stones in the gallbladder with sensitivity and specificity of >90%. Stones are acoustically dense and reflect the ultrasound waves back to the ultrasonic transducer. Because stones block the passage of sound waves to the region behind them, they also produce an acoustic shadow (Fig. 32-6). Stones move with changes in position. Polyps may be calcified and reflect shadows, but do not move with change in posture. Some stones form a layer in the gallbladder; others a sediment or sludge. A thickened gallbladder wall and local tenderness indicate cholecystitis. The patient has acute cholecystitis if a layer of edema is seen within the wall of the gallbladder or between the gallbladder and the liver in association with localized tenderness. When a stone obstructs the neck of the gallbladder, the gallbladder may become very large, but thin walled. A contracted, thick-walled gallbladder is indicative of chronic cholecystitis.

The extrahepatic bile ducts are also well visualized by ultrasound, except for the retroduodenal portion. Dilation of the ducts in a patient with jaundice establishes an extrahepatic obstruction as a cause for the jaundice. Frequently, the site and, sometimes, the cause of obstruction can be determined by ultrasound. Small stones in the common bile duct frequently get lodged at the distal end of it, behind the duodenum, and are, therefore, difficult to detect. A dilated common bile duct on ultrasound, small stones in the gallbladder, and the clinical presentation allow one to assume that a stone or stones are causing the obstruction. Periampullary tumors can be difficult to diagnose on ultrasound, but beyond the retroduodenal portion, the level of obstruction and the cause may be visualized quite well. Ultrasound can be helpful in evaluating tumor invasion and flow in the portal vein, an important guideline for resectability of periampullary and pancreatic head tumors.[14]

Oral Cholecystography

Once considered the diagnostic procedure of choice for gallstones, oral cholecystography has largely been replaced by ultrasonography. It involves oral administration of a radiopaque compound that is absorbed, excreted by the liver, and passed into the gallbladder. Stones are noted on a film as filling defects in a visualized, opacified gallbladder. Oral cholecystography is of no value in patients with intestinal malabsorption, vomiting, obstructive jaundice, and hepatic failure.

Biliary Radionuclide Scanning (HIDA Scan)

Biliary scintigraphy provides a noninvasive evaluation of the liver, gallbladder, bile ducts, and duodenum with both anatomic and functional information. ^{99m}Technetium-labeled derivatives of dimethyl iminodiacetic acid (HIDA) are injected intravenously, cleared by the Kupffer cells in the liver, and excreted in the bile. Uptake by the liver is detected within 10 minutes, and the gallbladder, the bile ducts, and the duodenum are visualized within 60 minutes in fasting subjects. The primary use of biliary scintigraphy is in the diagnosis of acute cholecystitis, which appears as a nonvisualized gallbladder, with prompt filling of the common bile duct and duodenum. Evidence of cystic duct obstruction on biliary scintigraphy is highly diagnostic for acute cholecystitis. The sensitivity and specificity for the diagnosis are about 95% each. False-positive results are increased in patients with gallbladder stasis, as in critically ill patients and in patients receiving parenteral nutrition. Filling of the gallbladder and common bile duct with delayed or absent filling of the duodenum indicates an obstruction at the ampulla. Biliary leaks as a complication of surgery of the gallbladder or the biliary tree can be confirmed and frequently localized by biliary scintigraphy.[15]

Computed Tomography

Abdominal CT scans are inferior to ultrasonography in diagnosing gallstones. The major application of CT scans is to define the course and status of the extrahepatic biliary tree and adjacent structures. It is the test of choice in evaluating the patient with suspected malignancy of the gallbladder, the extrahepatic biliary system, or nearby organs, in particular, the head of the pancreas. Use of CT scan is an integral part of the differential diagnosis of obstructive jaundice (Fig. 32-7). Spiral CT scanning provides additional staging information, including vascular involvement in patients with periampullary tumors.[16]

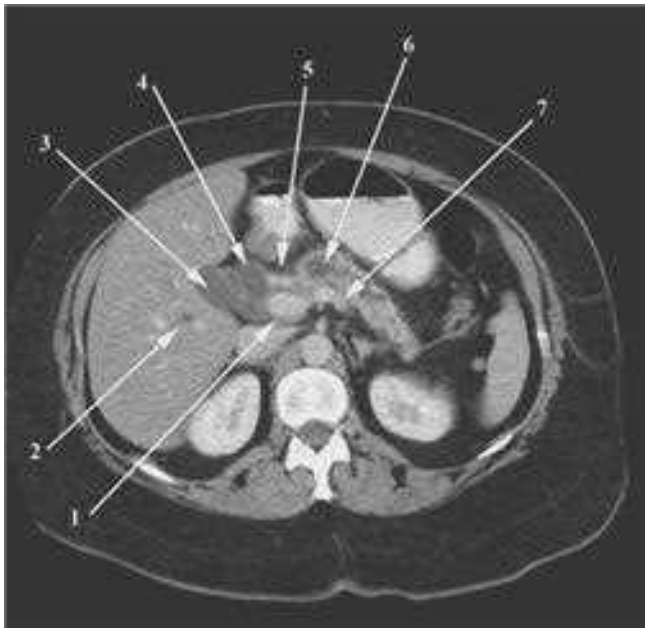

Figure 32-7. Computed tomography scan of the upper abdomen from a patient with cancer of the distal common bile duct. The cancer obstructs the common bile duct as well as the pancreatic duct. 1 = the portal vein; 2 = a dilated intrahepatic bile duct; 3 = dilated cystic duct and the neck of the gallbladder; 4 = dilated common hepatic duct; 5 = the bifurcation of the common hepatic artery into the gastroduodenal artery and the proper hepatic artery; 6 = dilated pancreatic duct; 7 = the splenic vein.

Percutaneous Transhepatic Cholangiography

Intrahepatic bile ducts are accessed percutaneously with a small needle under fluoroscopic guidance. Once the position in a bile duct has been confirmed, a guidewire is passed, and subsequently, a catheter is passed over the wire (Fig. 32-8). Through the catheter, a cholangiogram can be performed and therapeutic interventions done, such as biliary drain insertions and stent placements. Percutaneous transhepatic cholangiography (PTC) has little role in the management of patients with uncomplicated gallstone disease but is particularly useful in patients with bile duct strictures and tumors, as it defines the anatomy of the biliary tree proximal to the affected segment. As with any invasive procedure, there are potential risks. For PTC, these are mainly bleeding, cholangitis, bile leak, and other catheter-related problems.[15]

Magnetic Resonance Imaging

Available since the mid-1990s, MRI provides anatomic details of the liver, gallbladder, and pancreas similar to those obtained from CT. Many MRI techniques (i.e., heavily T2-weighted sequences, pulse sequences with or without contrast materials) can generate high-resolution anatomic images of the biliary tree and the pancreatic duct. It has a sensitivity and specificity of 95% and 89%, respectively, at detecting choledocholithiasis.[17] MRI with magnetic resonance cholangiopancreatography (MRCP) offers a single noninvasive test for the diagnosis of biliary tract and pancreatic disease[18] (Fig. 32-9). In many centers, MRCP is first performed for diagnosis of biliary and pancreatic duct pathology, reserving endoscopic retrograde cholangiopancreatography (ERCP) for therapeutic purposes only.

Endoscopic Retrograde Cholangiopancreatography

Using a side-viewing endoscope, the common bile duct can be cannulated and a cholangiogram performed using fluoroscopy (Fig. 32-10). The procedure requires intravenous (IV) sedation for the patient. The advantages of ERC include direct visualization of the ampullary region and direct access to the distal common bile duct, with the possibility of therapeutic intervention. The test is rarely needed for uncomplicated gallstone disease, but for stones in the common bile duct, in particular, when associated with obstructive jaundice, cholangitis, or gallstone pancreatitis, ERC is the diagnostic and often therapeutic procedure of choice. Once the endoscopic cholangiogram has shown ductal stones, sphincterotomy and stone extraction can be performed, and the common bile duct cleared of stones. In the hands of experts, the success rate of common bile duct cannulation and cholangiography is >90%. Complications of diagnostic ERC include pancreatitis and cholangitis and occur in up to 5% of patients.[19] The development of small fiber-optic cameras that can be threaded through endoscopes used for endoscopic retrograde cholangiopancreatography (ERCP) has facilitated the development of intraductal endoscopy. By providing direct visualization of the biliary and pancreatic ducts, this technology has been shown to increase the effectiveness of ERCP in the diagnosis of certain biliary and pancreatic diseases.[20,21] Intraductal endoscopy has been shown to have therapeutic applications that include biliary stone lithotripsy and extraction in high-risk surgical patients.[22] As with most endoscopic procedures, intraductal endoscopy generally is considered safe, but

Figure 32-8. there are no large trials that specifically address this issue. Typical complications such as bile duct perforation, minor bleeding from sphincterotomy or lithotripsy, and cholangitis have been described.[23] Further refinement of this technology will enhance ERCP as a diagnostic and therapeutic tool.

Endoscopic Ultrasound

Endoscopic ultrasound requires a special endoscope with an ultrasound transducer at its tip. The results are operator dependent, but offer noninvasive imaging of the bile ducts and adjacent structures. It is of particular value in the evaluation of tumors and their resectability. The ultrasound endoscope has a biopsy channel, allowing needle biopsies of a tumor under ultrasonic guidance. Endoscopic ultrasound also has been used to identify bile duct stones, and although it is less sensitive than ERC, the technique is less invasive as cannulation of the sphincter of Oddi is not necessary for diagnosis of choledocholithiasis.

GALLSTONE DISEASE

Prevalence and Incidence

Gallstone disease is one of the most common problems affecting the digestive tract. Autopsy reports have shown a prevalence of gallstones from 11% to 36%.[24] The prevalence of gallstones is related to many factors, including age, gender,

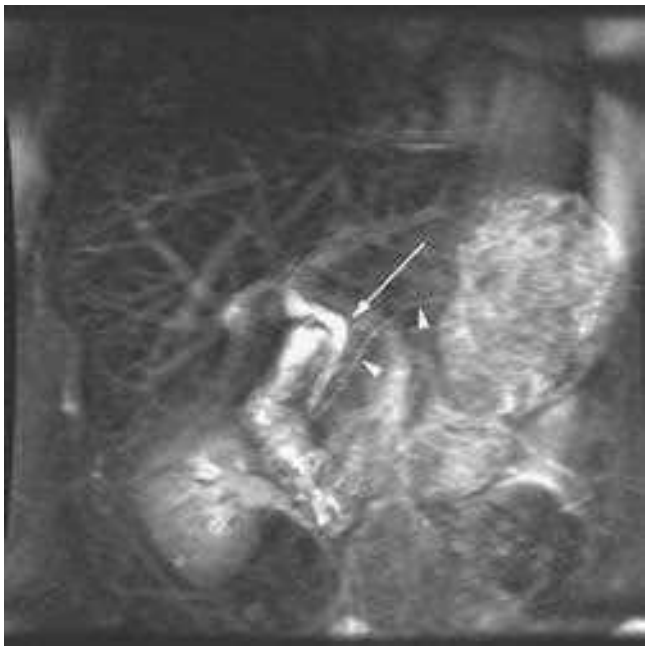

Figure 32-9. Magnetic resonance cholangiopancreatography. This view shows the course of the extrahepatic bile ducts (*arrow*) and the pancreatic duct (*arrowheads*).

and ethnic background. Certain conditions predispose to the development of gallstones. Obesity, pregnancy, dietary factors, Crohn's disease, terminal ileal resection, gastric surgery, hereditary spherocytosis, sickle cell disease, and thalassemia are all associated with an increased risk of developing gallstones.[8] Women are three times more likely to develop gallstones than men, and first-degree relatives of patients with gallstones have a twofold greater prevalence.[25]

Natural History

Most patients will remain asymptomatic from their gallstones throughout life. For unknown reasons, some patients progress to a symptomatic stage, with biliary colic caused by a stone obstructing the cystic duct. Symptomatic gallstone disease may progress to complications related to the gallstones.[26] These include acute cholecystitis, choledocholithiasis with or without cholangitis, gallstone pancreatitis, cholecystocholedochal fistula, cholecystoduodenal or cholecystoenteric fistula leading to gallstone ileus, and gallbladder carcinoma. Rarely, complication of gallstones is the presenting picture.

Gallstones in patients without biliary symptoms are commonly diagnosed incidentally on ultrasonography, CT scans, or abdominal radiography or at laparotomy. Several studies have examined the likelihood of developing biliary colic or developing significant complications of gallstone disease. Approximately 3% of asymptomatic individuals become symptomatic per year (i.e., develop biliary colic). Once symptomatic, patients tend to have recurring bouts of biliary colic. Complicated gallstone disease develops in 3% to 5% of symptomatic patients per year. Over a 20-year period, about two thirds of asymptomatic patients with gallstones remain symptom free.[27]

Because few patients develop complications without previous biliary symptoms, prophylactic cholecystectomy in asymptomatic persons with gallstones is rarely indicated. For elderly patients with diabetes, for individuals who will be isolated from medical care for extended periods of time, and in populations with increased risk of gallbladder cancer, a prophylactic cholecystectomy may be advisable. Porcelain gallbladder, a rare premalignant condition in which the wall of the

gallbladder becomes calcified, is an absolute indication for cholecystectomy.

Gallstone Formation

Gallstones form as a result of solids settling out of solution. The major organic solutes in bile are bilirubin, bile salts, phospholipids, and cholesterol. Gallstones are classified by their cholesterol content as either cholesterol stones or pigment stones. Pigment stones can be further classified as either black or brown. In Western countries, about 80% of gallstones are cholesterol stones and about 15% to 20% are black pigment stones.[28] Brown pigment stones account for only a small percentage. Both types of pigment stones are more common in Asia.

2▶

Cholesterol Stones. Pure cholesterol stones are uncommon and account for <10% of all stones. They usually occur as single large stones with smooth surfaces. Most other cholesterol stones contain variable amounts of bile pigments and calcium, but are always >70% cholesterol by weight. These stones are usually multiple, of variable size, and may be hard and faceted or irregular, mulberry-shaped, and soft (Fig. 32-11). Colors range from whitish yellow and green to black. Most cholesterol stones are radiolucent; <10% are radiopaque. Whether pure or of mixed nature, the common primary event in the formation of cholesterol stones is supersaturation of bile with cholesterol. Therefore, high bile cholesterol levels and cholesterol gallstones are considered as one disease. Cholesterol is highly nonpolar and insoluble in water and bile. Cholesterol solubility depends on the relative concentration of cholesterol, bile salts, and lecithin (the main phospholipid in bile). Supersaturation almost always is caused by cholesterol hypersecretion rather than by a reduced secretion of phospholipid or bile salts.[2]

Cholesterol is secreted into bile as cholesterol-phospholipid vesicles. Cholesterol is held in solution by micelles, a conjugated bile salt-phospholipid-cholesterol complex, as well as by the cholesterol-phospholipid vesicles. The presence of vesicles and micelles in the same aqueous compartment allows the movement of lipids between the two. Vesicular maturation occurs when vesicular lipids are incorporated into micelles. Vesicular phospholipids are incorporated into micelles more readily than vesicular cholesterol. Therefore, vesicles may become enriched in cholesterol, become unstable, and then nucleate cholesterol crystals. In unsaturated bile, cholesterol enrichment of vesicles is inconsequential. In the supersaturated bile, cholesterol-dense zones develop on the surface of the cholesterol-enriched vesicles, leading to the appearance of cholesterol crystals. About one third of biliary cholesterol is transported in micelles, but the cholesterol-phospholipid vesicles carry the majority of biliary cholesterol[29] (Fig. 32-12).

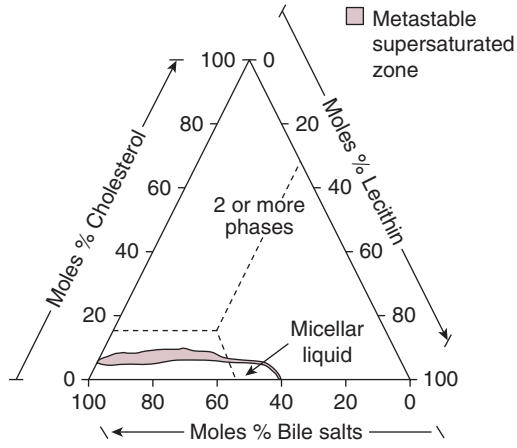

Figure 32-12. The three major components of bile plotted on triangular coordinates. A given point represents the relative molar ratios of bile salts, lecithin, and cholesterol. The area labeled "micellar liquid" shows the range of concentrations found consistent with a clear micellar solution (single phase), where cholesterol is fully solubilized. The shaded area directly above this region corresponds to a metastable zone, supersaturated with cholesterol. Bile with a composition that falls above the shaded area has exceeded the solubilization capacity of cholesterol and precipitation of cholesterol crystals occurs. *(Reproduced with permission from Holzbach RT. Pathogenesis and medical treatment of gallstones. In: Slesinger MH, Fordtran JS, eds.* Gastrointestinal Diseases. *Philadelphia: WB Saunders; 1989:1672.)*

Figure 32-11. Gallbladder with cholesterol stones. Note the different shapes and sizes.

Pigment Stones. Pigment stones contain <20% cholesterol and are dark because of the presence of calcium bilirubinate. Otherwise, black and brown pigment stones have little in common and should be considered as separate entities.

Black pigment stones are usually small, brittle, black, and sometimes spiculated. They are formed by supersaturation of calcium bilirubinate, carbonate, and phosphate, most often secondary to hemolytic disorders such as hereditary spherocytosis and sickle cell disease, and in those with cirrhosis. Like cholesterol stones, they almost always form in the gallbladder. Unconjugated bilirubin is much less soluble than conjugated bilirubin in bile. Deconjugation of bilirubin occurs normally in bile at a slow rate. Excessive levels of conjugated bilirubin, as in hemolytic states, lead to an increased rate of production of unconjugated bilirubin. Cirrhosis may lead to increased secretion of unconjugated bilirubin. When altered conditions lead to increased levels of deconjugated bilirubin in bile, precipitation with calcium occurs. In Asian countries such as Japan, black stones account for a much higher percentage of gallstones than in the Western hemisphere.

Brown stones are usually <1 cm in diameter, brownish-yellow, soft, and often mushy. They may form either in the gallbladder or in the bile ducts, usually secondary to bacterial

infection caused by bile stasis. Precipitated calcium bilirubinate and bacterial cell bodies compose the major part of the stone. Bacteria such as *Escherichia coli* secrete β-glucuronidase that enzymatically cleaves bilirubin glucuronide to produce the insoluble unconjugated bilirubin. It precipitates with calcium, and along with dead bacterial cell bodies, forms soft brown stones in the biliary tree.

Brown stones are typically found in the biliary tree of Asian populations and are associated with stasis secondary to parasite infection. In Western populations, brown stones occur as primary bile duct stones in patients with biliary strictures or other common bile duct stones that cause stasis and bacterial contamination.[2,30]

Symptomatic Gallstones

Chronic Cholecystitis (Biliary Colic). About two thirds of patients with gallstone disease present with chronic cholecystitis characterized by recurrent attacks of pain, often inaccurately labeled *biliary colic*. The pain develops when a stone obstructs the cystic duct, resulting in a progressive increase of tension in the gallbladder wall. The pathologic changes, which often do not correlate well with symptoms, vary from an apparently normal gallbladder with minor chronic inflammation in the mucosa, to a shrunken, nonfunctioning gallbladder with gross transmural fibrosis and adhesions to nearby structures. The mucosa is initially normal or hypertrophied, but later becomes atrophied, with the epithelium protruding into the muscle coat, leading to the formation of the so-called *Aschoff-Rokitansky sinuses*.

Clinical Presentation The chief symptom associated with symptomatic gallstones is pain. The pain is constant and increases in severity over the first half hour or so and typically lasts 1 to 5 hours. It is located in the epigastrium or right upper quadrant and frequently radiates to the right upper back or between the scapulae (Fig. 32-13). The pain is severe and comes on abruptly, typically during the night or after a fatty meal. It often is associated with nausea and sometimes vomiting. The pain is episodic. The patient suffers discrete attacks of pain, between which they feel well. Physical examination may reveal mild right upper quadrant tenderness during an episode of pain. If the patient is pain free, the physical examination is usually unremarkable. Laboratory values, such as WBC count and liver function tests, are usually normal in patients with uncomplicated gallstones.

Atypical presentation of gallstone disease is common. Association with meals is present in only about 50% of patients. Some patients report milder attacks of pain, but relate it to meals. The pain may be located primarily in the back or the left upper or lower right quadrant. Bloating and belching may be present and associated with the attacks of pain. In patients with atypical presentation, other conditions with upper abdominal pain should be sought out, even in the presence of gallstones. These include peptic ulcer disease, gastroesophageal reflux disease, abdominal wall hernias, irritable bowel disease, diverticular disease, liver diseases, renal calculi, pleuritic pain, and myocardial pain. Many patients with other conditions have gallstones.

When the pain lasts >24 hours, an impacted stone in the cystic duct or acute cholecystitis (see later Acute Cholecystitis section) should be suspected. An impacted stone without cholecystitis will result in what is called *hydrops of the gallbladder*. The bile gets absorbed, but the gallbladder epithelium continues to secrete mucus, and the gallbladder becomes distended with mucinous material. The gallbladder may be palpable but usually

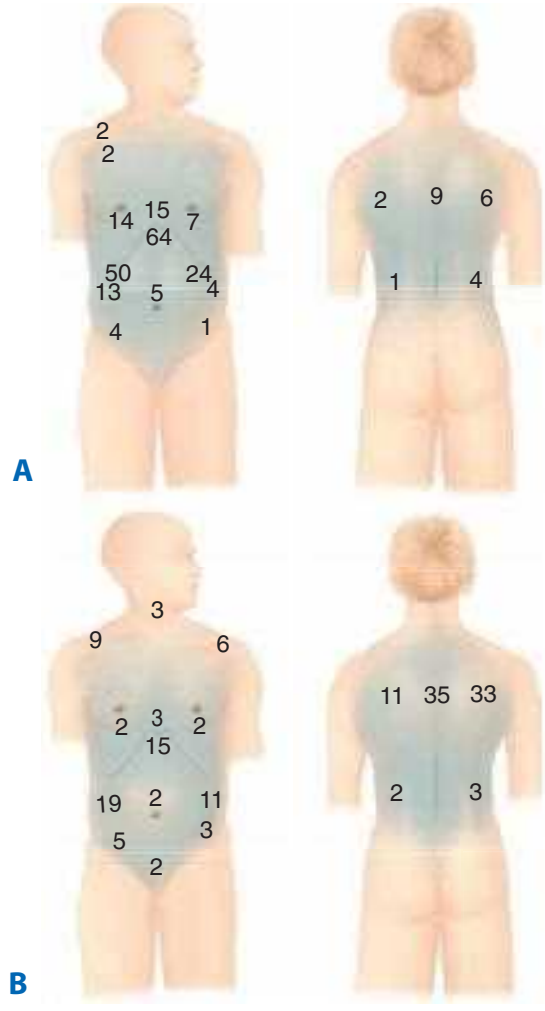

Figure 32-13. **A.** Sites of the most severe pain during an episode of biliary pain in 107 patients with gallstones (% values add up to >100% because of multiple responses). The subxiphoid and right subcostal areas were the most common sites; note that the left subcostal area was not an unusual site of pain. **B.** Sites of pain radiation (%) during an episode of biliary pain in the same group of patients. *(Reprinted from Gunn A, Keddie N. Some clinical observations on patients with gallstones.* Lancet. *1972;300(7771):239-241, Copyright 1972, with permission from Elsevier.)*

is not tender. Hydrops of the gallbladder may result in edema of the gallbladder wall, inflammation, infection, and perforation. Although hydrops may persist with few consequences, early cholecystectomy is generally indicated to avoid complications.

Diagnosis The diagnosis of symptomatic gallstones or chronic calculous cholecystitis depends on the presence of typical symptoms and the demonstration of stones on diagnostic imaging. An abdominal ultrasound is the standard diagnostic test for gallstones (see earlier Ultrasonography section).[31] Gallstones are occasionally identified on abdominal radiographs or CT scans. In these cases, if the patient has typical symptoms, an ultrasound of the gallbladder and the biliary tree should be added before surgical intervention. Stones diagnosed incidentally in patients without symptoms should be left in place as discussed previously in the Natural History section. Occasionally, patients with typical attacks of biliary pain have no evidence of stones on ultrasonography. Sometimes only sludge in the gallbladder

is demonstrated on ultrasonography. If the patient has recurrent attacks of typical biliary pain and sludge is detected on two or more occasions, cholecystectomy is warranted. In addition to sludge and stones, cholesterolosis and adenomyomatosis of the gallbladder may cause typical biliary symptoms and may be detected on ultrasonography. Cholesterolosis is caused by the accumulation of cholesterol in macrophages in the gallbladder mucosa, either locally or as polyps. It produces the classic macroscopic appearance of a "strawberry gallbladder." Adenomyomatosis or cholecystitis glandularis proliferans is characterized on microscopy by hypertrophic smooth muscle bundles and by the ingrowths of mucosal glands into the muscle layer (epithelial sinus formation). Granulomatous polyps develop in the lumen at the fundus, and the gallbladder wall is thickened and septae or strictures may be seen in the gallbladder. In symptomatic patients, cholecystectomy is the treatment of choice for patients with these conditions.[32]

Management Patients with symptomatic gallstones should be advised to have elective laparoscopic cholecystectomy. While waiting for surgery, or if surgery has to be postponed, the patient should be advised to avoid dietary fats and large meals. Diabetic patients with symptomatic gallstones should have a cholecystectomy promptly, as they are more prone to develop acute cholecystitis that is often severe. Pregnant women with symptomatic gallstones who cannot be managed expectantly with diet modifications can safely undergo laparoscopic cholecystectomy during the second trimester. Laparoscopic cholecystectomy is safe and effective in children as well as in the elderly.[33,34] Cholecystectomy, open or laparoscopic, for patients with symptomatic gallstones offers excellent long-term results. About 90% of patients with typical biliary symptoms and stones are rendered symptom free after cholecystectomy. For patients with atypical symptoms or dyspepsia (flatulence, belching, bloating, and dietary fat intolerance), the results are not as favorable.

3▶

Acute Cholecystitis

Pathogenesis Acute cholecystitis is secondary to gallstones in 90% to 95% of cases. Acute acalculous cholecystitis is a condition that typically occurs in patients with other acute systemic diseases (see later Acalculous Cholecystitis section). In <1% of acute cholecystitis, the cause is a tumor obstructing the cystic duct. Obstruction of the cystic duct by a gallstone is the initiating event that leads to gallbladder distention, inflammation, and edema of the gallbladder wall. Why inflammation develops only occasionally with cystic duct obstruction is unknown. It is probably related to the duration of obstruction of the cystic duct. Initially, acute cholecystitis is an inflammatory process, probably mediated by the mucosal toxin lysolecithin, a product of lecithin, as well as bile salts and platelet-activating factor. Increase in prostaglandin synthesis amplifies the inflammatory response. Secondary bacterial contamination is documented in 15% to 30% of patients undergoing cholecystectomy for acute uncomplicated cholecystitis. In acute cholecystitis, the gallbladder wall becomes grossly thickened and reddish with subserosal hemorrhages. Pericholecystic fluid often is present. The mucosa may show hyperemia and patchy necrosis. In severe cases, about 5% to 10%, the inflammatory process progresses and leads to ischemia and necrosis of the gallbladder wall. More frequently, the gallstone is dislodged and the inflammation resolves.[35]

When the gallbladder remains obstructed and secondary bacterial infection supervenes, an acute gangrenous cholecystitis develops, and an abscess or empyema forms within the gallbladder. Rarely, perforation of ischemic areas occurs. The perforation is usually contained in the subhepatic space by the omentum and adjacent organs. However, free perforation with peritonitis, intrahepatic perforation with intrahepatic abscesses, and perforation into adjacent organs (duodenum or colon) with cholecystoenteric fistula occur. When gas-forming organisms are part of the secondary bacterial infection, gas may be seen in the gallbladder lumen and in the wall of the gallbladder on abdominal radiographs and CT scans, an entity called an *emphysematous gallbladder*.

Clinical Manifestations About 80% of patients with acute cholecystitis give a history compatible with chronic cholecystitis. Acute cholecystitis begins as an attack of biliary colic, but in contrast to biliary colic, the pain does not subside; it is unremitting and may persist for several days. The pain is typically in the right upper quadrant or epigastrium and may radiate to the right upper part of the back or the interscapular area. It is usually more severe than the pain associated with uncomplicated biliary colic. The patient is often febrile, complains of anorexia, nausea, and vomiting, and is reluctant to move, as the inflammatory process affects the parietal peritoneum. On physical examination, focal tenderness and guarding are usually present in the right upper quadrant. A mass, the gallbladder and adherent omentum, is occasionally palpable; however, guarding may prevent this. A Murphy's sign, an inspiratory arrest with deep palpation in the right subcostal area, is characteristic of acute cholecystitis.

A mild to moderate leukocytosis (12,000–15,000 cells/mm^3) is usually present. However, some patients may have a normal WBC. A high WBC count (above 20,000) is suggestive of a complicated form of cholecystitis such as gangrenous cholecystitis, perforation, or associated cholangitis. Serum liver chemistries are usually normal, but a mild elevation of serum bilirubin, <4 mg/mL, may be present along with mild elevation of alkaline phosphatase, transaminases, and amylase.[31] Severe jaundice is suggestive of common bile duct stones or obstruction of the bile ducts by severe pericholecystic inflammation secondary to impaction of a stone in the infundibulum of the gallbladder that mechanically obstructs the bile duct (Mirizzi's syndrome). In elderly patients and in those with diabetes mellitus, acute cholecystitis may have a subtle presentation resulting in a delay in diagnosis. The incidence of complications is higher in these patients, who also have approximately 10-fold the mortality rate compared to that of younger and healthier patients.

The differential diagnosis for acute cholecystitis includes a peptic ulcer with or without perforation, pancreatitis, appendicitis, hepatitis, perihepatitis (Fitz-Hugh–Curtis syndrome), myocardial ischemia, pneumonia, pleuritis, and herpes zoster involving the intercostal nerve.

Diagnosis Ultrasonography is the most useful radiologic test for diagnosing acute cholecystitis. It has a sensitivity and specificity of 95%. In addition to being a sensitive test for documenting the presence or absence of stones, it will show the thickening of the gallbladder wall and the pericholecystic fluid (Fig. 32-14). Focal tenderness over the gallbladder when compressed by the sonographic probe (sonographic Murphy's sign) also is suggestive of acute cholecystitis. Biliary radionuclide scanning (HIDA scan) may be of help in the atypical case. Lack of filling of the gallbladder after 4 hours indicates an obstructed cystic duct and, in the clinical setting of acute cholecystitis, is highly sensitive and specific for acute cholecystitis. A normal

Figure 32-14. Ultrasonography from a patient with acute cholecystitis. The *arrowheads* indicate the thickened gallbladder wall. There are several stones in the gallbladder (*arrows*) throwing acoustic shadows.

HIDA scan excludes acute cholecystitis. CT scan is frequently performed on patients with acute abdominal pain. It demonstrates thickening of the gallbladder wall, pericholecystic fluid, and the presence of gallstones as well as air in the gallbladder wall, but is less sensitive than ultrasonography.

Treatment Patients who present with acute cholecystitis will need IV fluids, antibiotics, and analgesia. The antibiotics should cover gram-negative aerobes as well as anaerobes. A third-generation cephalosporin with good anaerobic coverage or a second-generation cephalosporin combined with metronidazole is a typical regimen. For patients with allergies to cephalosporins, an aminoglycoside with metronidazole is appropriate. Although the inflammation in acute cholecystitis may be sterile in some patients, more than one half will have positive cultures from the gallbladder bile. It is difficult to know who is secondarily infected; therefore, antibiotics have become a part of the management in most medical centers.

Cholecystectomy is the definitive treatment for acute cholecystitis.[36] In the past, the timing of cholecystectomy has been a matter of debate. Early cholecystectomy performed within 2 to 3 days of the illness is preferred over interval or delayed cholecystectomy that is performed 6 to 10 weeks after initial medical treatment and recuperation. Several studies have shown that unless the patient is unfit for surgery, early cholecystectomy should be recommended, as it offers the patient a definitive solution in one hospital admission, quicker recovery times, and an earlier return to work.[37]

Laparoscopic cholecystectomy is the procedure of choice for acute cholecystitis. The conversion rate to an open cholecystectomy is higher (10%–15%) in the setting of acute cholecystitis than with chronic cholecystitis. The procedure is more tedious and takes longer than in the elective setting. However, when compared to the delayed operation, early operation carries a similar complication rate.

When patients present late, after 3 to 4 days of illness, or if they are unfit for surgery, they can be treated with antibiotics with laparoscopic cholecystectomy scheduled for approximately 2 months later. Approximately 20% of patients will fail to respond to initial medical therapy and require an intervention. Laparoscopic cholecystectomy could be attempted, but the conversion rate is high and some prefer to go directly for an open cholecystectomy. For those unfit for surgery, a percutaneous cholecystostomy or an open cholecystostomy under local analgesia can be performed. Failure to improve after cholecystostomy usually is due to gangrene of the gallbladder or perforation. For these patients, surgery is unavoidable. For those who respond after cholecystostomy, the tube can be removed once cholangiography through it shows a patent ductus cysticus. Laparoscopic cholecystectomy may then be scheduled in the near future.[38] For the rare patients who can't tolerate surgery, the stones can be extracted via the cholecystostomy tube before its removal.[39]

Choledocholithiasis. Common bile duct stones may be small or large and single or multiple, and are found in 6% to 12% of patients with stones in the gallbladder. The incidence increases with age. About 20% to 25% of patients above the age of 60 with symptomatic gallstones have stones in the common bile duct as well as in the gallbladder.[40] The vast majority of ductal stones in Western countries are formed within the gallbladder and migrate down the cystic duct to the common bile duct. These are classified as secondary common bile duct stones, in contrast to the primary stones that form in the bile ducts. The secondary stones are usually cholesterol stones, whereas the primary stones are usually of the brown pigment type. The primary stones are associated with biliary stasis and infection and are more commonly seen in Asian populations. The causes of biliary stasis that lead to the development of primary stones include biliary stricture, papillary stenosis, tumors, or other (secondary) stones.

Clinical Manifestations Choledochal stones may be silent and often are discovered incidentally. They may cause obstruction, complete or incomplete, or they may manifest with cholangitis or gallstone pancreatitis. The pain caused by a stone in the bile duct is very similar to that of biliary colic caused by impaction of a stone in the cystic duct. Nausea and vomiting are common. Physical examination may be normal, but mild epigastric or right upper quadrant tenderness as well as mild icterus are common. The symptoms may also be intermittent, such as pain and transient jaundice caused by a stone that temporarily impacts the ampulla but subsequently moves away, acting as a ball valve. A small stone may pass through the ampulla spontaneously with resolution of symptoms. Finally, the stones may become completely impacted, causing severe progressive jaundice. Elevation of serum bilirubin, alkaline phosphatase, and transaminases are commonly seen in patients with bile duct stones. However, in about one third of patients with common bile duct stones, the liver chemistries are normal.

Commonly, the first test, ultrasonography, is useful for documenting stones in the gallbladder (if still present), as well as determining the size of the common bile duct. As stones in the bile ducts tend to move down to the distal part of the common duct, bowel gas can preclude their demonstration on ultrasonography. A dilated common bile duct (>8 mm in diameter) on ultrasonography in a patient with gallstones, jaundice, and biliary pain is highly suggestive of common bile duct stones. Magnetic resonance cholangiography (MRC) provides excellent anatomic detail and has a sensitivity and specificity of 95% and 89%, respectively, at detecting choledocholithiasis >5 mm in diameter.[18] Endoscopic cholangiography is the gold standard for diagnosing common bile duct stones. It has the distinct advantage of providing a therapeutic option at the time of diagnosis. In experienced hands, cannulation of the ampulla of Vater and diagnostic cholangiography are achieved in >90% of cases, with

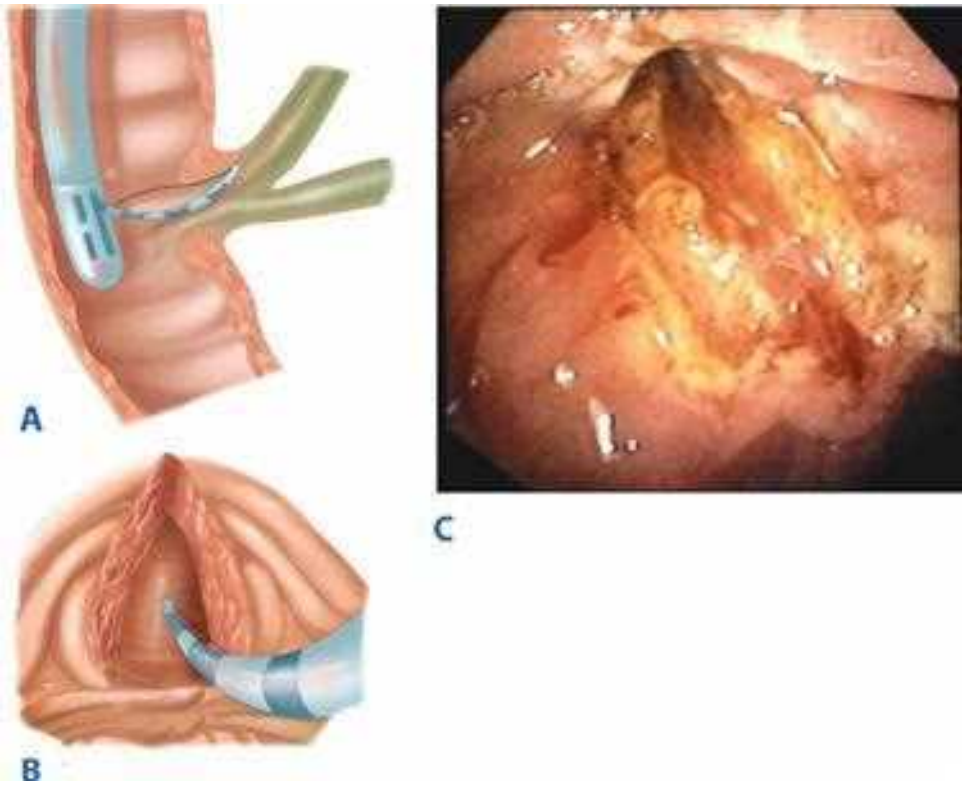

Figure 32-15. An endoscopic sphincterotomy. **A.** The sphincterotome in place. **B.** Completed sphincterotomy. **C.** Endoscopic picture of completed sphincterotomy.

associated morbidity of <5% (mainly cholangitis and pancreatitis). Endoscopic ultrasound has been demonstrated to be as good as ERCP for detecting common bile duct stones (sensitivity of 91% and specificity of 100%), but it lacks therapeutic intervention and requires expertise, making it less available.[41] PTC is rarely needed in patients with secondary common bile duct stones but is frequently performed for both diagnostic and therapeutic reasons in patients with primary bile duct stones.

Treatment For patients with symptomatic gallstones and suspected common bile duct stones, either preoperative endoscopic cholangiography or an intraoperative cholangiogram will document the bile duct stones.[42] If an endoscopic cholangiogram reveals stones, sphincterotomy and ductal clearance of the stones is appropriate, followed by a laparoscopic cholecystectomy. An intraoperative cholangiogram at the time of cholecystectomy will also document the presence or absence of bile duct stones[43] (Fig. 32-15). Laparoscopic common bile duct exploration via the cystic duct or with formal choledochotomy allows the stones to be retrieved in the same setting (see Choledochal Exploration section). If the expertise and/or the instrumentation for laparoscopic common bile duct exploration are not available, a drain should be left adjacent to the cystic duct and the patient scheduled for endoscopic sphincterotomy the following day. An open common bile duct exploration is an option if the endoscopic method has already been tried or is, for some reason, not feasible. If a choledochotomy is performed, a T tube is left in place. Stones impacted in the ampulla may be difficult for both endoscopic ductal clearance as well as common bile duct exploration (open or laparoscopic). In these cases the common bile duct is usually quite dilated (about 2 cm in diameter). A choledochoduodenostomy or a Roux-en-Y choledochojejunostomy may be the best option under this circumstance.[44]

Retained or recurrent stones following cholecystectomy are best treated endoscopically (Fig. 32-16). If the stones were deliberately left in place at the time of surgery or diagnosed shortly after the cholecystectomy, they are classified as *retained*; those diagnosed months or years later are termed *recurrent*. If a common bile duct exploration was performed and a T tube left in place, a T-tube cholangiogram is obtained before its removal. Retained stones can be retrieved either endoscopically or via the T-tube tract once it has matured (2–4 weeks). The T tube is then removed and a catheter passed through the tract into the common bile duct. Under fluoroscopic guidance, the stones are retrieved with baskets or balloons. Recurrent stones may be multiple and large. A generous endoscopic sphincterotomy will allow stone retrieval as well as spontaneous passage of retained and recurrent stones. Patients >70 years old presenting with bile duct stones should have their ductal stones cleared endoscopically. Studies comparing surgery to endoscopic treatment have documented less morbidity and mortality for endoscopic treatment in this group of patients.[45] They do not need to be submitted for a cholecystectomy, as only about 15% will become symptomatic from their gallbladder stones, and such patients can be treated as the need arises by a cholecystectomy.[46]

Cholangitis. Cholangitis is one of the two main complications of choledochal stones, the other being gallstone pancreatitis. Acute cholangitis is an ascending bacterial infection in association with partial or complete obstruction of the bile ducts. Hepatic bile is sterile, and bile in the bile ducts is kept sterile by continuous bile flow and by the presence of antibacterial substances in bile, such as immunoglobulin. Mechanical hindrance to bile flow facilitates bacterial contamination. Positive bile cultures are common in the presence of bile duct stones as well as with other causes of obstruction. Biliary bacterial contamination alone does not lead to clinical cholangitis; the combination of both significant bacterial contamination and biliary obstruction is required for its development. Gallstones are the most common cause of obstruction in cholangitis; other causes are benign

B

Figure 32-16. Retained common bile duct stones. The patient presented 3 weeks after laparoscopic cholecystectomy. **A.** An ultrasound shows a normal or mildly dilated common bile duct with a stone. Note the location of the right hepatic artery anterior to the common hepatic duct (an anatomic variation). **B.** An endoscopic retrograde cholangiography from the same patient shows multiple stones in the common bile duct. Only the top one showed on ultrasound as the other stones lie in the distal common bile duct behind the duodenum.

and malignant strictures, parasites, instrumentation of the ducts and indwelling stents, and partially obstructed biliary-enteric anastomosis. The most common organisms cultured from bile in patients with cholangitis include *Escherichia coli*, *Klebsiella pneumoniae*, *Streptococcus faecalis*, *Enterobacter*, and *Bacteroides fragilis*.[47]

Clinical Presentation Cholangitis may present as anything from a mild, intermittent, and self-limited disease to a fulminant, potentially life-threatening septicemia. The patient with gallstone-induced cholangitis is typically older and female. The most common presentation is fever, epigastric or right upper quadrant pain, and jaundice. These classic symptoms, well known as *Charcot's triad*, are present in about two thirds of patients. The illness may progress rapidly with septicemia and disorientation, known as *Reynolds' pentad* (e.g., fever, jaundice, right upper quadrant pain, septic shock, and mental status changes). However, the presentation may be atypical, with little if any fever, jaundice, or pain. This occurs most commonly in the elderly, who may have unremarkable symptoms until they collapse with septicemia. Patients with indwelling stents rarely become jaundiced. On abdominal examination, the findings are indistinguishable from those of acute cholecystitis.[48]

Diagnosis and Management Leukocytosis, hyperbilirubinemia, and elevation of alkaline phosphatase and transaminases are common and, when present, support the clinical diagnosis of cholangitis. Ultrasonography is helpful, as it will document the presence of gallbladder stones, demonstrate dilated ducts, and possibly pinpoint the site of obstruction; however, rarely will it elucidate the exact cause. The definitive diagnostic test is ERC. In cases in which ERC is not available, PTC is indicated. Both ERC and PTC will show the level and the reason for the obstruction, allow culture of the bile, possibly allow the removal of stones if present, and allow drainage of the bile ducts with drainage catheters or stents. CT scanning and MRI will show pancreatic and periampullary masses, if present, in addition to the ductal dilatation.

The initial treatment of patients with cholangitis includes IV antibiotics and fluid resuscitation. These patients may require intensive care unit monitoring and vasopressor support. Most patients will respond to these measures. However, the obstructed bile duct must be drained as soon as the patient has been stabilized. About 15% of patients will not respond to antibiotics and fluid resuscitation, and an emergency biliary decompression may be required. Biliary decompression may be accomplished endoscopically, via the percutaneous transhepatic route, or surgically. The selection of procedure should be based on the level and the nature of the biliary obstruction. Patients with choledocholithiasis or periampullary malignancies are best approached endoscopically, with sphincterotomy and stone removal, or by placement of an endoscopic biliary stent.[49] In patients in whom the obstruction is more proximal or perihilar, or when a stricture in a biliary-enteric anastomosis is the cause or the endoscopic route has failed, percutaneous transhepatic drainage is used. When neither ERC nor PTC is available, an emergent operation for decompression of the common bile duct with a T tube may be necessary and lifesaving. Definitive operative therapy should be deferred until the cholangitis has been treated and the proper diagnosis established. Patients with indwelling stents and cholangitis usually require repeated imaging and exchange of the stent over a guidewire.

Acute cholangitis is associated with an overall mortality rate of approximately 5%. When associated with renal failure, cardiac impairment, hepatic abscesses, and malignancies, the morbidity and mortality rates are much higher.

Biliary Pancreatitis. Gallstones in the common bile duct are associated with acute pancreatitis. Obstruction of the pancreatic duct by an impacted stone or temporary obstruction by a stone passing through the ampulla may lead to pancreatitis. The exact mechanism by which the obstruction of the pancreatic duct leads to pancreatitis is still not clear. An ultrasonogram of the biliary tree in patients with pancreatitis is essential. If gallstones are present and the pancreatitis is severe, an ERC with sphincterotomy and stone extraction may abort the episode of pancreatitis. Once the pancreatitis has subsided, the gallbladder should be removed during the same admission. When gallstones are present and the pancreatitis is mild and self-limited, the stone has probably passed. For these patients, a cholecystectomy and an intraoperative cholangiogram or a preoperative ERC is indicated.

Cholangiohepatitis

Cholangiohepatitis, also known as *recurrent pyogenic cholangitis*, is endemic to the Orient. It also has been encountered in the Chinese population in the United States, as well as in Europe and Australia. It affects both sexes equally and occurs most frequently in the third and fourth decades of life. Cholangiohepatitis is caused by bacterial contamination (commonly *E. coli*, *Klebsiella* species, *Bacteroides* species, or *Enterococcus faecalis*) of the biliary tree, and often is associated with biliary parasites such as *Clonorchis sinensis*, *Opisthorchis viverrini,* and *Ascaris lumbricoides*. Bacterial enzymes cause deconjugation of bilirubin, which precipitates as bile sludge. The sludge and dead bacterial cell bodies form brown pigment stones. The nucleus of the stone may contain an adult *Clonorchis* worm, an ovum, or an ascarid. These stones are formed throughout the biliary tree and cause partial obstruction that contributes to the repeated bouts of cholangitis. Biliary strictures form as a result of recurrent cholangitis and lead to further stone formation, infection, hepatic abscesses, and liver failure (secondary biliary cirrhosis).[50]

The patient usually presents with pain in the right upper quadrant and epigastrium, fever, and jaundice. Recurrence of symptoms is one of the most characteristic features of the disease. The episodes may vary in severity but, without intervention, will gradually lead to malnutrition and hepatic insufficiency. An ultrasound will detect stones in the biliary tree, pneumobilia from infection due to gas-forming organisms, liver abscesses, and, occasionally, strictures. The gallbladder may be thickened but is inflamed in about 20% of patients and rarely contains stones. MRCP and PTC are the mainstays of biliary imaging for cholangiohepatitis. They can detect obstructions, define strictures and stones, and allow emergent decompression of the biliary tree in the septic patient. Hepatic abscesses may be drained percutaneously. The long-term goal of therapy is to extract stones and debris and relieve strictures. It may take several procedures and require a Roux-en-Y hepaticojejunostomy to establish biliary-enteric continuity. Occasionally, resection of involved areas of the liver may offer the best form of treatment. Recurrences are common and the prognosis is poor once hepatic insufficiency has developed.[51]

OPERATIVE INTERVENTIONS FOR GALLSTONE DISEASE

Cholecystostomy

A cholecystostomy decompresses and drains the distended, inflamed, hydropic, or purulent gallbladder. It is applicable if the patient is not fit to tolerate an abdominal operation.[52] Ultrasound-guided percutaneous drainage with a pigtail catheter is the procedure of choice. The catheter is inserted over a guidewire that has been passed through the abdominal wall, the liver, and into the gallbladder (Fig. 32-17). By passing the catheter through the liver, the risk of bile leak around the catheter is minimized.[53] The catheter can be removed when the inflammation has resolved and the patient's condition improved. The gallbladder can be removed later, if indicated, usually by laparoscopy. Surgical cholecystostomy with a large catheter placed under local anesthesia is rarely required today.

Cholecystectomy

Cholecystectomy is the most common major abdominal procedure performed in Western countries. Carl Langenbuch performed the first successful cholecystectomy in 1882, and for >100 years, it was the standard treatment for symptomatic gallbladder stones. Open cholecystectomy was a safe and effective treatment for both acute and chronic cholecystitis. In 1987, laparoscopic cholecystectomy was introduced by Philippe Mouret in France and quickly revolutionized the treatment of gallstones. It not only supplanted open cholecystectomy, but also more or less ended attempts for noninvasive management of gallstones, such as extracorporeal shock wave and bile salt therapy. Laparoscopic cholecystectomy offers a cure for gallstones with a minimally invasive procedure, minor pain and scarring, and early return to full activity. Today, laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones.

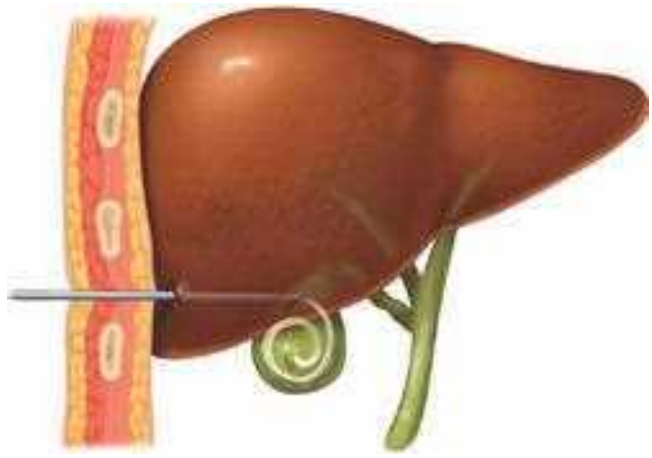

Figure 32-17. Percutaneous cholecystostomy. A pigtail catheter has been placed through the abdominal wall, the right lobe of the liver, and into the gallbladder.

Absolute contraindications for the procedure are uncontrolled coagulopathy and end-stage liver disease. In the latter instance, liver transplantation, with cholecystectomy, may be used for treatment of severe recurrent gallstone disease. Rarely, patients with severe obstructive pulmonary disease or congestive heart failure (e.g., cardiac ejection fraction <20%) may not tolerate pneumoperitoneum with carbon dioxide and require open cholecystectomy. Conditions formerly believed to be relative contraindications such as acute cholecystitis, gangrene and empyema of the gallbladder, biliary-enteric fistulae, obesity, pregnancy, ventriculoperitoneal shunt, cirrhosis, and previous upper abdominal procedures are now considered risk factors for a potentially difficult laparoscopic cholecystectomy. When important anatomic structures cannot be clearly identified or when no progress is made over a set period of time, a conversion to an open procedure is usually indicated. In the elective setting, conversion to an open procedure is needed in about 5% of patients.[54] Emergent procedures may require more skill on the part of the surgeon and be needed in patients with complicated gallstone disease; the incidence of conversion is 10% to 30%. Conversion to an open procedure is not a failure, and the possibility should be discussed with the patient preoperatively.

Serious complications are rare. The mortality rate for laparoscopic cholecystectomy is about 0.1%. Wound infection and cardiopulmonary complication rates are considerably lower following laparoscopic cholecystectomy than are those for an open procedure. However, laparoscopic cholecystectomy is associated with a higher injury rate to the bile ducts (see later section, Injury to the Biliary Tract).[55]

Patients undergoing cholecystectomy should have a complete blood count and liver function tests preoperatively. Prophylaxis against deep venous thrombosis with either low molecular weight heparin or compression stockings is indicated. The patient should be instructed to empty their bladder before coming to the operating room. Urinary catheters are rarely needed. An orogastric tube is placed if the stomach is distended with gas and is removed at the end of the operation.

Laparoscopic Cholecystectomy. The patient is placed supine on the operating table with the surgeon standing at the patient's left side. Some surgeons prefer to stand between the patient's legs while doing laparoscopic procedures in the upper abdomen. The pneumoperitoneum is created with carbon dioxide gas, either with an open technique or by closed needle technique. Initially, a small incision is made in the upper edge of the umbilicus. With the closed technique, a special hollow insufflation needle (Veress needle) that is spring-loaded with a retractable cutting outer sheath is inserted into the peritoneal cavity and used for insufflation. Once an adequate pneumoperitoneum is established, a 10-mm trocar is inserted through the supraumbilical incision. With the open technique, the supraumbilical incision is carried through the fascia and into the peritoneal cavity. A special blunt cannula (Hasson cannula) is inserted into the peritoneal cavity and anchored to the fascia. The laparoscope with the attached video camera is passed through the umbilical port and the abdomen inspected. Three additional ports are placed under direct vision (Fig. 32-18). A 10-mm port is placed in the epigastrium, a 5-mm port in the middle of the clavicular line, and a 5-mm port in the right flank, in line with the gallbladder fundus. Occasionally, a fifth port is required for better visualization in patients recovering from pancreatitis or those with semi-acute cholecystitis, as well as in very obese patients.

Through the lateral-most port, a grasper is used to grasp the gallbladder fundus. It is retracted over the liver edge upward and toward the patient's right shoulder to expose the proximal gallbladder and the hilar area. Exposure of the hilar area may be facilitated by placing the patient in reverse Trendelenburg position with slight tilting of the table to bring the right side up. Through the midclavicular port a second grasper is used to grasp the gallbladder infundibulum and retract it laterally to expose the triangle of Calot. Before this, it may be necessary to take down any adhesions between the omentum, duodenum, or colon, and the gallbladder. Most of the dissection is carried out through the epigastric port using a dissector, hook cautery, or scissors.

The dissection starts at the junction of the gallbladder and the cystic duct. A helpful anatomic landmark is the cystic artery lymph node. The peritoneum, fat, and loose areolar tissue around the gallbladder and the cystic duct–gallbladder junction is dissected off toward the bile duct. This is continued until the gallbladder neck and the proximal cystic duct are clearly identified. The next step is the identification of the cystic artery, which usually runs parallel to and somewhat behind the cystic duct. A hemoclip is placed on the proximal cystic duct. If an intraoperative cholangiogram is to be performed, a small incision is made on the anterior surface of the cystic duct, just proximal to the clip, and a cholangiogram catheter is passed into the cystic duct. Once the cholangiogram is completed, the catheter is removed and two clips are placed proximal to the incision, and the cystic duct is divided. A wide cystic duct may be too big for clips, requiring the placement of a pre-tied loop ligature to close. The cystic artery is then clipped and divided.

Finally, the gallbladder is dissected out of the gallbladder fossa, using either a hook or scissors with electrocautery. Before the gallbladder is removed from the liver edge, the operative field is carefully searched for bleeding points, and the placement of the clips on the cystic duct and cystic artery is inspected. The gallbladder is removed through the umbilical incision. The fascial defect and skin incision may need to be enlarged if the stones are large. If the gallbladder is acutely inflamed or gangrenous, or if the gallbladder is perforated, it is placed in a retrieval bag before it is removed from the abdomen. Any bile or blood that has accumulated during the procedure is sucked away, and if stones were spilled, they are retrieved, placed inside a retrieval bag, and removed. If the gallbladder was severely inflamed or gangrenous or if any bile or blood is expected to accumulate, a closed-suction drain can be placed through one of the 5-mm ports and left underneath the right liver lobe close to the gallbladder fossa.

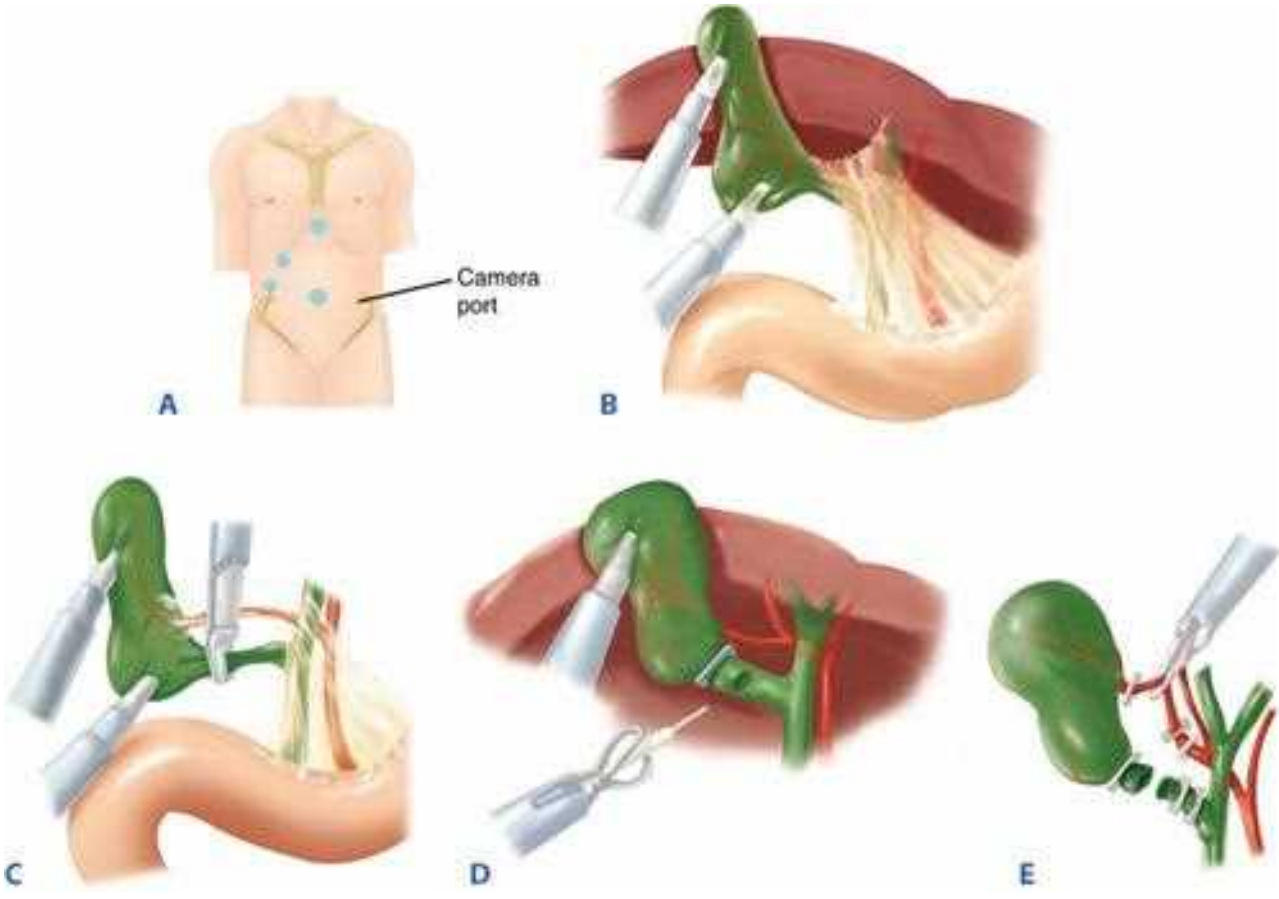
Open Cholecystectomy. The same surgical principles apply for laparoscopic and open cholecystectomies. Open cholecystectomy has become an uncommon procedure, usually performed either as a conversion from laparoscopic cholecystectomy or as a second procedure in patients who require laparotomy for another reason. After the cystic artery and cystic duct have been identified, the gallbladder is dissected free from the liver bed, starting at the fundus. The dissection is carried proximally toward the cystic artery and the cystic duct, which are then ligated and divided.

Intraoperative Cholangiogram or Ultrasound. The bile ducts are visualized under fluoroscopy by injecting contrast through a catheter placed in the cystic duct (Fig. 32-19A). Their size can then be evaluated, the presence or absence of common bile duct stones assessed, and filling defects confirmed, as the dye passes into the duodenum. Routine intraoperative cholangiography will detect stones in approximately 7% of patients, as well as outlining the anatomy and detecting injury[56,57] (Fig. 32-19B). A selective intraoperative cholangiogram can be performed when the patient has a history of abnormal liver function tests, pancreatitis, jaundice, a large duct and small stones, a dilated duct on preoperative ultrasonography, and if preoperative endoscopic cholangiography for the above reasons was unsuccessful. Laparoscopic ultrasonography is as accurate as intraoperative cholangiography in detecting common bile duct stones, and it is less invasive; however, it requires more skill to perform and interpret.[58,59]

Common Bile Duct Exploration

Common bile duct stones that are detected intraoperatively on intraoperative cholangiography or ultrasonography may be managed with laparoscopic choledochal exploration as a part of the laparoscopic cholecystectomy procedure. Patients with common bile duct stones detected preoperatively, but in whom endoscopic clearance was either not available or unsuccessful, should also have their ductal stones managed during the cholecystectomy.

If the stones in the duct are small, they may sometimes be flushed into the duodenum with saline irrigation via the cholangiography catheter after the sphincter of Oddi has been relaxed with glucagon. If irrigation is unsuccessful, a balloon catheter may be passed via the cystic duct and down the common bile duct, where it is inflated and withdrawn to retrieve the stones. The next attempt is usually made with a wire basket passed



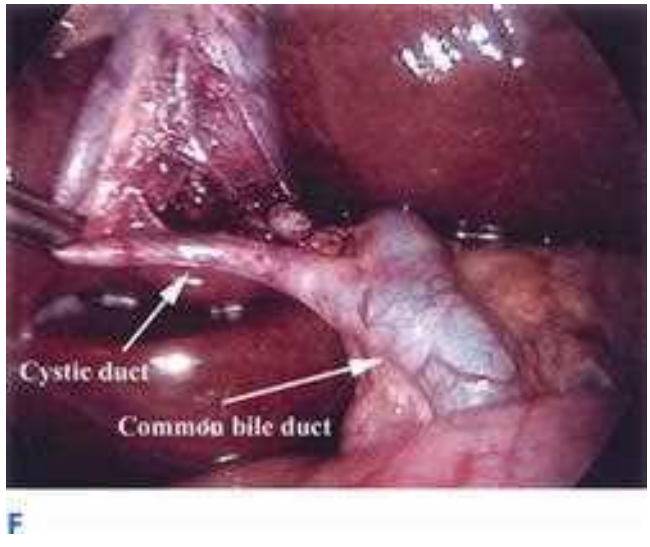


Figure 32-18. Laparoscopic cholecystectomy. **A.** The trocar placement. **B.** The fundus has been grasped and retracted cephalad to expose the proximal gallbladder and the hepatoduodenal ligament. Another grasper retracts the gallbladder infundibulum posterolaterally to better expose the triangle of Calot (hepatocystic triangle bound by the common hepatic duct, cystic duct, and liver margin). **C.** The triangle of Calot has been opened and the neck of the gallbladder and part of the cystic duct dissected free. A clip is being placed on the cystic duct–gallbladder junction. **D.** A small opening has been made into the cystic duct, and a cholangiogram catheter is to be inserted. **E.** The cystic duct has been divided, and the cystic artery is being divided. **F.** An intraoperative picture showing a grasper pulling the infundibulum of the gallbladder laterally, exposing the triangle of Calot that has been dissected. The cystic artery can be seen crossing the dissected area upward and to the left.

under fluoroscopic guidance to catch the stones (Fig. 32-20). If needed, a flexible choledochoscope is the next step. The cystic duct may have to be dilated to allow its passage. Once in the common bile duct, the stones may be caught into a wire basket under direct vision or pushed into the duodenum. When the duct has been cleared, the cystic duct is ligated and cut and the cholecystectomy completed. Occasionally, a choledochotomy, an incision into the common bile duct itself, is necessary. The flexible choledochoscope is then passed into the duct for visualization and clearance of stones. The choledochotomy is sutured

Figure 32-19. **A.** An intraoperative cholangiogram. The bile ducts are of normal size, with no intraluminal filling defects. The left and the right hepatic ducts are visualized, the distal common bile duct tapers down, and the contrast empties into the duodenum. Cholangiography grasper that holds the catheter and the cystic duct stump partly projects over the common hepatic duct. **B.** An intraoperative cholangiogram showing common bile duct stone (*arrow*). A small amount of contrast has passed into the duodenum.

with a T tube left in the common bile duct with one end taken out through the abdominal wall for decompression of the bile ducts. By managing common bile duct stones at the time of the cholecystectomy, the patients can have all of their gallstone disease treated with one invasive procedure. It does, however, depend on the available surgical expertise.[60]

Common Bile Duct Drainage Procedures

Rarely, when the stones cannot be cleared and/or when the duct is very dilated (>1.5 cm in diameter), a choledochal drainage procedure is performed (Fig. 32-21). Choledochoduodenostomy is performed by mobilizing the second part of the duodenum (a Kocher maneuver) and anastomosing it side to side with the common bile duct.

A choledochojejunostomy is done by bringing up a 45-cm Roux-en-Y limb of jejunum and anastomosing it end to side to the common bile duct.

Choledochojejunostomy or, more often, a hepaticojejunostomy, also can be used to repair common bile duct strictures or as a palliative procedure for malignant obstruction in the periampullary region. If the common bile duct has been transected or injured, it can be managed by an end-to-end choledochojejunostomy.

Transduodenal Sphincterotomy

In the majority of cases, endoscopic sphincterotomy has replaced open transduodenal sphincterotomy. If an open procedure for common bile duct stones is being done in which the stones are impacted, recurrent, or multiple, the transduodenal approach may be feasible. The duodenum is incised transversely. The sphincter then is incised at the 11 o'clock position to avoid injury to the pancreatic duct. The impacted stones are removed, as are large stones from the duct. There is no need to fully clear the duct of stones, as they can pass spontaneously through the cut sphincter.

OTHER BENIGN DISEASES AND LESIONS

Acalculous Cholecystitis

Acute inflammation of the gallbladder can occur without gallstones. Acalculous cholecystitis typically develops in critically ill patients in the intensive care unit. Patients on parenteral nutrition with extensive burns, sepsis, major operations, multiple trauma, or prolonged illness with multiple organ system failure are at risk for developing acalculous cholecystitis. The cause is unknown, but gallbladder distention with bile stasis and ischemia has been implicated as causative factors. Pathologic examination of the gallbladder wall reveals edema of the serosa and muscular layers, with patchy thrombosis of arterioles and venules.[61,62]

The symptoms and signs depend on the condition of the patient, but in the alert patient, they are similar to acute calculous cholecystitis, with right upper quadrant pain and tenderness, fever, and leukocytosis. In the sedated or unconscious patient, the clinical features are often masked, but fever and elevated WBC count, as well as elevation of alkaline phosphatase and bilirubin, are indications for further investigation.

Ultrasonography is usually the diagnostic test of choice, as it can be done bedside in the intensive care unit. It can demonstrate the distended gallbladder with thickened wall, biliary sludge, pericholecystic fluid, and the presence or absence of abscess formation. Abdominal CT scan can aid in the diagnosis of acalculous cholecystitis and additionally allows imaging of the abdominal cavity and chest to rule out other sources of infection. A HIDA scan can be useful and will show nonvisualization of

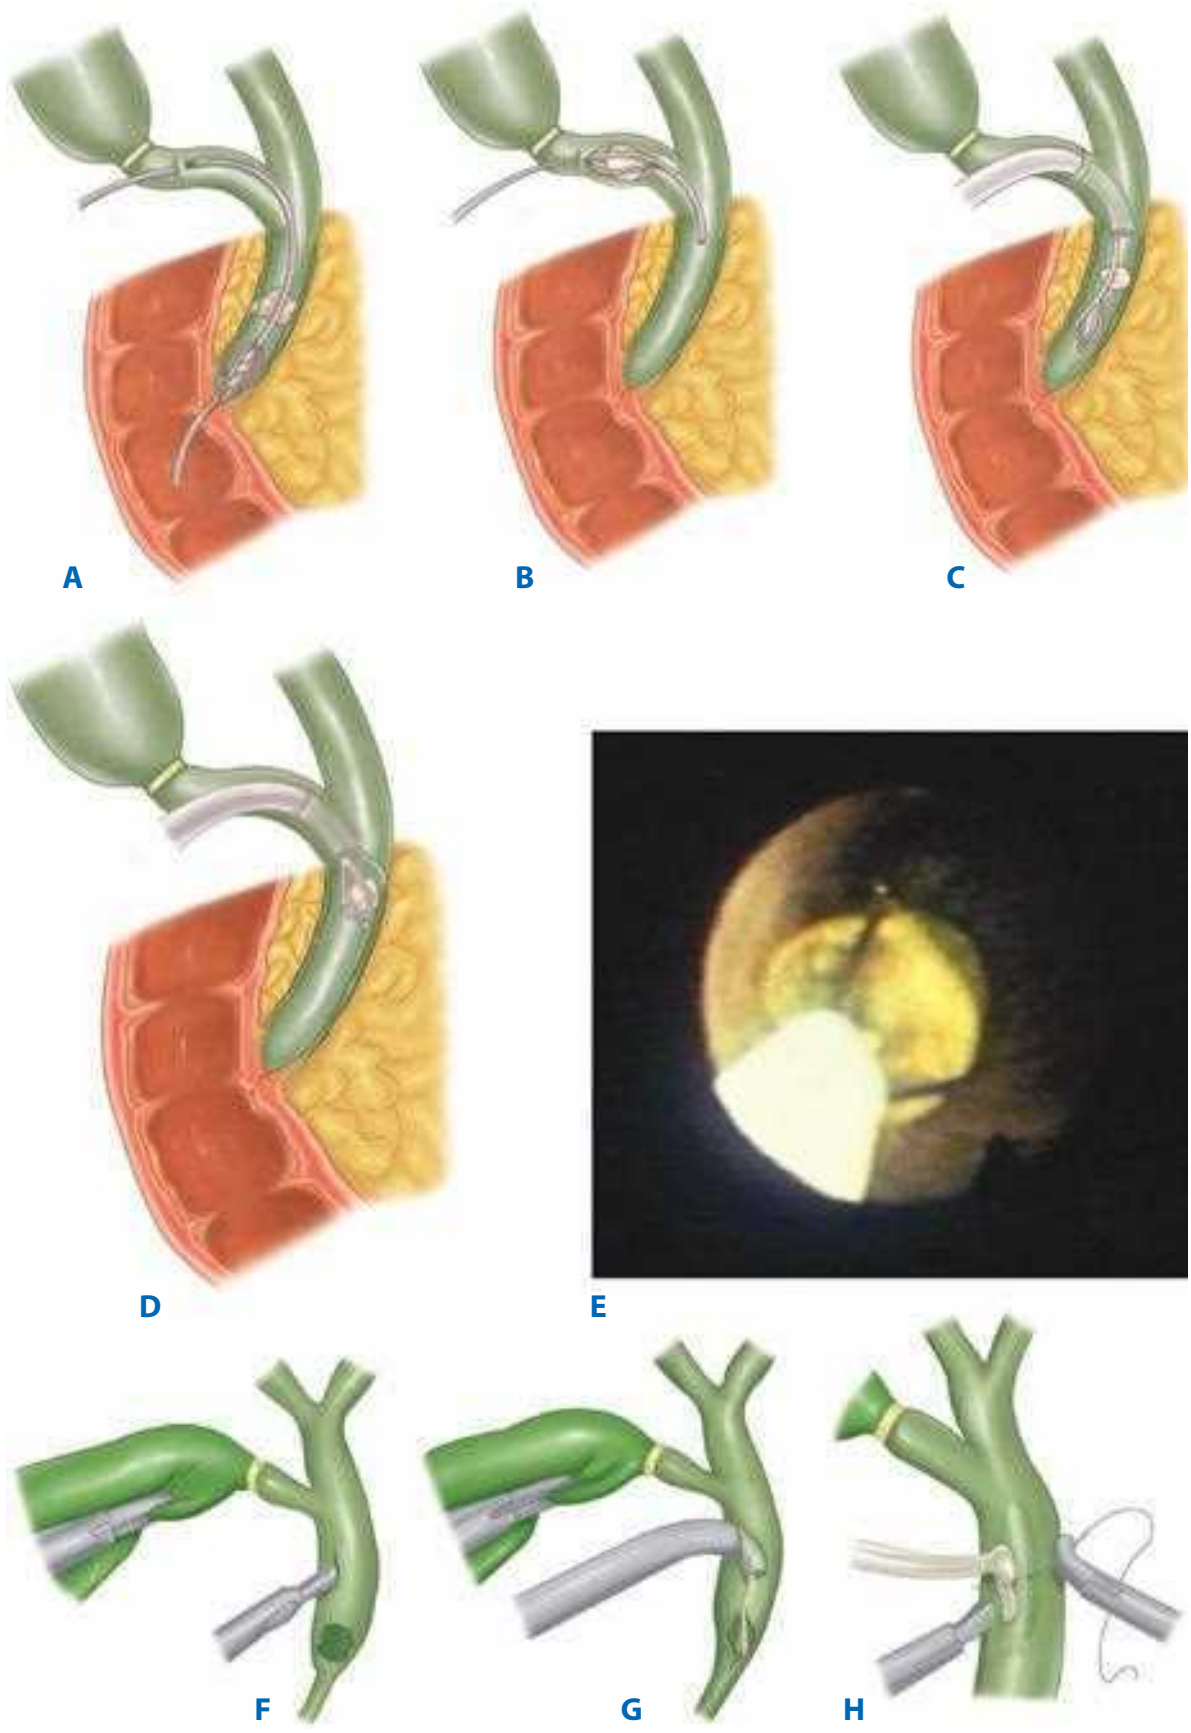

Figure 32-20. Laparoscopic bile duct exploration. I. the gallbladder, but it is a less sensitive test with high false-positive rates in patients who are fasting, on total parenteral nutrition, or have liver disease.[63] Acalculous cholecystitis requires urgent intervention. Percutaneous ultrasound- or CT-guided cholecystostomy is the treatment of choice for these patients, as they are usually unfit for surgery (see Fig. 32-17). If the diagnosis is uncertain, percutaneous cholecystostomy is both diagnostic and therapeutic. About 90% of patients will improve with the percutaneous cholecystostomy. However, if they do not improve, other steps, such as open cholecystostomy or cholecystectomy, may be required. If needed, cholecystectomy is performed after the patient has recovered from the underlying disease.

Biliary Cysts

Choledochal cysts are congenital cystic dilatations of the extrahepatic and/or intrahepatic biliary tree. They are rare—the incidence is between 1:100,000 and 1:150,000 in populations of Western countries—but are more commonly seen in populations of Eastern countries. Choledochal cysts affect females three to eight times more often than males. Although frequently diagnosed in infancy or childhood, as many as one half of the patients have reached adulthood when diagnosed. The cause is unknown. Weakness of the bile duct wall and increased pressure secondary to partial biliary obstruction are required for biliary cyst formation. More than 90% of patients have an anomalous pancreaticobiliary duct junction, with the pancreatic duct joining the common bile duct >1 cm proximal to the ampulla. This results in a long common channel that may allow free reflux of pancreatic secretions into the biliary tract, leading to inflammatory changes, increased biliary pressure, and cyst formation. Choledochal cysts are classified into five types (Fig. 32-22). The cysts are lined with cuboidal epithelium and can vary in size from 2 cm in diameter to giant cysts.

Adults commonly present with jaundice or cholangitis. Less than one half of patients present with the classic clinical triad of abdominal pain, jaundice, and a mass. Ultrasonography or CT scanning will confirm the diagnosis, but endoscopic cholangiography, transhepatic cholangiography, or MRC is required to assess the biliary anatomy and to plan the appropriate surgical treatment. For types I, II, and IV, excision of the extrahepatic biliary tree, including cholecystectomy, with a Roux-en-Y hepaticojejunostomy is ideal. In type IV, additional segmental resection of the liver may be appropriate, particularly if intrahepatic stones, strictures, or abscesses are present or if the dilatations are confined to one lobe. The risk of cholangiocarcinoma developing in choledochal cysts is as high as 15% in adults and supports complete excision when they are diagnosed. For type III, sphincterotomy is recommended.[64]

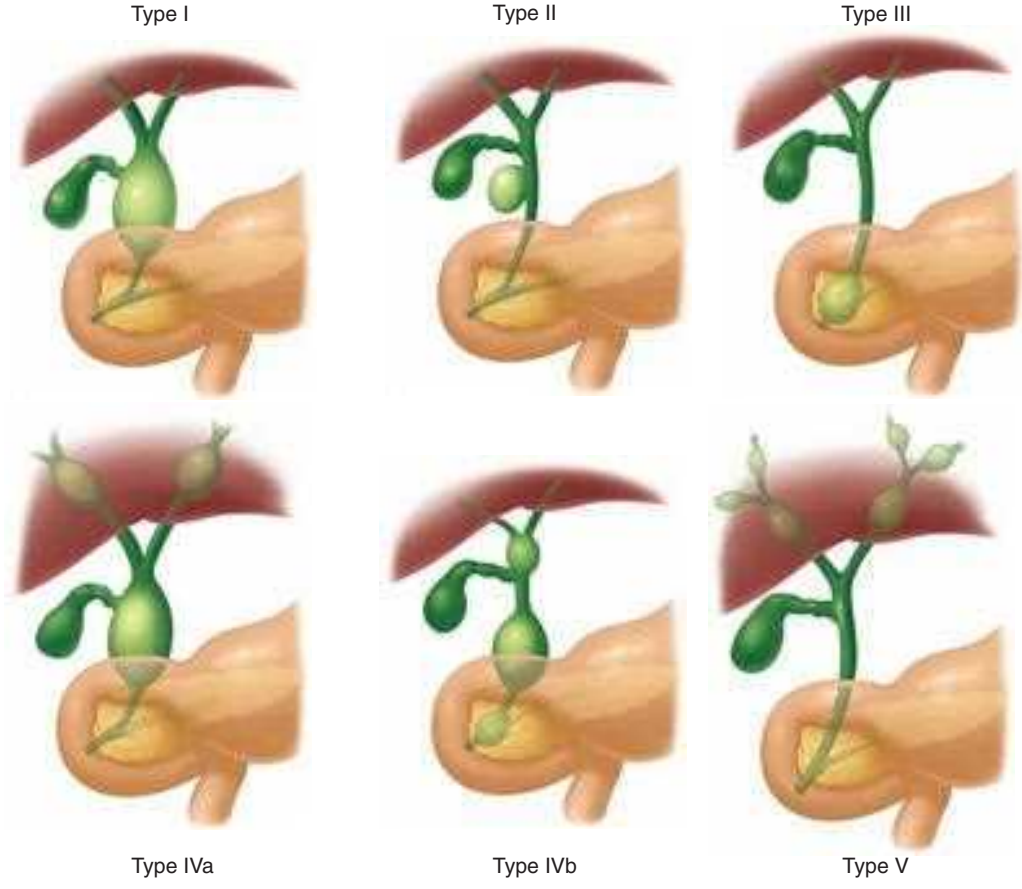

Figure 32-22. Classification of choledochal cysts. Type I, fusiform or cystic dilations of the extrahepatic biliary tree, is the most common type, making up >50% of the choledochal cysts. Type II, saccular diverticulum of an extrahepatic bile duct. Rare, <5% of choledochal cysts. Type III, bile duct dilatation within the duodenal wall (choledochoceles), makes up about 5% of choledochal cysts. Types IVa and IVb, multiple cysts, make up 5% to 10% of choledochal cysts. Type IVa affects both extrahepatic and intrahepatic bile ducts, whereas type IVb cysts affect the extrahepatic bile ducts only. Type V, intrahepatic biliary cysts, is very rare and makes up 1% of choledochal cysts.

Sclerosing Cholangitis

Sclerosing cholangitis is an uncommon disease characterized by inflammatory strictures involving the intrahepatic and extrahepatic biliary tree. It is a progressive disease that eventually results in secondary biliary cirrhosis. Sometimes, biliary strictures are clearly secondary to bile duct stones, acute cholangitis, previous biliary surgery, or toxic agents, and are termed *secondary sclerosing cholangitis*. However, primary sclerosing cholangitis is a disease entity of its own, with no known attributing cause. It is associated with ulcerative colitis in about two thirds of patients. Other diseases associated with sclerosing cholangitis include Riedel's thyroiditis and retroperitoneal fibrosis. Autoimmune reaction, chronic low-grade bacterial or viral infection, toxic reaction, and genetic factors have all been suggested to play a role in its pathogenesis. The human leukocyte antigen haplotypes HLA-B8, -DR3, -DQ2, and -DRw52A, commonly found in patients with autoimmune diseases, also are more frequently seen in patients with sclerosing cholangitis than in controls. Patients with sclerosing cholangitis are at risk for developing cholangiocarcinoma. Eventually, 10% to 20% of the patients will develop cancer. Cholangiocarcinoma can present at any time during the disease process and does not correlate with the extent of sclerosing cholangitis or the development of liver failure, but frequently follows an aggressive course.

The mean age of presentation is 30 to 45 years, and men are affected twice as commonly as women. The usual presentation is intermittent jaundice, fatigue, weight loss, pruritus, and abdominal pain. Symptoms of acute cholangitis are rare, without preceding biliary tract intervention or surgery. More than one half of patients are symptomatic when diagnosed. In several patients with ulcerative colitis, abnormal liver function tests found on routine testing lead to the diagnosis. The clinical course in sclerosing cholangitis is highly variable, but cyclic remissions and exacerbations are typical. However, some patients remain asymptomatic for years, while others progress rapidly with the obliterative inflammatory changes leading to secondary biliary cirrhosis and liver failure. In patients with associated ulcerative colitis, the course of each disease seems independent of the other. Colectomy for the colitis makes no difference to the course of primary sclerosing cholangitis. The median survival for patients with primary sclerosing cholangitis from the time of diagnosis ranges from 10 to 12 years, and most die from hepatic failure.[65]

The clinical presentation and elevation of alkaline phosphatase and bilirubin may suggest the diagnosis, but ERC, revealing multiple dilatations and strictures (beading) of both the intra- and extrahepatic biliary tree, confirms it. The hepatic duct bifurcation is often the most severely affected segment. A liver biopsy may not be diagnostic, but is important to determine the degree of hepatic fibrosis and the presence of cirrhosis. Sclerosing cholangitis is followed by ERC and liver biopsies to provide appropriate management.

There is no known effective medical therapy for primary sclerosing cholangitis and no known curative treatment. Corticosteroids, immunosuppressants, ursodeoxycholic acid, and antibiotics have been disappointing. Biliary strictures can be dilated and stented either endoscopically or percutaneously. These measures have given short-term improvements in symptoms and serum bilirubin levels and long-term improvements in only less than one half of the patients. Surgical management with resection of the extrahepatic biliary tree and hepaticojejunostomy has produced reasonable results in patients with extrahepatic and bifurcation strictures, but without cirrhosis or significant hepatic fibrosis.[66] In patients with sclerosing cholangitis and advanced liver disease, liver transplantation is the only option. It offers excellent results, with overall 5-year survival as high as 85%. Primary sclerosing cholangitis recurs in 10% to 20% of patients and may require retransplantation.[67,68]

Stenosis of the Sphincter of Oddi

A benign stenosis of the outlet of the common bile duct is usually associated with inflammation, fibrosis, or muscular hypertrophy. The pathogenesis is unclear, but trauma from the passage of stones, sphincter motility disorders, and congenital anomalies have been suggested. Episodic pain of the biliary type with abnormal liver function tests is a common presentation. However, recurrent jaundice or pancreatitis also may play a role. A dilated common bile duct that is difficult to cannulate with delayed emptying of the contrast are useful diagnostic features. Ampullary manometry and special provocation tests are available in specialized units. If the diagnosis is well established, endoscopic or operative sphincterotomy will yield good results.[69]

Bile Duct Strictures

Benign bile duct strictures can have numerous causes. However, the vast majority were caused by operative injury, most commonly by laparoscopic cholecystectomy (see later section, Injury to the Biliary Tract). Other causes include fibrosis due to chronic pancreatitis, common bile duct stones, acute cholangitis, biliary obstruction due to cholecystolithiasis (Mirizzi's syndrome), sclerosing cholangitis, cholangiohepatitis, and strictures of a biliary-enteric anastomosis. Bile duct strictures that go unrecognized or are improperly managed may lead to recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension.[70]

Patients with bile duct strictures most commonly present with episodes of cholangitis. Less commonly, they may present with jaundice without evidence of infection. Liver function tests usually show evidence of cholestasis. An ultrasound or a CT scan will show dilated bile ducts proximal to the stricture, as well as provide some information about the level of the stenosis. MRC will also provide good anatomic information about the location and the degree of dilatation. In patients with intrahepatic ductal dilatation, a percutaneous transhepatic cholangiogram will outline the proximal biliary tree, define the stricture and its location, and allow decompression of the biliary tree with transhepatic catheters or stents (Fig. 32-23). An endoscopic cholangiogram will outline the distal bile duct. Treatment depends on the location and the cause of the stricture. Percutaneous or endoscopic dilatation and/or stent placement give good results in more than one half of patients. Surgery with Roux-en-Y choledochojejunostomy or hepaticojejunostomy is the standard of care with good or excellent results in 80% to 90% of patients.[71] Choledochoduodenostomy may be a choice for strictures in the distal-most part of the common bile duct.

INJURY TO THE BILIARY TRACT

Gallbladder

Injuries to the gallbladder are uncommon. Penetrating injuries are usually caused by gunshot wounds or stab wounds, and rarely by a needle biopsy procedure of the liver. Nonpenetrating trauma is extremely rare. These types of injury to the gallbladder include contusion, avulsion, laceration, rupture, and

Figure 32-23. An endoscopic retrograde cholangiography showing stricture of the common hepatic duct (*arrow*). The patient had recently had a laparoscopic cholecystectomy; clips from the operation can be seen projected over the common bile duct.

traumatic cholecystitis. The treatment of choice is cholecystectomy, and the prognosis is directly related to the type and incidence of associated injury.

Extrahepatic Bile Ducts

Penetrating trauma to the extrahepatic bile ducts is rare and is usually associated with trauma to other viscera. The great majority of injuries of the extrahepatic biliary duct system are iatrogenic, occurring in the course of laparoscopic or open cholecystectomies.[72] Less commonly, biliary injury is associated with common bile duct exploration, division or mobilization of the duodenum during gastrectomy, and dissection of the hepatic hilum during liver resections. The exact incidence of bile duct injury during cholecystectomy is unknown, but data suggest that during open cholecystectomy, the incidence is relatively low (about 0.1% to 0.2%). However, the incidence during laparoscopic cholecystectomy, as derived from state and national databases, estimates the rate of major injury to range between 0.1% to 0.55%, and the incidence of minor injuries and bile leaks to be about 0.3%, a total of 0.85%. Limited view, difficult orientation and assessment of depth on a two-dimensional image, and the lack of tactile sensation and unusual manual skills that are needed have led to the rise in bile duct injury during laparoscopic cholecystectomy.[73]

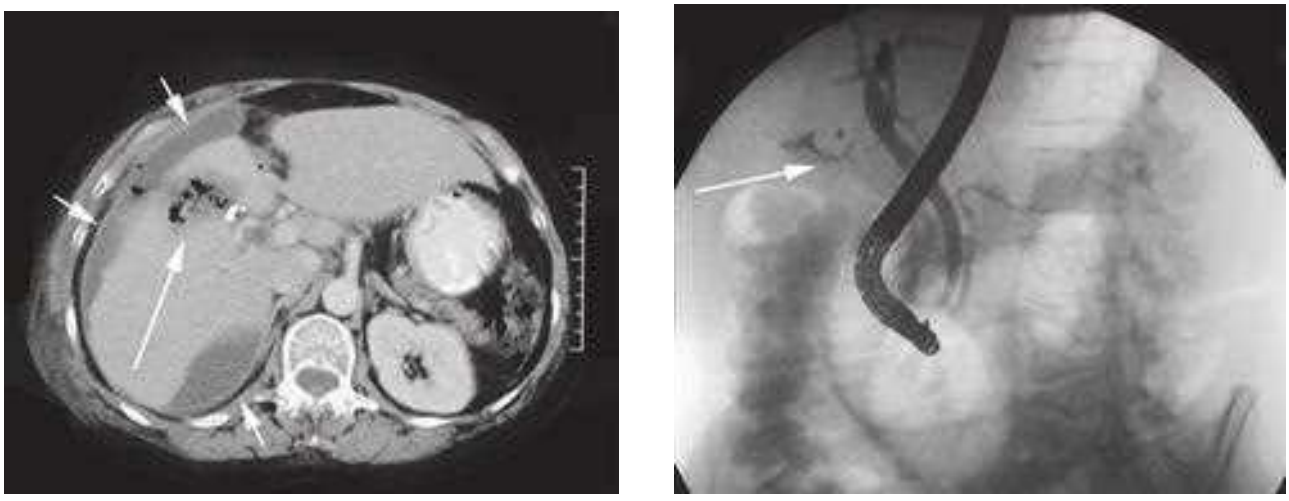
A number of different factors are associated with bile duct injury during laparoscopic cholecystectomy. These include acute or chronic inflammation, obesity, anatomic variations, and bleeding. Surgical technique with inadequate exposure and failure to identify structures before ligating or dividing them are the most common cause of significant biliary injury. The bile ducts may be narrow and can be mistaken for the cystic duct. The cystic duct may run along side the common bile duct before joining it, leading the surgeon to the wrong place. Additionally, the cystic duct may enter the right hepatic duct, and the right hepatic duct may run aberrantly, coursing through the triangle of Calot and entering the common hepatic duct. A number of intraoperative technical factors have been implicated in biliary injuries. Excessive cephalad retraction of the gallbladder may align the cystic duct with the common bile duct, and the latter is then mistaken for the cystic duct and clipped and divided. The use of an angled laparoscope instead of an end-viewing one will help visualize the anatomic structures, in particular those around the triangle of Calot. An angled scope also will aid in the proper placement of clips. Careless use of electrocautery may lead to thermal injury. Dissection deep into the liver parenchyma may cause injury to intrahepatic ducts, and poor clip placement close to the hilar area or to structures not well visualized can result in a clip across a bile duct.[74,75]

4▶

The routine use of intraoperative fluoroscopic cholangiography to prevent bile duct injury is controversial.[76] Routine use may limit the extent of injury but does not seem to prevent it entirely. Nonetheless, the frequency of bile duct injuries is cut by 50% when an intraoperative cholangiogram is performed. Critical to the successful use of cholangiography is accurate interpretation of the imaging. It is important to check that the whole biliary system fills with contrast, including both major ducts on the right and the left hepatic duct, and that there is no extravasation of contrast.

Diagnosis. Only about 25% of major bile duct injuries (common bile duct or hepatic duct) are recognized at the time of operation. Most commonly, intraoperative bile leakage, recognition of the correct anatomy, and an abnormal cholangiogram lead to the diagnosis of a bile duct injury. More than half of patients with biliary injury will present within the first postoperative month. The remainder will present months or years later, with recurrent cholangitis or cirrhosis from a remote bile duct injury. In the early postoperative period, patients present either with progressive elevation of liver function tests due to an occluded or a stenosed bile duct, or with a bile leak from an injured duct. Bile leak, most commonly from the cystic duct stump, a transected aberrant right hepatic duct, or a lateral injury to the main bile duct, usually presents with pain, fever, and a mild elevation of liver function tests. A CT scan or an ultrasound will show either a collection (biloma) in the gallbladder area or free fluid (bile) in the peritoneum (Fig. 32-24). Bilious drainage through operatively placed drains or through the wounds is abnormal. The site of the bile leak can be confirmed noninvasively with a HIDA scan. In patients with a surgical drain or a percutaneously placed catheter, injection of water-soluble contrast media through the drainage tract (sinogram) can often define the site of leakage and the anatomy of the biliary tree.[77]

CT scan and ultrasound also are important in the initial evaluation of the jaundiced patient, as they can demonstrate the dilated part of the biliary tree proximal to the stenosis or obstruction, and may identify the level of the extrahepatic bile duct obstruction. In the jaundiced patient with dilated intrahepatic ducts, a percutaneous cholangiogram will outline the anatomy and the proximal extent of the injury and allow decompression of the biliary tree with catheter or stent placements. An endoscopic cholangiogram demonstrates the anatomy distal to the injury and may allow the placement of stents across a stricture to



A **B**

Figure 32-24. A. Computed tomographic scan of a patient with bile leak after cholecystectomy. The *short arrows* indicate the intraperitoneal collections. Both air and bile are seen in the gallbladder bed (*long arrow*) as well as a surgical clip. **B.** An endoscopic retrograde cholangiography from the same patient showing a leak from the cystic duct stump (*arrow*). Note the filling of the pancreatic duct.

relieve an obstruction (see Fig. 32-23). MRI cholangiography, if available, provides an excellent, noninvasive delineation of the biliary anatomy both proximal and distal to the injury.

Management. The management of bile duct injuries depends on the type, extent, and level of injury, and the time of its diagnosis. Initial proper treatment of bile duct injury diagnosed during the cholecystectomy can avoid the development of a bile duct stricture. If a major injury is discovered and an experienced biliary surgeon is not available, an external drain and, if necessary, transhepatic biliary catheters are placed, and the patient is transferred to a referral center.[73]

Transected bile ducts <3 mm or those draining a single hepatic segment can safely be ligated. If the injured duct is ≥4 mm, it is likely to drain multiple segments or an entire lobe, and thus needs to be reimplanted. Lateral injury to the common bile duct or the common hepatic duct, recognized at the time of surgery, is best managed with a T-tube placement. If the injury is a small incision in the duct, the T tube may be placed through it as if it were a formal choledochotomy. In more extensive lateral injuries, the T tube should be placed through a separate choledochotomy and the injury closed over the T-tube end to minimize the risk of subsequent stricture formation.

Major bile duct injuries such as transection of the common hepatic or common bile duct are best managed at the time of injury. In many of these major injuries, the bile duct has not only been transected, but a variable length of the duct removed. This injury usually requires a biliary enteric anastomosis with a jejunal loop. Either an end-to-side Roux-en-Y choledochojejunostomy or, more commonly, a Roux-en-Y hepaticojejunostomy should be performed. Transhepatic biliary catheters are placed through the anastomosis to stent it and to provide access to the biliary tract for drainage and imaging. Although rare, when the injury is to the distal common bile duct, a choledochoduodenostomy can be performed. If there is no or minimal loss of ductal length, a duct-to-duct repair may be done over a T tube that is placed through a separate incision. It is critical to perform a tension-free anastomosis to minimize the high risk of postoperative stricture formation.[66]

Cystic duct leaks can usually be managed with percutaneous drainage of intra-abdominal fluid collections followed by an endoscopic biliary stenting (see Fig. 32-24).

Major injuries diagnosed postoperatively require transhepatic biliary catheter placement for biliary decompression as well as percutaneous drainage of intra-abdominal bile collections, if any. When the acute inflammation has resolved 6 to 8 weeks later, operative repair is performed.

Patients with bile duct stricture from an injury or as a sequela of previous repair usually present with either progressive elevation of liver function tests or cholangitis. The initial management usually includes transhepatic biliary drainage catheter placement for decompression as well as for defining the anatomy and the location and the extent of the damage. These catheters will also serve as useful technical aids during subsequent biliary enteric anastomosis. An anastomosis is performed between the duct proximal to the injury and a Roux loop of jejunum. Balloon dilatation of a stricture usually requires multiple attempts and rarely provides adequate long-term relief. Self-expanding metal or plastic stents, placed either percutaneously or endoscopically across the stricture, can provide temporary drainage and, in the high-risk patient, permanent drainage of the biliary tree.

Outcome. Good results can be expected in 70% to 90% of patients with bile duct injuries.[78] The best results are obtained when the injury is recognized during the cholecystectomy and repaired by an experienced biliary tract surgeon. The operative mortality rate varies from 0% to almost 30% in various series, but commonly is about 5% to 8%. Common complications that are specific for bile duct repairs include cholangitis, external biliary fistula, bile leak, subhepatic and subphrenic abscesses, and hemobilia. Restenosis of a biliary enteric anastomosis occurs in about 10% of patients, and may manifest up to 20 years after the initial procedure. Approximately two thirds of recurrent strictures become symptomatic within 2 years after repair. The more proximal strictures are associated with a lower success rate than are distal ones. The worst results are in patients with many operative revisions and in those who have evidence of

liver failure and portal hypertension. However, previous repair does not preclude successful outcome of repeated attempts, particularly in patients with good liver function. Patients with deteriorating liver function are candidates for liver transplants.

TUMORS

Carcinoma of the Gallbladder

Cancer of the gallbladder is a rare malignancy that occurs predominantly in the elderly. It is an aggressive tumor, with poor prognosis except when incidentally diagnosed at an early stage after cholecystectomy for cholelithiasis. The overall reported 5-year survival rate is about 5%.[79]

5▶

Incidence. Gallbladder cancer is the fifth most common GI malignancy in Western countries. However, it accounts for only 2% to 4% of all malignant GI tumors, with about 5000 new cases diagnosed annually in the United States. It is two to three times more common in females than males, and the peak incidence is in the seventh decade of life. Its occurrence in random autopsy series is about 0.4%, but approximately 1% of patients undergoing cholecystectomy for gallstone disease are found incidentally to have gallbladder cancer. The incidence of gallbladder cancer is particularly high in native populations of the United States, Mexico, and Chile. The annual incidence in Native American females with gallstones approaches 75 per 100,000, compared with the overall incidence of gallbladder cancer of 2.5 cases per 100,000 residents in the United States.[80]

Etiology. Cholelithiasis is the most important risk factor for gallbladder carcinoma, and up to 95% of patients with carcinoma of the gallbladder have gallstones.[81] However, the 20-year risk of developing cancer for patients with gallstones is <0.5% for the overall population and 1.5% for high-risk groups. The pathogenesis has not been defined but is probably related to chronic inflammation. Larger stones (>3 cm) are associated with a 10-fold increased risk of cancer.[82] The risk of developing cancer of the gallbladder is higher in patients with symptomatic than asymptomatic gallstones.

Polypoid lesions of the gallbladder are associated with increased risk of cancer, particularly in polyps >10 mm.[83] The calcified "porcelain" gallbladder is associated with >20% incidence of gallbladder carcinoma. These gallbladders should be removed, even if the patients are asymptomatic. Patients with choledochal cysts have an increased risk of developing cancer anywhere in the biliary tree, but the incidence is highest in the gallbladder. Sclerosing cholangitis, anomalous pancreaticobiliary duct junction, and exposure to carcinogens (azotoluene, nitrosamines) also are associated with cancer of the gallbladder.

Pathology. Between 80% and 90% of the gallbladder tumors are adenocarcinomas. Squamous cell, adenosquamous, oat cell, and other anaplastic lesions occur rarely. The histologic subtypes of gallbladder adenocarcinomas include papillary, nodular, and tubular. Less than 10% are of the papillary type, but these are associated with an overall better outcome, as they are most commonly diagnosed while localized to the gallbladder. Cancer of the gallbladder spreads through the lymphatics, with venous drainage, and with direct invasion into the liver parenchyma. Lymphatic flow from the gallbladder drains first to the cystic duct node (Calot's), then the pericholedochal and hilar nodes, and finally the peripancreatic, duodenal, periportal, celiac, and superior mesenteric artery nodes. The gallbladder veins drain directly into the adjacent liver, usually segments IV and V, where tumor invasion is common (Fig. 32-25). The gallbladder wall differs histologically from the intestines in that it lacks a muscularis mucosa and submucosa. Lymphatics are present in the subserosal layer only. Therefore, cancers invading but not growing through the muscular layer have minimal risk of nodal disease. When diagnosed, about 25% of gallbladder cancers are localized to the gallbladder wall, 35% have regional nodal involvement and/or extension into adjacent liver, and approximately 40% have distant metastasis.[84]

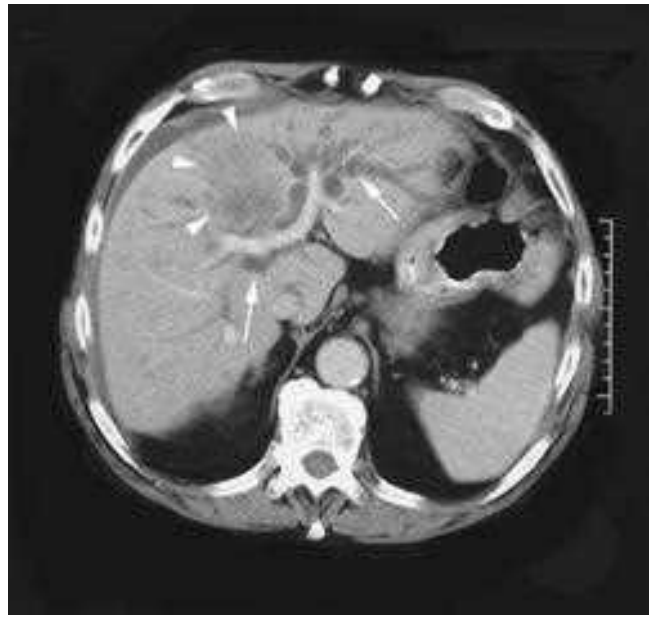


Figure 32-25. Computed tomography scan of a patient with gallbladder cancer. The image shown is at the level of the liver hilum. The portal vein is bifurcating into the left and right portal branch. The tumor has invaded segment IV of the liver (*arrowheads*) and obstructed the common hepatic duct, resulting in intrahepatic ductal dilatation (*arrows*).

Clinical Manifestations and Diagnosis. Signs and symptoms of carcinoma of the gallbladder are generally indistinguishable from those associated with cholecystitis and cholelithiasis. These include abdominal discomfort, right upper quadrant pain, nausea, and vomiting. Jaundice, weight loss, anorexia, ascites, and abdominal mass are less common presenting symptoms. More than one half of gallbladder cancers are not diagnosed before surgery. Common misdiagnoses include chronic cholecystitis, acute cholecystitis, choledocholithiasis, hydrops of the gallbladder, and pancreatic cancer. Laboratory findings are not diagnostic but, if abnormal, are most often consistent with biliary obstruction. Ultrasonography often reveals a thickened, irregular gallbladder wall or a mass replacing the gallbladder. Ultrasonography may visualize tumor invasion of the liver, lymphadenopathy, and a dilated biliary tree. The sensitivity of ultrasonography in detecting gallbladder cancer ranges from 70% to 100%. A CT scan is an important tool for staging and may identify a gallbladder mass or local invasion into adjacent organs. In addition, a spiral CT scan can demonstrate vascular invasion; however, CT scan is a poor method for identifying nodal spread. In jaundiced patients, a percutaneous transhepatic or endoscopic cholangiogram may be helpful to delineate the extent of biliary tree involvement, and typically shows a long stricture of the common bile duct. With newer MRI techniques,

MRCP has evolved into a single noninvasive imaging method that allows complete assessment of biliary, vascular, nodal, hepatic, and adjacent organ involvement.[85] If diagnostic studies suggest that the tumor is unresectable, a CT scan or ultrasound-guided biopsy of the tumor can be obtained to provide a pathologic diagnosis.

Treatment. Surgery remains the only curative option for gallbladder cancer as well as for cholangiocarcinoma. However, palliative procedures for patients with unresectable cancer and jaundice or duodenal obstruction remain the most frequently performed surgery for gallbladder cancers. Today, patients with obstructive jaundice can frequently be managed with either endoscopic or percutaneously placed biliary stents. There are no proven effective options for adjuvant radiation or chemotherapy for patients with gallbladder cancer.

The pathologic stage of gallbladder cancer determines the operative treatment for patients with localized gallbladder cancer. Patients without evidence of distant metastasis warrant exploration for tissue diagnosis, pathologic staging, and possible curative resection.

Tumors limited to the muscular layer of the gallbladder (T1) are usually identified incidentally, after cholecystectomy for gallstone disease. There is near universal agreement that simple cholecystectomy is an adequate treatment for T1 lesions and results in a near 100% overall 5-year survival rate. When the tumor invades the perimuscular connective tissue without extension beyond the serosa or into the liver (T2 tumors), an extended cholecystectomy should be performed.[86] That includes resection of liver segments IVB and V, and lymphadenectomy of the cystic duct and pericholedochal, portal, right celiac, and posterior pancreatoduodenal lymph nodes. One half of patients with T2 tumors are found to have nodal disease on pathologic examination. Therefore, regional lymphadenectomy is an important part of surgery for T2 cancers.[87] For tumors that grow beyond the serosa or invade the liver or other organs (T3 and T4 tumors), there is a high likelihood of intraperitoneal and distant spread. If no peritoneal or nodal involvement is found, complete tumor excision with an extended right hepatectomy (segments IV, V, VI, VII, and VIII) must be performed for adequate tumor clearance. An aggressive approach in patients who will tolerate surgery has resulted in an increased survival for T3 and T4 lesions.

Prognosis. Most patients with gallbladder cancer have unresectable disease at the time of diagnosis. The 5-year survival rate of all patients with gallbladder cancer is <5%, with a median survival of 6 months.[88] Patients with T1 disease treated with cholecystectomy have an excellent prognosis (85%–100% 5-year survival rate). The 5-year survival rate for T2 lesions treated with an extended cholecystectomy and lymphadenectomy compared with simple cholecystectomy is >70% vs. 25% to 40%, respectively. Patients with advanced but resectable gallbladder cancer are reported to have 5-year survival rates of 20% to 50%. However, the median survival for patients with distant metastasis at the time of presentation is only 1 to 3 months.

Recurrence after resection of gallbladder cancer occurs most commonly in the liver or the celiac or retropancreatic nodes. The prognosis for recurrent disease is very poor. Death occurs most commonly secondary to biliary sepsis or liver failure. The main goal of follow-up is to provide palliative care. The most common problems are pruritus and cholangitis associated with obstructive jaundice, bowel obstruction secondary to carcinomatosis, and pain.

Bile Duct Carcinoma

Cholangiocarcinoma is a rare tumor arising from the biliary epithelium and may occur anywhere along the biliary tree. About two thirds are located at the hepatic duct bifurcation. Surgical resection offers the only chance for cure; however, many patients have advanced disease at the time of diagnosis. Therefore, palliative procedures aimed to provide biliary drainage to prevent liver failure and cholangitis are often the only therapeutic possibilities. Most patients with unresectable disease die within 1 year of diagnosis.[89]

Incidence. The autopsy incidence of bile duct carcinoma is about 0.3%. The overall incidence of cholangiocarcinoma in the United States is about 1.0 per 100,000 people per year, with about 3000 new cases diagnosed annually. The male-to-female ratio is 1.3:1, and the average age of presentation is between 50 and 70 years.

Etiology. Risk factors associated with cholangiocarcinoma include primary sclerosing cholangitis, choledochal cysts, ulcerative colitis, hepatolithiasis, biliary-enteric anastomosis, and biliary tract infections with *Clonorchis* or in chronic typhoid carriers. Features common to most risk factors include biliary stasis, bile duct stones, and infection. Other risk factors associated with cholangiocarcinoma are liver flukes, dietary nitrosamines, Thorotrast, and exposure to dioxin.[90,91]

Pathology. Over 95% of bile duct cancers are adenocarcinomas. Morphologically, they are divided into nodular (the most common type), scirrhous, diffusely infiltrating, or papillary. Anatomically, they are divided into distal, proximal, or perihilar tumors. Intrahepatic cholangiocarcinomas occur, but they are treated like hepatocellular carcinoma, with hepatectomy when possible. About two thirds of cholangiocarcinomas are located in the perihilar location. Perihilar cholangiocarcinomas, also referred to as Klatskin tumors, are further classified based on anatomic location by the Bismuth-Corlette classification (Fig. 32-26). Type I tumors are confined to the common

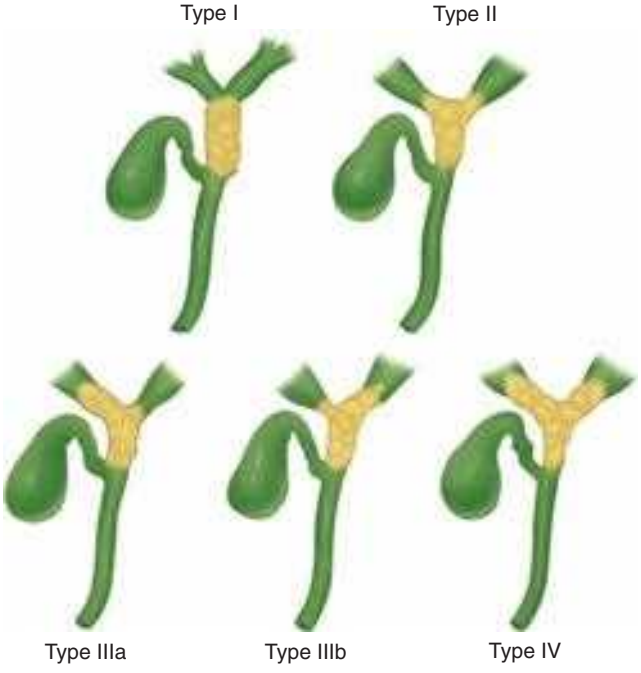

Figure 32-26. Bismuth-Corlette classification of bile duct tumors.

hepatic duct, but type II tumors involve the bifurcation without involvement of the secondary intrahepatic ducts. Type IIIa and IIIb tumors extend into the right and left secondary intrahepatic ducts, respectively. Type IV tumors involve both the right and left secondary intrahepatic ducts.

Clinical Manifestations and Diagnosis. Painless jaundice is the most common presentation. Pruritus, mild right upper quadrant pain, anorexia, fatigue, and weight loss also may be present. Cholangitis is the presenting symptom in about 10% of patients, but occurs more commonly after biliary manipulation in these patients. Except for jaundice, physical examination is usually normal in patients with cholangiocarcinoma. Occasionally, asymptomatic patients are found to have cholangiocarcinoma while being evaluated for elevated alkaline phosphatase and γ-glutamyltransferase levels. Tumor markers such CA 125 and carcinoembryonic antigen can be elevated in cholangiocarcinoma but tend to be nonspecific because they also increase in other GI and gynecologic malignancies or cholangiopathologies. The tumor marker most commonly used to aid the diagnosis of cholangiocarcinoma is CA 19-9, which has a sensitivity of 79% and specificity of 98% if the serum value is >129 U/mL.[92] However, mild elevations in CA 19-9 can be seen in cholangitis, other GI and gynecologic neoplasms, and patients who lack the Lewis blood type antigen.[93]

The initial tests are usually ultrasound or CT scan. A perihilar tumor causes dilatation of the intrahepatic biliary tree, but normal or collapsed gallbladder and extrahepatic bile ducts distal to the tumor. Distal bile duct cancer leads to dilatation of the extra- and intrahepatic bile ducts as well as the gallbladder. Ultrasound can establish the level of obstruction and rule out the presence of bile duct stones as the cause of the obstructive jaundice (Fig. 32-27). It is usually difficult to visualize the tumor itself on ultrasound or on a standard CT scan. Either ultrasound or spiral CT can be used to determine portal vein patency. The biliary anatomy is defined by cholangiography. PTC defines the proximal extent of the tumor, which is the most important factor in determining resectability. ERC is used, particularly in the evaluation of distal bile duct tumors. For the evaluation of vascular involvement, celiac angiography may be necessary. With the newer types of MRI, a single noninvasive test has the potential of evaluating the biliary anatomy, lymph nodes, and vascular involvement, as well as the tumor growth itself.[94]

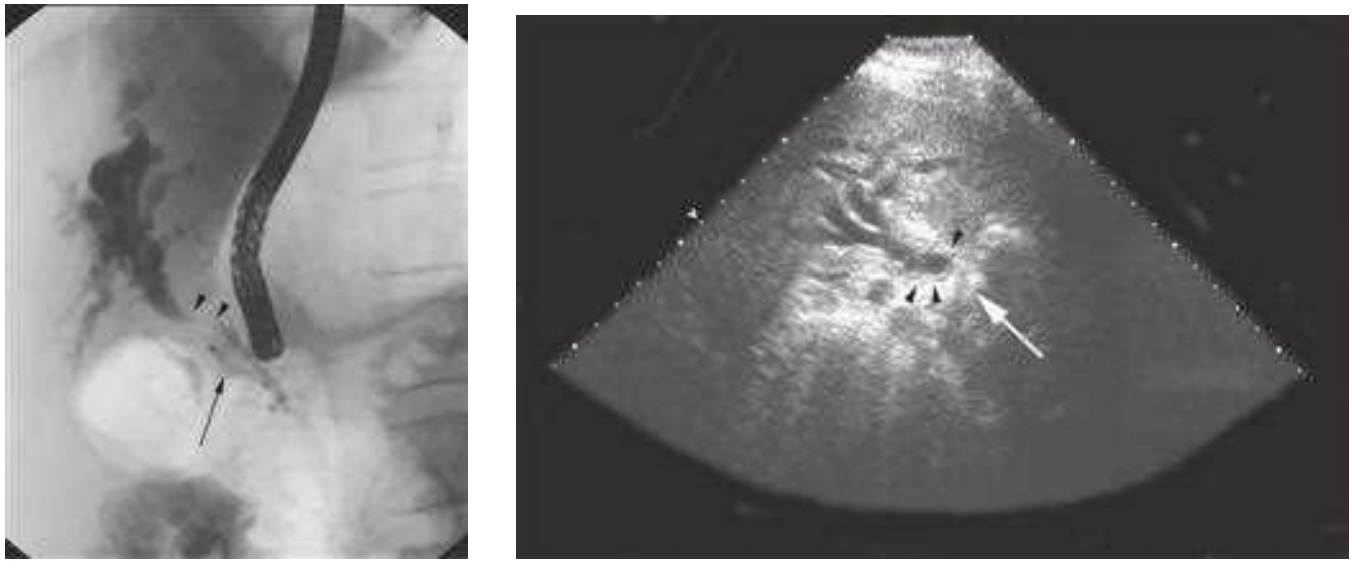
Tissue diagnosis may be difficult to obtain nonoperatively except in advanced cases. Percutaneous fine-needle aspiration biopsy, biliary brush or scrape biopsy, and cytologic examination have a low sensitivity in detecting malignancy. Patients with potentially resectable disease should, therefore, be offered surgical exploration based on radiographic findings and clinical suspicion.[95]

Treatment. Surgical excision is the only potentially curative treatment for cholangiocarcinoma. In the past one to two decades, improvements in surgical techniques have resulted in lower mortality and better outcome for patients undergoing aggressive surgical excision for cholangiocarcinoma.[96]

Patients should undergo surgical exploration if they have no signs of metastasis or locally unresectable disease. However, despite improvements in ultrasonography, CT scanning, and MRI, more than one half of patients who are explored are found to have peritoneal implants, nodal or hepatic metastasis, or locally advanced disease that precludes resection. For these patients, surgical bypass for biliary decompression and cholecystectomy to prevent the occurrence of acute cholecystitis should be performed.[97]

For unresectable perihilar cholangiocarcinoma, Roux-en-Y cholangiojejunostomy to either segment II or III bile ducts or to the right hepatic duct can be performed.

For curative resection, the location and local extension of the tumor dictates the extent of the resection. Perihilar tumors involving the bifurcation or proximal common hepatic duct (Bismuth-Corlette type I or II) with no signs of vascular



A **B**

Figure 32-27. **A.** An endoscopic retrograde cholangiography from a patient with cancer of the common hepatic duct (*arrowheads*). The common bile duct is of normal size, as is the cystic duct (*arrow*), but the proximal biliary tree is dilated. The gallbladder is not visualized because of tumor obstructing its neck. **B.** An ultrasound from the same patient showing dilated ducts and tumor obstructing the common hepatic duct (*arrow*). The walls of the bile ducts adjacent to the obstruction are thickened by tumor infiltration (*arrowheads*).

involvement are candidates for local tumor excision with portal lymphadenectomy, cholecystectomy, common bile duct excision, and bilateral Roux-en-Y hepaticojejunostomies. If the tumor involves the right or left hepatic duct (Bismuth-Corlette type IIIa or IIIb), right or left hepatic lobectomy, respectively, should also be performed. Frequently, resection of the adjacent caudate lobe is required because of direct extension into caudate biliary radicals or parenchyma.[95]

Distal bile duct tumors are more often resectable. They are treated with pylorus-preserving pancreatoduodenectomy (Whipple procedure). For patients with distal bile duct cancer found to be unresectable on surgical exploration, Roux-en-Y hepaticojejunostomy, cholecystectomy, and gastrojejunostomy to prevent gastric outlet obstruction should be performed.

Nonoperative biliary decompression is performed for patients with unresectable disease on diagnostic evaluation. Percutaneous placement of expandable metal stents or drainage catheters is usually the appropriate approach for proximal tumors. However, for distal bile duct tumors, endoscopic placement is often the preferred approach (Fig. 32-28). There is a significant risk of cholangitis with internal and external drainage, and stent occlusion is not uncommon. However, although surgical bypass offers improved patency and fewer episodes of cholangitis, an operative intervention is not warranted in patients with metastatic disease.[98]

There is no proven role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. Adjuvant radiation therapy has also not been shown to increase either quality of life or survival in resected patients. Patients with unresectable disease often are offered treatment with 5-fluorouracil alone or in combination with mitomycin C and doxorubicin, but the response rates are low, <10% and <30%, respectively. The combination of radiation and chemotherapy may be more effective than either treatment alone for unresectable disease, but no data from randomized trials are available. Giving chemoradiation to these patients can be difficult because of the high incidence of cholangitis. External-beam radiation has not been shown to be an effective treatment for unresected disease. The use of interstitial (intraoperative) radiation, brachytherapy with iridium-192 via percutaneous or endoscopic stents, and combined interstitial and external-beam radiation for unresectable cholangiocarcinoma has been reported with some encouraging results. However, no randomized, prospective trials have been reported.[95] A palliative measure that has been shown effective in a multicenter randomized trial is photodynamic therapy. In this trial, patients with a diagnosis of unresectable cholangiocarcinoma were randomized to biliary stenting with photodynamic therapy or stenting alone. The authors found that photodynamic therapy prolonged survival by approximately 400 days and improved quality of life on standardized questionnaire.[99]

Prognosis. Most patients with perihilar cholangiocarcinoma present with advanced, unresectable disease. Patients with unresectable disease have a median survival between 5 and 8 months. The most common causes of death are hepatic failure and cholangitis. The overall 5-year survival rate for patients with resectable perihilar cholangiocarcinoma is between 10% and 30%, but for patients with negative margins, it may be as high as 40%.

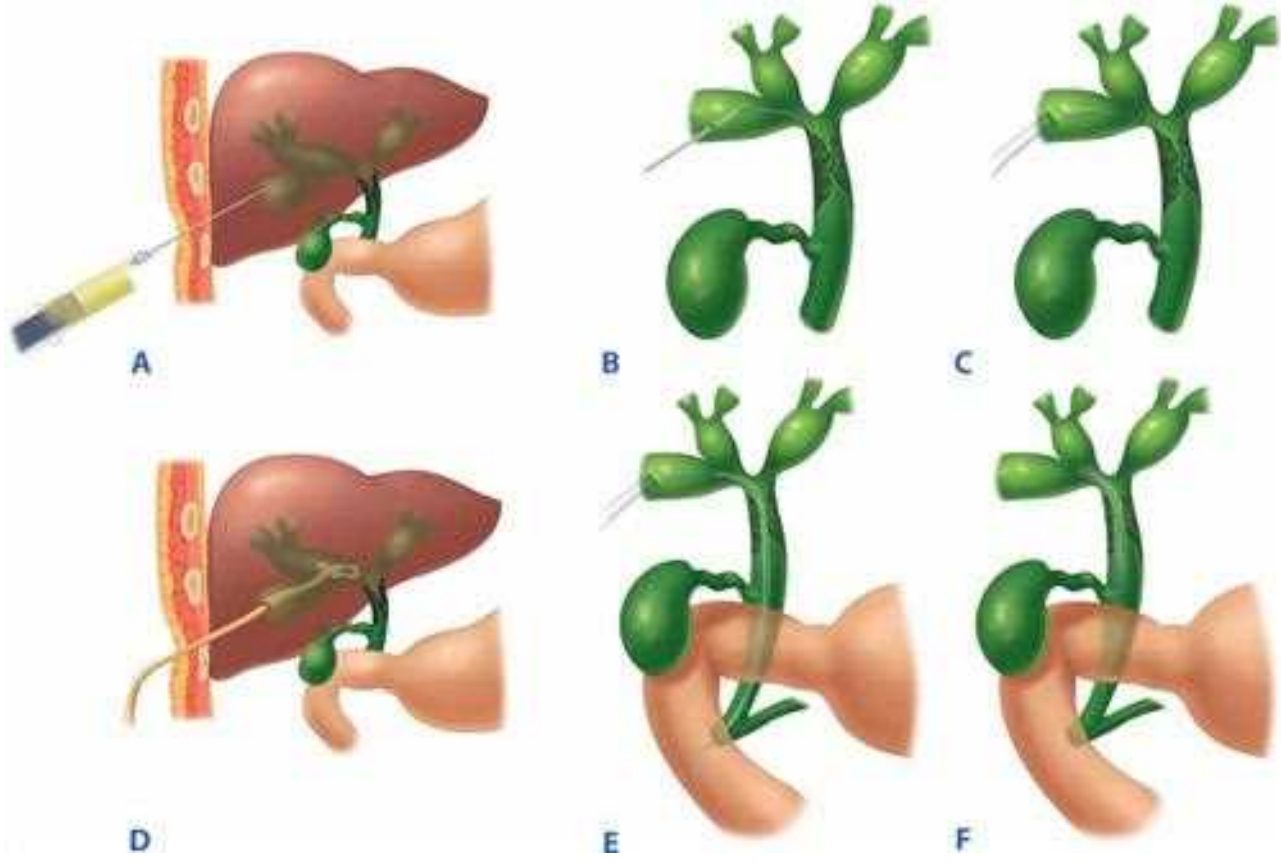


Figure 32-28. **A** through **F.** Percutaneous transhepatic cholangiography and placement of a biliary drainage catheter. The catheter has been passed through the tumor area (distal cholangiocarcinoma) that is obstructing the distal common bile duct and into the duodenum.

The operative mortality for perihilar cholangiocarcinoma is 6% to 8%. Patients with distal cholangiocarcinoma are more likely to have resectable disease and improved prognosis compared to perihilar cholangiocarcinoma. The overall 5-year survival rate for resectable disease is 30% to 50%, and the median survival is 32 to 38 months.

The greatest risk factors for recurrence after resection are the presence of positive margins and lymph node–positive tumors. Therapy for recurrent disease is palliation of symptoms. Surgery is not recommended for patients with recurrent disease.[94]

chapter 33

Pancreas

William E. Fisher, Dana K. Andersen, John A. Windsor, Ashok K. Saluja, and F. Charles Brunicardi

ANATOMY

The pancreas is perhaps the most unforgiving organ in the human body, leading most surgeons to avoid even palpating it unless necessary. Situated deep in the center of the abdomen, the pancreas is surrounded by numerous important structures and major blood vessels. Seemingly minor trauma to the pancreas can result in the release of pancreatic enzymes and cause life-threatening pancreatitis. Therefore, knowledge of the relationships of the pancreas to surrounding structures is critically important for all surgeons to ensure that pancreatic injury is avoided during abdominal surgery.

Gross Anatomy

The pancreas is a retroperitoneal organ that lies in an oblique position, sloping upward from the C-loop of the duodenum to the splenic hilum (Fig. 33-1). In an adult, the pancreas weighs 75 to 100 g and is about 15 to 20 cm long. The fact that the pancreas is situated so deeply in the abdomen and is sealed in the retroperitoneum explains the poorly localized and sometimes ill-defined nature with which pancreatic pathology presents. Patients with pancreatic cancer without bile duct obstruction usually present after months of vague upper abdominal discomfort, or no antecedent symptoms at all. Due to its retroperitoneal location, pain associated with pancreatitis often is characterized as penetrating through to the back.

Regions of the Pancreas

Surgeons typically describe the location of pathology within the pancreas in relation to four regions: the head, neck, body, and tail. The head of the pancreas is nestled in the C-loop of the duodenum and is posterior to the transverse mesocolon. Just posterior to the head of the pancreas lie the vena cava, the right renal artery, and both renal veins. The neck of the pancreas lies directly anterior to the portal vein. At the inferior border of the neck of the pancreas, the superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein. Sometimes, the inferior mesenteric

Key Points

1. Incomplete fusion of the dorsal and ventral pancreatic ducts results in pancreas divisum, but a variety of ductal anomalies can be seen. Magnetic resonance cholangiopancreatography as well as endoscopic retrograde cholangiopancreatography can identify these ductal anomalies, and clarification of the ductal pattern of the pancreas is important before attempts at interventions.
2. The "replaced right hepatic artery" occurs in 15% of patients and needs to be identified preoperatively to prevent inadvertent injury with resulting hepatic necrosis. Anomalous hepatic arterial anatomy can result in hepatic ischemia during dissection of the porta hepatis as well. "Thin cut" multidetector com. puted tomographic images are usually able to identify the relevant arterial and venous patterns around the pancreas.
3. Regardless of the etiology, the management of the early phase of acute pancreatitis is critical to achieve a successful outcome. Aggressive fluid resuscitation and early enteral feeding both reduce the risk of complications. It is no longer considered appropriate to "rest the pancreas" if the patient can tolerate enteral nutrients.
4. Surgical intervention in acute pancreatitis is reserved for patients with infected collections or infected necrosis only, or to relieve an impacted gallstone in the ampulla if endoscopic or radiologic treatments are unavailable or unsuccessful. Infection is usually confirmed by a pattern of air in the retroperitoneum on computed tomographic scan, or by documentation of bacteria on Gram's stain or culture from fine-needle aspiration of a suspected infected fluid collection. Fine-needle aspiration of suspicious fluid collections should not be converted to percutaneous drainage unless infection is confirmed, and the consensus decision has been made that percutaneous drainage is appropriate for the individual patient.
5. The appearance of chronic pancreatitis on computed tomographic scan varies dramatically, and multiple diagnostic studies are usually needed to establish the extent of disease. Calcific pancreatitis is not a marker of alcoholic pancreatitis alone, and rarely indicates autoimmune pancreatitis. Endoscopic ultrasound provides a better assessment of the disease than computed tomography and is useful to disclose indolent or unsuspected cancer, which can occur in up to 10% of patients.
6. The nidus of inflammation in chronic pancreatitis due to any cause is the head of the gland. Therefore, treatment approaches that address the disease in the head have the best long-term results. The Whipple procedure, the Beger procedure, and the Frey procedure, with or without longitudinal duct drainage, are the best surgical options, as all three approaches remove all or most of the disease in the head of the gland.
7. The precursor lesion that probably leads to most cases of ductular adenocarcinoma is the ductal epithelial hyperplasia/dysplasia process described by the pancreatic intraepithelial neoplasia classification system. Pancreatic intraepithelial neoplasia 2 and pancreatic intraepithelial neoplasia 3 lesions may be associated with other, nonspecific changes in pancreatic morphology seen on imaging studies, or may only be seen histologically. Resection margins for pancreatic neoplasms should be examined for advanced pancreatic intraepithelial neoplasia stage patterns of ductal hyperplasia to ensure adequate resection status.
8. Intraductal papillary mucinous neoplasms are small macroscopic polypoid or plaque-like adenomas that develop in the main pancreatic duct or in side-branch ducts, and secrete mucin. They are often silent symptomatically, but cause characteristic appearances of small cyst-like collections of mucus, or diffuse dilatation of the main pancreatic duct with mucus. These premalignant lesions may be multifocal or single and can evolve into invasive adenocarcinoma in a similar pattern as with other adenomatous polypoid lesions of the gastrointestinal tract. They have been diagnosed with increasing frequency, and account for more than one third of pancreatic resections at some centers. Main-duct intraductal papillary mucinous neoplasms are an indication for resection; side-branch intraductal papillary mucinous neoplasms have a lower incidence of malignancy and are sometimes followed with serial imaging surveillance.

vein joins the superior mesenteric vein or merges with the superior mesenteric portal venous junction to form a trifurcation (Fig. 33-2). The superior mesenteric artery lies parallel to and just to the left of the superior mesenteric vein. The uncinate process and the head of the pancreas wrap around the right side of the portal vein and end posteriorly near the space between the superior mesenteric vein and superior mesenteric artery. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins during pancreatic resection, unless the tumor is invading the vein anteriorly. The common bile duct runs in a deep groove on the posterior aspect of the pancreatic head until it passes through the pancreatic parenchyma to join the main pancreatic duct at the ampulla of Vater. The body and tail of the pancreas lie just anterior to the splenic artery and vein. The vein runs in a groove on the back of the pancreas and is fed by multiple fragile venous branches from the pancreatic parenchyma. These branches must be divided to perform a spleen-sparing distal pancreatectomy. The splenic artery runs parallel and just superior to the vein along the posterior superior edge of the body and tail of the pancreas. The splenic artery often is tortuous. The anterior surface of the body of the pancreas is covered by peritoneum. Once the gastrocolic omentum is divided, the body and tail of the pancreas can be seen along the floor of the lesser sac, just posterior to the stomach.

Pancreatic pseudocysts commonly develop in this area, and the posterior aspect of the stomach can form the anterior wall of the pseudocyst, allowing drainage into the stomach. The base of the transverse mesocolon attaches to the inferior margin of the body and tail of the pancreas. The transverse mesocolon often forms the inferior wall of pancreatic pseudocysts or inflammatory processes, allowing surgical drainage through the transverse mesocolon. The body of the pancreas is anterior to the

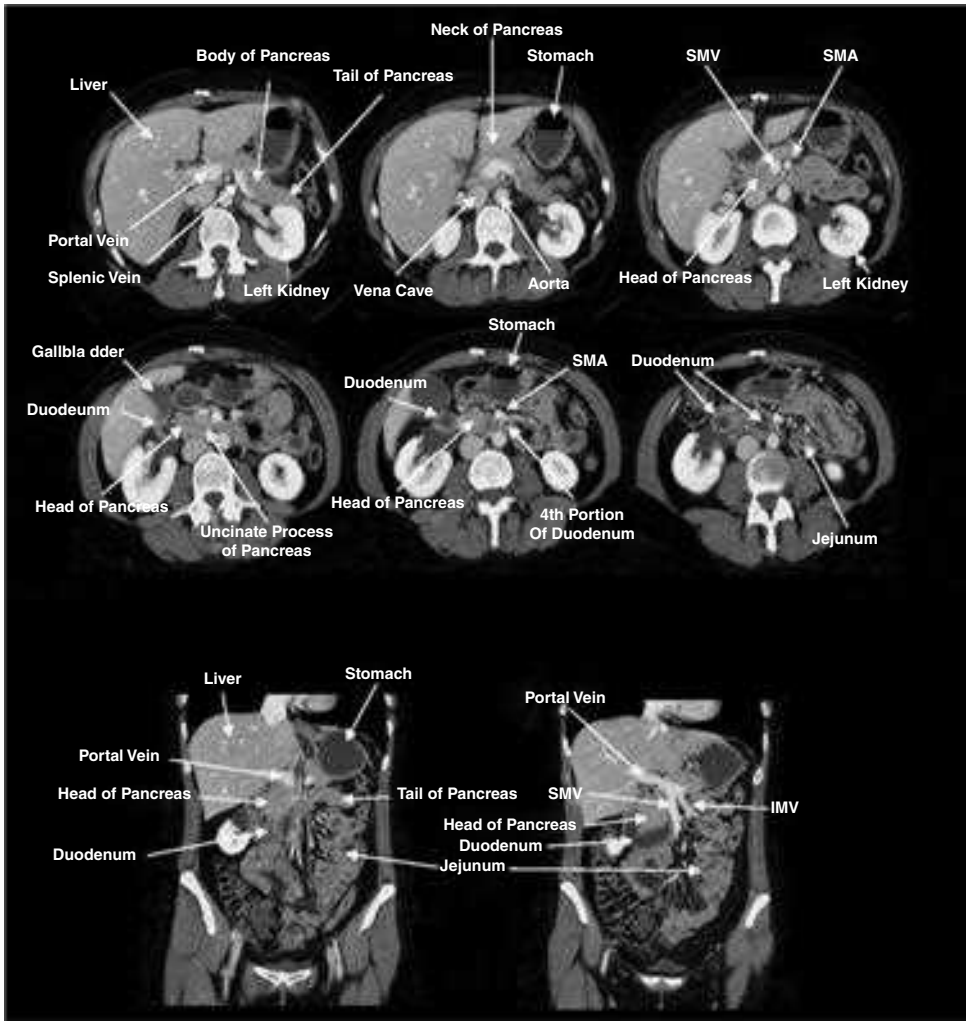

Figure 33-1. Pancreatic anatomy as seen on computed tomography. Knowledge of the relationship of the pancreas with surrounding structures is important to ensure that injury is avoided during abdominal surgery. IMV = inferior mesenteric vein; SMA = superior mesenteric artery; SMV = superior mesenteric vein.

aorta at the origin of the superior mesenteric artery. The neck of the pancreas is anterior to the vertebral body of L1 and L2, and blunt anteroposterior trauma can compress the neck of the pancreas against the spine, causing parenchymal and, sometimes, ductal injury. The neck divides the pancreas into approximately two equal halves. The small portion of the pancreas anterior to the left kidney is referred to as the *tail* and is nestled in the hilum of the spleen near the splenic flexure of the left colon. Awareness of these anatomic relationships is important to avoid injury to the pancreatic tail during left colectomy or splenectomy.

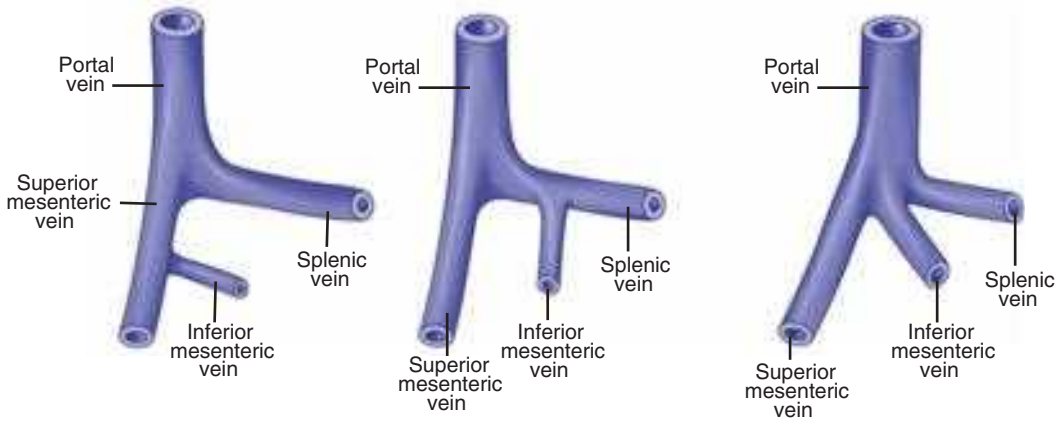

Figure 33-2. Variations in portal venous anatomy. The superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein, but sometimes joins the superior mesenteric vein; or the three veins merge as a trifurcation to form the portal vein.

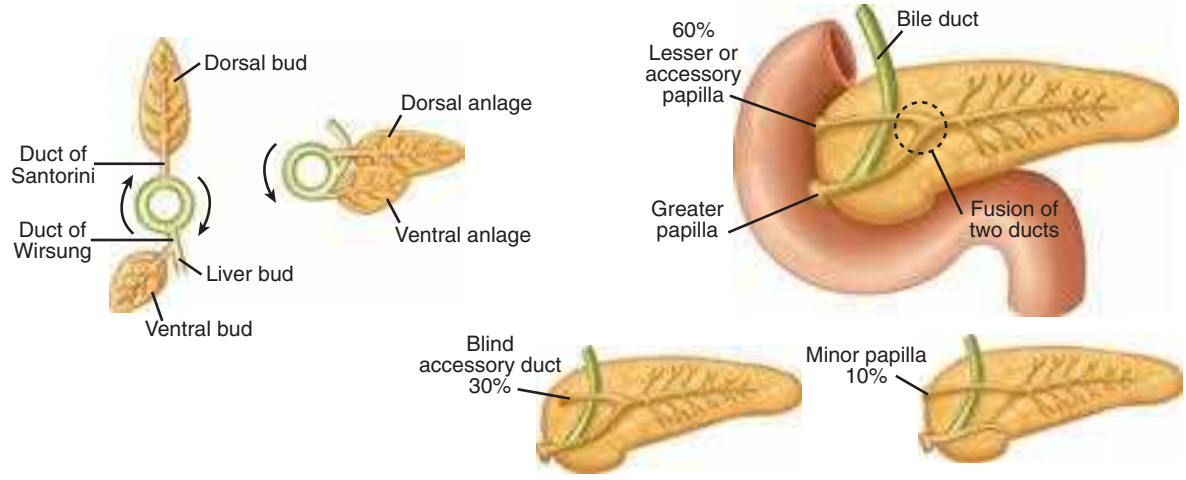

Figure 33-3. Embryology of pancreas and duct variations. The duct of Wirsung from the ventral bud connects to the bile duct, while the duct of Santorini from the larger dorsal bud connects to the duodenum. With gut rotation, the two ducts fuse in most cases such that the majority of the pancreas drains through the duct of Wirsung to the major papilla. The duct of Santorini can persist as a blind accessory duct or drain through the lesser papilla. In a minority of patients, the ducts remain separate, and the majority of the pancreas drains through the duct of Santorini, a condition referred to as *pancreas divisum*.

Pancreatic Duct Anatomy

An understanding of embryology is required to appreciate the common variations in pancreatic duct anatomy. The pancreas is formed by the fusion of a ventral and dorsal bud (Fig. 33-3). The duct from the smaller ventral bud, which arises from the hepatic diverticulum, connects directly to the common bile duct. The duct from the larger dorsal bud, which arises from the duodenum, drains directly into the duodenum. The duct of the ventral anlage becomes the duct of Wirsung, and the duct from the dorsal anlage becomes the duct of Santorini. With gut rotation, the ventral anlage rotates to the right and around the posterior side of the duodenum to fuse with the dorsal bud. The ventral anlage becomes the inferior portion of the pancreatic head and the uncinate process, while the dorsal anlage becomes the body and tail of the pancreas. The ducts from each anlage usually fuse together in the pancreatic head such that most of the pancreas drains through the duct of Wirsung, or main pancreatic duct, into the common channel formed from the bile duct and pancreatic duct. The length of the common channel is variable. In about one third of patients, the bile duct and pancreatic duct remain distinct to the end of the papilla, the two ducts merge at the end of the papilla in another one third, and in the remaining one third, a true common channel is present for a distance of several millimeters. Commonly, the duct from the dorsal anlage, the duct of Santorini, persists as the lesser pancreatic duct, and sometimes drains directly into the duodenum through the lesser papilla just proximal to the major papilla. In approximately 30% of patients, the duct of Santorini ends as a blind accessory duct and does not empty into the duodenum. In 10% of patients, the ducts of Wirsung and Santorini fail to fuse.[1] This results in the majority of the pancreas draining through the duct of Santorini and the lesser papilla, while the inferior portion of the pancreatic head and uncinate process drains through the duct of Wirsung and major papilla. This normal anatomic variant, which occurs in one out of 10 patients, is referred to as *pancreas divisum* (Fig. 33-3). In a minority of these patients, the minor papilla can be inadequate to handle the flow of pancreatic juices from the majority of the gland. This relative outflow obstruction can result in pancreatitis and is sometimes treated by sphincteroplasty of the minor papilla.

1▶

The main pancreatic duct is usually only 2 to 3 mm in diameter and runs midway between the superior and inferior borders of the pancreas, usually closer to the posterior than to the anterior surface. Pressure inside the pancreatic duct is about twice that in the common bile duct, which is thought to prevent reflux of bile into the pancreatic duct. The main pancreatic duct joins with the common bile duct and empties at the ampulla of Vater or major papilla, which is located on the medial aspect of the second portion of the duodenum. The muscle fibers around the ampulla form the sphincter of Oddi, which controls the flow of pancreatic and biliary secretions into the duodenum. Contraction and relaxation of the sphincter is regulated by complex neural and hormonal factors. When the accessory pancreatic duct or lesser duct drains into the duodenum, a lesser papilla can be identified approximately 2 cm proximal to the ampulla of Vater.

Vascular and Lymphatic Anatomy

The blood supply to the pancreas comes from multiple branches from the celiac and superior mesenteric arteries (Fig. 33-4). The common hepatic artery gives rise to the gastroduodenal artery before continuing toward the porta hepatis as the proper hepatic artery. The right gastric artery branches off the gastroduodenal artery just superior to the duodenum. The gastroduodenal artery then travels inferiorly anterior to the neck of the pancreas and posterior to the duodenal bulb. A posterior ulcer in the duodenal bulb can erode into the gastroduodenal artery in this location. At the inferior border of the duodenum, the gastroduodenal artery then gives rise to the right gastroepiploic artery then continues on as the anterior superior pancreaticoduodenal artery, which branches into the anterior and posterior superior pancreaticoduodenal arteries. As the superior mesenteric artery passes behind the neck of the pancreas, it gives off the inferior pancreaticoduodenal artery at the inferior margin of the neck of the pancreas. This vessel quickly divides into the anterior and posterior inferior pancreaticoduodenal arteries. The superior and inferior pancreaticoduodenal arteries join together within the parenchyma of the anterior and posterior sides of the head of the pancreas along the medial aspect of the C-loop of the duodenum to form arcades that give off numerous branches to the duodenum and head of the pancreas. Therefore, it is impossible to resect the head of the

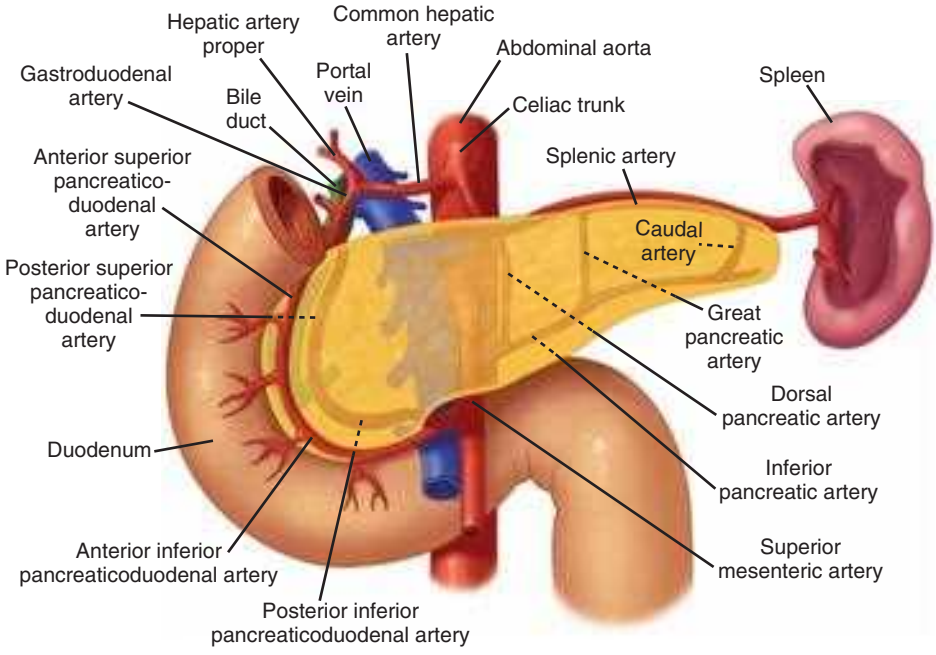

Figure 33-4. Arterial supply to the pancreas. Multiple arcades in the head and body of the pancreas provide a rich blood supply. The head of the pancreas cannot be resected without devascularizing the duodenum unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved.

pancreas without devascularizing the duodenum, unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved. Variations in the arterial anatomy occur in one out of five patients. The right hepatic artery, common hepatic artery, or gastroduodenal arteries can arise from the superior mesenteric artery. In 15% to 20% of patients, the right hepatic artery will arise from the superior mesenteric artery and travel upwards toward the liver along the posterior aspect of the head of the pancreas (referred to as a *replaced right hepatic artery*). It is important to look for this variation on preoperative computed tomographic (CT) scans and in the operating room so the replaced hepatic artery is recognized and injury is avoided. The body and tail of the pancreas are supplied by multiple branches of the splenic artery. The splenic artery arises from the celiac trunk and travels along the posterior-superior border of the body and tail of the pancreas toward the spleen. The inferior pancreatic artery usually arises from the superior mesenteric artery and runs to the left along the inferior border of the body and tail of the pancreas, parallel to the splenic artery. Three vessels run perpendicular to the long axis of the pancreatic body and tail and connect the splenic artery and inferior pancreatic artery. They are, from medial to lateral, the dorsal, great, and caudal pancreatic arteries. These arteries form arcades within the body and tail of the pancreas, and account for the rich blood supply of the organ.

2▶

The venous drainage of the pancreas follows a pattern similar to that of the arterial supply (Fig. 33-5). The veins are usually

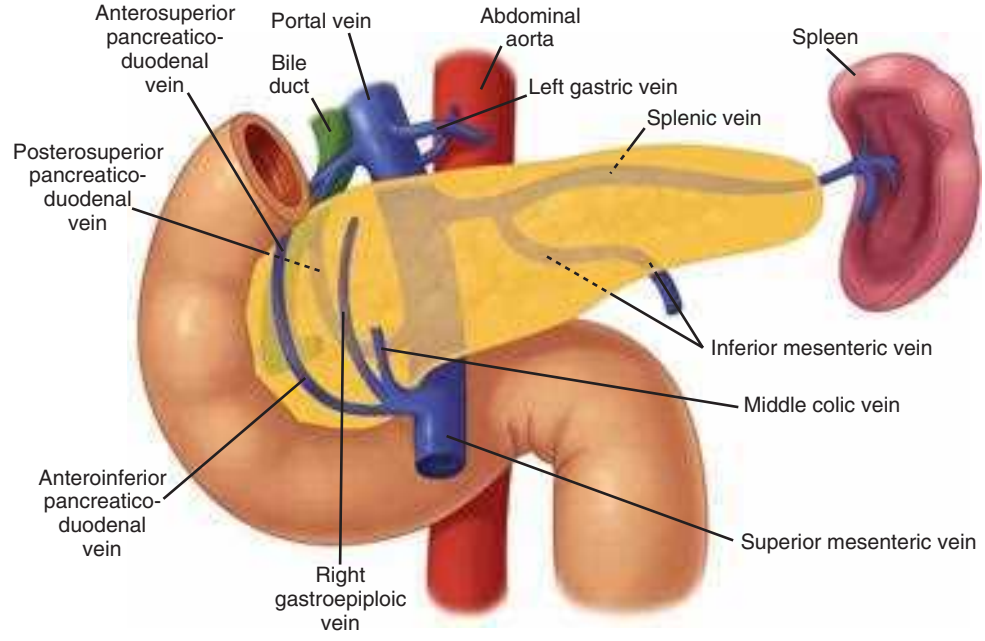

Figure 33-5. Venous drainage from the pancreas. The venous drainage of the pancreas follows a pattern similar to the arterial supply, with the veins usually superficial to the arteries. Anterior traction on the transverse colon can tear fragile branches along the inferior border of the pancreas, which then retract into the parenchyma of the pancreas. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins.

superficial to the arteries within the parenchyma of the pancreas. There is an anterior and posterior venous arcade within the head of the pancreas. The superior veins drain directly into the portal vein just above the neck of the pancreas. The posterior inferior arcade drains directly into the inferior mesenteric vein at the inferior border of the neck of the pancreas. These venous tributaries must be divided during a Whipple procedure. The anterior inferior pancreaticoduodenal vein joins the right gastroepiploic vein and the middle colic vein to form a common venous trunk, which enters into the superior mesenteric vein. Traction on the transverse colon during colectomy can tear these fragile veins, which then retract into the parenchyma of the pancreas, making control tedious. There also are numerous small venous branches coming from the pancreatic parenchyma directly into the lateral and posterior aspect of the portal vein. Venous return from the body and tail of the pancreas drains into the splenic vein.

The lymphatic drainage from the pancreas is diffuse and widespread (Fig. 33-6). The profuse network of lymphatic vessels and lymph nodes draining the pancreas provides egress to tumor cells arising from the pancreas. This diffuse lymphatic drainage contributes to the fact that pancreatic cancer often presents with positive lymph nodes and a high incidence of local recurrence after resection. Lymph nodes can be palpated along the distal bile duct and posterior aspect of the head of the pancreas in the pancreaticoduodenal groove, where the mesenteric vein passes under the neck of the pancreas, along the inferior border of the body, at the celiac axis and along the hepatic artery ascending into the porta hepatis, and along the splenic artery and vein. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas often metastasize to these nodes and lymph nodes along the splenic vein and in the hilum of the spleen.

Neuroanatomy

The pancreas is innervated by the sympathetic and parasympathetic nervous systems. The acinar cells responsible for exocrine secretion, the islet cells responsible for endocrine secretion, and the islet vasculature are innervated by both systems. The parasympathetic system stimulates endocrine and exocrine secretion and the sympathetic system inhibits secretion.[2]The pancreas is also innervated by neurons that secrete amines and peptides, such as somatostatin, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and galanin. The exact role of these neurons in pancreatic physiology is uncertain, but they do appear to affect both exocrine and endocrine function. The pancreas also has a rich supply of afferent sensory fibers, which are responsible for the intense pain associated with advanced pancreatic cancer, as well as acute and chronic pancreatitis. These somatic fibers travel superiorly to the celiac ganglia (Fig. 33-7). Interruption of these somatic fibers can stop transmission of pain sensation.

HISTOLOGY AND PHYSIOLOGY

The exocrine pancreas accounts for about 85% of the pancreatic mass; 10% of the gland is accounted for by extracellular matrix, and 4% by blood vessels and the major ducts, whereas only 2% of the gland is comprised of endocrine tissue. The endocrine and exocrine pancreas are sometimes thought of as functionally separate, but these different components of the organ are coordinated to allow an elegant regulatory feedback system for digestive enzyme and hormone secretion. This complex system regulates the type of digestion, its rate, and the processing and distribution of absorbed nutrients. This coordination is facilitated by the physical approximation of the islets and the exocrine pancreas, the presence of specific islet hormone receptors on the plasma membranes of pancreatic acinar cells, and the existence of an islet-acinar portal blood system.

Although patients can live without a pancreas when insulin and digestive enzyme replacement are administered, the loss of this islet-acinar coordination leads to impairments in digestive function. Although only approximately 20% of the normal pancreas is required to prevent insufficiency, in many patients undergoing pancreatic resection, the remaining pancreas is not normal, and pancreatic endocrine and exocrine insufficiency can develop with removal of smaller portions of the gland.

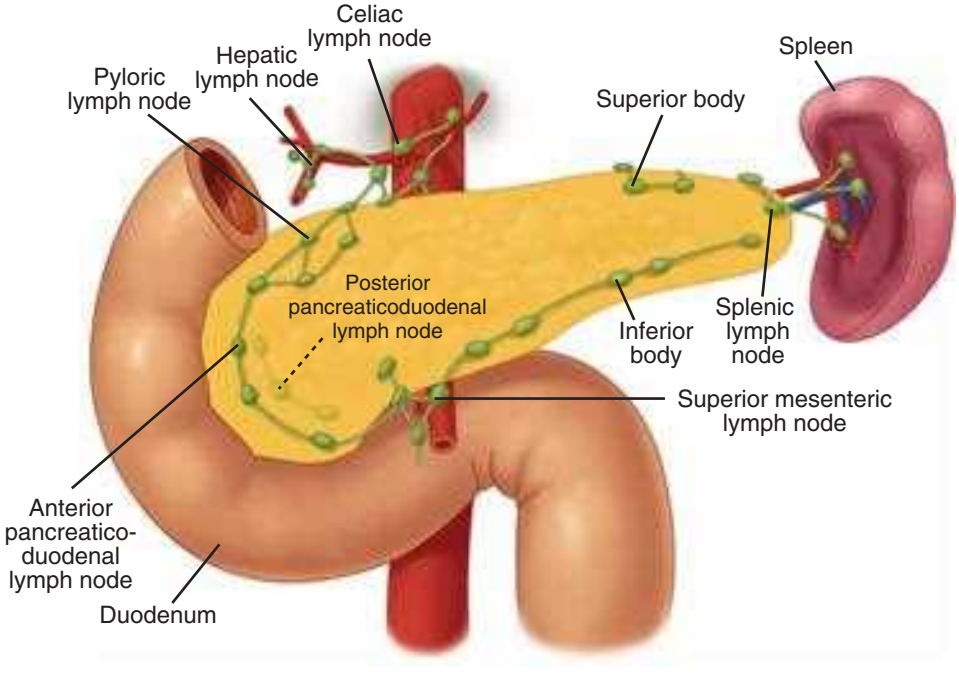

Figure 33-6. Lymphatic supply to the pancreas. The lymphatic drainage from the pancreas is diffuse and widespread, which explains the high incidence of lymph node metastases and local recurrence of pancreatic cancer. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas are often unresectable because they metastasize to these lymph nodes. *(Reproduced with permission from Bell RH Jr: Atlas of pancreatic surgery, in Bell RH Jr, Rikkers LF, Mulholland MW (eds): Digestive Tract Surgery: A Text and Atlas. Philadelphia: Lippincott-Raven, 1996, p 969.)*

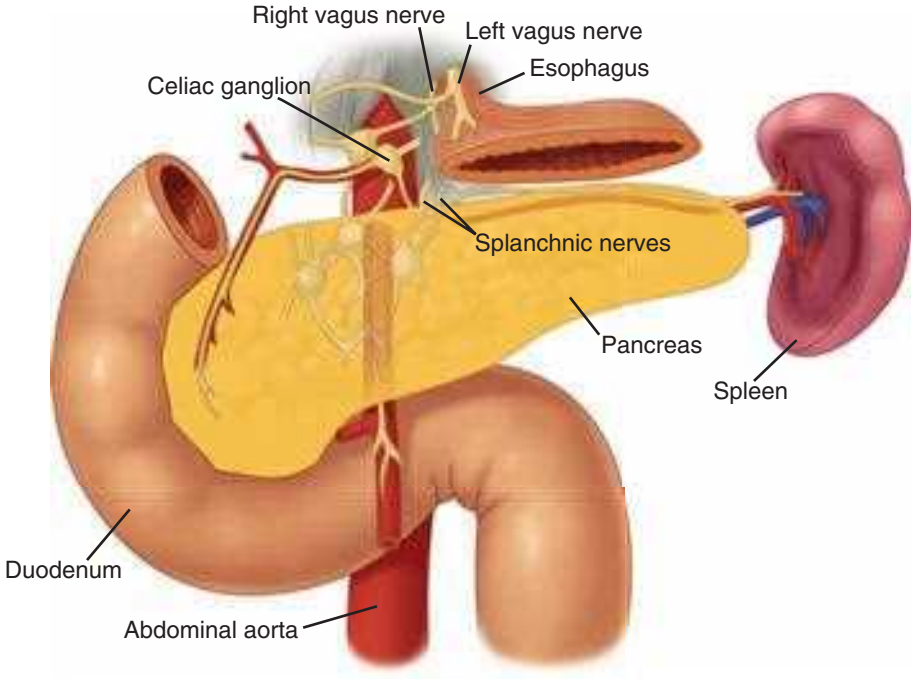

Figure 33-7. Innervation of the pancreas. The pancreas has a rich supply of afferent sensory fibers that travel superiorly to the celiac ganglia. Interruption of these somatic fibers with a celiac plexus block can interfere with transmission of pancreatic pain. *(Reproduced with permission from Bell RH Jr: Atlas of pancreatic surgery, in Bell RH Jr, Rikkers LF, Mulholland MW* [*eds*]*:* Digestive Tract Surgery: A Text and Atlas. *Philadelphia: Lippincott-Raven, 1996, p 969.)*

Exocrine Pancreas

The pancreas secretes approximately 500 to 800 mL per day of colorless, odorless, alkaline, isosmotic pancreatic juice. Pancreatic juice is a combination of acinar cell and duct cell secretions. The acinar cells secrete amylase, proteases, and lipases, enzymes responsible for the digestion of all three food types: carbohydrate, protein, and fat. The acinar cells are pyramid-shaped, with their apices facing the lumen of the acinus. Near the apex of each cell are numerous enzyme-containing zymogen granules that fuse with the apical cell membrane (Fig. 33-8). Unlike the endocrine pancreas, where islet cells specialize in the secretion of one hormone type, individual acinar cells secrete all types of enzymes. However, the ratio of the different enzymes released is adjusted to the composition of digested food through nonparallel regulation of secretion.

Pancreatic amylase is secreted in its active form and completes the digestive process already begun by salivary amylase. Amylase is the only pancreatic enzyme secreted in its active form, and it hydrolyzes starch and glycogen to glucose, maltose, maltotriose, and dextrins. These simple sugars are transported across the brush border of the intestinal epithelial cells by active transport mechanisms. Gastric hydrolysis of protein yields peptides that enter the intestine and stimulate intestinal endocrine cells to release cholecystokinin (CCK)-releasing peptide, CCK, and secretin, which then stimulate the pancreas to secrete enzymes and bicarbonate into the intestine.

The proteolytic enzymes are secreted as proenzymes that require activation. Trypsinogen is converted to its active form, trypsin, by another enzyme, enterokinase, which is produced by the duodenal mucosal cells. Trypsin, in turn, activates the other proteolytic enzymes. Trypsinogen activation within the pancreas is prevented by the presence of inhibitors that are also secreted by the acinar cells. A failure to express a normal trypsinogen inhibitor, pancreatic secretory trypsin inhibitor (PSTI), also known as serine protease inhibitor Kazal type 1 (SPINK1), is a cause of familial pancreatitis. Inhibition of trypsinogen activation ensures that the enzymes within the pancreas remain in an inactive precursor state and are activated only within the duodenum. Trypsinogen is expressed in several isoforms, and a missense mutation on the cationic trypsinogen, or *PRSS1*, results in premature, intrapancreatic activation of trypsinogen. This accounts for about two-thirds of cases of hereditary pancreatitis. Chymotrypsinogen is activated to form chymotrypsin.

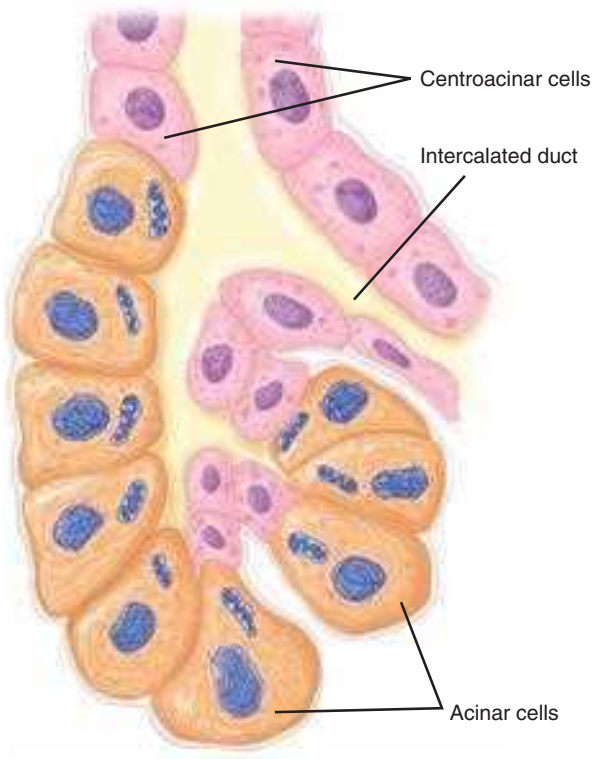

Figure 33-8. Acinar cell. Zymogen granules fuse with the apical membrane and release multiple enzymes to digest carbohydrates, proteins, and fat. (*Reproduced with permission from Bloom W, Fawcett DW:* A Textbook of Histology, *10th ed. Philadelphia: Saunders,1975, p 738.*)

Elastase, carboxypeptidase A and B, and phospholipase are also activated by trypsin. Trypsin, chymotrypsin, and elastase cleave bonds between amino acids within a target peptide chain, and carboxypeptidase A and B cleave amino acids at the end of peptide chains. Individual amino acids and small dipeptides are then actively transported into the intestinal epithelial cells. Pancreatic lipase hydrolyzes triglycerides to 2-monoglyceride and fatty acid. Pancreatic lipase is secreted in an active form. Colipase is also secreted by the pancreas and binds to lipase, changing its molecular configuration and increasing its activity. Phospholipase A2 is secreted by the pancreas as a proenzyme that becomes activated by trypsin. Phospholipase A2 hydrolyzes phospholipids and, as with all lipases, requires bile salts for its action. Carboxylic ester hydrolase and cholesterol esterase hydrolyze neutral lipid substrates like esters of cholesterol, fat-soluble vitamins, and triglycerides. The hydrolyzed fat is then packaged into micelles for transport into the intestinal epithelial cells, where the fatty acids are reassembled and packaged inside chylomicrons for transport through the lymphatic system into the bloodstream (Table 33-1).

The centroacinar and intercalated duct cells secrete the water and electrolytes present in the pancreatic juice. About 40 acinar cells are arranged into a spherical unit called an *acinus*. Centroacinar cells are located near the center of the acinus and are responsible for fluid and electrolyte secretion. These cells contain the enzyme carbonic anhydrase, which is needed for bicarbonate secretion. The amount of bicarbonate secreted varies with the pancreatic secretory rate, with greater concentrations of bicarbonate being secreted as the pancreatic secretory rate increases. Chloride secretion varies inversely with bicarbonate secretion such that the sum of these two remains constant. In contrast, sodium and potassium concentrations are kept constant throughout the spectrum of secretory rates[3] (Fig. 33-9). The hormone secretin is released from cells in the duodenal mucosa in response to acidic chyme passing through the pylorus into the duodenum. Secretin is the major stimulant for bicarbonate secretion, which buffers the acidic fluid entering the duodenum from the stomach. CCK also stimulates bicarbonate secretion, but to a much lesser extent than secretin. CCK potentiates secretin-stimulated bicarbonate secretion. Gastrin and acetylcholine, both stimulants of gastric acid secretion, are also weak stimulants of pancreatic bicarbonate secretion.[4] Truncal vagotomy produces a myriad of complex effects on the downstream digestive tract, but the sum effect on the exocrine pancreas is a reduction in bicarbonate and fluid secretion.[5] The endocrine pancreas also influences the adjacent exocrine pancreatic secretions. Somatostatin, pancreatic polypeptide (PP), and glucagon are all thought to inhibit exocrine secretion.

The acinar cells release pancreatic enzymes from their zymogen granules into the lumen of the acinus, and these proteins combine with the water and bicarbonate secretions of the centroacinar cells. The pancreatic juice then travels into small intercalated ducts. Several small intercalated ducts join to form an interlobular duct. Cells in the interlobular ducts contribute fluid and electrolytes to adjust the final concentrations of the pancreatic fluid. Interlobular ducts then join to form about 20 secondary ducts that empty into the main pancreatic duct. Destruction of the branching ductal tree from recurrent inflammation, scarring, and deposition of stones eventually contributes to destruction of the exocrine pancreas and exocrine pancreatic insufficiency.

Endocrine Pancreas

There are nearly 1 million islets of Langerhans in the normal adult pancreas. They vary greatly in size from 40 to 900 μm. Larger islets are located closer to the major arterioles and smaller islets are embedded more deeply in the parenchyma of the pancreas. Most islets contain 3000 to 4000 cells of five major types: alpha cells that secrete glucagon, β-cells that secrete insulin, delta cells that secrete somatostatin, epsilon cells that secrete ghrelin, and PP cells that secrete PP (Table 33-2).

Table 33-1

Pancreatic enzymes

ENZYME	SUBSTRATE	PRODUCT
Carbohydrate Amylase (active)	Starch, glycogen	Glucose, maltose, maltotriose, dextrins
Protein Endopeptidases Trypsinogen (inactive) $\xrightarrow{\text{Enterokinase}}$ Trypsin (active) Chymotrypsinogen (inactive) $\xrightarrow[\text{Trypsin}]{\text{Enterokinase}}$ Chymotrypsin (active) Proelastase (inactive) $\xrightarrow[\text{Trypsin}]{\text{Enterokinase}}$ Elastase (active)	Cleave bonds between amino acids	Amino acids, dipeptides

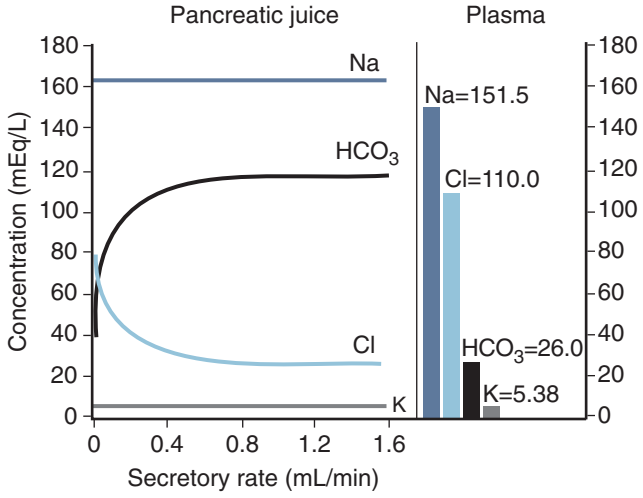

Figure 33-9. Composition of pancreatic exocrine secretions. Greater concentrations of bicarbonate are secreted at higher secretory rates, and chloride secretion varies inversely with bicarbonate secretion. In contrast, sodium and potassium concentrations are independent of the secretory rate. (*Reproduced with permission from Bro-Rasmussen F et al: The composition of pancreatic juice as compared to sweat, parotid saliva, and tears.* Acta Phys Scandinav. *37:97–113, 1956.*)

Insulin is the best-studied pancreatic hormone. The discovery of insulin in 1920 by Frederick Banting, an orthopedic surgeon, and Charles Best, a medical student, was recognized with the awarding of the Nobel Prize in Physiology or Medicine. They produced diabetes in dogs by performing total pancreatectomy and then treated them with crude pancreatic extracts from dog and calf pancreata using techniques to prevent the breakdown of insulin by the proteolytic enzymes of the exocrine pancreas. Insulin was subsequently purified and found to be a 56-amino acid peptide with two chains, an α and a β chain, joined by two disulfide bridges and a connecting peptide, or C-peptide. Proinsulin is made in the endoplasmic reticulum and then is transported to the Golgi complex, where it is packaged into granules and the C-peptide is cleaved off. There are two phases of insulin secretion. In the first phase, stored insulin is released. This phase lasts about 5 minutes after a glucose challenge. The second phase of insulin secretion is a longer, sustained release due to ongoing production of new insulin. β-cell synthesis of insulin is regulated by plasma glucose levels, neural signals, and the paracrine influence of other islet cells. The diagnosis of diabetes is made by using oral and intravenous (IV) glucose tolerance tests. Oral glucose not only enters the bloodstream but also stimulates the release of enteric hormones such as gastric inhibitory peptide (also known as *glucose-dependentinsulinotropic polypeptide* or *GIP*), glucagon-like peptide-1 (GLP-1), and CCK that augment the secretion of insulin, and are therefore referred to as *incretins*. As a result, oral glucose is a more vigorous stimulus to insulin secretion than IV glucose. In the oral glucose tolerance test (OGTT), the patient is fasted overnight, and a basal glucose value is determined. Forty g/m^{2}or 75 g of glucose is given orally over 10 minutes. Blood samples are taken every 30 minutes for 2 hours. Normal values and criteria for diabetes vary by age, but essentially all values should be <200 mg/dL, and the 120-minute value should be <140 mg/dL.

Insulin secretion by the β-cell is also influenced by plasma levels of amino acids such as arginine, lysine, leucine, and free fatty acids. Glucagon, GIP, GLP-1, and CCK stimulate insulin release, while somatostatin, amylin, and pancreastatin inhibit insulin release.[6] Cholinergic fibers and beta sympathetic fibers stimulate insulin release, while alpha sympathetic fibers inhibit insulin secretion.

Insulin's glucoregulatory function is to inhibit endogenous (hepatic) glucose production and to facilitate glucose transport

Table 33-2

Pancreatic islet peptide products

HORMONES	ISLET CELL	FUNCTIONS
Insulin	β (beta cell)	Decreased gluconeogenesis, glycogenolysis, fatty acid breakdown, and ketogenesis Increased glycogenesis, protein synthesis, and glucose uptake
Glucagon	α (alpha cell)	Opposite effects of insulin; increased hepatic glycogenolysis and gluconeogenesis
Somatostatin	δ (delta cell)	Inhibits GI secretion Inhibits secretion and action of all GI endocrine peptides Inhibits cell growth
Pancreatic polypeptide	PP (PP cell)	Inhibits pancreatic exocrine secretion and section of insulin Facilitates hepatic effect of insulin
Amylin (IAPP)	β (beta cell)	Counterregulates insulin secretion and function
Pancreastatin	β (beta cell)	Decreases insulin and somatostatin release Increases glucagon release Decreases pancreatic exocrine secretion
Ghrelin	(epsilon cell)	Decreases insulin release and insulin action

IAPP = islet amyloid polypeptide.

Table 33-3

Clinical and laboratory findings in types of diabetes mellitus

PARAMETER	TYPE 1	TYPE 2	TYPE 3C
	IDDM	NIDDM	Pancreatogenic
Ketoacidosis	Common	Rare	Rare
Hyperglycemia	Severe	Usually Mild	Mild
Hypoglycemia	Common	Rare	Common
Peripheral Insulin Sensitivity	Normal or Increased	Decreased	Increased
Hepatic Insulin Sensitivity	Normal	Normal or Decreased	Decreased
Insulin Levels	Low	High	Low
Glucagon Levels	Normal or High	Normal or High	Low
PP Levels	Normal or Low (late)	High	Low
GIP Levels	Normal or Low	Normal or High	Low
GLP-1 Levels	Normal	Normal or High	Normal or High
Typical Age of Onset	Childhood or adolescence	Adulthood	Any

Abbreviations: IDDM, insulin dependent diabetes mellitus; NIDDM, non-insulin dependent diabetes mellitus; PP, pancreatic polypeptide; GIP, glucose-dependent insulinotropic polypeptide; GLP-1, glucagon-like peptide 1. [Reproduced with permission from Cui YF & Andersen DK. Copyright Elsevier[159]]

into cells, thus lowering plasma glucose levels. Insulin also inhibits glycogenolysis, fatty acid breakdown, and ketone formation, and stimulates protein synthesis. There is a considerable amount of functional reserve in insulin secretory capacity. If the remaining portion of the pancreas is healthy, about 80% of the pancreas can be resected without the patient becoming diabetic.[7] In patients with chronic pancreatitis, or other conditions in which much of the gland is diseased, resection of a smaller fraction of the pancreas can result in pancreatogenic, or type 3c diabetes (Table 33-3).

Insulin receptors are dimeric, tyrosine kinase–containing transmembrane proteins that are located on all cells. Insulin deficiency (seen in type 1 and type 3c diabetes) results in an overexpression or upregulation of insulin receptors, which causes an enhanced sensitivity to insulin in muscle and adipocytes (and therefore increases the risk of insulin-induced hypoglycemia). Type 2 diabetes is associated with a downregulation of insulin receptors and relative hyperinsulinemia, with resulting insulin resistance. Some forms of diabetes are associated with selected impairments of hepatic or peripheral insulin receptors, such as pancreatogenic or type 3c diabetes (T3cDM) or maturity-onset diabetes of the young (MODY).

Glucagon is a 29-amino-acid, single-chain peptide that promotes hepatic glycogenolysis and gluconeogenesis and counteracts the effects of insulin through its hyperglycemic action. Glucose is the primary regulator of glucagon secretion, as it is with insulin, but it has an inhibitory rather than stimulatory effect. Glucagon release is stimulated by hypoglycemia, and by the amino acids arginine and alanine. GLP-1 inhibits glucagon secretion in vivo, and insulin and somatostatin inhibit glucagon secretion in a paracrine fashion within the islet. The same neural impulses that regulate insulin secretion also regulate glucagon secretion, so that the two hormones work together in a balance of actions to maintain glucose levels. Cholinergic and beta sympathetic fibers stimulate glucagon release, while alpha sympathetic fibers inhibit glucagon release.[8] In pancreatogenic or type 3c diabetes, glucagon responsiveness to a fall in blood glucose is lost, thereby increasing the risk for hypoglycemia.

Although originally isolated from the hypothalamus, somatostatin is a peptide that is now known to have a wide anatomic distribution, not only in neurons but also in the pancreas, gut, and other tissues. It is a highly conserved peptide hormone, as it is found in lower vertebrates, and is now realized to be of fundamental importance in regulatory processes throughout the body. One gene encodes for a common precursor that is differentially processed to generate tissue-specific amounts of two bioactive products, somatostatin-14, and somatostatin-28. These peptides inhibit endocrine and exocrine secretion and affect neurotransmission, GI and biliary motility, intestinal absorption, vascular tone, and cell proliferation.

Five different somatostatin receptors (SSTRs) have been cloned and the biologic properties of each are being unraveled.[9] All five are G-protein-coupled receptors with seven highly conserved transmembrane domains and unique amino and carboxy termini. Phosphorylation sites located within the second and third intracellular loops and in the cytoplasmic C-terminal segment are thought to mediate receptor regulation. Although the naturally occurring peptides bind to all five receptors, somatostatin-28 is relatively selective for SSTR5. The hexapeptide and octapeptide analogues such as octreotide bind only to SSTR2, SSTR3, and SSTR5. These analogues have a longer serum half-life, and their potent inhibitory effect has been used clinically to treat both endocrine and exocrine disorders. For example, octreotide has been shown to decrease fistula output and speed the time it takes for enteric and pancreatic fistulas to close.[10]

Endocrine release of somatostatin occurs during a meal. The major stimulant is probably intraluminal fat. Acidification of the gastric and duodenal mucosa also releases somatostatin in isolated perfused organ preparations. Acetylcholine from the cholinergic neurons inhibits somatostatin release.

Pancreatic polypeptide (PP) is a 36-amino-acid, straight-chain peptide discovered by Kimmel in 1968 during the process of insulin purification. Protein is the most potent enteral stimulator of PP release, closely followed by fat, whereas glucose has a weaker effect.[11] Hypoglycemia, whether or not it is insulin

induced, strongly stimulates PP secretion through cholinergic stimulation.[12] Phenylalanine, tryptophan, and fatty acids in the duodenum stimulate PP release, probably by inducing CCK and secretin release. In the isolated perfused pancreas, insulin and gastric inhibitory peptide stimulate PP release, while glucagon and somatostatin inhibit it. Vagal stimulation of the pancreas is the most important regulator of PP secretion. In fact, vagotomy eliminates the rise in PP levels usually seen after a meal. This can be used as a test for the completeness of a surgical vagotomy or for the presence of diabetic autonomic neuropathy.

PP has been shown to inhibit choleresis (bile secretion), gallbladder contraction, and secretion by the exocrine pancreas. However, PP's most important role is in glucose regulation through its regulation of hepatic insulin receptor gene expression. A deficiency in PP secretion due to proximal pancreatectomy, severe chronic pancreatitis, or cystic fibrosis,is associated with diminished hepatic insulin sensitivity due to reduced hepatic insulin receptor availability.[13] This effect is reversed by PP administration.[14]

Recent studies have shown that a fifth islet peptide, ghrelin, is secreted from a distinct population of islet cells, called *epsilon cells*.[15,16] Ghrelin also is present in the gastric fundus in large amounts and stimulates growth hormone secretion via growth hormone releasing hormone release from the pituitary. It is an orexigenic, or appetite-stimulating, peptide the plasma levels of which are increased in obesity. Ghrelin has also been shown to block insulin effects on the liver, and inhibits the β-cell response to incretin hormones and glucose.[17] Therefore, ghrelin secretion from and within the islet may modulate the responses of other islet cells to nutrient and hormonal stimuli.

In addition to the five main peptides secreted by the pancreas, there are a number of other peptide products of the islet cells, including amylin and pancreastatin, as well as neuropeptides such as VIP, galanin, and serotonin. Amylin or islet amyloid polypeptide (IAPP) is a 37-amino-acid polypeptide that is predominantly expressed by the pancreatic β-cells, where it is stored along with insulin in secretory granules.[18] The function of IAPP seems to be the modulation or counterregulation of insulin secretion and function. Pancreastatin is a recently discovered pancreatic islet peptide product that inhibits insulin, and possibly somatostatin release, and augments glucagon release.[19,20] In addition to this effect on the endocrine pancreas, pancreastatin inhibits pancreatic exocrine secretion.[21]

Islet Distribution

The β-cells are generally located in the central portion of each islet and make up about 70% of the total islet cell mass. The other cell types are located predominantly in the periphery. The delta cells are least plentiful, making up only 5%; the α-cells make up 10%, and the PP cells make up 15%.[22] In contrast to the acinar cells that secrete the full gamut of exocrine enzymes, the islet cells seem to specialize in the secretion of predominantly one hormone. However, individual islet cells can secrete multiple hormones. For example, the β-cells secrete both insulin and amylin, which counterregulates the actions of insulin. In reality, more than 20 different hormones are secreted by the islets, and the exact functions of this milieu are very complex. There is diversity among the islets depending on their location within the pancreas. The α- and δ-cells are evenly distributed throughout the pancreas, but islets in the head and uncinate process (ventral anlage) have a higher percentage of PP cells and fewer α-cells, whereas islets in the body and tail (dorsal anlage) contain the majority of α-cells and few PP cells. This is clinically significant because pancreatoduodenectomy removes 95% of the PP cells in the pancreas. This may partially explain the higher incidence of glucose intolerance after the Whipple procedure compared to a distal pancreatectomy with an equivalent amount of tissue resected. In addition, chronic pancreatitis, which disproportionately affects the pancreatic head, is associated with PP deficiency and pancreatogenic diabetes.[23] The relative preponderance of α-cells in the body and tail of the pancreas explains the typical location of glucagonomas.

ACUTE PANCREATITIS

Definition, Incidence, and Epidemiology

Acute pancreatitis is a common and challenging disease that can develop both local and systemic complications. Its hallmark is acute pancreatic inflammation associated with little or no fibrosis. It ranges from a mild self-limiting inflammation of the pancreas to critical disease characterized by infected pancreatic necrosis, multiple organ failure and a high risk of mortality.[24] The clinical outcome has improved over recent decades, even in the absence of specific treatments that target outcome-determining pathophysiology, probably because of a more consistent approach to diagnosis, monitoring and management.

Acute pancreatitis is the most common gastrointestinal discharge diagnosis in the United States (274,119 patients in 2009), an incidence which has increased 30% since 2000, and is associated with the highest aggregate inpatient costs at 2.6 billion dollars per year.[25] The crude mortality rate of 1.0/100,000 ranks it as the 14th most fatal illness overall and the ninth most common noncancer gastrointestinal death. Worldwide the incidence of acute pancreatitis ranges from 5 to 80/100,000 population with the highest incidence recorded in Finland and United States.[26] The racial incidence of acute pancreatitis also shows significant variation related to the prevalence of etiological factors and ethnicity. The annual incidence of acute pancreatitis in Native Americans is 4 per 100,000 population; in whites it is 5.7 per 100,000 population; and in blacks it is 20.7 per 100,000 population.[27] Smoking is an independent risk factor for acute pancreatitis.[28]

Etiology

Many factors have been causally related to the onset of acute pancreatitis (Table 33-4), but in many instances the mechanism is poorly understood. The most common causes are gallstones and alcohol, accounting for up to 80% of cases, but it is not uncommon to diagnose acute pancreatitis in the absence of these etiological factors. Therefore it is important that a systematic approach is taken to the identification of other, less common, and potentially modifiable, factors. The median age of the onset of acute pancreatitis varies with etiology; alcohol and drug induced pancreatitis typically present in the third or fourth decade compared with gallstone and trauma induced disease in the sixth decade. The gender difference is probably more related to etiology: in males alcohol is more often the cause while in females it is gallstones.

Gallstones

Evidence that passage of a gallstone is related to the onset of acute pancreatitis comes from the characteristic transient derangement of liver function tests and the high retrieval rate

of gallstones from feces within 10 days of an attack of acute pancreatitis compared with those without acute pancreatitis (88% vs. 11%).[29] The mechanism by which small gallstones migrating down the common bile duct, past the pancreatic duct junction and into the duodenum, cause acute pancreatitis is not clear. Opie made the seminal observation of a gallstone impacted in the sphincter of Oddi in two fatal cases of acute pancreatitis, which lead to the "common channel" hypothesis. It was proposed that a gallstone transiently lodged in the distal common channel of the ampulla of Vater allowed bile to reflux into the pancreatic duct, but this cannot be reliably reproduced in experimental models. Another proposal suggested that transient incompetence caused by the passage of a stone through the sphincter might allow duodenal fluid and bile to reflux into the pancreatic duct, but this is refuted by the usual absence of acute pancreatitis after endoscopic sphincterotomy or surgical sphinteroplasty. A third possibility is that acute pancreatitis is due to a gallstone obstructing the pancreatic duct, leading to ductal hypertension. It has been postulated that this backpressure might lead to minor ductal disruption, extravasation of pancreatic juice into the less alkaline interstitium of the pancreas, and promotion of enzyme activation. When gallstones and other etiological factors cannot be identified there is still the possibility of finding microlithiasis, seen as birefringent crystals, on bile microscopy.[30] This occult microlithiasis is probably responsible for up to half of those with idiopathic acute pancreatitis.

Alcohol

Alcohol ingestion is associated with acute pancreatitis and sustained alcohol ingestion is associated with recurrent acute pancreatitis and development of chronic pancreatitis in susceptible individuals who have been drinking for more than a decade. The type of alcohol consumed is less important than the amount consumed (typically 100 to 150 grams per day) and the pattern of drinking. It is common for patients with alcohol associated acute pancreatitis to have a history of excess alcohol consumption prior to the first attack. There are several mechanisms by which ethanol causes acute pancreatitis. Ethanol is a metabolic toxin to pancreatic acinar cells and causes a brief secretory increase followed by inhibition. The secretory burst coupled with ethanol induced spasm of the sphincter of Oddi is thought to incite acute pancreatitis. Ethanol also induces ductal permeability, which would allow prematurely activated enzymes to cause damage to the pancreatic parenchyma. Ethanol also increases the protein content of pancreatic juice, decreases bicarbonate levels, and trypsin inhibitor concentration. The formation of protein plugs may also contribute by causing an obstructive element to pancreatic outflow.

Iatrogenic

Acute pancreatitis can result from a number of treatments, including pancreatic biopsy, exploration of the extrahepatic biliary tree and ampulla of Vater, distal gastrectomy, splenectomy, colectomy, nephrectomy, aortic aneurysmorraphy, and retroperitoneal lymphadenectomy. As the pancreas is susceptible to ischemia it can also occur secondary to splanchnic hypoperfusion with cardio-pulmonary bypass or cardiac transplant. Most commonly, acute pancreatitis occurs as a complication of ERCP in 5% to 10% of procedures, and in many series it is the third most common identified etiological factor. The risk of post-ERCP acute pancreatitis is increased if the contrast agent is infused repeatedly under high pressure by the endoscopist and in patients with sphincter of Oddi dysfunction. Recent evidence demonstrates that the risk can be decreased with prophylactic, rectally administered, nonsteroidal drugs.[31]

Hereditary Pancreatitis

Hereditary pancreatitis is an autosomal dominant disorder usually related to mutations of the cationic trypsinogen gene (PRSS1). Mutations in this gene cause premature activation of trypsinogen to trypsin and cause abnormalities of ductal secretion, both of which promote acute pancreatitis. Mutations in the SPINK1 protein, which blocks the active binding site of trypsin, is also likely to have a role in predisposing to acute pancreatitis. Variations in penetration and phenotype are common and there are many other mutations that may become implicated. Mutant enzymes activated within acinar cells can overwhelm the first line of defense (pancreatic secretory trypsin inhibitor) and resist backup defenses (e.g., proteolytic degradation, enzyme Y, and trypsin itself) allowing activated mutant cationic trypsin to trigger the entire zymogen activation cascade.[32]

Tumors

A pancreatic or periampullary tumor should be considered in any patient with idiopathic acute pancreatitis. Approximately 1% to 2% of patients with acute pancreatitis have a pancreatic tumor, and an episode of acute pancreatitis can be the first clinical manifestation of the tumor. If no historical information leads to an etiologic diagnosis, cross sectional pancreatic imaging after the resolution of an unexplained episode of acute pancreatitis is indicated.

Hyperlipidemia

Patients with types I and V hyperlipoproteinemia can experience episodes of abdominal pain, and these often occur in association with marked hypertriglyceridaemia. Lipase is thought to liberate

toxic fatty acids into the pancreatic microcirculation, leading to microcirculatory impairment and ischemia. Dietary modifications to restrict triglycerides are usually effective, but clofibrate may be prescribed in refractory cases of hypertriglyceridemia.

Drugs and Miscellaneous Causes

Many drugs can produce hyperamylasemia and/or abdominal pain, and a drug is considered suspect if the pancreatitis-like illness resolves with its discontinuation. Ethical considerations generally rule out rechallenge with the suspect drug, so the connection often remains vague. However, despite these limitations, certain drugs are known to be capable of causing acute pancreatitis. These include the thiazide diuretics, furosemide, estrogens, azathioprine, l-asparaginase, 6-mercaptopurine, methyldopa, the sulfonamides, tetracycline, pentamidine, procainamide, nitrofurantoin, dideoxyinosine, valproic acid, and acetylcholinesterase inhibitors. In addition, lipid-based intravenous drugs and solutions, such as propofol, can also cause acute pancreatitis.[33] A history of verified or suspected drug-induced pancreatitis should serve as a contraindication to prescribing that medication again.

Hypercalcemic states arising from hyperparathyroidism can result in both acute and chronic pancreatitis; the mechanism most likely involves hypersecretion and the formation of calcified stones intraductally. Also implicated are infestations by *Ascaris lumbricoides* and the liver fluke *Clonorchis sinensis*, which is endemic to China, Japan, and Southeast Asia. These cause Oriental cholangitis, which is associated with cholangiocarcinoma obstructing the pancreatic duct.

Other implicated factors include azotemia, vasculitis, and the sting of the Trinidadian scorpion Tityus trinitatis. This scorpion's venom has been shown to cause neurotransmitter discharge from cholinergic nerve terminals, leading to massive production of pancreatic juice. Poisoning with antiacetylcholinesterase insecticides has a similar effect. Finally, no apparent cause can be ascribed to some episodes of acute pancreatitis, and these constitute the group referred to as idiopathic pancreatitis. Some of these patients are eventually found to have gallstone-related pancreatitis, which calls for caution in labeling any episode "idiopathic."

Pathophysiology

Acute pancreatitis occurs in various degrees of severity, the determinants of which are multifactorial. The generally prevalent belief today is that pancreatitis begins with the activation of digestive zymogens inside acinar cells, which cause acinar cell injury. Studies suggest that the ultimate severity of the resulting pancreatitis may be determined by the events that occur subsequent to acinar cell injury.[34] These include inflammatory cell recruitment and activation, as well as generation and release of cytokines and other chemical mediators of inflammation (Fig. 33-10).

Precipitating Initial Events

Acinar Cell Events. Acute pancreatitis is an inflammatory disorder believed to begin in the pancreas and is generally restricted to it; although in some cases its effects can be systemic, diverse and result in multiple organ failure. In 1896, Chiari advanced the understanding of acute pancreatitis by proposing the concept that the pancreatitis is essentially the premature, intrapancreatic activation of digestive enzymes, resulting in auto-digestion of the organ. Since then the intra-acinar activation of zymogens

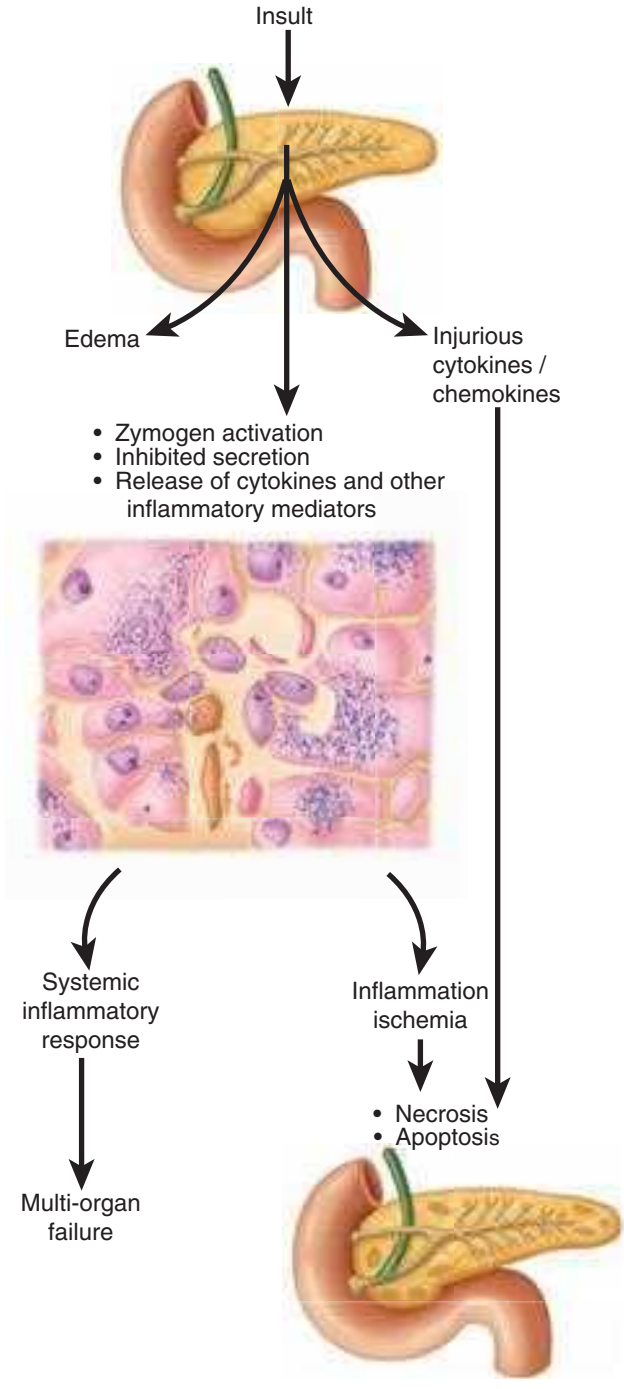

Figure 33-10. Pathophysiology of acute pancreatitis.

has been demonstrated consistently in multiple animal models of acute pancreatitis and is considered a central piece in the puzzle of acute pancreatitis.[35, 36] The key role of trypsin activation in acute pancreatitis has gained additional support from recent studies showing that mice lacking trypsinogen-7 (the isoform of trypsinogen which is activated during acute pancreatitis in mice) have significantly less pancreatic injury during acute pancreatitis[37] and that intra-acinar expression of active trypsin causes pancreatitis in mice.[38] The role of trypsin activation in the pathophysiology of acute pancreatitis has also been suggested by clinical studies; e.g., hereditary pancreatitis is associated with mutations that lead to elevated intracellular trypsin activation[39] and activation of trypsinogen has been demonstrated in clinical pancreatitis as well.[40]

The mechanisms by which injurious stimuli lead to intra-acinar activation of trypsinogen and autodigestion of the gland have been the focus of research in pancreatitis for decades. Because the exocrine pancreas produces enzymes that are potentially injurious to it, several protective mechanisms have evolved to prevent autodigestion under normal conditions. Enzymes are synthesized as inactive precursors called proenzymes or zymogens, which are then transported and secreted outside the gland. Their activation occurs safely in the duodenum, where the brush-border enzyme enteropeptidase (or enterokinase) activates the trypsinogen, and the resulting trypsin then activates the other zymogens in a cascade reaction. This separates the site of production of these enzymes from the site of activation and thus the pancreas is insulated against enzymatic attack. Within the acinar cell itself, the potentially harmful digestive enzymes are segregated from the surrounding cytoplasm by being enclosed within membrane-bound organelles referred to as zymogen granules. Another layer of protection is provided by the synthesis of trypsin inhibitors, which are transported and stored along with the digestive enzyme zymogens. These are available to inhibit small amounts of prematurely-activated trypsinogen within the pancreatic acinar cells. It is theorized that acute pancreatitis occurs when this process goes awry and the gland is injured by the erroneously-activated enzymes that it produces. Although the mechanism(s) of erroneous activation are not fully understood, it has been shown that intra-acinar activation of trypsinogen goes hand-in-hand with inhibition of acinar secretion.[41, 42] Furthermore, in the presence of injurious stimuli, the zymogens responsible for initiating the disease are not secreted outside, but are observed to co-localize with cytoplasmic vacuoles that contain lysosomal enzymes such as cathepsin B.[43] Data suggest that cathepsin B in these vacuoles activates trypsinogen. Thus, inhibition of cathepsin B by pharmacological inhibitors[44] or by genetic deletion of cathepsin B eliminates trypsin activation and decreases the severity of pancreatitis in animal models.[45] What leads to the coming together of zymogens and lysosomal hydrolases is unclear, but injurious stimuli leading to sustained cytosolic calcium increase have been indicted. Blocking this calcium increase prevents co-localization and activation of trypsin, and decreases injury due to pancreatitis.[46] Based on these data, pre-ERCP supplementation of magnesium, a natural antagonist of calcium, is currently being evaluated as a strategy to decrease post-ERCP pancreatitis.[47] How activation of trypsin in the co-localization vacuoles leads to pancreatic damage is also not clear. Recent work has led to the novel hypothesis that the lysosomal hydrolase cathepsin B activates trypsinogen to trypsin within the co-localization vacuoles. Trypsin then permeabilizes these co-localization vacuoles causing the release of cathepsin B into the cytosol. Once in the cytosol, cathepsin B initiates apoptotic cell death by permeabilizing mitochondrial membranes, which allows cytochrome C to be released into the cytosol. This initiates the apoptotic cascade and results in the apoptotic death of the acinar cells (Fig. 33-11).[48]

Intrapancreatic Events

Activated neutrophils are attracted to a focus of tissue injury and after activation release superoxides (the "respiratory burst") and proteolytic enzymes (cathepsins, elastase and collagenase) which cause further injury. In addition macrophages release cytokines (including tumor necrosis factor-alpha (TNF-α), interleukin (IL)-6, and IL-8) which mediate the local and the systemic inflammatory responses. These inflammatory mediators cause an increased pancreatic vascular permeability, leading to edema, hemorrhage, and microthrombi. Fluid may collect in and around the pancreas. The failure of the pancreatic microcirculation, a feature of more severe acute pancreatitis, results in pancreatic hypoperfusion and necrosis. Acute inflammation of the pancreatic parenchyma and peripancreatic tissues, but without recognizable necrosis is termed interstitital edematous pancreatitis.[24] When necrosis is present, and evidenced by pancreatic hypoperfusion with constrast CT, it is termed necrotizing pancreatitis (Fig. 33-12). The updated morphological definitions and the contrast enhanced CT criteria for the diagnosis of the local complications of acute pancreatitis have recently been published in the revised Atlanta statement,[49] and summarized in Table 33-5.[50]

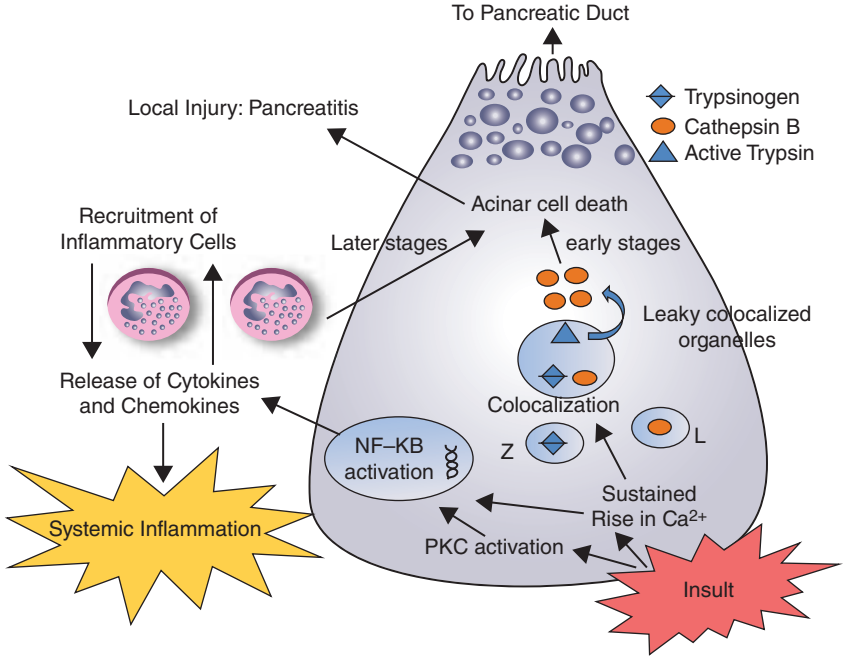

Figure 33-11. Schematic representation of the acinar cell events in acute pancreatitis. When acinar cells are pathologically stimulated, their lysosomal (L) and zymogen (Z) contents colocalize, consequently trypsinogen is activated to trypsin by cathepsin B. Increased cytosolic calcium is required for colocalization. Once trypsin has permeabilized the contents of the cytosol, cathepsin B and other contents of these colocalized organelles are released. Once in the cytosol, cathepsin B activates apoptosis by causing cytochrome c to be released from the mitochondria. Activation of PKC results in a sudden activation of nuclear factor kappa beta (NKκβ) which in turn triggers the release of cytokines that attract inflammatory response cells which mediate local and systemic inflammation cascades.[37]

Figure 33-12. CT scan showing well perfused interstitial edematous acute pancreatitis of the neck and tail of the pancreas with a confluent area of necrosis of the pancreatic body. Pancreas surrounded by fluid, inflammation, and possible peripancreatic fat necrosis.

Systemic Events

An important aspect of the pathophysiology of acute pancreatitis is the mechanism by which events occurring in the pancreas induce systemic inflammation and multiorgan failure. The NFκB- dependent inflammatory pathway is one such key pathway. NFκB activation parallels trypsin activation in acute pancreatitis but appears to be independent of it. The role of trypsin in NFκB activation was debated for a long time, but this issue seems to be largely settled following the observation that NFκB activation still occurs in acini from trypsin knockout mice, which obviously do not have pathologic trypsin activation.[37] However, sustained calcium increase, which leads to trypsinogen activation, is critical for NFκB activation as well, since attenuation of cytosolic calcium also abrogates NFκB activation.[51] Once activated, NFκB regulates synthesis of multiple cytokines and chemokines, leading to recruitment of various inflammatory cells that then magnify and propagate systemic inflammation.

Although intra-acinar events initiate acute pancreatitis, events occurring subsequent to acinar cell injury determine the severity of pancreatitis. Once recruited to the pancreas, various inflammatory cells lead to further acinar cell injury and cause an elevation of various pro-inflammatory mediators such as TNF-α; IL-1, IL-2, IL-6, and other chemokines and anti-inflammatory factors.[36] Elucidation of these mediators has encouraged efforts to target their production or activity with an aim to modulate the course of severe acute pancreatitis.

Organ failure can develop at any stage of acute pancreatitis, associated with an overwhelming proinflammatory response early, or later secondary to the development of infected local complications. The drivers of the systemic response are poorly understood, although factors include the elaboration of proinflammatory cytokines, and it appears that mesenteric lymph, bypassing the liver and containing these constituents, may contribute to the development of organ failure.[52] The development of pancreatic necrosis, the breakdown of the intestinal barrier and the suppression of the immune response through the compensatory inflammatory response contribute to the development of infected pancreatic necrosis, the incidence of which peaks in the third to fourth week. This is usually associated with deterioration in the patient and may be associated with the late development of the systemic inflammatory response syndrome (SIRS) and multiorgan dysfunction syndrome/failure (MODS/F).

Organ failure is scored using the Marshall or Sequential Organ Failure Assessment (SOFA) systems (Table 33-6). The three organ systems most frequently involved are cardiovascular, respiratory, and renal. Multiple organ failure is defined as two or more organs registering 2 or more points on these scoring systems.[49] Monitoring organ failure over time and in response to treatment is important in the clinical care of the disease.

Management of the Patient

General Considerations. The management of acute pancreatitis covers a wide spectrum of severity. Patients with suspected acute pancreatitis should be admitted to hospital. Those with mild acute pancreatitis usually remain in hospital for less than a week, while those with severe and critical acute pancreatitis may require many weeks or months of intensive treatment. The risk of mortality reflects this spectrum of severity. The risk is less than 1% for those with mild disease, increasing to around 10% for those with moderate disease, but for severe and critical disease the mortality risk is much higher (20% to 40% and greater than 50%, respectively). The earlier identification of these high-risk categories and the transfer of these patients to specialized centers is an important priority of management.[53] Scoring systems such as Ranson's Criteria identify these high-risk patients (Table 33-7). The management of acute pancreatitis should be multidisciplinary and it is important that a coordinated care plan is carefully supervised.

Diagnosis

The diagnosis of acute pancreatitis requires the patient to present with abdominal pain consistent with acute pancreatitis (acute onset of a severe constant epigastric pain which often radiates through to the mid back) and the elevation of serum amylase or lipase (>3 times upper limit of normal). Imaging (usually by contrast enhanced CT scanning) is only required for the diagnosis of acute pancreatitis when these diagnostic criteria are not met.[49] Because of the many causes of hyperamylasemia,

Table 33-5

Local complications of acute pancreatitis[50]

Table 33-6

Sequential organ failure assessment (SOFA) score in acute pancreatitis[49]

	0	1	2	3	4
Respiration (PaO_2FIO_2) (mm Hg)	>400	≤400	≤300	≤200 with respiratory support	≤100 with respiratory support
Coagulation Platelets (xl0[1] per µL)	>150	≤150	≤100	≤50	≤20
Liver Bilirubin (µmol/L)	<20	20–32	33–101	102–204	>204
Cardiovascular Hypotension	No hypotension	MAP <70mm Hg	Dopamine ≤5 or dobutamine (any dose)*	Dopamine >5 or epi ≤0.1* or norepi ≤0.1*	Dopamine >15 or epi >0.1* or norepi >0.1*
Central nervous system Glasgow coma score	15	13–14	10–12	6–9	<6
Kidney Creatinine (µmol/L) or urine output	<110	110–170	171–299	300–440 or <500 ml/day	>440 or <200 ml/day

MAP = mean arterial pressure. Epi = epineptvine. Norepi = norepinephrine. *Adrenergic agents administered for at least 1 h (doses given in µg/kg per min). A score of 2 or more in any two systems indicates the presence of multiple organ failure.

Table 33-7

Ranson's prognostic signs of pancreatitis

Criteria for acute pancreatitis not due to gallstones	
At admission	During the initial 48 h
Age >55 y	Hematocrit fall >10 points
WBC >16,000/mm^3	BUN elevation >5 mg/dL
Blood glucose >200 mg/dL	Serum calcium <8 mg/dL
Serum LDH >350 IU/L	Arterial PO_2 <60 mm Hg
Serum AST >250 U/dL	Base deficit >4 mEq/L
	Estimated fluid sequestration >6 L
Criteria for acute gallstone pancreatitis	
At admission	During the initial 48 h
Age >70 y	Hematocrit fall >10 points
WBC >18,000/mm^3	BUN elevation >2 mg/dL
Blood glucose >220 mg/dL	Serum calcium <8 mg/dL
Serum LDH >400 IU/L	Base deficit >5 mEq/L
Serum AST >250 U/dL	Estimated fluid sequestration >4 L

AST = aspartate transaminase; BUN = blood urea nitrogen; LDH = lactate dehydrogen-ase; PO_2 = partial pressure of oxygen; WBC = white blood cell count.

Note: Fewer than 3 positive criteria predict mild, uncomplicated disease whereas more than 6 positive criteria predict severe disease with a mortality risk of 50%.

Prognostic signs and the role of operative management in acute pancreatitis. *Surg Gynecol Obstet* 139:69, 1974.

it is important to measure either the pancreatic isoenzyme of amylase or lipase.

The serum amylase concentration increases almost immediately with the onset of disease and peaks within several hours.[54] It remains elevated for 3 to 5 days before returning to normal. There is no significant correlation between the magnitude of serum amylase elevation and severity of pancreatitis; in fact, a milder form of acute pancreatitis is often associated with higher levels of serum amylase compared with that in a more severe form of the disease.

It is important to note that hyperamylasemia can also occur as a result of conditions not involving pancreatitis. For example, hyperamylasemia can occur in a patient with small bowel obstruction, perforated duodenal ulcer, or other intra-abdominal inflammatory conditions. In contrast, a patient with acute pancreatitis may have a normal serum amylase level, which could be due to several reasons. In patients with hyperlipidemia, values might appear to be normal because of interference by lipids with chemical determination of serum amylase. In many cases, urinary clearance of pancreatic enzymes from the circulation increases during pancreatitis; therefore, urinary levels may be more sensitive than serum levels. For these reasons, it is recommended that amylase concentrations also be measured in the urine. Urinary amylase levels usually remain elevated for several days after serum levels have returned to normal. In patients with severe pancreatitis associated with significant necrotic damage, the pancreas may not release large amounts of enzymes into the circulation.

With increasing severity of disease, the intravascular fluid loss may become life-threatening as a result of sequestration of edematous fluid in the retroperitoneum. Hemoconcentration then results in an elevated hematocrit. However, there also may be bleeding into the retroperitoneum or the peritoneal cavity. In some patients (about 1%), the blood from necrotizing pancreatitis may dissect through the soft tissues and manifest itself as a bluish discoloration around the umbilicus (Cullen's sign) or in the flanks

(Grey Turner's sign). The severe fluid loss may lead to prerenal azotemia with elevated blood urea nitrogen and creatinine levels. There also may be hyperglycemia, hypoalbuminemia, and hypocalcemia sufficient in some cases to produce tetany.

Pain Management

Pain is the cardinal symptom of acute pancreatitis and its relief is a clinical priority. There is a lack of high quality evidence to guide the choice of analgesic. Because of unpredictable absorption analgesia should be administered intravenously, at least at the outset and before oral intake has been established. Those with mild pain can usually be managed with a nonsteroidal anti-inflammatory drug (e.g., metamizole 2g/8h IV) while those with more severe pain are best managed with opioid analgesia (e.g., buprenorphine 0.3mg/4h IV). Administration of buprenorphine, pentazocine, procaine hydrochloride, and meperidine are all of value in controlling abdominal pain. Morphine is to be avoided, due to its potential to cause sphincter of Oddi spasm.

Predicting Severity

Where classification relates to the present or past severity of acute pancreatitis, prediction is about the future and ultimate severity and outcome of the patient. Accurately predicting acute pancreatitis severity is important in making triage decisions about whether a patient should be transferred to a tertiary hospital, or admitted to an intensive care unit, and in making decisions about fluid therapy, whether an ERCP is indicated, and other issues. There is a long history of attempts to find prognostic or predictive markers that accurately stratify the risk, with the most widely used being the Ranson's criteria (Table 33-7) or modified Glasgow criteria. Both use clinical and biochemical parameters scored over the first 48 hours of admission. When there are 3 or more positive criteria, the disease is considered "predicted severe." There are many other approaches to predicting severity. At 24 hours after admission an APACHE II score of 8 or more or a serum C-reactive protein level of >150mg/dl has a similar accuracy in predicting severity as Ranson's criteria.[54] The more recently proposed Bedside Index for Severity of Acute Pancreatitis (BISAP) is calculated from blood urea nitrogen (> 25 mg/dl), impaired mental status (GCS <15), presence of systemic inflammatory response syndrome (SIRS), age >60 years, and pleural effusion. Although it has the advantage of simplicity and can be performed within the first 24 hours of admission it has performed no better than other predictors in comparison studies.[55] The presence of SIRS also has prognostic significance.[56] There remains some controversy as to the importance of obesity as a risk factor for severe and critical acute pancreatitis.[57] Another approach has been taken in seeking to predict those with 'harmless' acute pancreatitis[58] using three factors that can be determined on admission; absence of rebound tenderness or guarding, normal hematocrit, and normal serum creatinine. The accuracy of this approach appears to be over 90%, and triages most patients with acute pancreatitis away from intensive care.

Unfortunately these and many other single and combined predictors of severity have an accuracy of only around 70%.[54] This means that there is misclassification error of 30% that limits the value in predicting the severity of acute pancreatitis in individual patients. In the absence of any new biomarkers of ultimate disease severity, making better use of existing predictors through sequencing tests, combining tests or using artificial neural network methodologies has shown promise.[59]

Classification of the Severity of Acute Pancreatitis

Accurately classifying or staging acute pancreatitis severity is important for clinical decision-making, communication, and enrollment into trials. The wide spectrum of pancreatitis severity has not been captured in the previous binary classifications (mild or severe). A four-category classification of severity (mild, moderate, severe, critical) (Table 33-8) has been developed on the principle of casual inference, derived by meta-analysis, refined by an international multidisciplinary process and independently validated.[60] The key determinants of severity are local complications (absent, sterile or infected) and systemic complications (absent, transient organ failure, or persistent organ failure).[61]The tracking of patient severity is important in delineating the clinical trajectory of a patient, and this classification of severity can be applied on a frequent basis. It can also be used in retrospect for audit purposes.

Determining the Etiology

A history of alcohol ingestion must be ascertained and preferably confirmed with blood ethanol levels. Gallstones should be investigated by ultrasonography. A gallstone etiology is more likely in females over the age of 50 with an elevation of alkaline phosphatase (>300 IU/L), alanine transferase (>100 IU/L) and amylase (>4000 IU/L). In the absence of gallstones and alcohol, a systematic approach to the identification of another factor will include taking a history for drug use, trauma, ERCP, infection, and measuring serum triglycerides, calcium, and others (Table 33-4).

Fluid Resuscitation

Fluid therapy to restore and maintain circulating blood volume is the most important intervention in the early management of acute pancreatitis.[62] A recent systematic review has shown that

Table 33-8

Four categories of acute pancreatitis severity based on organ failure and local complications[61]

DETERMINANTS	NO LOCAL COMPLICATIONS	STERILE LOCAL COMPLICATIONS	INFECTED LOCAL COMPLICATIONS
NO ORGAN FAILURE	MILD	MODERATE	SEVERE
TRANSIENT ORGAN FAILURE	MODERATE	MODERATE	SEVERE
PERSISTENT ORGAN FAILURE	SEVERE	SEVERE	CRITICAL

the evidence base for fluid therapy is scant, however.[63] It is not known which fluid to give, how aggressively to administer it or what goal to use as a guide or to monitor the response to it. While there are proponents for aggressive fluid therapy and for specific resuscitation goals, it is probably best to resuscitate with a balanced crystalloid and to restore normal blood volume, blood pressure, and urine output. On the basis of recent data it appears that lactated Ringer's solution may be superior to normal saline in reducing the systemic inflammatory response.[64] Caution needs to be exercised in those with cardiac and renal disease and in the elderly.

Nutritional Support

In contrast to analgesia and fluid therapy there is a sound evidence base for nutritional support in acute pancreatitis.[65] It is no longer acceptable to "rest the pancreas" by avoiding enteral nutrition, and parenteral nutrition should only be offered if the patient's calculated nutritional requirements cannot be achieved by the enteral route. Enteral nutrition should be commenced after initial fluid resuscitation and within the first 24 hours of admission. It can be introduced through a nasogastric tube and increased in step-wise fashion over 2 to 3 days.[66] The tube can be advanced to the jejunum, by endoscopy or fluoroscopy, if there is evidence of feeding intolerance. A delay in commencing enteral nutrition may contribute to the development of intestinal ileus and feeding intolerance. Aggressive early enteral feeding, particularly prior to adequate resuscitation, may put the patient at risk of nonocclusive mesenteric ischemia. There is no evidence to support the use of elemental or immune-enhancing formulas over standard polymeric formulas.[67]

3▶ In predicted mild acute pancreatitis the transition from oral fluids to food is usually timed to when the patient's abdominal pain has resolved, but the trend is toward allowing patients to resume intake ad libidum (i.e., patient controlled nutrition).

Cross-sectional Imaging

It may be necessary to perform a CT scan to diagnose acute pancreatitis in patients who are severely ill, or in those presenting with undifferentiated abdominal pain. But there is no advantage in using CT findings, or a "CT Severity Index," over other methods in predicting the severity of acute pancreatitis.[54] The primary purpose of cross sectional imaging is the diagnosis of local complications, in particular the development and extent of pancreatic necrosis or the presence of different fluid collections. CT scanning is important to guide the insertion of percutaneous drains in the management of local complications. MR is superior to CT scanning in detecting any solid content within collections (Fig. 33-13). When bleeding is suspected in association with a local complication, an arterial phase CT scan (CTa) is useful in detecting a pseudoaneurysm, active bleeding, and/or hematoma.

Therapeutic Endoscopic Retrograde Cholangiopancreatography (ERCP)

Randomized trials have demonstrated that early ERCP (within 24 or 48 hours of admission) reduces complications, but not mortality, in patients with predicted severe gallstone-associated acute pancreatitis. The benefits of this invasive modality (release of the presumed impacted stone) may be offset, however, but the risks of the procedure, which include an increase in the severity of pancreatitis, bleeding, cholangitis, and duodenal perforation. More recent evidence has suggested that early ERCP confers no benefit in the absence of concomitant cholangitis, as the offending common duct stone usually passes before ERCP can be performed.[68] If symptoms and chemical abnormalities persist or increase after intial presentation, magnetic resonance cholangio-pancreatography (MRCP) can detect a filling defect in the distal common bile duct, and may be used as prerequisite for attempted ERCP.[69] Persistent cholestasis without cholangitis may require an ERCP but is rarely indicated in the acute setting.

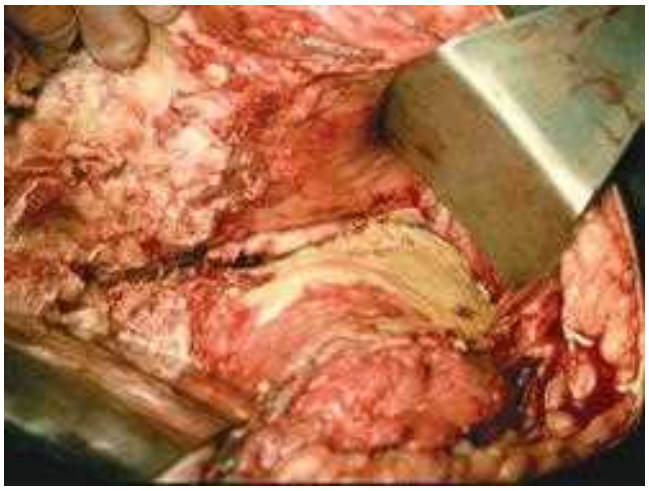

Figure 33-14. Operative view of infected acute pancreatitis. Peripancreatic infection, characterized by mucopurulent exudate, extends far beyond the boundaries of the pancreas in the retroperitoneum.

Antibiotics

Although the use of broad-spectrum antibiotics to treat established infection in acute pancreatitis is a well-established practice, there has been considerable controversy surrounding the use of prophylactic antibiotics. The overuse of antibiotics has been associated with a documented rise in fungal infections and resistant organisms. Overall, it appears that the most recent and generally better designed studies do not support the use of prophylactic antibiotics to reduce the frequency of pancreatic infectious complications, surgical intervention, and death.[70]

Managing Local Complications

Vigilance is required for the timely and accurate diagnosis of local complications. The decisions regarding how and when to intervene are often difficult. While guided by the information gained by cross-sectional imaging, the decision to intervene is based on the clinical status and trajectory of the patient and the poor response to maximal intensive care support. This means close monitoring of the patient by serial examination, supplemented by regular measurement of inflammatory markers (e.g., C reactive protein) and a pancreatic protocol CT scan if a local complication is suspected and intervention considered warranted. In practice, intervention is delayed in order to allow demarcation of necrosis, and a reduced the risk of bleeding, disseminated infection and collateral damage to adjacent organs by an intervention (Fig. 33-14). Appreciation of this has resulted in a notable trend toward delayed intervention, now uncommon before 3 to 4 weeks from the onset of symptoms. An important emerging approach is the increasing use of percutaneous catheter drainage in patients with suspected infected complications.[71] Fine needle aspiration is now rarely used to confirm infection because the insertion of a needle at the time of planned drainage allows confirmation of the suspected infection. Preemptive drainage with one or more catheters often produces improvement or stabilization of the patient's overall clinical status.[72] In this way drainage "buys time" and allows the lesion to become more walled off and safer to treat. Recent data suggest that primary percutaneous catheter drainage may be the only intervention required in a third to a half of patients and that this proportion might increase further if there were a standard protocol of regular catheter exchange, upsizing and irrigation.[72] A proportion of patients do however require further treatment when they fail to respond (the so-called "step up approach") and there is a wide array of minimally invasive options to choose from[73](Fig. 33-15). These interventions can be classified on the basis of the method of visualization, route taken to the lesion and the purpose of the intervention.[74] In practice the approach taken will depend on local expertise and equipment as well as

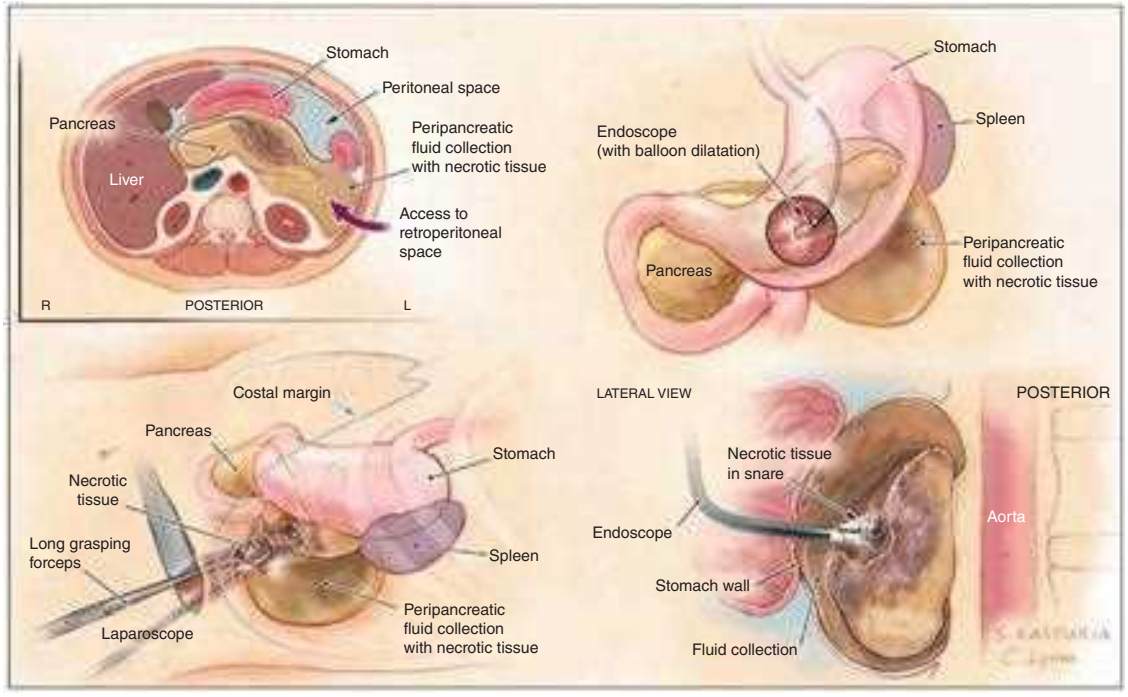

Figure 33-15. Two minimally invasive interventions for local complications of acute pancreatitis: **A.** video-assisted retroperitoneal debridement and **B.** endoscopic transgastric necrosectomy [76]. *(Reproduced with permission from Bakker OJ et al. Endoscopic transgastric vs surgical necrosectomy for infected necrotizing pancreatitis: A randomized trial.* JAMA. *2012;307(10):1053. Copyright © 2012 American Medical Association. All rights reserved.)*

the location and type of the specific local complication. A large Dutch randomized trial has shown that open surgical techniques should only be considered in those who fail to respond to the step-up approach, that is prior percutaneous drainage and minimally invasive intervention.[75] The exception is to be found in the rare situation where an abdominal compartment syndrome requires open decompression, but this is usually earlier than the optimal time to intervene for local complications. A recent landmark randomized trial has compared two minimally invasive techniques, endoscopic transgastric drainage and the videoscope assisted retroperitoneal debridement through a flank incision (Fig. 33-15). The data show that the former approach is superior, although the latter has a role when the walled off necrosis is remote from the stomach or duodenum, as in the left flank.[76]

The management of an acute noninfected pseudocyst is usually conservative, as about half of these will resolve spontaneously. When symptoms of pain or inability to eat persist or infection occurs, intervention is required. Pseudocysts persist because of communication with the main pancreatic duct and/or distal ductal stenosis. Percutaneous drainage should be avoided in this situation because of the risk of external pancreatic fistula.[77] EUS guided internal drainage into stomach, duodenum, or transpapillary pancreatic duct stenting is the preferred approach.

Managing Organ Failure

The specific management of multiple organ failure is beyond the scope of this chapter. The early identification of organ dysfunction and failure is important because it is a key determinant of severity and outcome and to facilitate the timely transfer of the patient to an intensive care unit to optimize management, provide organ support, and allow more intensive monitoring. The severity of organ failure can be scored (Table 33-6). The responsiveness of organ failure to resuscitation over the first 48 hours is an important prognostic clue; those that respond have transient organ failure and have a better outlook than those who do not respond and have persistent organ failure.[78] Organ failure that develops later in the disease course is usually secondary to infection of a local complication and should be managed accordingly (Table 33-9).

Table 33-9

Algorithm for the evaluation and management of acute pancreatitis

1. Diagnosis
   - History of abdominal pain consistent with acute pancreatitis
   - >3x elevation of pancreatic enzymes
   - CT scan if required to confirm diagnosis
2. Initial assessment / management (first 4 hrs)
   - Analgesia
   - Fluid resuscitation
   - Predict severity of pancreatitis
     - Ranson's criteria
     - HAPS score
   - Assess systemic response
     - SIRS score
     - SOFA (organ failure)
3. Reassessment / management (4 to 6 hrs)
   - Assess response to fluid resuscitation
     - mean arterial pressure
     - heart rate
     - urine output
     - hematocrit
   - Determine etiology
     - Ultrasound for gallstones/sludge
     - History of alcohol consumption
     - Laboratory evaluation of other causes
   - MRCP and/or Urgent ERCP if concomitant cholangitis is present
     - not for cholestasis or predicted severe disease per se
   - Transfer to ICU or specialist center as needed
     - Deterioration or failure to respond to initial management
     - Intensive support for persistent organ failure
   - Commence enteral nutrition
     - Once normovolemia restored (usually after 6 hours)
     - Commence via NG tube if no gastric stasis
   - No prophylactic antibiotics or probiotics
4. Conservative management and monitoring (at least daily)
   - Clinical evaluation
     - Assess cardiovascular, respiratory, and renal function
     - Detect peritonitis and abdominal compartment syndrome
   - Daily C-Reactive Protein
   - Classify severity (mild, moderate, severe, critical)
   - Detect intolerance of NG EN
     - Advance tube for NJ feeding if needed
     - Consider supplemental Parenteral Nutrition by day 4
5. Indications for "pancreatic protocol CT scan" (rarely in 1st week)
   - For significant clinical deterioration and elevated CRP
   - For suspicion of local pancreatic complications
   - For suspected bowel ischemia
   - For acute bleeding (CTa) (if stable enough & consider embolization)
   - For abdominal compartment syndrome
6. Invasive intervention
   - For deteriorating patient with suspected infected local complication
   - "Step up approach" with initial drain guided by current CT scan (percutaneous or endoscopic drainage)
   - Delay for 3 to 4 weeks with intensive care support, if possible
   - If failure to respond or secondary deterioration, repeat CT scan, and select appropriate minimally invasive technique based on available expertise and equipment
     - Video-assisted retroperitoneal debridement or percutaneous nephroscopic debridement
     - Endoscopic transluminal debridement
     - Ongoing large bore drainage and irrigation
7. Indication for laparotomy
   - Failed "step-up approach" for further debridement/ drainage
   - Acute abdomen (perforation or ischemia)
   - Severe abdominal compartment syndrome (rarely)

Cholecystectomy

While it is widely accepted that cholecystectomy is essential to prevent gallstone pancreatitis recurrence, the timing of cholecystectomy is important. Index cholecystectomy, done in the same admission and prior to discharge, appears safe and can almost always be accomplished laparoscopically.[79] But index cholecystectomy is not suitable for all patients, particularly some who have had local pancreatic complications which includes a large phlegmon which extends into the porta hepatis. These patients may require an interval cholecystectomy after resolution of the inflammatory process. If surgery is required for the management of local complications, then a cholecystectomy is often performed at that time.

The management of acute pancreatitis remains a formidable challenge due to the variety and severity of many associated complications (Table 33-10), and continues to evolve. Although specific treatments for acute pancreatitis remain elusive, progress has been made in the management of pain, fluid resuscitation, antibiotic prophylaxis, enteral nutrition, therapeutic ERCP, and cholecystectomy. Progress has also been made in the intensive care management of systemic complications and in the development of less invasive interventions for the treatment of local complications, particularly infected pancreatic necrosis.

4▶

Table 33-10

Complications of acute pancreatitis

I. Local
- A. Pancreatic phlegmon
- B. Pancreatic abscess
- C. Pancreatic pseudocyst
- D. Pancreatic ascites
- E. Involvement of adjacent organs, with hemorrhage, thrombosis, bowel infarction, obstructive jaundice, fistula formation, or mechanical obstruction

II. Systemic
- A. Pulmonary
  1. Pneumonia, atelectasis
  2. Acute respiratory distress syndrome
  3. Pleural effusion
- B. Cardiovascular
  1. Hypotension
  2. Hypovolemia
  3. Sudden death
  4. Nonspecific ST-T wave changes
  5. Pericardial effusion
- C. Hematologic
  1. Hemoconcentration
  2. Disseminated intravascular coagulopathy
- D. GI hemorrhage
  1. Peptic ulcer
  2. Erosive gastritis
  3. Portal vein or splenic vein thrombosis with varices
- E. Renal
  1. Oliguria
  2. Azotemia
  3. Renal artery/vein thrombosis
- F. Metabolic
  1. Hyperglycemia
  2. Hypocalcemia
  3. Hypertriglyceridemia
  4. Encephalopathy
  5. Sudden blindness (Purtscher's retinopathy)
- G. Central nervous system
  1. Psychosis
  2. Fat emboli
  3. Alcohol withdrawal syndrome
- H. Fat necrosis
  1. Intra-abdominal saponification
  2. Subcutaneous tissue necrosis

CHRONIC PANCREATITIS

Definition, Incidence, and Prevalence

Chronic pancreatitis is an incurable, chronic inflammatory condition that is multifactorial in its etiology, highly variable in its presentation, and a challenge to treat successfully. Autopsy studies indicate that evidence of chronic inflammation, such as fibrosis, duct ectasia, and acinar atrophy is seen in up to 5% of the population,[80] although these data are difficult to interpret because many of these changes are also present in asymptomatic elderly patients.[81] Population studies suggest a prevalence that ranges from 5 to 40 persons per 100,000 population, with considerable geographic variation.[82] Differences in diagnostic criteria, regional nutrition, alcohol consumption, and medical access account for variations in the frequency of the diagnosis, but the overall incidence of the disease has risen progressively over the past 50 years.

Etiology

There are multiple etiologies of chronic pancreatitis, including genetic mutations, alcohol exposure, duct obstruction due to trauma, gallstones, and tumors, metabolic diseases such as hyperlipidemia and hyperparathyroidism, and auto-immune disease. In addition, nutritional causes include so-called "tropical pancreatitis," which has been thought to result from ingestion of certain starches. A significant number of patients have no discernible cause of the disease despite extensive testing, and are said to have idiopathic chronic pancreatitis.

Genetic Causes

In 1952, Comfort and Steinberg reported a kindred of "hereditary chronic relapsing pancreatitis" after treating the proband, a 24-year-old woman, at the Mayo Clinic.[83] Subsequently, familial patterns of chronic, nonalcoholic pancreatitis have been described worldwide, and a familiar pattern has emerged. Typically, patients first present in childhood or adolescence with abdominal pain and are found to have chronic calcific pancreatitis on imaging studies. Progressive pancreatic dysfunction is common, and many patients present with symptoms due to pancreatic duct obstruction. The risk of subsequent carcinoma formation is increased, reaching a prevalence, in some series, of 40%, but the age of onset for carcinoma is typically >50 years old.[84] The disorder is characterized by an autosomal dominant pattern of inheritance, with 80% penetrance and variable expression. The incidence is equal in both sexes.

Whitcomb and colleagues,[85] and separately LeBodic and associates,[86] performed gene linkage analysis and identified a linkage for hereditary pancreatitis to chromosome 7q35. Subsequently, the region was sequenced and revealed eight trypsinogen genes. Mutational analysis revealed a missense mutation resulting in an Arg to His substitution at position 117 of the cationic trypsinogen gene, or PRSS1, one of the primary sites for proteolysis of trypsin. This gain-of-function mutation results in an excess production of trypsinogen, which results in persistent and uncontrolled proteolytic activity and autodestruction within the pancreas.[87] The position 117 mutation of PRSS1 and an additional mutation, now known collectively as the R122H and N291 mutations of PRSS1, account for about two-thirds of cases of hereditary pancreatitis. Recently, Masson and associates described a gain-of-function mutation in the anionic trypsinogen gene, PRSS2, that is also present in some cases.[88]

Similarly,SPINK1, an inflammation-induced trypsin inhibitor secreted in acinar cells, has been found to have a role in hereditary pancreatitis. SPINK1 specifically inhibits trypsin action by competitively blocking the active site of the enzyme. Witt and colleagues investigated 96 unrelated children with chronic pancreatitis in Germany and found a variety of SPINK1 mutations in 23% of the patients.[89] Several studies have now confirmed an association of loss-of-function SPINK1 mutations with familial and idiopathic forms of chronic pancreatitis, as well as so-called tropical pancreatitis.[90, 91] SPINK1 mutations are common in the general population as well, and the frequency of these mutations varies in different cohorts of idiopathic chronic pancreatitis, from 6.4% in France[92] to 25.8% in the United States.[93] Thus, hereditary pancreatitis results from one or more mutational defects that incapacitate an auto-protective process that normally prevents proteolysis within the pancreas.

Cystic fibrosis, originally termed cystic fibrosis of the pancreas, results from a variety of mutations of the cystic fibrosis transmembrane receptor (CFTR). The CFTR is present in pancreatic duct cells, and controls the amount of chloride and bicarbonate secreted into the normally alkaline pancreatic juice. The CFTR gene contains over 4300 nucleotides, divided into 24 exons, which encode a 1480-amino acid protein. Over 1000 polymorphisms have been reported, and many are common.[32] The CFTR mutation associated with the classic pulmonary disease, F508, is rarely observed in chronic pancreatitis. But other CFTR mutations have been noted to be associated with chronic idiopathic pancreatitis and auto-immune pancreatitis in which the pulmonary, intestinal, and cutaneous manifestations of the disease are silent.[94]

Many studies have been undertaken to determine whether specific genetic abnormalities are associated with alcoholic chronic pancreatitis, and which might confer susceptibility to the disease. A 5.8% rate of SPINK1 mutations in patients with alcoholic pancreatitis has been shown, compared to a 0.8% rate in the control population, and studies of the known mutations of the CFTR gene have failed to demonstrate a strong association with alcoholic chronic pancreatitis.[89]

In 2012, a landmark study by Whitcomb and associates demonstrated a likely genetic cause of the predisposition to alcohol-induced chronic pancreatitis in men[95]. In a genome-wide association study of more than 2000 patients, these researchers discovered that a common DNA variant on the X chromosome is present in 26% of men without pancreatitis, but jumps to nearly 50% of men diagnosed with alcoholic pancreatitis. The variant involves the claudin 2 (CLDN2) gene, which encodes a tight junction protein normally present in ductal cells. In cases of chronic pancreatitis, the CLDN2 protein is abnormally expressed in acinar cells, and may alter the secretory dynamics of enzyme release. The abnormality does not appear to cause pancreatitis but if pancreatitis occurs for any reason in a person with the CLDN2 variant, it is more likely that the person will develop chronic pancreatitis; the risk is increased even further among alcohol users. Only 10% of women have the X chromosome-linked variant on both X chromosomes, and most women with the CLDN2 variant on one X chromosome appear to be protected from alcoholic chronic pancreatitis by the other X chromosome, if it is normal. Men, with only one X chromosome, have no protection if they inherit a CLDN2 mutation. This helps to explain the high prevalence of alcoholic chronic pancreatitis among men, although the mechanism remains unclear. This study does not demonstrate a genetic cause for all cases of alcohol-related chronic pancreatitis, but shows that a genetic element contributes to many patients with the disease (Fig. 33-16).

Alcohol

In 1878, Friedreich proposed that "a general chronic interstitial pancreatitis may result from excessive alcoholism (drunkard's pancreas)."[96] Since that observation, numerous studies have shown that a causal relationship exists between alcohol and chronic pancreatitis, but the prevalence of alcohol as the etiology of the disease in Western countries ranges widely, from 38% to 94%[97](Fig. 33-17).

There is a linear relationship between exposure to alcohol and the development of chronic pancreatitis.[98] The risk of disease is present in patients with even a low or occasional exposure to alcohol (1 to 20 g/d), perhaps due to the CLDN2 gene mutation described above, so there is no threshold level of alcohol exposure below which there is no risk of developing chronic pancreatitis. Furthermore, although the risk of disease is dose related, and highest in heavy (>150 g/d) drinkers, the prevalence of chronic pancreatitis among confirmed alcohol abusers is only 5% to15%.[99] However, the duration of alcohol consumption is definitely associated with the development of pancreatic disease. The onset of disease typically occurs between ages 35 to 40 years, after 16 to 20 years of heavy alcohol consumption. Recurrent episodes of acute pancreatitis are typically followed by chronic symptoms after 4 or 5 years.[100]

Although the pattern of disease presentation is well known in those alcohol users who develop pancreatic disease, the pathophysiology of alcohol-induced pancreatic disease is still an area of active investigation. In their 1946 classic study, Comfort, Gambrill, and Baggenstoss proposed that chronic pancreatitis was the result of multiple episodes of acute inflammation, with residual and progressively increasing chronic inflammation.[101] Subsequently, other investigators proposed that initial acute inflammation was not necessarily linked to chronic changes in the pancreas,[102] and Kondo and associates showed that other, additional factors were necessary for repeated exposure to alcohol to cause chronic pancreatitis.[103] Regardless of the requirement for other predisposing or facilitative factors, the concept that multiple episodes (or a prolonged course) of pancreatic injury ultimately leads to chronic disease is widely accepted as the pathophysiologic sequence[104] (Fig. 33-18).

Although direct alcohol exposure to the pancreatic ductal system, or elevated levels of alcohol in the bloodstream, has

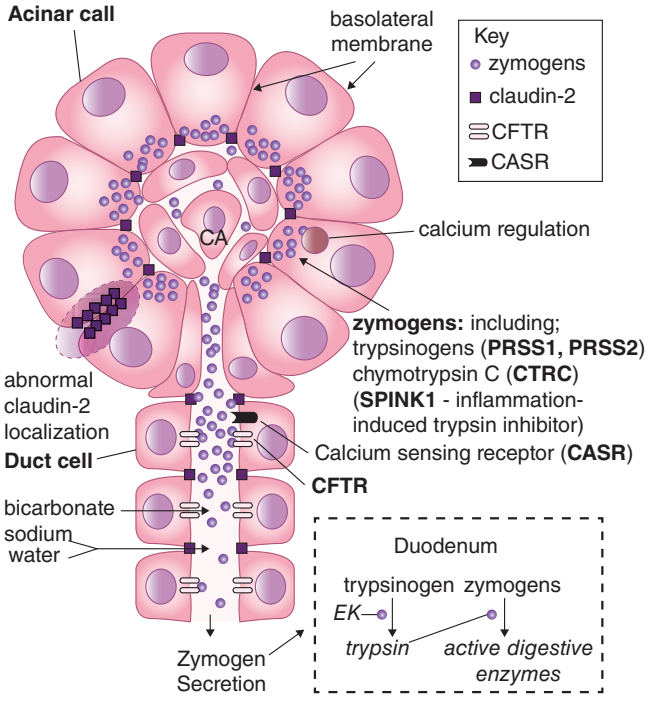

Figure 33-16. Schematic model of genetic causes of chronic pancreatitis. A pancreatic acinus is portrayed showing the pathway for digestive enzymes (**zymogens**) to be secreted by the **acinar cell** into the ductal system where water, sodium, and bicarbonate are secreted by the **duct and centroacinar (CA) cells**. Mutations in at least five genes have been identified as risk factors for chronic pancreatitis: gain-of function mutations in the cationic trypsinogen genes (**PRSS1, PRSS2**) cause hereditary pancreatitis. Cationic and anionic trypsinogen are normally active in the duodenum by enterokinase (**EK**). Premature activation of the trypsin in the acinar cell leads to zymogen activation, local cellular injury, and inflammation. Mutations of the trypsin inhibitors **SPINK1** or chymotrypsin C (**CTRC**), or of the calcium sensing receptor **CASR,** result in premature activation of trypsinogen. Mutations in the cystic fibrosis transmembrane receptor **CFTR** results in trypsinogen stasis within the ducts due to insufficient secretion by duct cells. A Mutation in claudin-2 (**CLDN2**) results in abnormal expression in acinar cells, instead of its normal location between duct cells, and is associated with the accelerated development of chronic pancreatitis in alcohol abusers. (*Adapted with permission from Macmillan Publishers, Ltd. Whitcomb DC et al: Common genetic variants in the CLDN2 and PRSS1-PRSS2 loci alter risk for alcohol-related and sporadic pancreatitis.* Nat Genet. *2012;44:1349. Copyright © 2012.*)

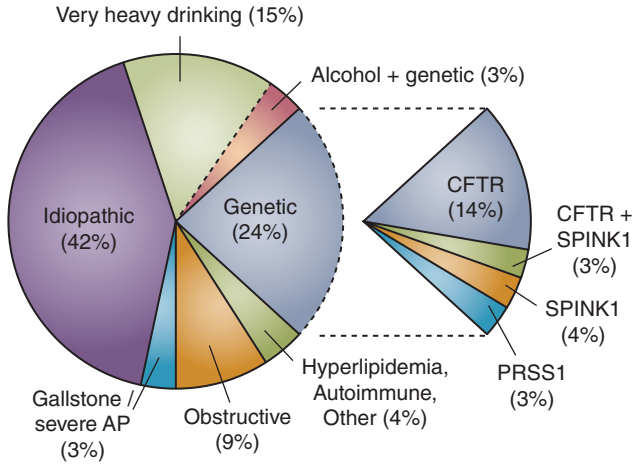

Figure 33-17. Etiologies of chronic pancreatitis. (*Reproduced with permission from Whitcomb DC. Acad Med. 86:1353,2011.*)

been shown to alter the integrity and function of pancreatic ducts and acini directly,[105] most investigators believe that alcohol metabolites such as acetaldehyde, combined with oxidant injury, result in local parenchymal injury that is preferentially targeted to the pancreas in predisposed individuals. Repeated or severe episodes of toxin-induced injury activate a cascade of cytokines, which, in turn, induces pancreatic stellate cells (PSCs) to produce collagen and cause fibrosis (Fig. 33-19). It remains to be determined whether alcohol sensitizes the pancreas of susceptible individuals to another cause of acute inflammation, or whether genetic or other factors predispose to direct alcohol-related injury.[104]

Alcohol may interfere with the intracellular transport and discharge of digestive enzymes, and may contribute to the colocalization of digestive enzymes and lysosomal hydrolase within acinar cells, leading to autodigestion[106, 107] (see section on Acute Pancreatitis). A high-protein, low-bicarbonate, low-volume secretory output is seen after chronic alcohol exposure which may contribute to the precipitation of proteins in secondary ducts in the early stages of chronic pancreatitis.[108] Calcium is complexed to protein plugs in small ductules, secondary ducts, and, eventually, in the main ductal system, which causes ductal cell injury and obstruction of the secretory system, which further promotes an inflammatory response.

Cigarette smoking has been strongly associated with chronic pancreatitis,[109] but until recently it was unclear whether this was a causative risk factor. Studies have now shown that smoking actually accelerates the development of alcoholic pancreatitis,[110] and the risk of cancer in chronic pancreatitis is increased significantly by smoking. In hereditary pancreatitis, smoking has been found to lower the age of onset of carcinoma

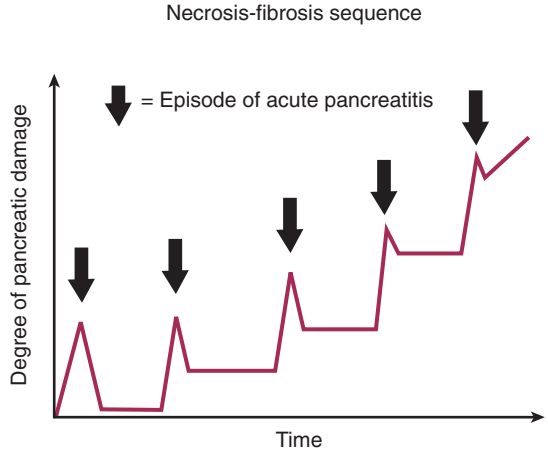

Figure 33-18. "Multiple hit" theory of the etiology of chronic pancreatitis. Multiple episodes of acute pancreatitis cause progressively more organized inflammatory changes that ultimately result in chronic inflammation and scarring. by about 20 years.[111] Smoking therefore appears to be an independent risk factor for the late complications of alcoholic pancreatitis, if not an early cofactor for the development of fibrosis.

Hyperparathyroidism

Hypercalcemia is a known cause of pancreatic hypersecretion,[112] and chronic hypercalcemia caused by untreated hyperparathyroidism is associated with chronic calcific pancreatitis.[113] Hypercalcemia is also a stimulant for pancreatic calcium secretion, which contributes to calculus formation and obstructive pancreatopathy. The treatment is correction of the hyperparathyroidism and assessment of any additional endocrinopathies.

Hyperlipidemia

In addition to the risk of acute pancreatitis, hyperlipidemia and hypertriglyceridemia predispose women to chronic pancreatitis when they receive estrogen replacement therapy.[114] Fasting triglyceride levels <300 mg/dL are below the threshold for this to occur, and the mechanism of estrogen potentiation of hyperlipidemia-induced chronic pancreatitis is unknown. It is assumed that chronic changes occur after repeated subclinical episodes of acute inflammation. Aggressive therapy of hyperlipidemia is therefore important in peri- or postmenopausal patients who are candidates for estrogen therapy.

Classification

A major impediment to a better understanding of the etiology, frequency and severity of chronic pancreatitis has been the difficulty with which investigators and clinicians have struggled to identify a useful classification system. Multiple classification systems have been proposed. The TIGAR-O scheme categorizes chronic pancreatitis according to risk factors and etiologies, such as a) toxic-metabolic, b) idiopathic, c) genetic, d) auto-immune, e) recurrent and severe acute pancreatitis, or f) obstructive.[115] A recent classification system based on histopathology as well as etiology, as delineated by Singer and Chari,[116] is shown in Table 33-11.

Chronic Calcific (Lithogenic) Pancreatitis

This type is the largest subgroup in the classification scheme proposed by Singer and Chari, and includes patients with calcific pancreatitis of most etiologies. Although the majority of patients with calcific pancreatitis have a history of alcohol abuse, stone formation and parenchymal calcification can develop in a variety of etiologic subgroups; hereditary pancreatitis and tropical pancreatitis are particularly noteworthy for the formation of stone disease. The clinician should therefore avoid the assumption that calcific pancreatitis confirms the diagnosis of alcohol abuse.

Chronic Obstructive Pancreatitis

This refers to chronic inflammatory changes that are caused by the compression or occlusion of the proximal ductal system by tumor, gallstone, posttraumatic scar, or inadequate duct caliber (as in pancreas divisum). Obstruction of the main pancreatic duct by inflammatory (posttraumatic) or neoplastic processes can result in diffuse fibrosis, dilated main and secondary pancreatic ducts, and acinar atrophy. The patient may have little in the way of pain symptoms or may present with signs of exocrine insufficiency. Intraductal stone formation is rare, and both functional and structural abnormalities may improve when the obstructive process is relieved or removed. Trauma to the pancreas frequently results in duct injury and leakage, which may result in pseudocyst formation as well as local scar formation. Inadequately treated pancreatic trauma may result in persistent inflammatory changes in the distal gland.[117]

Pancreas divisum represents a special case of obstructive pancreatitis. It is the most common congenital anomaly involving the pancreas and occurs in up to 10% of children. It is thought to predispose the pancreas to recurrent acute pancreatitis and chronic pancreatitis, due to functional obstruction of a diminutive duct of Santorini that fails to communicate with

Table 33-11

Classification of chronic pancreatitis based on etiologic causes

CHRONIC CALCIFIC PANCREATITIS	CHRONIC OBSTRUCTIVE PANCREATITIS	CHRONIC INFLAMMATORY PANCREATITIS	CHRONIC AUTOIMMUNE PANCREATITIS	ASYMPTOMATIC PANCREATIC FIBROSIS
Alcohol	Pancreatic tumors	Unknown	Associated with autoimmune disorders (e.g., primary sclerosing cholangitis)	Chronic alcoholic
Hereditary	Ductal stricture			Endemic in asymptomatic residents in tropical climates
Tropical	Gallstone- or trauma-induced or pancreas divisum			
Hyperlipidemia			Sjögren's syndrome	
Hypercalcemia			Primary biliary cirrhosis	
Drug-induced				
Idiopathic

Wirsung's duct (Fig. 33-20). However, the classic picture of obstructive pancreatopathy with a dilated dorsal duct is unusual in pancreas divisum, so a decompressive operation or a lesser papilla sphincteroplasty is frequently not feasible or unsuccessful. Endoscopic stenting through the lesser papilla may result in temporary relief of symptoms, and this response would increase the possibility that a permanent surgical or endoscopic intervention will be successful. Although some authors emphasize the pathologic implications of pancreas divisum,[118] others express skepticism that it represents a true risk to pancreatic secretory capacity or contributes to the development of chronic pancreatitis.[119, 120]A recent French study reveals that pancreas divisum is equally prevalent among patients with idiopathic chronic pancreatitis and normal controls (7%), and is minimally increased in patients with PRSS1 and SPINK1 mutations. It is accompanied by CFTR mutations in 47% of patients, however, suggesting that the presence of pancreas divisum together with mutational events may increase the susceptibility to pancreatitis.[121]

Chronic Inflammatory Pancreatitis

Chronic inflammatory pancreatitis is characterized by diffuse fibrosis and a loss of acinar elements with a predominant mononuclear cell infiltration throughout the gland.

A variant of chronic pancreatitis is a nonobstructive, diffusely infiltrative disease associated with fibrosis, a mononuclear cell (lymphocyte, plasma cell, or eosinophil) infiltrate, and an increased titer of one or more autoantibodies.[122] This type, referred to as *autoimmune pancreatitis* (AIP), is associated with a variety of illnesses with suspected or proven autoimmune etiology, such as Sjögren's syndrome, rheumatoid arthritis, and type I diabetes mellitus. AIP has been characterized as either type I, with accompanying systemic or multiorgan dysfunction, or type II, which is restricted to the pancreas.

Compressive stenosis of the intrapancreatic portion of the common bile duct is frequently seen in both types of AIP, along with symptoms of obstructive jaundice. Increased levels of serum β-globulin or immunoglobulin G4 are also present. Steroid therapy is uniformly successful in ameliorating the disease, including any associated bile duct compression.[123] CFTR mutations which result in dislocation of the transmembrane protein have been found in AIP, and steroid therapy results in a normalization of the CFTR localization, and a resumption of normal chloride and bicarbonate secretion.[124] The differential diagnosis includes lymphoma, plasmacytoma ("pseudotumor" of the pancreas), and diffuse infiltrative carcinoma. Although the diagnosis is confirmed on pancreatic biopsy, presumptive treatment with steroids is usually undertaken, especially when clinical and laboratory findings, such as an elevation in IgG4 levels, support the diagnosis. Failure to obtain a cytologic specimen may lead to an unnecessary resectional procedure, and an untreated inflammatory component may cause sclerosis of the extrahepatic or intrahepatic bile ducts, with eventual liver failure.[125]

Tropical (Nutritional) Pancreatitis

Chronic pancreatitis is highly prevalent among adolescents and young adults in Indonesia, southern India, and tropical Africa. Abdominal pain develops in adolescence, followed by the development of a brittle form of pancreatogenic diabetes. Parenchymal and intraductal calcifications are seen, and the pancreatic duct stones may be quite large.[126] Many of the patients appear malnourished, some present with extreme emaciation, and a characteristic cyanotic coloration of the lips may be seen.[127] In addition to protein-caloric malnutrition, toxic products of some indigenous foodstuffs have also been thought to contribute to the disease. Because of the geographic concentration of this early-onset form of chronic pancreatitis, it has been termed "*tropical pancreatitis*," although the exact etiology remains unclear.

Clinically, tropical pancreatitis presents much like hereditary pancreatitis, and a familial pattern among cases is not unusual.

SPINK1mutations have been documented in 20% to 55% of patients with tropical pancreatitis, and CFTR mutations have been reported as well.[90, 91]The accelerated deterioration of endocrine and exocrine function, the chronic pain due to obstructive disease, and the recurrence of symptoms despite decompressive procedures characterize the course of disease. As immigrants from the tropical regions increasingly find their way to all parts of the world, an awareness of this severe form of chronic pancreatitis is helpful for those who treat patients with pancreatic disease.

Asymptomatic Pancreatic Fibrosis

Pancreatic fibrosis is seen in some asymptomatic elderly patients, in tropical populations, or in asymptomatic alcohol users. There is diffuse perilobar fibrosis and a loss of acinar cell mass, but without a main ductular component.

A shortcoming of these clinical classification systems is the lack of histologic criteria of chronic inflammation due to the usual absence of a biopsy specimen. The differentiation of recurrent acute pancreatitis from chronic pancreatitis with exacerbations of pain can be difficult to establish and is not facilitated by the current system. Similarly, cystic fibrosis is known to cause fibrosis and acinar dysfunction but is not included in the classification despite increasing evidence for its possible role in idiopathic chronic pancreatitis.[128] Therefore, further refinements in the classification system for chronic pancreatitis are needed to allow a better prediction of its clinical course and a more accurate diagnosis of a likely etiologic agent.

Idiopathic Pancreatitis

When a definable cause for chronic pancreatitis is lacking, the term *idiopathic* is used to categorize the illness. Classically, the idiopathic group includes young adults and adolescents who lack a family history of pancreatitis but who may represent individuals with spontaneous gene mutations encoding regulatory proteins in the pancreas. A variable percentage of SPINK1 and CFTR mutations have been described in various studies. In addition, the idiopathic group has included a large number of older patients for whom no obvious cause of recurrent or chronic pancreatitis can be found.[129] However, because the prevalence of biliary calculi increases steadily with age, it is not surprising that, as methods of biliary stone detection have improved, many elderly "idiopathic" pancreatitis patients are found to have biliary tract disease.[130]

As previously noted , an increasing number of mutations of the SPINK1 and CFTR genes have been identified in association with various forms of chronic pancreatitis. However, the role of genetic analysis in the management of these patients remains unclear, as guidelines have yet to be developed to allow physicians to use the data consistently.[32] The clinical management of patients who harbor a minor CFTR mutation and chronic pancreatitis, for example, is still dictated by the clinical manifestations of the pancreatitis.

Pathology

Histology. In early chronic pancreatitis, the histologic changes are unevenly distributed and are characterized by induration, nodular scarring, and lobular regions of fibrosis (Fig. 33-21). As the disease progresses, there is a loss of normal lobulation, with thicker sheets of fibrosis surrounding a reduced acinar cell mass, and dilatation of ductular structures (Fig. 33-22). The ductular epithelium is usually atypical and may display features of dysplasia, as evidenced by cuboidal cells with hyperplastic features, accompanied by areas of mononuclear cell infiltrates or patchy

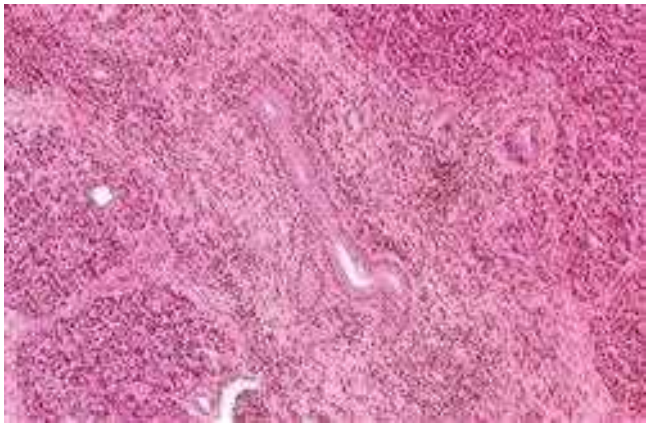

Figure 33-21. Histology of early chronic pancreatitis. (*Courtesy of Rhonda Yantiss, Weill Cornell Medical College.*)

areas of necrosis. Cystic changes may be seen, but areas of relatively intact acinar elements and normal-appearing islets persist. In severe chronic pancreatitis, there is considerable replacement of acinar tissue by broad, coalescing areas of fibrosis, and the islet size and number are reduced (Fig. 33-23). Small arteries appear thickened and neural trunks become prominent.[131]

Tropical pancreatitis and hereditary pancreatitis are histologically indistinguishable from chronic alcoholic pancreatitis. In obstructive chronic pancreatitis, calculi are absent, although periacinar fibrosis and dilated ductular structures are prominent. In pancreatic lobular fibrosis seen in elderly subjects, small ducts are dilated, sometimes with small calculi trapped within. Hypertrophy of ductular epithelia is thought to cause this small-duct disease, which is accompanied by perilobular fibrosis.[132]

Fibrosis. A common feature of all forms of chronic pancreatitis is the perilobular fibrosis that forms surrounding individual acini, then propagates to surround small lobules, and eventually coalesces to replace larger areas of acinar tissue. The pathogenesis of this process involves the activation of pancreatic

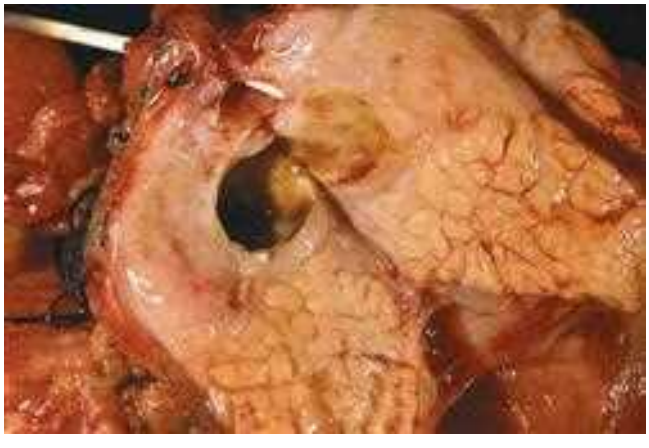

Figure 33-22. Gross appearance of chronic pancreatitis. Areas of fibrosis and scarring are seen adjacent to other areas within the gland in which the lobar architecture is grossly preserved. stellate cells (PSCs) that are found adjacent to acini and small arteries.[133] The extended cytoplasmic processes of PSCs encircle the acini but appear quiescent in the normal gland, where they contain lipid vacuoles and cytoskeletal proteins. In response to pancreatic injury, the PSCs become activated and proliferate (similarly to hepatic stellate cells), lose their lipid vesicles, and transform into myofibroblast-like cells. These cells respond to proliferative factors such as transforming growth factor beta, platelet-derived growth factor, and proinflammatory cytokines and synthesize and secrete type I and III collagen and fibronectin. Studies indicate that vitamin A metabolites, similar to those present in quiescent PSCs, can inhibit the collagen production of activated cultured PSCs.[134] This raises the possibility that early intervention may be possible to interrupt or prevent the fibrosis resulting from ongoing activation of PSCs.

The overall pathogenic sequence proposed by Schneider and Whitcomb[135] whereby alcohol induces acute pancreatitis and, with ongoing exposure, promotes the development of chronic fibrosis, is summarized in Fig. 33-19. PSCs surrounding the acinus are activated in acute pancreatitis but may be inactivated by anti-inflammatory cytokines and, in the absence of further injury, may revert to a quiescent state. The role of proinflammatory macrophages, cytokines, and PSCs in models of acute and chronic pancreatitis represents an important area of current research.

Stone Formation. Pancreatic stones are composed largely of calcium carbonate crystals trapped in a matrix of fibrillar and other material. The fibrillar center of most stones contains no calcium but rather a mixture of other metals. This suggests that stones form from an initial noncalcified protein precipitate, which serves as a focus for layered calcium carbonate precipitation. The same low-molecular-weight protein is present in stones and protein plugs and was initially named *pancreatic stone protein*, or PSP.[136] PSP was found to be a potent inhibitor of calcium carbonate crystal growth and has subsequently been renamed *lithostathine*.[137] Independently, a 15-kDa fibrillar protein isolated from the pancreas was named *pancreatic thread protein*, and it has been shown to be homologous with lithostathine. Finally, a protein product of the *reg* gene, so named because it is expressed in association with regenerating islets in models of pancreatic injury, was isolated and called *reg* protein, and was subsequently found to be homologous with lithostathine.[138] No overall homology has been found between lithostathine and other pancreatic proteins. The PSP/pancreatic thread protein/reg/lithostathine gene encodes for a 166-amino acid product that undergoes post-translational modification to produce isoforms present in pancreatic juice. The protein is expressed in all rodents and mammals, both in the pancreas as well as in brain tissue, where it is found in particularly high concentrations in pyramidal neurons in Alzheimer's disease and Down syndrome. It is also found in the renal tubules, which is consistent with its biologic action of preventing calcium carbonate precipitation.

Calcium and bicarbonate ions are normally present in pancreatic juice in high concentrations, and the solubility product of calcium carbonate is greatly exceeded under normal conditions. Microcrystals of calcium carbonate can be seen in normal pancreatic juice but are usually clinically silent. Lithostathine is a potent inhibitor of calcium carbonate crystal formation, at a concentration of only 0.1 µmol/L. However, lithostathine concentrations in normal pancreatic juice are in the range of 20 to 25 µmol/L, so a constant suppression of calcium carbonate crystal formation is present in the normal pancreas.

In alcoholics and in patients with alcoholic chronic pancreatitis, lithostathine expression and secretion are dramatically inhibited[139] (Fig. 33-24). In addition, elevated levels of precipitated lithostathine in the duct fluid in chronic pancreatitis patients suggests that the availability of the protein may be further reduced by the action of increased proteases and other proteins present in the duct fluid of alcoholic patients. Increased pancreatic juice protein levels in alcoholic men are reversible by abstinence from alcohol,[140] so the availability and effectiveness of lithostathine may be restored in patients with early-stage disease by timely intervention. Nevertheless, calcific stone formation represents an advanced stage of disease, which can further promote injury or symptoms due to mechanical damage to duct epithelium or obstruction of the ductular network.

Duct Distortion. Although calcific stone disease is normally a marker for an advanced stage of disease, parenchymal and

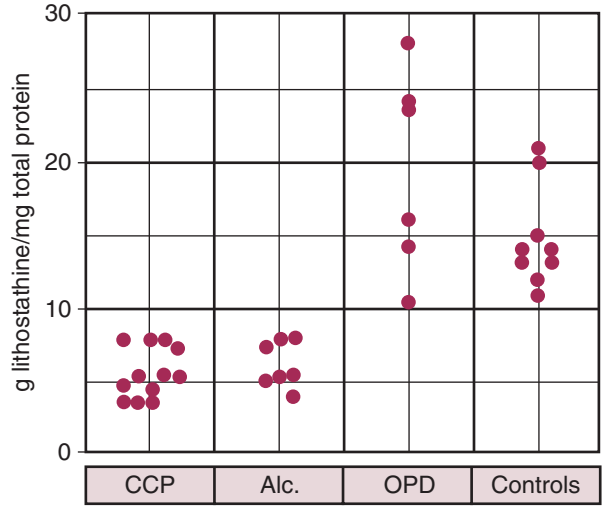

Figure 33-24. Lithostathine levels in chronic calcific pancreatitis (CCP) patients, patients with alcohol abuse (Alc.), patients with other pancreatic disease (OPD), and controls. (*Reproduced with permission of Wiley-Blackwell. From Goggin et al.*[140])

ductular calcifications do not always correlate with symptoms. Obstructing main duct stones are commonly observed and are thought to be an indication for endoscopic or surgical removal. The ball-valve effect of a stone in a secreting system produces inevitable episodes of duct obstruction, usually accompanied by pain. But some patients with complete duct obstruction have prolonged periods of painlessness. Ductular hypertension has been documented in patients with proximal stenosis of the main pancreatic duct, and prolonged ductular distention after secretin administration is taken as a sign of ductular obstruction.[141] Although calculus disease and duct enlargement appear together as late stages of chronic pancreatitis, controversy persists over whether they are associated, are independent events, or are causally related.

Radiology. Radiologic imaging of chronic pancreatitis assists in four areas: (a) diagnosis, (b) the evaluation of severity of disease, (c) detection of complications, and (d) assistance in determining treatment options.[142] With the advent of cross-sectional imaging techniques such as CT and magnetic resonance imaging (MRI), the contour, content, ductal pattern, calcifications, calculi, and cystic disease of the pancreas are all readily discernible. Transabdominal ultrasonography is frequently used as a screening method for patients with abdominal symptoms or trauma, and the extension of ultrasonic imaging to include endoscopic ultrasound (EUS) and laparoscopic US have resulted in the highest-resolution images that are capable of detecting very small (<1 cm) abnormalities in the pancreas. EUS is now frequently used as a preliminary step in the evaluation of patients with pancreatic disease, and magnetic resonance cholangiopancreatography (MRCP) is increasingly being used to select patients who are candidates for the most invasive imaging method, ERCP. The staging of disease is important in the care of patients, and a combination of imaging methods is usually used (Table 33-12).

5▶

Ultrasonography is frequently used as an initial imaging method in patients with abdominal symptoms, and changes consistent with pancreatic duct dilatation, intraductal filling defects, cystic changes, and a heterogeneous texture are seen in chronic pancreatitis (Fig. 33-25). The sensitivity of transabdominal ultrasonography ranges from 48% to 96%, and is operator dependent.[143] However, the contour, texture, and ductal pattern are usually quite discernible, and it is a reliable method for periodic re-examination to determine the efficacy of treatment.

EUS has heavily impacted the evaluation and management of patients with chronic pancreatitis. Although it is more operator dependent and less widely available than transabdominal ultrasonography, EUS provides not only imaging capability but adds the capacity to obtain cytologic and chemical samples of tissue and fluid aspirated with linear array monitoring (Fig. 33-26). EUS images obtained through a high-frequency (7.5- to 12.5-mHz) transducer are able to evaluate subtle changes in 2- to 3-mm structures within the pancreas and can detect indolent neoplasms in the setting of chronic inflammation. Small intraductal lesions, intraductal mucus, cystic lesions, and subtle ductular abnormalities are recognizable by EUS (Table 33-13). This allows ERCP to be reserved for these patients who require therapeutic maneuvers, or for the evaluation of more complex problems. EUS is comparable to ERCP in the detection of advanced changes in chronic pancreatitis and may be more sensitive than ERCP in the detection of mild disease.[144]

CT scanning has affected the diagnosis of pancreatic disease more broadly than any other method. With the advent of faster helical CT scanning and CT angiography, visualization of the nature, extent, location, and relative relationships of pancreatic structures and lesions is possible with great clarity. Duct dilatation, calculous disease, cystic changes, inflammatory events, and anomalies are all detectable with a resolution of 3 to 4 mm (Fig. 33-27). CT scanning has a false-negative rate of <10% for chronic pancreatitis, but early or mild chronic

Table 33-12

Cambridge classification of pancreatic morphology in chronic pancreatitis

CLASSIFICATION	ERCP FINDINGS	CT AND US FINDINGS
Normal	No abnormal SBDs	Normal gland size, shape; homogeneous parenchyma
Equivocal	MPD normal	One of the following: less than three abnormal SBDs; MPD 2–4 mm; gland enlarged more than two times normal size; heterogeneous parenchyma
Mild	MPD normal	Two or more of the following: less than three abnormal SBDs; MPD 2–4 mm; slight gland enlargement; heterogeneous parenchyma
Moderate	MPD changes	Small cysts <10 mm; MPD irregularity
	SBD changes	Focal acute pancreatitis; increased echogenicity of MPD walls; gland-contour irregularity
Severe	Any of the above changes plus one or more of the following: Cysts <10 mm; intraductal filling defects; calculi; MPD obstruction or stricture; severe MPD irregularity; contiguous organ invasion	—

CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; MPD = main pancreatic duct; SBD = side-branch duct; US = ultrasound.

disease may go undetected by CT imaging. The earliest changes are dilatation of secondary ducts and heterogeneous parenchymal changes, which are detectable by EUS and ERCP. Another drawback of CT scanning is its lower sensitivity for detecting small neoplasms, which are seen with increased frequency in chronic pancreatitis and may be invisible to all modalities except EUS.

An MRI, in both the cross-sectional mode and the coronally oriented heavily weighted T2 or high spin ratio imaging (MRCP) that can disclose fluid-filled ducts and cystic lesions, has added greatly to the imaging options for chronic pancreatitis (Fig. 33-28). The resolution of cross-sectional MRI scanning is now approaching that of CT scanning, although the availability of MRI scanners and the complexity of the images produced have limited their large-scale use for routine imaging of the pancreas. MRCP has been shown to be an effective screening technique for disclosing ductal abnormalities that correlates closely with

Figure 33-26. Endoscopic ultrasound of chronic pancreatitis. the contrast-filled ducts imaged by ERCP.[145] The advantages of MRCP include its noninvasive methodology and its ability to image obstructed ducts that are not opacified by ERCP injection. It is therefore a useful screening study to detect duct abnormalities and to confirm the need for interventional procedures. Oral, IV, and intraductal contrast are unnecessary for MRCP, and its lack of ionizing radiation makes this the safest method to image the ductal system in high-risk patients.

For the diagnosis and staging of chronic pancreatitis, ERCP is considered to be the gold standard . It also serves as a vehicle that enables other diagnostic and therapeutic maneuvers, such as

Figure 33-27. Computed tomographic imaging of chronic pancreatitis. A dilated pancreatic duct is seen, with evidence of intraductal stones and parenchymal calcification. biopsy or brushing for cytology, or the use of stents to relieve obstruction or drain a pseudocyst (Fig. 33-29). Unfortunately, ERCP also carries a risk of procedure-induced pancreatitis that occurs in approximately 5% of patients.[31,145] Patients at increased risk include those with sphincter of Oddi dysfunction and those with a previous history of post-ERCP pancreatitis. Post-ERCP pancreatitis occurs after uncomplicated procedures, as well as after those that require prolonged manipulation. Severe pancreatitis and deaths have occurred after ERCP. It should be reserved for patients in whom the diagnosis is unclear despite the use of other imaging methods, or in whom a diagnostic or therapeutic maneuver is specifically indicated.

Figure 33-29. Pancreatic duct stenting. At endoscopic retrograde cholangiopancreatography, a stent is placed in the proximal pancreatic duct to relieve obstruction and reduce symptoms of pain. Pancreatic duct stents are left in place for only a limited time to avoid further inflammation.

Presentation, Natural History, and Complications

Presenting Signs and Symptoms. Pain is the most common symptom of chronic pancreatitis. It is usually midepigastric in location but may localize or involve either the left or right upper quadrant of the abdomen. Occasionally, it is perceived in the lower midabdomen but is frequently described as penetrating through to the back (Fig. 33-30). The pain is typically steady and boring, but not colicky. It persists for hours or days and may be chronic with exacerbations caused by eating or drinking alcohol. Chronic alcoholics also describe a steady, constant pain that is temporarily relieved by alcohol, followed by a more severe recurrence hours later.

Patients with chronic pancreatic pain typically flex their abdomen and either sit or lie with their hips flexed, or lie on their side in a fetal position. Unlike ureteral stone pain or biliary colic, the pain causes the patient to be still. Nausea or vomiting may accompany the pain, but anorexia is the most common associated symptom.

Pain from chronic pancreatitis has been ascribed to three possible etiologies. Ductal hypertension, due to strictures or stones, may predispose to pain that is initiated or exacerbated by eating. Chronic pain without exacerbation may be related to parenchymal disease or retroperitoneal inflammation with persistent neural involvement. Acute exacerbations of pain in the setting of chronic pain may be due to acute increases in duct pressure or recurrent episodes of acute inflammation in the setting of chronic parenchymal disease. Nealon and Matin have described these various pain syndromes as being predictive of the response to various surgical procedures.[146] Pain that is found in association with ductal hypertension is most readily relieved by pancreatic duct decompression, through endoscopic stenting or surgical decompression.

The surgical relief of pain due to obstructive pancreatopathy may be dependent on the degree of underlying fibrosis rather than the presence of ductal obstruction, per se, according to a recent study from Johns Hopkins by Cooper et al.[147]About 35 patients with chronic pain associated with evidence of duct obstruction were treated with Local Resection of the pancreatic head and Longitudinal Pancreatico-Jejunostomy (LR-LPJ), or Frey

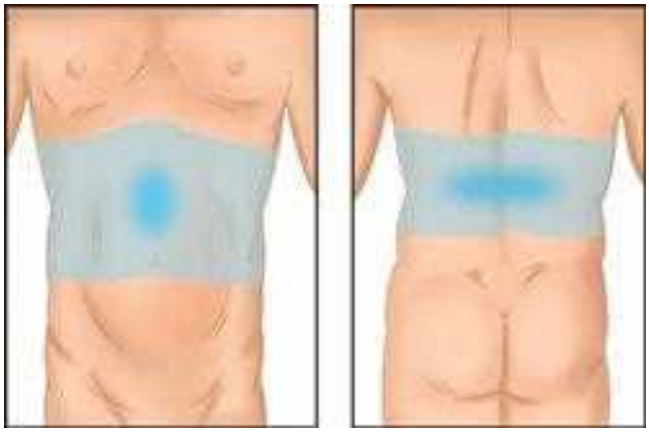

Figure 33-30. Pain location in chronic pancreatitis. (*Reproduced with permission from Murayama KM, Jochl RJ. Chronic pancreatitis, in Greenfield LJ et al (eds):* Surgery, Scientific Principles and Practice, *3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, p 969.*)

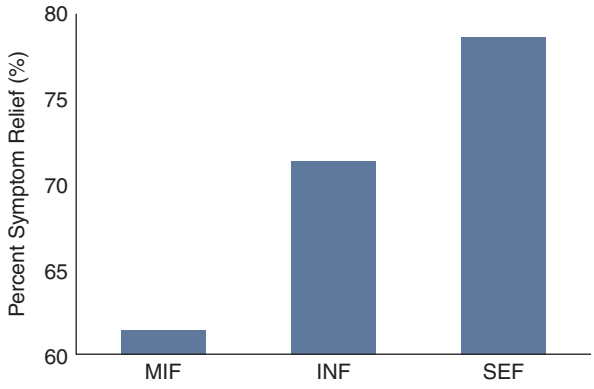

Figure 33-31. Pain relief from chronic pancreatitis treated with the Frey procedure correlates with the degree of underlying fibrosis. procedure, and the degree of pain resolution after surgery was compared to the degree of underlying parenchymal fibrosis. After a follow-up that averaged 22 months, patients with more than 80% fibrosis had 100% pain relief, whereas only 60% patients with less than 10% fibrosis experienced substantial or complete pain relief (Fig. 33-31). These findings suggest that minimal fibrosis, or "minimal change chronic pancreatitis," may produce chronic pain due to extrapancreatic or "peri-pancreatic" inflammatory events which are not ameliorated by decompression.

The pain of chronic pancreatitis may decrease or disappear completely over a period of years, as symptoms of exocrine and endocrine deficiency become apparent.[148] This is referred to as *burned outpancreatitis* and correlates with the progression of disease from a mild or moderate stage to severe destruction of the pancreas. Although this evolution of painful to nonpainful disease is sometimes used as a justification to avoid intervention in painful chronic pancreatitis, noninterventional approaches to the treatment of chronic pancreatitis are inevitably accompanied by the development of narcotic addiction, inability to work, and the sequelae of chronic illness.

Although increased ductal pressure, and therefore parenchymal pressure, is thought to be the cause of pain in chronic obstructive pancreatitis, the role of chronic inflammation per se, and the development of actual nerve damage in the diseased gland, are also thought to contribute to pain.[149] Chronic inflammation results in the infiltration of tissue by macrophages, which secrete prostaglandins and other nociceptive agents that cause chronic stimulation of afferent neural fibers. Inflammatory damage to the perineurial layers surrounding the unmyelinated pancreatic nerves and a focal infiltration of inflammatory cells around nerves suggest that neural fibers are a target for the cellular response to inflammation in the pancreas.[150]

Strategies to relieve pain are therefore based on three approaches: (a) reducing secretion and/or decompress the secretory compartment, (b) resecting the focus of chronic inflammatory change, or (c) interrupting the transmission of afferent neural impulses through neural ablative procedures. A trial of antisecretory therapy or endoscopic duct drainage may select those patients who will benefit preferentially from a decompressive procedure.

Malabsorption and Weight Loss. When pancreatic exocrine capacity falls below 10% of normal, diarrhea and steatorrhea develop[151] (Fig. 33-32). Patients describe a bulky, foul-smelling, loose (but not watery) stool that may be pale in color and float on the surface of toilet water. Frequently, patients will describe a greasy or oily appearance to the stool, or may describe an "oil slick" on the water's surface. In severe steatorrhea, an orange, oily stool is often reported. As exocrine deficiency increases, symptoms of steatorrhea are often accompanied by weight loss. Patients may describe a good appetite despite weight loss, or diminished food intake due to abdominal pain.

In severe symptomatic chronic pancreatitis, anorexia or nausea may occur with or separate from abdominal pain. The combination of decreased food intake and malabsorption of nutrients usually results in chronic weight loss. As a result, many patients with severe chronic pancreatitis are below ideal body weight.

Lipase deficiency tends to manifest itself before trypsin deficiency, so the presence of steatorrhea may be the first functional sign of pancreatic insufficiency.[152] As pancreatic exocrine function deteriorates further, the secretion of bicarbonate into the duodenum is reduced, which causes duodenal acidification and further impairs nutrient absorption.[153] Pancreatic exocrine insufficiency is frequently asymptomatic, however, and pancreatic exocrine function is difficult to measure, so a diagnosis of chronic pancreatitis is sufficient to justify a trial of pancreatic enzyme supplements. Each meal should be followed by 90,000 United States Pharmacopeia units of lipase, and the metabolic and symptomatic status of the patients should be followed.[154]

Pancreatogenic Diabetes. The islets comprise only 2% of the mass of the pancreas, but they are preferentially conserved when pancreatic inflammation occurs. In chronic pancreatitis, acinar tissue loss and replacement by fibrosis is greater than the degree of loss of islet tissue, although islets are typically smaller than normal and may be isolated from their surrounding vascular network by the fibrosis. With progressive destruction of the gland, endocrine insufficiency commonly occurs. Frank diabetes is seen initially in about 20% of patients with chronic pancreatitis, and impaired glucose metabolism can be detected in up to 70% of patients. In a study of 500 patients with predominantly

B Distribution of causes of T3cDM

Figure 33-33. Distribution of types of diabetes (**A**) and causes of type 3c (pancreatogenic) diabetes (**B**) based on studies of 1922 diabetic patients referred to an academic medical center as reported by Hardt et al.[157] (*Reproduced from Cui YF and Andersen DK[159] with permission. Copyright Elsevier.*)

alcoholic chronic pancreatitis, diabetes developed in 83% within 25 years of the clinical onset of chronic pancreatitis, and more than half of the diabetic patients required insulin treatment.[155] Ketoacidosis and diabetic nephropathy are relatively uncommon in pancreatogenic diabetes (Table 33-3), but retinopathy and neuropathy are seen to occur with a similar frequency as in type 1 and type 2 diabetes.[156]

Pancreatogenic diabetes is most common in cases of chronic pancreatitis, and is often seen after surgical resection for benign or malignant disease[157,158] (Fig. 33-33). Distal pancreatectomy and Whipple procedures have a higher incidence of diabetes than do drainage procedures, and the severity of diabetes is usually worse after subtotal or total pancreatectomy. Pancreatogenic, or type 3c diabetes (T3cDM), is seen in cystic fibrosis, in association with pancreatic cancer, and in cases of severe hemachomatosis.[159]

The etiology and pathophysiology of pancreatogenic diabetes is distinct from that of either autoimmune (type 1) or obesity-related (type 2) diabetes. In type 3c diabetes, the loss of functioning pancreatic tissue by disease or surgical removal results in a global deficiency of all three glucoregulatory islet cell hormones: insulin, glucagon, and PP. In addition, there is a paradoxical combination of enhanced peripheral sensitivity to insulin and decreased hepatic sensitivity to insulin.[160] As a result, insulin therapy is frequently difficult; patients are hyperglycemic when insulin replacement is insufficient (due to unsuppressed hepatic glucose production) or hypoglycemic when insulin replacement is barely excessive (due to enhanced peripheral insulin sensitivity and a deficiency of pancreatic glucagon secretion to counteract the hypoglycemia). This form of diabetes is referred to as *brittle* diabetes and requires special attention.

PP deficiency correlates with the severity of chronic pancreatitis, and impairments in the hepatic action of insulin are reversed in PP-deficient chronic pancreatitis patients by administration of PP[161]. In addition, a recent study of type 1 and type 3c diabetic patients on insulin pump therapy revealed that the addition of a continuous subcutaneous infusion of PP reduced the insulin requirements needed for glycemic control.[162] This suggests that the treatment of pancreatogenic diabetes may be improved by the use of a clinically suitable PP analog or PP receptor agonist.

Laboratory Studies. The diagnosis of chronic pancreatitis depends on the clinical presentation, a limited number of indirect measurements that correlate with pancreatic function, and selected imaging studies (Table 33-14).The direct measurement of pancreatic enzymes (e.g., lipase and amylase) by blood test is highly sensitive and fairly specific in acute pancreatitis but is seldom helpful in the diagnosis of chronic pancreatitis. The pancreatic endocrine product that correlates most strongly with chronic pancreatitis is the PP response to a test meal (Fig. 33-34). Severe chronic pancreatitis is associated with a blunted or absent PP response to feeding but, as with many other tests, a normal PP response does not rule out the presence of early disease.[14]

Table 33-14

Tests for chronic pancreatitis

I. Measurement of pancreatic products in blood
A. Enzymes
B. Pancreatic polypeptide
II. Measurement of pancreatic exocrine secretion
A. Direct measurements
1. Enzymes
2. Bicarbonate
B. Indirect measurement
1. Bentiromide test
2. Schilling test
3. Fecal fat, chymotrypsin, or elastase concentration
4. [^{14}C]-olein absorption
III. Imaging techniques
A. Plain film radiography of abdomen
B. Ultrasonography
C. Computed tomography
D. Endoscopic retrograde cholangiopancreatography
E. Magnetic resonance cholangiopancreatography
F. Endoscopic ultrasonography

The measurement of pancreatic exocrine secretion requires aspiration of pancreatic juice from the duodenum after nutrient (Lundh test meal) or hormonal (CCK or secretin) stimulation.[163,164] Direct aspiration of pancreatic juice by endoscopic cannulation of the duct is performed in some centers, but is not risk free, comfortable for the patient, or more sensitive than luminal intubation methods.[165]

Indirect tests of pancreatic exocrine function are based on the measurement of metabolites of compounds that are altered

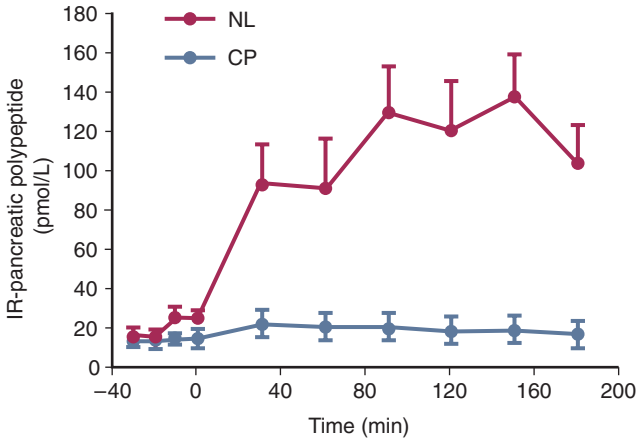

Figure 33-34. Pancreatic polypeptide (PP) response to a test meal. Immunoreactive PP (IR-PP) responses in control subjects (NL, $n = 6$) and patients with severe chronic pancreatitis (CP) accompanied by PP deficiency (CP, $n = 5$) are shown. A test meal was administered at 0 minutes. Means ± standard error of the mean are shown. (*Reproduced with permission from Brunicardi et al.*[161] *Copyright 1996 The Endocrine Society.*)

("digested") by pancreatic exocrine products and can be quantified by serum or urine measurements. A commonly used indirect test is the bentiromide test, in which *N*-benzoyl-L-tyrosyl-p-aminobenzoic acid is ingested by the subject, and the urinary excretion of the proteolytic metabolite p-aminobenzoic acid (PABA) is measured.[166] Although the sensitivity of the test is as high as 100% in patients with severe chronic pancreatitis, it identifies only 40% to 50% of patients with mild disease, and reduced PABA excretion is found in patients with a variety of other GI, hepatic, and renal diseases. The quantification of stool fat has also been used as a measure of pancreatic lipase secretion, either through the direct measurement of total fecal fat levels while the subject consumes a diet of known fat content, or by the measurement of exhaled $^{14}CO_2$ after ingestion of [^{14}C]-triolein or [^{14}C]-olein. This so-called triolein breath test is less cumbersome than intubation methods, and avoids the necessity of stool collections and analysis, but also has a high false-negative rate.[167]

Fecal levels of chymotrypsin[168] and elastase[169] have been proposed as simpler, less expensive tests of exocrine function and correlate well with loss of pancreatic function. As with other test methods, however, these tests lose their sensitivity in patients with mild to moderate chronic pancreatitis and may be more sensitive for other causes of pancreatic dysfunction, including cystic fibrosis. Fecal elastase C1 measurements have become widespread in their use, and levels above 200 µg/g are considered normal, whereas levels below 100 µg/g are indicative of pancreatic exocrine insufficiency.[170] The sensitivity and specificity of fecal elastase C1 measurements fall short of those needed for definitive diagnosis of pancreatic exocrine insufficiency, however.[171]

Radiologic imaging has become the principal method of diagnosis of chronic pancreatitis, with the codification of classification systems that correlate with proven disease. ERCP has been considered the most sensitive radiologic test for the diagnosis of chronic pancreatitis, with specific ERCP findings that are highly correlative with the degree or stage of chronic disease[172] (Table 33-15). CT scanning is sensitive for the diagnosis of chronic pancreatitis when calcification, duct dilatation, or

Table 33-15

Cambridge classification of chronic pancreatitis by endoscopic retrograde cholangiopancreatography

GRADE	MAIN PANCREATIC DUCT	SIDE BRANCHES
Normal	Normal	Normal
Suggestive	Normal	<3 Abnormal
Mild	Normal	≥3 Abnormal
Moderate	Abnormal	>3 Abnormal
Severe	Abnormal plus at least one of the following: Large cavity, Duct obstruction, Dilation or duct irregularity, Intraductal filing defects

cystic disease is present, but is not accurate in the absence of these findings. CT is helpful as a screening study to guide interventional therapy or other diagnostic modalities,[142] although EUS has become the preferred method for the diagnosis of pancreatic disease and offers the advantage of very-high-resolution images of the pancreatic parenchyma, the main and secondary ductal systems, cystic lesions, and calcific changes. EUS findings may be inconclusive in mild or "minimal change" pancreatitis, however, and improved criteria for an EUS-based diagnosis are still a work in progress. Most importantly, EUS is highly reliable in ruling out pancreatic carcinoma when CT findings are normal or equivocal.[173]

Prognosis and Natural History. The prognosis for patients with chronic pancreatitis is dependent on the etiology of the disease, the development of complications, and on the age and socioeconomic status of the patient. The influence of treatment is less evident in long-term studies, although the general absence of randomized, prospective trials clouds the issue of whether specific forms of therapy alter the long-term outlook for patients with the disease.

Several studies have demonstrated that, although symptoms of pain decrease over time in about half of the patients, this decline is also accompanied by a progression of exocrine and endocrine insufficiency.[174] In general, the likelihood of eventual pain relief is dependent upon the stage of disease at diagnosis, and the persistence of alcohol use in patients with alcoholic chronic pancreatitis. Miyake and colleagues found that pain relief was achieved in 60% of alcoholic patients who successfully discontinued drinking, but in only 26% who did not.[175]

The long-term survival of patients with chronic pancreatitis is less than for patients without pancreatitis. In an international multicenter study of >2000 patients, Lowenfels and colleagues found that the 10- and 20-year survival rates for patients with chronic pancreatitis were 70% and 45%, respectively, compared to 93% and 65% for patients without pancreatitis.[174] The mortality risk was found to be 1.6-fold higher in patients who continued to abuse alcohol, compared to those who did not. Continued alcohol abuse has a similar effect on the response to surgical treatment (Fig. 33-35), and results in a twofold increase in mortality over a 10- to 14-year follow-up period.[176]

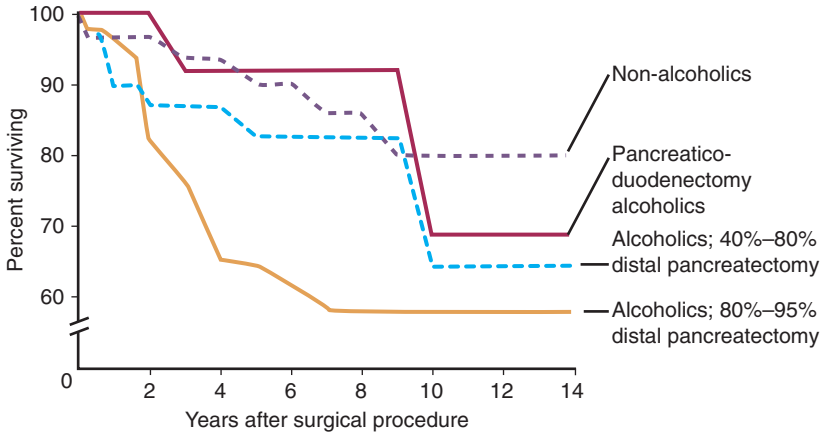

Figure 33-35. Effect of alcohol use on survival after surgical procedures. The cumulative survival of patients with chronic pancreatitis following pancreaticoduodenectomy or distal pancreatectomy is shown for nonalcoholic and alcoholic patients. (*Reproduced with permission from Frey et al.*[176])

In addition to progressive endocrine and exocrine dysfunction, and the risk of the specific complications outlined below and in Table 33-16, the other significant long-term risk for the patient with chronic pancreatitis is the development of pancreatic carcinoma.[178] There is a progressive, cumulative increased risk of carcinoma development in patients with chronic pancreatitis, which continues throughout the subsequent lifetime of the patient (Fig. 33-36). The incidence of carcinoma in patients with chronic pancreatitis ranges from 1.5% to 6%,[177] which is at least 10-fold greater than that of patients of similar age seen in a hospital setting. In a recent study, the risk of carcinoma among patients with chronic pancreatitis accompanied by diabetes was found to be increased 33-fold compared to healthy, comparably aged controls.[178] In patients with advanced chronic pancreatitis referred for surgical therapy, indolent, undiagnosed carcinoma can be seen in as many as 10% of patients.[179]

The development of carcinoma in the setting of chronic pancreatitis is no doubt related to the dysregulation of cellular proliferation and tissue repair processes in the setting of chronic inflammation, as is seen throughout the alimentary tract

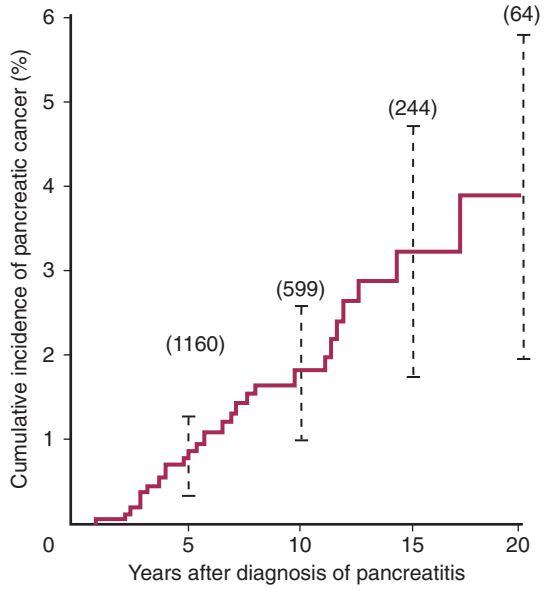

Figure 33-36. Cumulative risk of pancreatic cancer in patients with chronic pancreatitis. The number of patients evaluated at different time intervals is shown in parentheses. Table 33-16

Complications of chronic pancreatitis

Intrapancreatic complications
Pseudocysts
Duodenal or gastric obstruction
Thrombosis of splenic vein
Abscess
Perforation
Erosion into visceral artery
Inflammatory mass in head of pancreas
Bile duct stenosis
Portal vein thrombosis
Duodenal obstruction
Duct strictures and/or stones
Ductal hypertension and dilatation
Pancreatic carcinoma
Extrapancreatic complications
Pancreatic duct leak with ascites or fistula
Pseudocyst extension beyond lesser sac into mediastinum, retroperitoneum, lateral pericolic spaces, pelvis, or adjacent viscera

and elsewhere. In the setting of chronic pancreatitis, carcinoma development can be especially cryptic, and the diagnosis of early-stage tumors is particularly difficult. Awareness of this risk justifies close surveillance for cancer in patients with chronic pancreatitis. Periodic measurement of tumor markers such as CA19-9, and periodic imaging of the pancreas with CT scan and EUS seem logical in order to detect the development of carcinoma in the patient with chronic pancreatitis, although no evidence exists to indicate that this alters the outcome of patients who develop pancreatic cancer. Surgical procedures performed for presumed chronic pancreatitis should always include biopsy of the tissue to exclude the diagnosis of malignancy.

Complications

Pseudocyst. A chronic collection of pancreatic fluid surrounded by a nonepithelialized wall of granulation tissue and fibrosis is referred to as a *pseudocyst*. Pseudocysts occur in up to 10% of patients with acute pancreatitis, and in 20% to 38%

Table 33-17

Definitions of pancreatic fluid collections

TERM	DEFINITION
Peripancreatic fluid collection	A collection of enzyme-rich pancreatic juice that occurs early in the course of acute pancreatitis, or that forms after a pancreatic duct leak; located in or near the pancreas; it lacks a well-organized wall of granulation or fibrous tissue
Early pancreatic (sterile) necrosis	A focal or diffuse area of nonviable pancreatic parenchyma, typically occupying >30% of the gland and containing liquefied debris and fluid
Late pancreatic (sterile) necrosis	An organized collection of sterile necrotic debris and fluid with a well-defined margin or wall within the normal domain of the pancreas
Acute pseudocyst	A collection of pancreatic juice enclosed within a perimeter of early granulation tissue, usually as a consequence of acute pancreatitis that has occurred within the preceding 3–4 wk
Chronic pseudocyst	A collection of pancreatic fluid surrounded by a wall of normal granulation and fibrous tissue, usually persisting for >6 wk
Pancreatic abscess	Any of the above in which gross purulence (pus) is present, with bacterial or fungal organisms documented to be present

of patients with chronic pancreatitis, and thus, they comprise the most common complication of chronic pancreatitis.[180-182] The identification and treatment of pseudocysts requires definition of the various forms of pancreatic fluid collections that occur (Table 33-17). In chronic pancreatitis, a pancreatic duct leak with extravasation of pancreatic juice results in a peri-pancreatic fluid collection (PPFC). Over a period of 3 to 4 weeks, the PPFC is sealed by an inflammatory reaction that leads to development of a wall of acute granulation tissue without much fibrosis. This is referred to as an *acute pseudocyst*. Acute pseudocysts may resolve spontaneously in up to 50% of cases, over a course of 6 weeks or longer.[183] Pseudocysts >6 cm resolve less frequently than smaller ones but may regress over a period of weeks to months. Pseudocysts are multiple in 17% of patients,[182] or may be multilobulated. They may occur intrapancreatically or extend beyond the region of the pancreas into other cavities or compartments (Fig. 33-37).

Pseudocysts may become secondarily infected, in which case they become abscesses. They can compress or obstruct adjacent organs or structures, leading to superior mesenteric-portal vein thrombosis or splenic vein thrombosis.[184] They can erode into visceral arteries and cause intracystic hemorrhage or pseudoaneurysms (Fig. 33-38). They also can perforate and cause peritonitis or intraperitoneal bleeding.[185]

Figure 33-37. Extensive pseudocyst disease. A computed tomographic scan in a patient with alcoholic chronic pancreatitis demonstrates multiloculated pseudocyst disease.

Pseudocysts usually cause symptoms of pain, fullness, or early satiety. Asymptomatic pseudocysts can be managed expectantly and may resolve spontaneously or persist without complication.[181] Symptomatic or enlarging pseudocysts require treatment, and any presumed pseudocyst without a documented antecedent episode of acute pancreatitis requires investigation to determine the etiology of the lesion.[183] Although pseudocysts comprise roughly two thirds of all pancreatic cystic lesions, they resemble cystadenomas and cystadenocarcinoma radiographically. An incidentally discovered cystic lesion should be examined by EUS and aspirated to determine whether it is a true neoplasm or a pseudocyst.

The timing and method of treatment requires careful consideration. Pitfalls in the management of pseudocysts result from the incorrect (presumptive) diagnosis of a cystic neoplasm masquerading as a pseudocyst, a failure to appreciate the solid or debris-filled contents of a pseudocyst that appears to be fluid filled on CT scan, and a failure to document true adherence with

Figure 33-38. Pseudoaneurysm of the gastroduodenal artery. A pseudocyst can erode into an adjacent artery, which results in contained hemorrhage otherwise known as a *pseudoaneurysm*. A contrast-injected computed tomographic scan reveals active bleeding (area marked **B**) into a pseudocyst (*arrows*) as a result of this process. an adjacent portion of the stomach before attempting transgastric internal drainage.

If infection is suspected, the pseudocyst should be aspirated (not drained) by CT- or US-guided FNA, and the contents examined for organisms by Gram's stain and culture.[185] If infection is present, and the contents resemble pus, external drainage is employed, using either surgical or percutaneous techniques.

If the pseudocyst has failed to resolve with conservative therapy, and symptoms persist, internal drainage is usually preferred to external drainage, to avoid the complication of a pancreaticocutaneous fistula. Pseudocysts communicate with the pancreatic ductal system in up to 80% of cases,[186] so external drainage creates a pathway for pancreatic duct leakage to and through the catheter exit site. Internal drainage may be performed with either percutaneous catheter-based methods (transgastric puncture and stent placement to create a cystogastrostomy), endoscopic methods (transgastric or transduodenal puncture and multiple stent placements, with or without a nasocystic irrigation catheter), or surgical methods (a true cystoenterostomy, biopsy of cyst wall, and evacuation of all debris and contents). Surgical options include a cystogastrostomy (Fig. 33-39), a Roux-en-Y cystojejunostomy, or a cystoduodenostomy. Cystojejunostomy is the most versatile method, and it can be applied to pseudocysts that penetrate into the transverse mesocolon, the paracolic gutters, or the lesser sac. Cystogastrostomy can be performed endoscopically[187] (Fig. 33-40), laparoscopically,[188] or by a combined laparoscopic-endoscopic method.[189]

Because pseudocysts often communicate with the pancreatic ductal system, two newer approaches to pseudocyst management are based on main duct drainage, rather than pseudocyst drainage per se. Transpapillary stents inserted at the time of ERCP may be directed into a pseudocyst through the ductal communication itself (Fig. 33-41), or can be left across the area of suspected duct leakage to facilitate decompression and cyst drainage, analogous to the use of common bile duct stents in the setting of a cystic duct leak.[186] In a surgical series of patients with chronic pancreatitis, ductal dilatation, and a coexisting pseudocyst, Nealon and Walser showed that duct drainage alone, without a separate cystoenteric anastomosis, was as successful as a combined drainage procedure.[190] Furthermore, the "duct drainage only" group enjoyed a shorter hospital stay and fewer complications than the group who underwent a separate

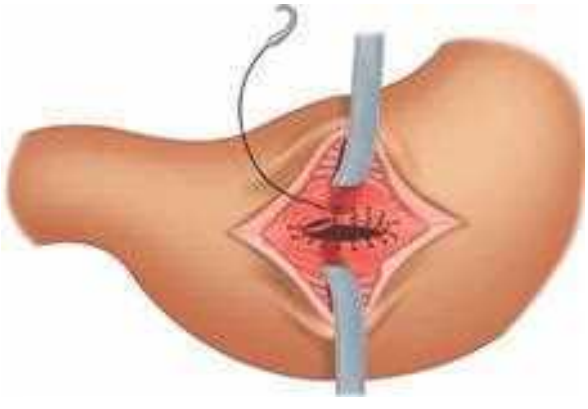

Figure 33-39. Cystogastrostomy drainage of a retrogastric pancreatic pseudocyst. A larger opening is made through the common wall of a retrogastric pseudocyst, and a portion of the pseudocyst wall is submitted for histologic confirmation of the diagnosis. Suture reinforcement of the communication is performed to avoid the complication of bleeding. (*Reproduced with permission from Bell.*[188])

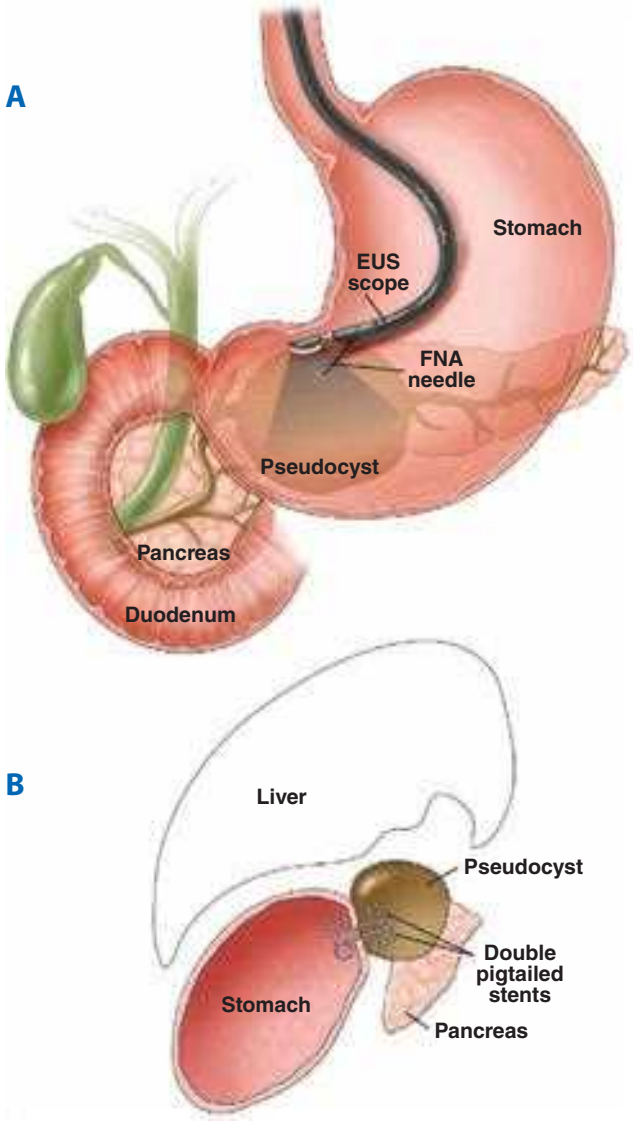

Figure 33-40. Technique of endoluminal cystogastrostomy. **A.** Endoscopic ultrasound (EUS)-guided transgastric puncture of pancreatic pseudocyst. **B.** Transgastric stents placed across fused posterior wall of stomach and anterior wall of pseudocyst. cystoenterostomy. These observations suggest that transductal drainage may be a safe and effective approach to the management of pseudocystic disease.

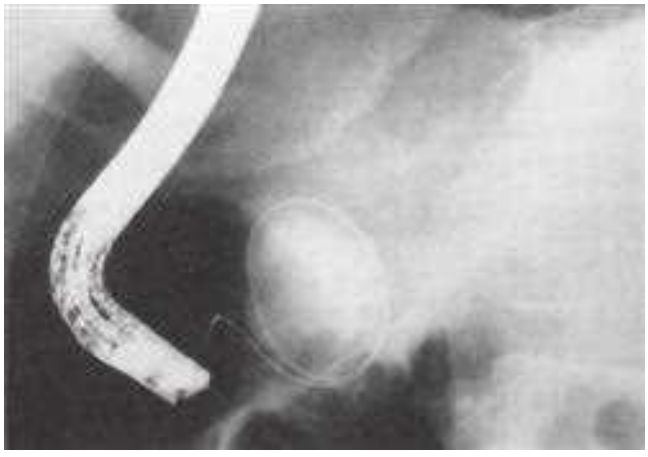
The complications of endoscopic or radiologic drainage of pseudocysts often require surgical intervention. Bleeding from the cystoenterostomy, and inoculation of a pseudocyst with failure of resolution and persistence of infection, may require surgical treatment. Bleeding risks may be lessened by the routine use of EUS in the selection of the site for transluminal stent placement.[191] Percutaneous and endoscopic treatment of pseudocysts requires large-bore catheters, multiple stents, and an aggressive approach to management for success to be achieved. Failure of nonsurgical therapy, with subsequent salvage procedures to remove infected debris and establish complete drainage, is associated with increased risks for complications and death.[192] The most experienced therapeutic endoscopists report a complication rate of 17% to 19% for the treatment of sterile



A

B

Figure 33-41. Transpapillary drainage of a pancreatic pseudocyst. **A.** Endoscopic passage of a flexible wire through the major papilla, through the pancreatic duct, and into a communicating pseudocyst. **B.** Placement of a stent over the wire into the pseudocyst with transpapillary drainage. (*Reproduced with permission from Kozarek et al.*[187])

pseudocysts, and deaths as a result of endoscopic therapy have occurred.[193] Therefore, the use of endoscopic methods to treat sterile or infected pancreatic necrosis has a higher complication rate and is limited to specialized centers.

Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail, or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis. An internal drainage procedure of the communicating duct or of the pseudocyst itself should be considered when distal resection is being contemplated.

Pancreatic Ascites. When a disrupted pancreatic duct leads to pancreatic fluid extravasation that does not become sequestered as a pseudocyst, but drains freely into the peritoneal cavity, pancreatic ascites occurs. Occasionally, the pancreatic fluid tracks superiorly into the thorax, and a pancreatic pleural effusion occurs. Referred to as *internal pancreatic fistulae*, both complications are seen more often in patients with chronic pancreatitis rather than after acute pancreatitis. Pancreatic ascites and pleural effusion occur together in 14% of patients, and 18% have a pancreatic pleural effusion alone.[194]

Figure 33-42. Pancreatic ascites. Computed tomographic scan of a patient with a ruptured pancreatic pseudocyst resulting in intraperitoneal pancreatic fluid. (*Reproduced with permission from Cameron JL, Cameron AM (eds):* Current Surgical Therapy, *11th ed. Philadelphia: Elsevier, 2014, p 458. Copyright Elsevier.*)

Patients demonstrate the general demographics of chronic pancreatitis and usually present with a subacute or recent history of progressive abdominal swelling despite weight loss. Pain and nausea are rarely present. The abdominal CT scan discloses ascites and the presence of chronic pancreatitis or a partially collapsed pseudocyst (Fig. 33-42). Paracentesis or thoracentesis reveals noninfected fluid with a protein level >25 g/L and a markedly elevated amylase level. Serum amylase may also be elevated, presumably from reabsorption across the parietal membrane. Serum albumin may be low, and patients may have coexisting liver disease. Paracentesis is therefore critical to differentiate pancreatic from hepatic ascites.

ERCP is most helpful to delineate the location of the pancreatic duct leak and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP, but if nonsurgical therapy is undertaken and then abandoned, repeat imaging of the pancreatic duct is appropriate to guide surgical treatment.

Antisecretory therapy with the somatostatin analogue octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients.[195] Reapposition of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage may facilitate closure of the internal fistula.[195] Surgical therapy is reserved for those who fail to respond to medical treatment. If the leak originates from the central region of the pancreas, a Roux-en-Y pancreaticojejunostomy is performed to the site of duct leakage (Fig. 33-43). If the leak is in the tail, a distal pancreatectomy may be considered, or an internal drainage procedure can be performed. The results of surgical treatment are usually favorable if the ductal anatomy has been carefully delineated preoperatively.

Pancreatic-Enteric Fistula. The erosion of a pancreatic pseudocyst into an adjacent hollow viscus can result in a pancreatic-enteric fistula. The most common site of communication is the transverse colon or splenic flexure. The fistula usually presents with evidence of GI or colonic bleeding and sepsis. If the fistula communicates with the stomach or duodenum, it may close spontaneously or persist as a pancreatic-enteric fistula. When the fistula involves the colon, operative correction is usually required.[196]

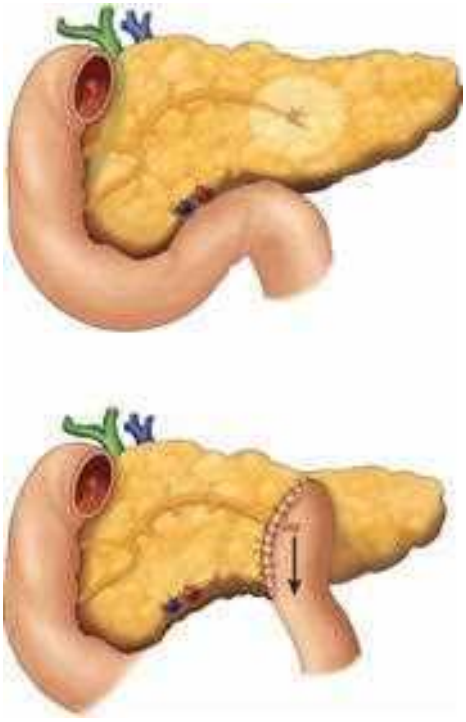


Figure 33-43. Internal drainage for leaking pancreatic duct. A Roux-en-Y pancreaticojejunostomy is performed at the site of duct rupture to accomplish internal drainage of the pancreatic duct leak. (*Reproduced with permission from Lipsett.*[196])

Head-of-Pancreas Mass. In up to 30% of patients with advanced chronic pancreatitis, an inflammatory mass develops in the head of the pancreas.[197] The clinical presentation includes severe pain, and frequently includes stenosis of the distal common bile duct, duodenal stenosis, compression of the portal vein, and stenosis of the proximal main pancreatic duct (Table 33-18). Mutations and polymorphisms of p53 have been found in these patients, and a focus of ductular carcinoma was found in 3.7% of patients with pancreatic head enlargement in one series.[198] It was concluded that an accelerated transformation from hyperplasia to dysplasia exists in patients with pancreatic head enlargement, although the etiology for this process remains unclear.

Splenic and Portal Vein Thrombosis. Vascular complications of chronic pancreatitis are fortunately infrequent, because they are difficult to treat successfully. Portal vein compression and occlusion can occur as a consequence of an inflammatory mass in the head of the pancreas, and splenic vein thrombosis occurs in association with chronic pancreatitis in 4% to 8% of cases.[199] Variceal formation can occur as a consequence of either portal or splenic venous occlusion, and splenic vein thrombosis with gastric variceal formation is referred to as *left-sided* or *sinistral portal hypertension*. Although bleeding complications are infrequent, the mortality risk of bleeding is >20%. When gastroesophageal varices are caused by splenic vein thrombosis, the addition of splenectomy to prevent variceal hemorrhage is prudent when surgery is otherwise indicated to correct other problems.

Table 33-18

Signs and symptoms of chronic pancreatitis with and without a pancreatic head mass

SIGNS AND SYMPTOMS	WITH HEAD ENLARGEMENT (n = 138) (%)	WITHOUT HEAD ENLARGEMENT (n = 141) (%)
Daily severe pain	67	40
Cholestasis	46	11

Treatment

Medical Therapy. The medical treatment of chronic or recurrent pain in chronic pancreatitis requires the use of analgesics, a cessation of alcohol use, oral enzyme therapy, and the selective use of antisecretory therapy. Interventional procedures to block visceral afferent nerve conduction or to treat obstructions of the main pancreatic duct are also an adjunct to medical treatment.

Analgesia. Oral analgesics are prescribed as needed, alone or with analgesia-enhancing agents such as gabapentin. Adequate pain control usually requires the use of narcotics, but these should be titrated to achieve pain relief with the lowest effective dose. Opioid addiction is common, and the use of long-acting analgesics by transdermal patch together with oral agents for pain exacerbations slightly reduces the sedative effects of high-dose oral narcotics.

It is essential for patients to abstain from alcohol. In addition to removing the causative agent, alcohol abstention results in pain reduction or relief in 60% to 75% of patients with chronic pancreatitis.[200] Despite this benefit, roughly half of alcoholic chronic pancreatitis patients continue to abuse alcohol.

Enzyme Therapy. Pancreatic enzyme administration serves to reverse the effects of pancreatic exocrine insufficiency. Adequate pancreatic enzyme replacement reverses the exocrine insufficiency seen in most patients, and prevents secondary complications such as metabolic bone disease due to inadequate absorption of the fat-soluble vitamins A, D, E, and K. In addition, pancreatic enzyme replacement may reduce or alleviate the pain experienced by patients. The choice of enzyme supplement and the dose should be selected based on whether malabsorption or pain (or both) are the indications for therapy[201] (Table 33-19). Conventional (nonenteric-coated) enzyme preparations are partially degraded by gastric acid but are available within the duodenal and jejunal regions to bind to CCK-releasing peptide, and downregulate the release of CCK. This theoretically reduces the enteric signal for pancreatic exocrine secretion, which reduces the pressure within a partially or completely obstructed pancreatic duct.[202] Enteric-coated preparations result in little to no pain relief, presumably due to their reduced bioavailability in the proximal gut. Due to the loss of pancreatic enzymes by acid hydrolysis and proteolysis, relatively large doses are required to achieve effective levels of enzyme within the proximal small bowel. Enteric-coated preparations are protected from acid degradation but are presumably not released in the critical proximal gut in sufficient quantity to inhibit the stimulus for endogenous pancreatic enzyme secretion. Nonalcoholic patients may experience more effective pain relief than alcoholic patients, but it is recommended that all patients with chronic pancreatitis pain

Table 33-19

Pancreatic enzyme preparations

PRODUCT	FORMULATION	MANUFACTURER	LIPASE CONTENT (USP)/PILL OR CAPSULE

Viokace	Tablet non-enteric-coated porcine	Aptalis	10,440, 20,880

USP: United States Pharmacopeia, the standard for lipase content in the United States. An average meal requires roughly 90,000 USP units of lipase for fat digestion. Enzyme therapy of exocrine deficiency typically begins with a dose of 50,000 USP units per meal with subsequent adjustment.

begin a trial of nonenteric-coated enzyme supplements together with an acid-suppressive medication for 1 month. If pain relief is achieved, therapy is continued. If enzyme therapy fails, further investigation of the pancreatic ductal system by ERCP guides the therapy based on specific anatomical findings (Fig. 33-44).

Antisecretory Therapy. Somatostatin administration has been shown to inhibit pancreatic exocrine secretion and CCK release.[203] The somatostatin analogue octreotide acetate has therefore been investigated for pain relief in patients with chronic pancreatitis. In a double-blind, prospective, randomized 4-week trial, 65% of patients who received 200 µg of octreotide acetate subcutaneously three times daily reported pain relief, compared with 35% of placebo-treated subjects[204]. Patients who had the best results were patients with chronic abdominal pain, suggestive of obstructive pancreatopathy. However, in another trial that used a 3-day duration of treatment, no significant pain relief was observed.[205] Anecdotal reports suggest that severe pain exacerbations in chronic pancreatitis can benefit from a combination of octreotide therapy and TPN, and a pilot study of the effectiveness of the sustained-release form of octreotide suggested that it was as effective as three-times-per-day administration of the short-acting form of the drug [206].

Neurolytic Therapy. Celiac plexus neurolysis with alcohol injection has been an effective form of analgesic treatment in patients with pancreatic carcinoma. However, the use of radiologically- or endoscopically-guided celiac plexus blockade in chronic pancreatitis has been disappointing. Due to the risk of alcohol injury and the need for repeated injections, celiac plexus blockade in chronic pancreatitis has used short-acting analgesics or other drugs rather than 50% alcohol. A trial of EUS-guided celiac plexus blockade revealed successful pain relief in 55% of patients, but the benefit lasted beyond 6 months in only 10% of patients.[207] The procedure therefore appears safe, but the effect is short lived in those patients who obtain pain relief.

Endoscopic Management. The techniques of endoscopic treatment of pancreatic duct obstruction, stone disease, pseudocyst formation, pancreatic duct leak, and for the diagnosis and management of associated pancreatic tumors have expanded greatly over the past 10 years. Newer endoscopes with expanded therapeutic capabilities have been introduced, and the role of EUS and EUS-guided needle and catheter insertion has expanded the ability of the therapeutic endoscopist in the diagnosis and treatment of chronic pancreatitis and its complications.[208]

Pancreatic duct stenting is used for treatment of proximal pancreatic duct stenosis, decompression of a pancreatic duct leak, and for drainage of pancreatic pseudocysts that can be catheterized through the main pancreatic duct. Pancreatic duct stents can induce an inflammatory response within the duct, so prolonged stenting is usually avoided. Patients with sphincter of Oddi dyskinesia are at high risk for developing post-ERCP pancreatitis after biliary sphincterotomy, and the prophylactic placement of a pancreatic duct stent reduces the amylase level and development of pancreatitis after biliary sphincterotomy.[209] Pancreatic duct leaks are seen in 37% of patients with acute pancreatitis, and pancreatic duct stenting appear to facilitate the resolution of the leak.[210] Similarly, pancreatic duct stenting has been used to treat postsurgical pancreatic duct leaks and post-traumatic leaks.[210–212]

Pancreas divisum (see Fig. 33-3) is thought to cause pain and chronic pancreatitis due to functional or mechanical obstruction of the dorsal duct draining exclusively, or predominantly, through the lesser papilla. A study from Marseille reported good long-term results in 24 patients after minor papilla sphincterotomy and dorsal duct stenting.[213] The number of patients with chronic pain decreased from 83% before stenting to 29% after stenting, but pancreatitis or recurrent papillary stenosis occurred in 38%. Patients that responded best were those with intermittent pain, and this subset may be preferentially treated with endoscopic therapy.

Idiopathic pancreatitis patients have been treated with endoscopic stenting, pancreatic duct sphincterotomy, and endoscopic stone removal with good results. In a prospective randomized trial, 53% of idiopathic recurrent pancreatitis patients in the control group experienced continued episodes of pancreatitis, although only 11% of the treated patients had continued symptoms.[214]

Extracorporeal shock wave lithotripsy (ESWL) has been used for pancreatic duct stones, together with endoscopic stenting and stone removal.[215] A single ESWL session was used in 35 patients with pancreatic duct stones, together with 86 ERCP sessions to complete the stone removal process. After 2.4 years,

80% of patients had significant relief of symptoms (Fig. 33-45). However, due to the tendency for recurrent stone formation, the use of ESWL for long-term management of calcific pancreatitis remains uncertain.

Surgical Therapy

Indications and History The traditional approach to surgical treatment of chronic pancreatitis and its complications has maintained that surgery should be considered only when the medical therapy of symptoms has failed. Nealon and Thompson published a landmark study in 1993, however, that showed that the progression of chronic obstructive pancreatitis could be delayed or prevented by pancreatic duct decompression.[216] No other therapy has been shown to prevent the progression of chronic pancreatitis, and this study demonstrated the role of surgery in the early management of the disease (Table 33-20). Small-duct disease or "minimal change chronic pancreatitis" are causes for uncertainty over the choice of operation, however. Major resections have a high complication rate, both early and late, in chronic alcoholic pancreatitis, and lesser procedures often result in symptomatic recurrence. So the choice of operation and the timing of surgery are based on each patient's pancreatic anatomy, the likelihood

Table 33-20

Effect of surgical drainage on progression of chronic pancreatitis

TREATMENT GROUP	24-MONTH EVALUATION
Operated ($n = 47$)	Mild to moderate 48 (87%); severe 6 (13%)
Nonoperated ($n = 36$)	Mild to moderate 8 (22%); severe 28 (78%)

Eighty-three patients with chronic pancreatitis were evaluated by exocrine, endocrine, nutritional, and endoscopic retrograde cholangiopancreatography studies, and all had mild to moderate disease and dilated pancreatic ducts. A Puestow-type duct decompression procedure was performed in 47 patients, and all subjects were restaged by the same methods 24 months later. Source: Reproduced with permission from Nealon et al.[216]

(or lack thereof) that further medical and endoscopic therapy will halt the symptoms of the disease, and the chance that a good result will be obtained with the lowest risk of morbidity and mortality. Finally, preparation for surgery should include restoration of protein-caloric homeostasis, abstinence from alcohol and tobacco, and a detailed review of the risks and likely outcomes to establish a bond of trust and commitment between the patient and the surgeon.

Historically, the surgery for chronic pancreatitis before the second half of the twentieth century was a true demonstration of trial and error.[217] Obtaining good surgical outcomes before the availability of CT scans and ERCP was either the result of serendipity or due to the skill and creativity of the surgeon. In 1911, Link described an operation he devised on the spot, when a laparotomy in a young woman with abdominal pain revealed a fluctuant, obstructed pancreatic duct. After performing a dochotomy and evacuating multiple stones, he inserted a rubber tube, and exteriorized the pancreatostomy just above her navel.[218] He later described the operation as having been a success for the next 30 years of the patient's life, during which the patient managed the care of the drainage tube without apparent problems.[219]

With the demonstration in 1942 by Priestley that total pancreatectomy was technically feasible,[220] and the report in 1946 by Whipple that proximal pancreatic resection was beneficial in (three) patients with chronic pancreatitis,[221] the option of surgical resection as treatment for chronic pancreatitis was established. By the mid 1950s, however, growing disappointment with the high risk of resection and the lack of long-term benefit overshadowed the surgical treatment of chronic pancreatitis. The choice of resection vs. drainage was largely based on surgeon preference until the 1970s, when the widespread adoption of ERCP and CT scans provided the ability to preoperatively diagnose obstructive and sclerotic disease, and this resulted in the rational selection of operative procedures. During this period, the major drawbacks to surgical therapy remained the recurrence of symptoms despite surgery, the corresponding development of an inflammatory (or malignant) mass in the undrained pancreatic head (Fig. 33-46), or the high morbidity and mortality of major resectional procedures that seemed to predispose the patients to a cascade of metabolic problems.[222]

Sphincteroplasty The sphincter of Oddi and the pancreatic duct sphincter serve as gatekeepers for the passage of pancreatic juice into the duodenum (Fig. 33-47). Stenosis of either sphincter

Figure 33-46. Head-of-pancreas mass after Puestow procedure. The computed tomographic appearance of an inflammatory mass occupying the head of the pancreas, which developed 2 years after Puestow decompression of the body and tail of pancreas.

(sclerosing papillitis), due to scarring from pancreatitis or from the passage of gallstones, may result in obstruction of the pancreatic duct and chronic pain.[223] As gallstone pancreatitis became a popular diagnosis in the 1940s and 1950s, attention was focused on the ampullary region as a possible cause of chronic symptoms, and surgical sphincteroplasty was advocated. Although endoscopic techniques are now used routinely to perform sphincterotomy of either the common bile duct or pancreatic duct, a true (permanent) sphincteroplasty can only be performed surgically. Transduodenal sphincteroplasty with incision of the septum between the pancreatic duct and common bile duct appears to offer significant relief for patients with obstruction and inflammation isolated to this region (Fig. 33-48).

Drainage Procedures After the early reports of success with pancreatostomy for the relief of symptoms of chronic pancreatitis,[219] Cattell described pancreaticojejunostomy for relief of pain in unresectable pancreatic carcinoma.[224] Shortly thereafter, Duval,[225] and separately, Zollinger and associates,[226] described the caudal Roux-en-Y pancreaticojejunostomy for the treatment of chronic pancreatitis in 1954 (Fig. 33-49). The so-called Duval procedure was used for decades by some surgeons, but it almost invariably failed due to restenosis and segmental obstruction of the pancreas due to progressive scarring. In 1958, Puestow and Gillesby described these segmental narrowings and dilatations of the ductal system as a "chain of lakes," and proposed a longitudinal decompression of the body and tail of the pancreas into a Roux limb of jejunum[227] (Fig. 33-50). Four of Puestow and Gillesby's 21 initial cases were side-to-side anastomoses, and 2 years after their report, Partington and Rochelle described a much simpler version of the longitudinal, or side-to-side Roux-en-Y pancreaticojejunostomy that became universally known as the Puestow procedure[228] (Fig. 33-51).

The effectiveness of decompression of the pancreatic duct is dependent on the extent to which ductal hypertension is the etiologic agent for the disease. Thus, the diameter of the pancreatic duct is a surrogate for the degree of ductal hypertension, and the Puestow procedure has been shown to be effective for pain relief when the maximum duct diameter is 6 mm. Results are less impressive in glands with smaller caliber ducts, although Izbicki and associates have described good results with a conization method that allows a longitudinal decompression of more normal caliber ducts.[229] Successful pain relief after the Puestow-type decompression procedure has been reported in 75% to 85% of patients for the first few years after surgery, but pain recurs in >20% of patients after 5 years,[148] even in patients who are abstinent from alcohol.

With the advent of therapeutic endoscopy and techniques for transluminal stone removal and lithotripsy, multiple series have reported the successful endoscopic treatment of pancreatic duct calculi, although the long-term outcomes of these efforts has been uneven.[230–233] Endoscopic removal of pancreatic duct stones is usually coupled to prolonged pancreatic duct stenting, which carries the risk of further inflammation.[234,235] Despite the risk of perioperative

complications, the surgical management of pancreatic duct stones and stenosis has been shown to be superior to endoscopic treatment in randomized clinical trials in which the long, side-to-side technique of pancreaticojejunostomy is used.[236,237]

Resectional Procedures

Distal Pancreatectomy For patients with focal inflammatory changes localized to the body and tail, or in whom no significant ductal dilatation exists, the technique of partial (40%–80%) distal pancreatectomy has been advocated (Fig. 33-52). Although distal pancreatectomy is less morbid than more extensive resectional procedures, the operation leaves untreated a major portion of the gland, and is therefore associated with a significant risk of symptomatic recurrence. It has been a more popular operation in British centers, where its success seems to be greater, perhaps due to the lower incidence of alcoholic chronic pancreatitis.[238] However, long-term outcomes reveal good pain relief in only 60% of patients, with completion pancreatectomy required for pain relief in 13% of patients.

Laparoscopic distal pancreatectomy has been shown to be feasible for the removal of focal lesions of the distal pancreas[239] but is more difficult in the setting of chronic pancreatitis.

Ninety-Five Percent Distal Pancreatectomy In 1965, Fry and Child proposed the more radical 95% distal pancreatectomy, which was intended for patients with sclerotic (small duct) disease, and which attempted to avoid the morbidity of total pancreatectomy by preserving the rim of pancreas in the pancreaticoduodenal groove, along with its associated blood vessels and distal common bile duct.[222] The operation was found to be associated with pain relief in 60% to 77% of patients long term, but is accompanied by a high risk of brittle diabetes, hypoglycemic coma, and malnutrition.[240] Although the operation was the first attempt to resect the pancreatic head while preserving the duodenum and distal bile duct, the extensive degree of pancreatic removal led to its failure as viable treatment for the symptoms of pancreatic sclerosis.

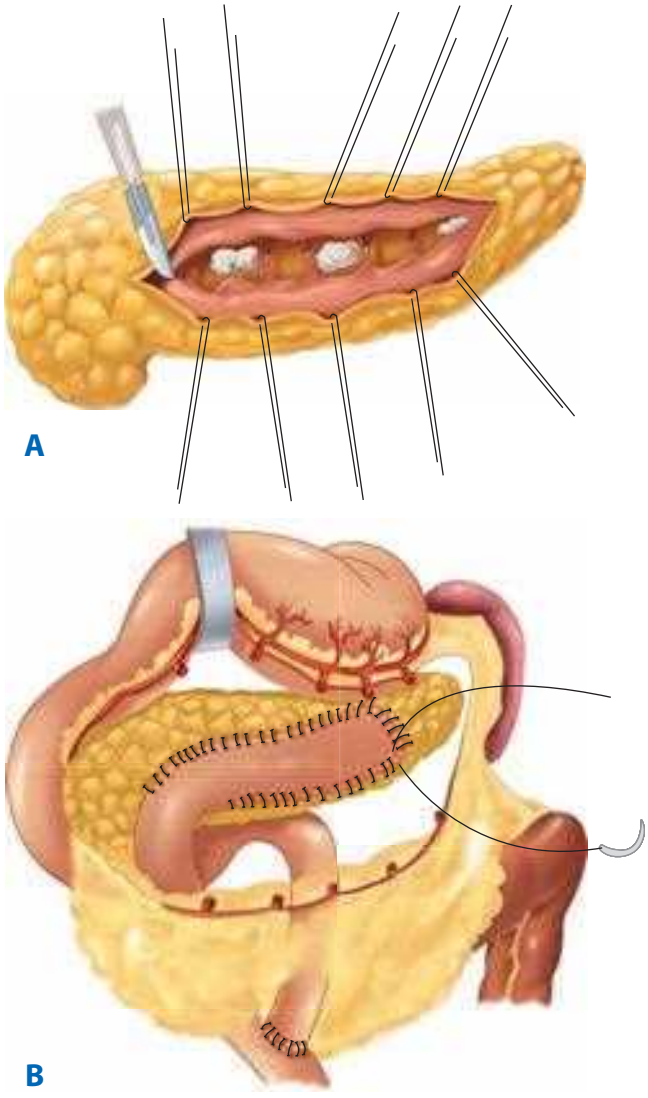

Figure 33-51. Longitudinal dochotomy in obstructing calcific pancreatitis. A longitudinal pancreatotomy typically discloses segmental stenosis of the pancreatic duct and the presence of intraductal calculi in a patient with chronic calcific pancreatitis (**A**). Following mobilization of a Roux limb of jejunum, a longitudinal pancreaticojejunostomy is performed to permit extensive drainage of the pancreatic duct system (**B**). This technique, described by Partington and Rochelle, is the typical method used for the Puestow procedure. (*Data from Partington et al.*[228])

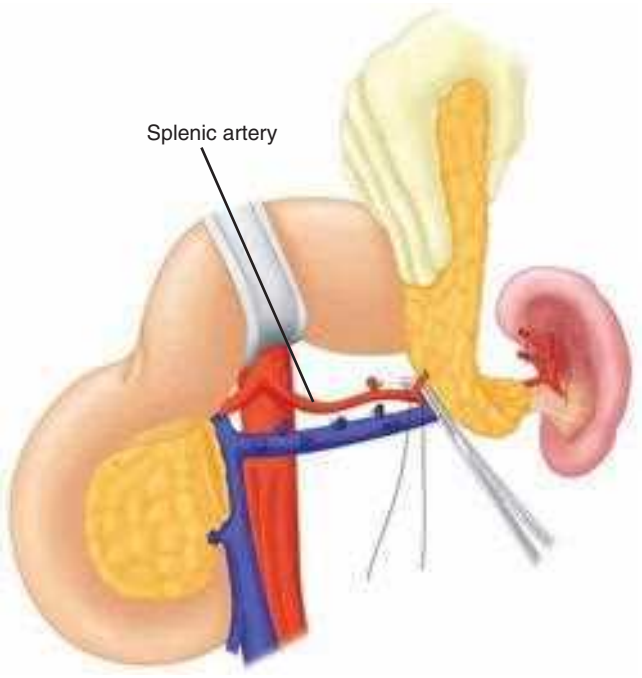

Figure 33-52. Distal (spleen-sparing) pancreatectomy. A distal pancreatectomy for chronic pancreatitis is usually performed with en bloc splenectomy, using either an open or laparoscopic technique. In the presence of minimal inflammation, a spleen-sparing version can be performed, as shown here.

Proximal Pancreatectomy In 1946, Whipple reported a series of five patients treated with either pancreaticoduodenectomy or total pancreatectomy for symptomatic chronic pancreatitis, with one operative death.[221] Subsequently, proximal pancreatectomy or pancreaticoduodenectomy, with or without pylorus preservation (Fig. 33-53), has been widely used for the treatment of chronic pancreatitis.[217,241] In the three largest modern (circa 2000) series of the treatment of chronic pancreatitis by the Whipple procedure, pain relief 4 to 6 years after operation was found in 71% to 89% of patients. However, mortality ranged from 1.5% to 3%, and major complications occurred in 25% to 38% of patients at the Johns Hopkins Hospital,[242] the Mayo Clinic,[243] and the Massachusetts General Hospital.[244] In follow-up, 25% to 48% of patients developed diabetes, and about the same percentage required exocrine therapy. Advocates of the Whipple procedure uniformly suggest that the high rate of symptomatic relief outweighs the metabolic consequences and the mortality risk of the procedure.

Total Pancreatectomy Priestley and associates first described successful total pancreatectomy in 1944 in a patient with hyperinsulinism,[220] and two of Whipple's original five cases of chronic pancreatitis reported in 1946 were treated with total pancreatectomy.[221] Subsequently, surgeons who used total pancreatectomy found that the operation produces no better pain relief for their patients than pancreaticoduodenectomy (about 80%–85%). Moreover, the metabolic consequences of total pancreatectomy in the absence of islet cell transplantation are profound and life-threatening. The patients have a "brittle" form of diabetes in which avoidance of hyper- and hypoglycemia is problematic.[245–247] In addition, lethal episodes of hypoglycemia are common in severe apancreatic diabetes. These are due to hypoglycemic unresponsiveness, due to the absence of pancreatic glucagon, and to hypoglycemia unawareness, despite an ongoing need to treat with exogenous insulin.[248] In a series of >100 patients treated with total pancreatectomy, Gall and colleagues showed that half of all the late deaths after this operation were due to (iatrogenic) hypoglycemia.[249] Despite newer forms of insulin, insulin delivery systems, and blood glucose monitoring, severe pancreatogenic diabetes remains an adverse outcome, as complete prevention of the physiologic consequences of total pancreatectomy remains an unfulfilled goal. With the growing acceptance of islet auto-transplantation as an adjunct to the procedure (see below), total pancreatectomy itself is now used only rarely for the treatment of refractory chronic pancreatitis.

Hybrid Procedures In 1980, Beger and associates described the Duodenum-preserving Pancreatic Head Resection or DPPHR[250]

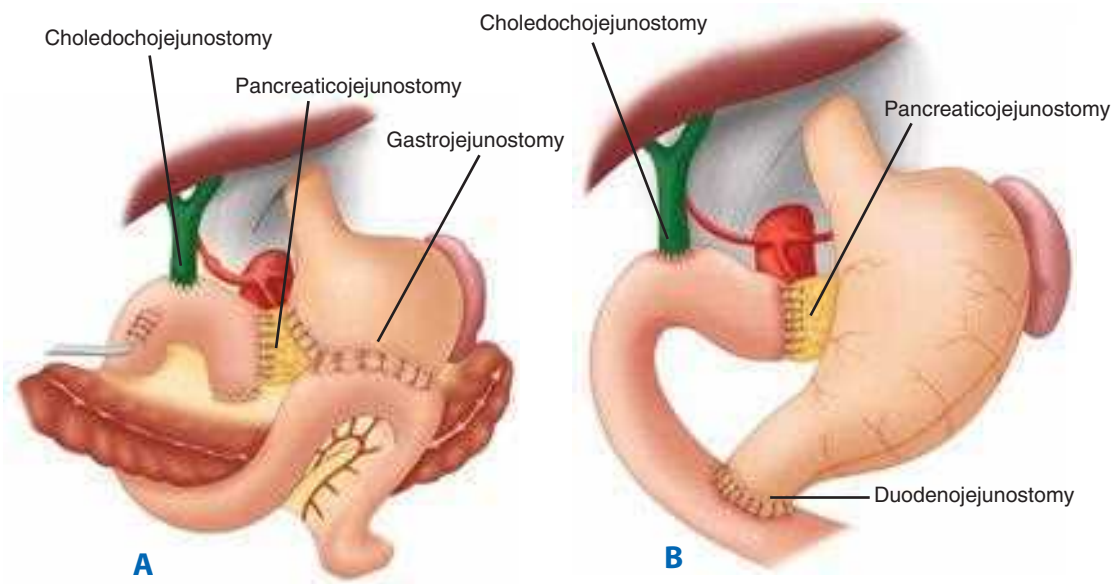

Figure 33-53. The pancreaticoduodenectomy (Whipple procedure) can be performed either with the standard technique, which includes distal gastrectomy (**A**), or with preservation of the pylorus (**B**). The pylorus-sparing version of the procedure is used most commonly. (*Reproduced from Gaw JU, Andersen DK: Pancreatic surgery, in Wu GY, Aziz K, Whalen GF (eds): An Internist's Illustrated Guide to Gastrointestinal Surgery. Totowa: Humana Press, 2003, p 229, with permission.*)

(Fig. 33-54), and published long-term results with DPPHR for the treatment of chronic pancreatitis in 1985,[251] and again in 1999.[252] In 388 patients who were followed for an average of 6 years after DPPHR, pain relief was reportedly maintained in 91%, mortality was <1%, and diabetes developed in 21%, with 11% demonstrating a reversal of their preoperative diabetic status. These authors also compared the DPPHR procedure with the pylorus-sparing Whipple procedure in a randomized trial of 40 patients with chronic pancreatitis.[253] The mortality was reportedly zero in both groups, and the morbidity was also comparable. Pain relief (over 6 months) was seen in 94% of DPPHR patients, but in only 67% of Whipple patients. Furthermore, the insulin secretory capacity and glucose tolerance were noted to deteriorate in the Whipple group, but actually improved in the DPPHR patients.

The DPPHR requires the careful dissection of the gastroduodenal artery and the creation of two anastomoses (Fig. 33-55), and carries a similar complication risk as the Whipple procedure due to the risk of pancreatic leakage and intra-abdominal fluid collections.

In 1987, Frey and Smith described the local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ), which included excavation of the pancreatic head, including the ductal structures in continuity with a long dichotomy of the dorsal duct[254] (Fig. 33-56). The Frey procedure provides thorough decompression of the pancreatic head as well as the body and tail of the gland, and a long-term follow-up suggested that improved outcomes are associated with this more extensive decompressive procedure. Frey and Amikura reported their results in 50 patients followed for >7 years, and found complete or substantial pain relief in 87% of patients. There was no operative mortality, but 22% of patients developed postoperative complications.[255]

Key steps in the performance of the LR-LPJ include preservation of the pancreatic neck as well as the capsule of the posterior pancreatic head. In the pancreaticoduodenectomy and the DPPHR, the pancreatic neck is freed up from the portal and superior mesenteric vein confluence and divided. In the LR-LPJ, the neck of the pancreas is preserved intact as are the body and tail of the pancreas. Not having to divide the pancreatic neck, as in the pancreaticoduodenectomy or DPPHR, reduces the risk of the operation, as it avoids intraoperative problems with the venous structures lying posterior to the gland. To reduce the risk of penetrating the posterior capsule of the head, Frey recommended in his 1994 report that the posterior limit of resection be the back wall of the opened duct of Wirsung and duct to the uncinate (Fig. 33-57).

Subsequent to Frey's own modification of the technique, other surgeons have described modifications of the extent or technique of the LR-LPJ. Andersen and Topazian advocated performing the LR-LPJ as it was originally described, in which the entirety of the ducts are excised from the head (Fig. 33-58), and described the use of the ultrasonic aspirator and dissector for this purpose.[256] The use of this device permits precise removal of the ducts and adjacent tissue with good visualization and without complications. There is little pancreatic tissue behind these ducts and the pancreatic capsule is continuously palpated as the dissection proceeds to ensure a safe margin of resection. The intrapancreatic portion of the common bile duct is usually exposed, and avoiding injury to it is enhanced by the ultrasonic aspirator. The majority of the parenchyma of the uncinate process is spared, and the excavation of the pancreatic head is made contiguous with a generous dochotomy of the dorsal duct. Whether merely unroofing as opposed to removal of the proximal ducts contributes to better pain relief is not known and awaits a randomized trial to compare the two versions of the LR-LPJ. Izbicki and colleagues at the University of Hamburg also recommend a more extensive excavation of the pancreatic head, and use a technique that they refer to as the *Hamburg modification* of the LR-LPJ[257] (Fig. 33-59). This wider excavation of the pancreatic head is created in continuity with the dorsal dochotomy, and is followed by a single, side-to-side pancreaticojejunostomy.

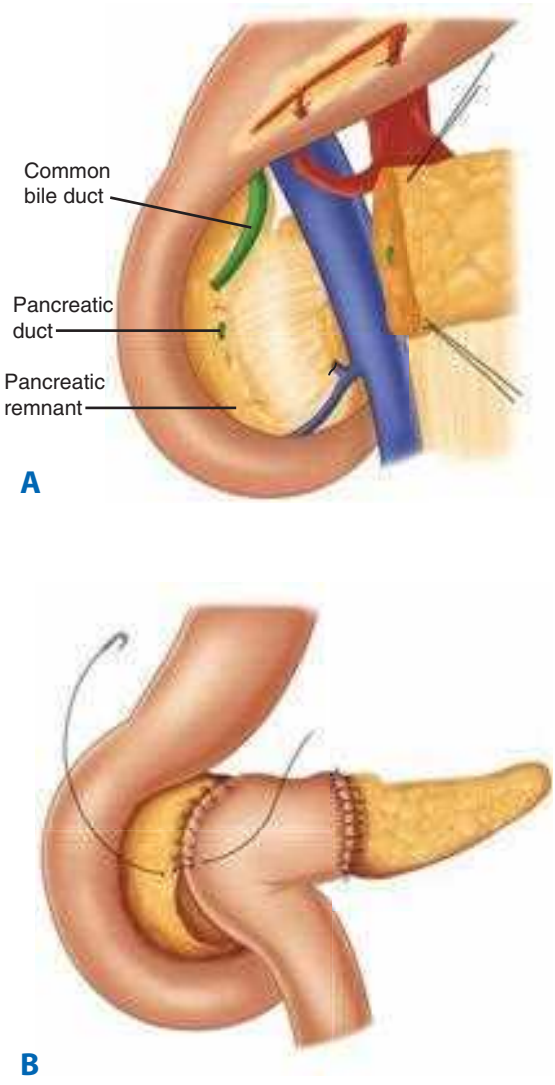

Figure 33-54. The duodenum-preserving pancreatic head resection described by Beger and colleagues. **A**. The completed resection after transection of the pancreatic neck, and subtotal removal of the pancreatic head, with preservation of the distal common bile duct and duodenum. **B**. Completion of the reconstruction with anastomosis to the distal pancreas and to the proximal pancreatic rim by the same Roux limb of jejunum. (*Reproduced with permission from Bell.*[188])

In 2001, Ho and Frey subsequently described merely excavating the core of the pancreatic head, and draining the excavation with a Roux-en-Y pancreaticojejunostomy, but without any effort to include the dorsal duct[258,259] (Fig. 33-60). In 2003, Farkas and colleagues described a similar excavation of the central portion of the pancreatic head without any effort to include the duct of the body in the lateral pancreaticojejunostomy,[260] and reported excellent results with what they termed an *organ-preserving pancreatic head resection* (OPPHR) in a randomized comparison to the pylorus-preserving pancreaticoduodenectomy (PPPD).[261]

This approach was advocated by Gloor and associates in Bern as an alternative to the DPPHR procedure in patients with portal hypertension,[262] and was described as the *Berne modification of the DPPHR* (Fig. 33-61). Köninger and colleagues in Heidelberg subsequently published a randomized, controlled trial of the "Berne" version of the excavation method compared

Figure 33-55. Intraoperative view of the Beger procedure. The gastroduodenal artery is encircled by a vessel loop. Just below, the intrapancreatic portion of the common bile duct is exposed as it courses toward the ampulla. A rim of well-vascularized pancreatic tissue remains in the duodenal C-loop. Preservation of the posterior branch of the gastroduodenal artery is essential to preserve viability of these structures.

to the "classic" Beger procedure.[263] Operative times and length of stay were shorter in the group undergoing excavation of the pancreatic head, while long-term outcomes and quality-of-life scores were identical over 2 years postoperatively.

The common element of these variations on the theme of LR-LPJ remains the excavation or "coring out" of the central portion of the pancreatic head. It remains uncertain, however, whether and to what degree the dochotomy needs to be extended into the body and tail. The logical conclusion of all of these efforts is that the head of the pancreas is the nidus of the chronic inflammatory process in chronic pancreatitis, and that removal of the central portion of the head of the gland is the key to the successful resolution of pain long-term.

Complications Initial and long-term results of the LR-LPJ demonstrate pain relief that is equivalent to that of pancreaticoduodenectomy and the DPPHR.[264,265] The observed mortality rate has been virtually zero, and therefore, less than with the Whipple procedure. Major complications were less with the LR-LPJ (16%) than with pancreaticoduodenectomy (40%) or DPPHR (25%) in one single-site series, and the incidence of new postoperative diabetes after LR-LPJ was 8% with an average follow-up of 3 years.[179]

Comparisons of the three operative procedures: Pancreaticoduodenectomy (Whipple procedure), DPPHR (Beger procedure), and LR-LPJ (Frey procedure). There has been considerable interest to apply evidence-based methods to the study of the three operations currently advocated for the treatment of

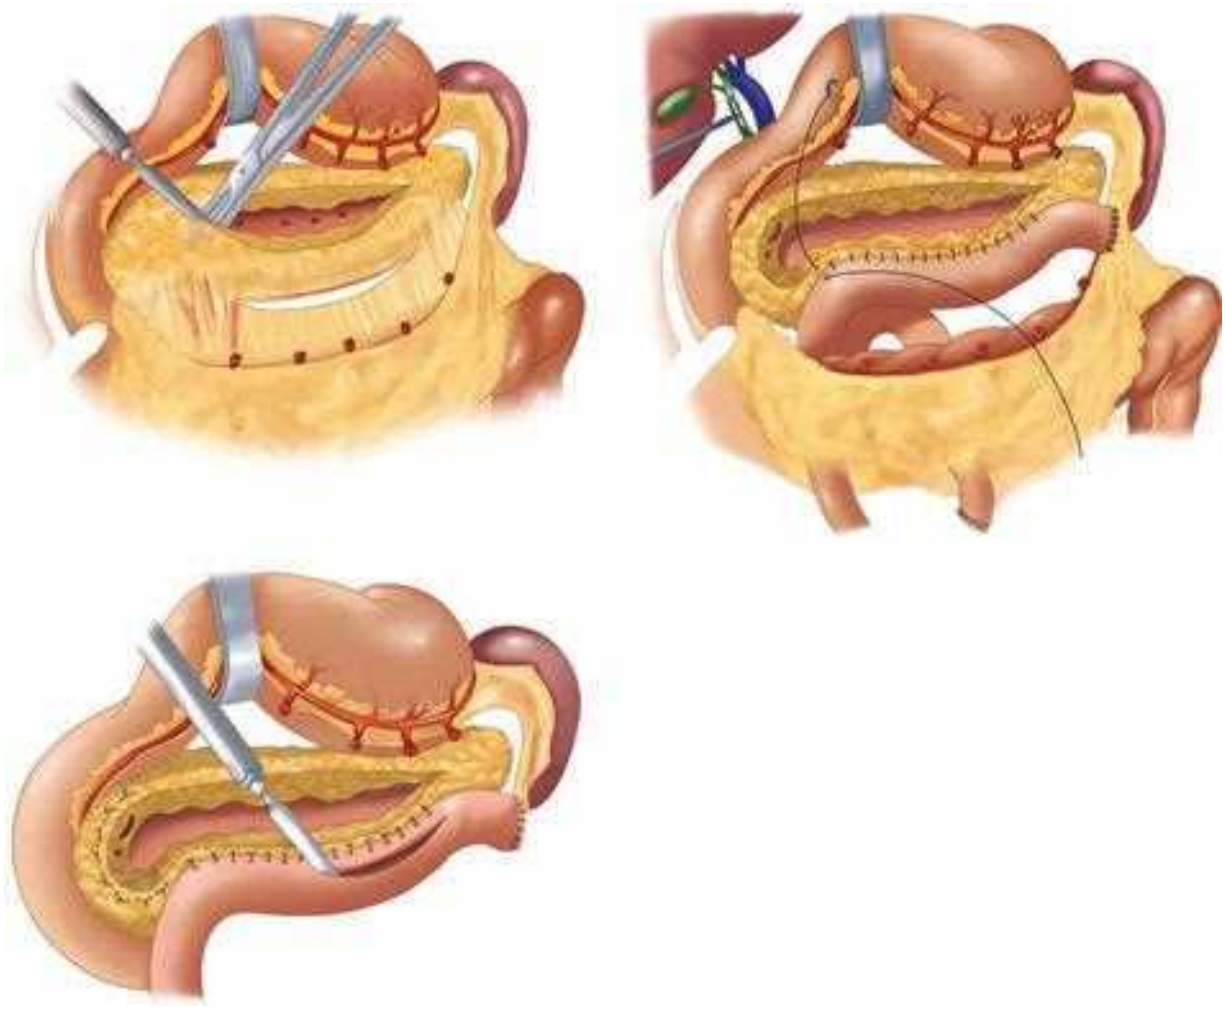

Figure 33-56. Frey procedure. The local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ) provides complete decompression of the entire pancreatic ductal system. chronic pancreatitis. The best studies, or level 1 data by the Strength of Recommendation Taxonomy, are prospective, randomized controlled trials comparing two or more operations from a single or multi-institutional study. Retrospective, cohort-based studies are regarded as level 2 data by the Strength of Recommendation Taxonomy criteria.

To date, six published level 1 studies and three level 2 studies have examined various comparisons between these three operations. In the level 1 study of 43 patients by Klempa and colleagues,[266] DPPHR patients had a shorter hospital stay, greater weight gain, less postoperative diabetes, and exocrine dysfunction than standard Whipple patients over a 3- to 5-year follow-up. Pain control was similar between the two procedures. This was confirmed in a level 1 study of 40 patients by Buchler and associates,[267] in which DPPHR patients reported better pain relief, glucose tolerance, and weight gain compared to pylorus-preserving pancreaticoduodenectomy (PPPD) patients; however, the follow-up averaged <1 year. Similar results were observed in a recent level 2 retrospective study of 123 patients.[268]

In a level 1 study of 61 patients randomized to PPPD or LR-LPJ, Izbicki and colleagues found a lower postoperative complication rate associated with the Frey procedure (19%) compared to the PPPD group (53%), and better global quality-of-life scores (71% vs. 43%, respectively).[264] Both operations were equally effective in controlling pain over a 2-year follow-up. More recently, the level 1 study by Farkas and associates[261] examined 40 patients randomized to PPPD or the method of excavation of the pancreatic head that their group described as an *organ-preserving pancreatic head resection* (OPPHR), and found that OPPHR was associated with a shorter operating time,

less postoperative morbidity, shorter hospital stay, and better quality of life than PPPD. The degree of pain relief was equal over a 1- to 3-year follow-up. Operation times have been shown to be shorter with the LR-LPJ and DPPHR compared to the PPPD, and intraoperative blood loss and perioperative transfusion requirements are less with LR-LPJ and DPPHR procedures.

Late Morbidity and Mortality In 2005, Izbicki's group reported on a level 1 study of 74 patients randomized to the DPPHR or LR-LPJ who were then followed for an average of 8.5 years.[269] There were no significant differences between the groups with regard to global quality of life, pain scores, late mortality, and exocrine or endocrine insufficiency. The level 1 study by Köninger, which compared the classic DPPHR with excavation of the pancreatic head, showed identical outcomes at 2 years after an initial reduction in morbidity associated with the excavation procedure.[263] These results were echoed in the level 2 study by Aspelund and associates, which demonstrated fewer complications with both the DPPHR and LR-LPJ procedures compared to pancreaticoduodenectomy, a lower incidence of new diabetes (8%) for both DPPHR and LR-LPJ compared to the Whipple procedure (25%), but no significant differences in outcomes or pain relief between DPPHR and LR-LPJ.[179] Finally, level 2 data support the efficacy of both DPPHR and LR-LPJ in patients with dilated as well as nondilated ducts.[270–272]

Long-term exocrine and/or endocrine insufficiency in chronic pancreatitis patients treated surgically is a product of the surgical intervention as well as the progression of the underlying disease. Although the short-term (3-year) incidence of new diabetes after operation appears less with the LR-LPJ and DPPHR than with the PPPD, the late incidence of diabetes appears similar in all groups. After an average of 7 years of follow-up after LR-LPJ or PPPD, survival, pain relief, and pancreatic function were similar in both groups. The rate of diabetes was slightly lower after LR-LPJ (61%) than after PPPD (65%), but these had both more than doubled from their preoperative status.[260–266] Therefore, although the limited pancreatic procedures of DPPHR and LR-LPJ have a lower initial rate of endocrine dysfunction, the long-term risk of diabetes is more related to the progression of the underlying disease than to the effects of operation.

The decreased incidence of postoperative diabetes in the near-term after the duodenum-sparing operations may be the result of a preserved β-cell mass in the more conservative resections, and may also be due to the conservation of the PP-secreting cells localized to the posterior head and uncinate process. Preservation of near-normal glucose metabolism and the avoidance of pancreatogenic diabetes is therefore a significant but time-limited benefit of the newer operative procedures.

Total Pancreatectomy with Islet Auto-Transplantation Islet cell transplantation for the treatment of diabetes is an attractive adjunct to pancreatic surgery in the treatment of benign pancreatic disease, but problems due to rejection of allotransplanted islets have plagued this method since its initial clinical application in the early 1970s. However, despite the difficulties in recovering islets from a chronically inflamed gland, Najarian and associates demonstrated the utility of autotransplantation of islets in patients with chronic pancreatitis in 1980.[273] Subsequently, through refinements in the methods of harvesting and gland preservation, and through standardization of the methods by which islets are infused into the portal venous circuit for intrahepatic engraftment, the success of total pancreatectomy combined with islet auto-transplantation has steadily increased to achieve insulin independence in the majority of patients treated in recent series.[274,275] Although 2 to 3 million islets are required for successful engraftment in an allogeneic recipient, the auto-transplant recipient can usually achieve long-term, insulin-independent status after engraftment of only 300,000 to 400,000 islets.[276]

The ability to recover a sufficient quantity of islets from a sclerotic gland is dependent on the degree of fibrotic disease present, so the selection of patients as candidates for autologous islet transplantation is important. The impressive improvement in quality of life measures and pain relief seen after total pancreatectomy with islet auto-transplantation (TP-IAT) indicate that it is a highly successful form of therapy for some patients. The significant morbidity risk of TP-IAT, and the likelihood of unsuccessful recovery of sufficient numbers of islets due to advanced disease, however, suggest that further definition is needed regarding criteria for considering TP-IAT vs. hybrid or resectional procedures for patients with persistent symptoms. The recent study which compared degree of fibrosis with the extent of pain relief after the LR-LPJ procedure suggests that the extent of pancreatic fibrosis may be a useful guide to the selection of surgical therapy for refractory symptomatic chronic pancreatits.[147] Further studies will require accurate methods to quantify the extent of fibrosis preoperatively.

PANCREATIC NEOPLASMS

Neoplasms of the Endocrine Pancreas

Neoplasms of the endocrine pancreas are relatively uncommon but do occur with enough frequency (five cases per million population) that most surgeons will encounter them in an urban practice. The cells of the endocrine pancreas, or islet cells, originate from neural crest cells, also referred to as *amine precursor uptake and decarboxylation cells*. Multiple endocrine neoplasia (MEN) syndromes occur when these cells cause tumors in multiple sites. The MEN1 syndrome involves pituitary tumors, parathyroid hyperplasia, and pancreatic neoplasms. Some pancreatic endocrine neoplasms are functional, secreting peptide products that produce interesting clinical presentations. Neoplasms of the endocrine pancreas that are not associated with excess hormone levels and a recognizable clinical syndrome are considered nonfunctional. Special immunohistochemical stains allow pathologists to confirm the peptide products being produced within the cells of a pancreatic endocrine tumor. However, the histologic characteristics of these neoplasms do not predict their clinical behavior, and malignancy is usually determined by the presence of local invasion and lymph node or hepatic metastases. Unfortunately, most pancreatic endocrine tumors are malignant, but the course of the disease is far more favorable than that seen with pancreatic exocrine cancer. The key to diagnosing these rare tumors is recognition of the classic clinical syndrome; confirmation is achieved by measuring serum levels of the elevated hormone. Localization of the tumor can be a challenging step, but once accomplished, the surgery is relatively straightforward. The goals of surgery range from complete resection, often accomplished with insulinomas, to controlling symptoms with debulking procedures. Unresectable disease in the liver is often addressed with chemoembolization.

As with pancreatic exocrine tumors, the initial diagnostic imaging test of choice for pancreatic endocrine tumors is a multidetector CT scan with four phases of contrast and fine cuts through the pancreas and liver. Neuroendocrine tumors of the

pancreas often enhance with contrast. EUS also can be valuable in localizing these tumors, which can produce dramatic symptoms despite their small (<1 cm) size. In contrast to pancreatic exocrine tumors, many of the endocrine tumors have somatostatin receptors (SSTRs) that allow them to be detected by a radiolabeled octreotide scan. A radioactive somatostatin analogue is injected intravenously, followed by whole-body radionuclide scanning (Fig. 33-62). The success of this modality in localizing tumors and detecting metastases has decreased the use of older techniques such as angiography and selective venous sampling.

Insulinoma

Insulinomas are the most common functional pancreatic endocrine neoplasms and present with a typical clinical syndrome known as Whipple's triad. The triad consists of symptomatic fasting hypoglycemia, a documented serum glucose level <50 mg/dL, and relief of symptoms with the administration of glucose. Patients can present with a profound syncopal episode or less severe symptoms that are averted by frequent eating. Common symptoms include palpitations, trembling, diaphoresis, confusion or obtundation, and seizure, and family members may report that the patient has undergone a personality change.

Routine laboratory studies will uncover a low blood sugar, the cause of all of these symptoms. Serum insulin levels are elevated. C-peptide levels should also be elevated and rule out the unusual case of surreptitious administration of insulin or oral hypoglycemic agents, because excess endogenous insulin production leads to excess C-peptide. The diagnosis can be clinched with a monitored fast in which blood is sampled every 4 to 6 hours for glucose and insulin levels until the patient becomes symptomatic. However, this can be dangerous and must be done with close supervision.

Figure 33-62. Radioactive octreotide scan demonstrating pancreatic endocrine tumor in the body of the pancreas (*arrow*).

Insulinomas are usually localized with CT scanning and EUS. Technical advances in EUS have led to preoperative identification of >90% of insulinomas.[277] Visceral angiography with venous sampling is rarely required to accurately localize the tumor. Insulinomas are evenly distributed throughout the head, body, and tail of the pancreas.[278]

Unlike most endocrine pancreatic tumors, the majority (90%) of insulinomas are benign and solitary, and only 10% are malignant. They are typically cured by simple enucleation. However, tumors located close to the main pancreatic duct and large (>2 cm) tumors may require a distal pancreatectomy or pancreaticoduodenectomy. Intraoperative US is useful to determine the tumor's relation to the main pancreatic duct and guides intraoperative decision making. Enucleation of solitary insulinomas and distal pancreatectomy for insulinoma can sometimes be performed using a minimally invasive technique.

Approximately 90% of insulinomas are sporadic, and 10% are associated with the MEN1 syndrome. Insulinomas associated with the MEN1 syndrome are more likely to be multifocal and have a higher rate of recurrence.

Noninsulinoma Hyperinsulinemia Hypoglycemia Syndrome

A syndrome of noninsulinoma pancreatogenous hypoglycemia was described by Service et al. in 1999.[279] The syndrome is associated with beta-cell hypertrophy, islet hyperplasia and increased beta-cell mass. When these findings are accompanied by ectopic islet tissue, multilobulated islets, and ductulo-insular complexes, the definition of nesideoblastosis is met. Nesideoblastosis accompanied by hyperinsulinism was previously considered a disease of neonates, where subtotal or total pancreatectomy was required to correct potentially fatal neonatal hyperinsulinism. However, dozens of cases of nesideoblastosis associated with hyperinsulinism have now been reported in patients 2 to 5 years after Roux-en-Y gastric bypass.[280] Many of these patients have undergone partial or total pancreatectomy to prevent potentially fatal hypoglycemia. The illness in former bariatric surgery patients appears to result from an idiosyncratically-prolonged hypersecretion of the incretin hormones GIP and GLP-1after the gastric bypass. GLP-1 is a potent stimulant of the expression of the transcription factor PDX-1, which normally regulates beta-cell development and growth. Conversion of the gastric bypass to a form of bariatric procedure which restores normal intestinal flow of nutrients, such as the gastric sleeve, or the addition of a restriction element such as an adjustable gastric band, appears to prevent episodes of hypoglycemia in these patients. Pancreatic resection without conversion of the Roux-en-Y gastric bypass allows the abnormal entero-insular relationship to continue, and hyperinsulinemia persists or recurs after partial pancreatectomy.

Gastrinoma

Zollinger-Ellison syndrome (ZES) is caused by a *gastrinoma*, an endocrine tumor that secretes gastrin, leading to acid hypersecretion and peptic ulceration. Many patients with ZES present with abdominal pain, peptic ulcer disease, and severe esophagitis. However, in the era of effective antacid therapy, the presentation can be less dramatic. Although most of the ulcers

are solitary, multiple ulcers in atypical locations that fail to respond to antacids should raise suspicion for ZES and prompt a work-up. At the time of diagnosis, 21% of patients with gastrinoma have diarrhea .

The diagnosis of ZES is made by measuring the serum gastrin level. It is important that patients stop taking proton pump inhibitors for this test. In most patients with gastrinomas, the level is >1000 pg/mL. Gastrin levels can be elevated under-conditions other than ZES. Common causes of hypergastrinemia include pernicious anemia, treatment with proton pump inhibitors, renal failure, G-cell hyperplasia, atrophic gastritis, retained or excluded antrum, and gastric outlet obstruction. In equivocal cases, when the gastrin level is not markedly elevated, a secretin stimulation test is helpful.

In 70% to 90% of patients, the primary gastrinoma is found in Passaro's triangle, an area defined by a triangle with points located at the junction of the cystic duct and common bile duct, the second and third portion of the duodenum, and the neck and body of the pancreas (Fig. 33-63). However, because gastrinomas can be found almost anywhere, whole-body imaging is required. The test of choice is SSTR (octreotide) scintigraphy in combination with CT. The octreotide scan is more sensitive than CT, locating about 85% of gastrinomas and detecting tumors <1 cm. With the octreotide scan, the need for tedious and technically demanding selective angiography and measurement of gastrin gradients has declined. EUS is another modality that assists in the preoperative localization of gastrinomas. It is particularly helpful in localizing tumors in the pancreatic head or duodenal wall, where gastrinomas are usually <1 cm in size. A combination of octreotide scan and EUS detects >90% of gastrinomas.

It is important to rule out MEN1 syndrome by checking serum calcium levels before surgery because resection of the gastrinoma(s) in these patients rarely results in normalization of serum gastrin concentrations or a prolongation of survival. Only one fourth of gastrinomas occur in association with the MEN1 syndrome. One half of patients with gastrinomas will have solitary tumors while the remainder will have multiple gastrinomas. Multiple tumors are more common in patients with MEN1 syndrome. Aggressive surgical treatment is justified in patients with sporadic gastrinomas. If patients have MEN1 syndrome, the parathyroid hyperplasia is addressed with total parathyroidectomy and implantation of parathyroid tissue in the forearm.

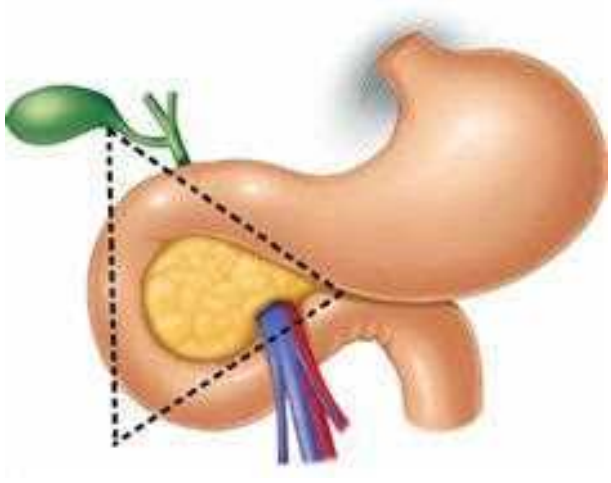

Figure 33-63. Passaro's triangle. The typical location of a gastrinoma is described by this anatomic region, including the head of the pancreas, duodenum, and the lymphatic bed posterior and superior to the duodenum, as originally described by E. Passaro. (*Reproduced with permission from Stable BE, Morrow DJ, Passaro E: The gastrinoma triangle: operative implications.* Am J Surg. *1984;147:25. Copyright Elsevier.*)

Approximately 50% of gastrinomas metastasize to lymph nodes or the liver, and are therefore considered malignant. Patients who meet criteria for operability should undergo exploration for possible removal of the tumor. Although the tumors are submucosal, a full-thickness excision of the duodenal wall is performed if a duodenal gastrinoma is found. All lymph nodes in Passaro's triangle are excised for pathologic analysis. If the gastrinoma is found in the pancreas and does not involve the main pancreatic duct, it is enucleated. Pancreatic resection is justified for solitary gastrinomas with no metastases. A highly selective vagotomy can be performed if unresectable disease is identified or if the gastrinoma cannot be localized. This may reduce the amount of expensive proton pump inhibitors required. In cases in which hepatic metastases are identified, resection is justified if the primary gastrinoma is controlled and the metastases can be safely and completely removed. Debulking or incomplete removal of multiple hepatic metastases is probably not helpful, especially in the setting of MEN1. The application of new modalities such as radiofrequency ablation seems reasonable, but data to support this approach are limited.[281] Postoperatively, patients are followed with fasting serum gastrin levels, secretin stimulation tests, octreotide scans, and CT scans. In patients found to have inoperable disease, chemotherapy with streptozocin, doxorubicin, and 5-fluorouracil (5-FU) is used. Other approaches such as somatostatin analogues, interferon, and chemoembolization also have been used in gastrinoma with some success.

Unfortunately, a biochemical cure is achieved in only about one-third of the patients operated on for ZES. Despite the lack of success, long-term survival rates are good, even in patients with liver metastases. The 15-year survival rate for patients without liver metastases is about 80%, while the 5-year survival rate for patients with liver metastases is 20% to 50%. Pancreatic tumors are usually larger than tumors arising in the duodenum, and more often have lymph node metastases. In gastrinomas, liver metastases decrease survival rates, but lymph node metastases do not. The best results are seen after complete excision of small sporadic tumors originating in the duodenum. Large tumors associated with liver metastases, located outside of Passaro's triangle, have the worst prognosis.

Vasoactive Intestinal Peptide-Secreting Tumor

In 1958, Verner and Morrison first described the syndrome associated with a pancreatic neoplasm secreting VIP. The classic clinical syndrome associated with this pancreatic endocrine neoplasm consists of severe intermittent watery diarrhea leading to dehydration, and weakness from fluid and electrolyte losses. Large amounts of potassium are lost in the stool. The *vasoactive intestinal peptide-secreting tumor* (*VIPoma*) *syndrome* is also called the *WDHA syndrome* due to the presence of *w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria. The massive (5 L/d) and episodic nature of the diarrhea associated with the appropriate electrolyte abnormalities should raise suspicion of the diagnosis. Serum VIP levels must be measured on multiple occasions because the excess secretion of VIP is episodic and single measurements might be normal and misleading. ACT scan localizes most VIPomas, although as with all islet cell tumors, EUS is the most sensitive imaging method. Electrolyte and fluid balance

is sometimes difficult to correct preoperatively and must be pursued aggressively. Somatostatin analogues are helpful in controlling the diarrhea and allowing replacement of fluid and electrolytes. VIPomas are more commonly located in the distal pancreas and most have spread outside the pancreas. Palliative debulking operations can sometimes improve symptoms for a period, along with somatostatin analogues. Hepatic artery embolization also has been reported as a potentially beneficial treatment.[282]

Glucagonoma

Diabetes in association with dermatitis should raise the suspicion of a glucagonoma. The diabetes usually is mild. The classic necrolytic migratory erythema manifests as cyclic migrations of lesions with spreading margins and healing centers typically on the lower abdomen, perineum, perioral area, and feet. Patients also complain of an enlarged, sensitive tongue. The diagnosis is confirmed by measuring serum glucagon levels, which are usually >500 pg/mL. Glucagon is a catabolic hormone, and most patients present with malnutrition. The rash associated with glucagonoma is thought to be caused by low levels of amino acids. Preoperative treatment usually includes control of the diabetes, parenteral nutrition, and octreotide. Like VIPomas, glucagonomas are more often in the body and tail of the pancreas and tend to be large tumors with metastases. Again, debulking operations are recommended in good operative candidates to relieve symptoms.

Somatostatinoma

Because somatostatin inhibits pancreatic and biliary secretions, patients with a somatostatinoma present with gallstones due to bile stasis, diabetes due to inhibition of insulin secretion, and steatorrhea due to inhibition of pancreatic exocrine secretion and bile secretion. Most somatostatinomas originate in the proximal pancreas or the pancreatoduodenal groove, with the ampulla and periampullary area as the most common site (60%). The most common presentations are abdominal pain (25%), jaundice (25%), and cholelithiasis (19%).[283] This rare type of pancreatic endocrine tumor is diagnosed by confirming elevated serum somatostatin levels, which are usually >10 n g/mL. Although most reported cases of somatostatinoma involve metastatic disease, an attempt at complete excision of the tumor and cholecystectomy is warranted in fit patients.

Nonfunctioning Pancreatic Endocrine Tumors

Although some pancreatic endocrine neoplasms secrete one or more hormones and are associated with interesting characteristic clinical syndromes, most are not associated with elevated serum hormone levels that cause symptoms. Pancreatic endocrine tumors are considered functional if they are associated with a clinical syndrome and nonfunctioning if not associated with clinical symptoms. The majority of pancreatic endocrine tumors (PET), also called pancreatic neuroendocrine tumors (PNET), are malignant because they have the potential for uncontrolled growth and metastasis. Immunohistochemical markers such as synaptophysin, chromogranin A (CgA), and neuron-specific enolase can be helpful in the diagnosis but the gross histology is not a reliable predictor of biologic behavior. CgA is used by some as a serum marker to monitor patients for disease recurrence or response to treatment but the test performs poorly for this purpose. Patients often present similar to patients with pancreatic adenocarcinoma with vague pain, or weight loss but PNETs are increasingly discovered incidentally when imaging is performed for another reason. The tumor frequently enhances with arterial contrast.(Fig. 33-64) Sometimes a cystic component is seen due to central necrosis. Octreoscan (somatostatin receptor scintigraphy) can be helpful to stage the disease. Surgical resection is always recommended in fit patients in the absence of metastatic disease. Adjuvant treatment after resection is withheld in the absence of radiographically demonstrable metastatic disease even if CgA levels remain elevated. Although these tumors have a slow growth pattern compared to pancreatic ductal adenocarcinoma, many patients with PNETs will die of their disease even after an apparent complete resection. Incomplete resection (debulking) for locally advanced or metastatic PNETs of the pancreas is controversial because of the favorable survival duration of patients without surgery. However, in carefully selected fit patients with a PNET in the head of the pancreas and minimal disease in the liver, a pancreaticoduodenectomy with wedge resection of the liver metastasis might be appropriate because this avoids the morbidity of gastrointestinal hemorrhage, biliary and gastric outlet obstruction before death from the metastatic disease. Recently molecular analysis has shown that PNETs have activation of mammalian target of rapamycin (mTOR) and the VEGF pathway. Antitumor activity has been demonstrated in recent clinical trials with Everolimus, an mTOR inhibitor in combination with temozolomide and sunitinib.[284,285] In addition, some centers are combining resection with transarterial chemoembolization (TACE) of metastatic disease in the liver.

Neoplasms of the Exocrine Pancreas

Epidemiology and Risk Factors. It is estimated that in 2012, 43,920 Americans were diagnosed with pancreatic cancer and 37,390 died from the disease. Worldwide, over 265,000 people contract this disease annually, of which 74% of patients die within the first year after diagnosis.[286,287] Overall, pancreatic cancer has the worst prognosis of all malignancies with a 5-year survival rate of only 6%.[288] The incidence of pancreatic cancer continues to increase, perhaps related to the increased incidence of risk factors such as obesity and diabetes,[289] and as a result, it is predicted that pancreatic cancer will become the leading cause of cancer deaths in the United States by 2050.[287] Despite its ubiquity, this disease is extremely difficult to treat, and its exact cause is unknown. However, epidemiologic studies linking various environmental and host factors provide some clues. Recent discoveries using modern molecular biologic techniques have also improved our understanding of the causes of pancreatic cancer. The etiology of pancreatic cancer likely involves a complex interaction of genetic and environmental factors. These factors will become more fully understood as better diagnostic tools such as DNA sequencing become clinically available to screen populations at risk for developing pancreatic cancer.

Pancreatic cancer is more common in the elderly with most patients being >60 years old. Pancreatic cancer is more common in African Americans and slightly more common in men than women. The risk of developing pancreatic cancer is two to three times higher if a parent or sibling had the disease. Another risk factor that is consistently linked to pancreatic cancer is cigarette smoking. Smoking increases the risk of developing pancreatic cancer by at least twofold due to the carcinogens in cigarette smoke.[290] Coffee and alcohol consumption have been investigated as possible risk factors, but the data are inconsistent. As in other GI cancers, diets high in fat and low in fiber, fruits, and vegetables are thought to be associated with an increased risk of pancreatic cancer.

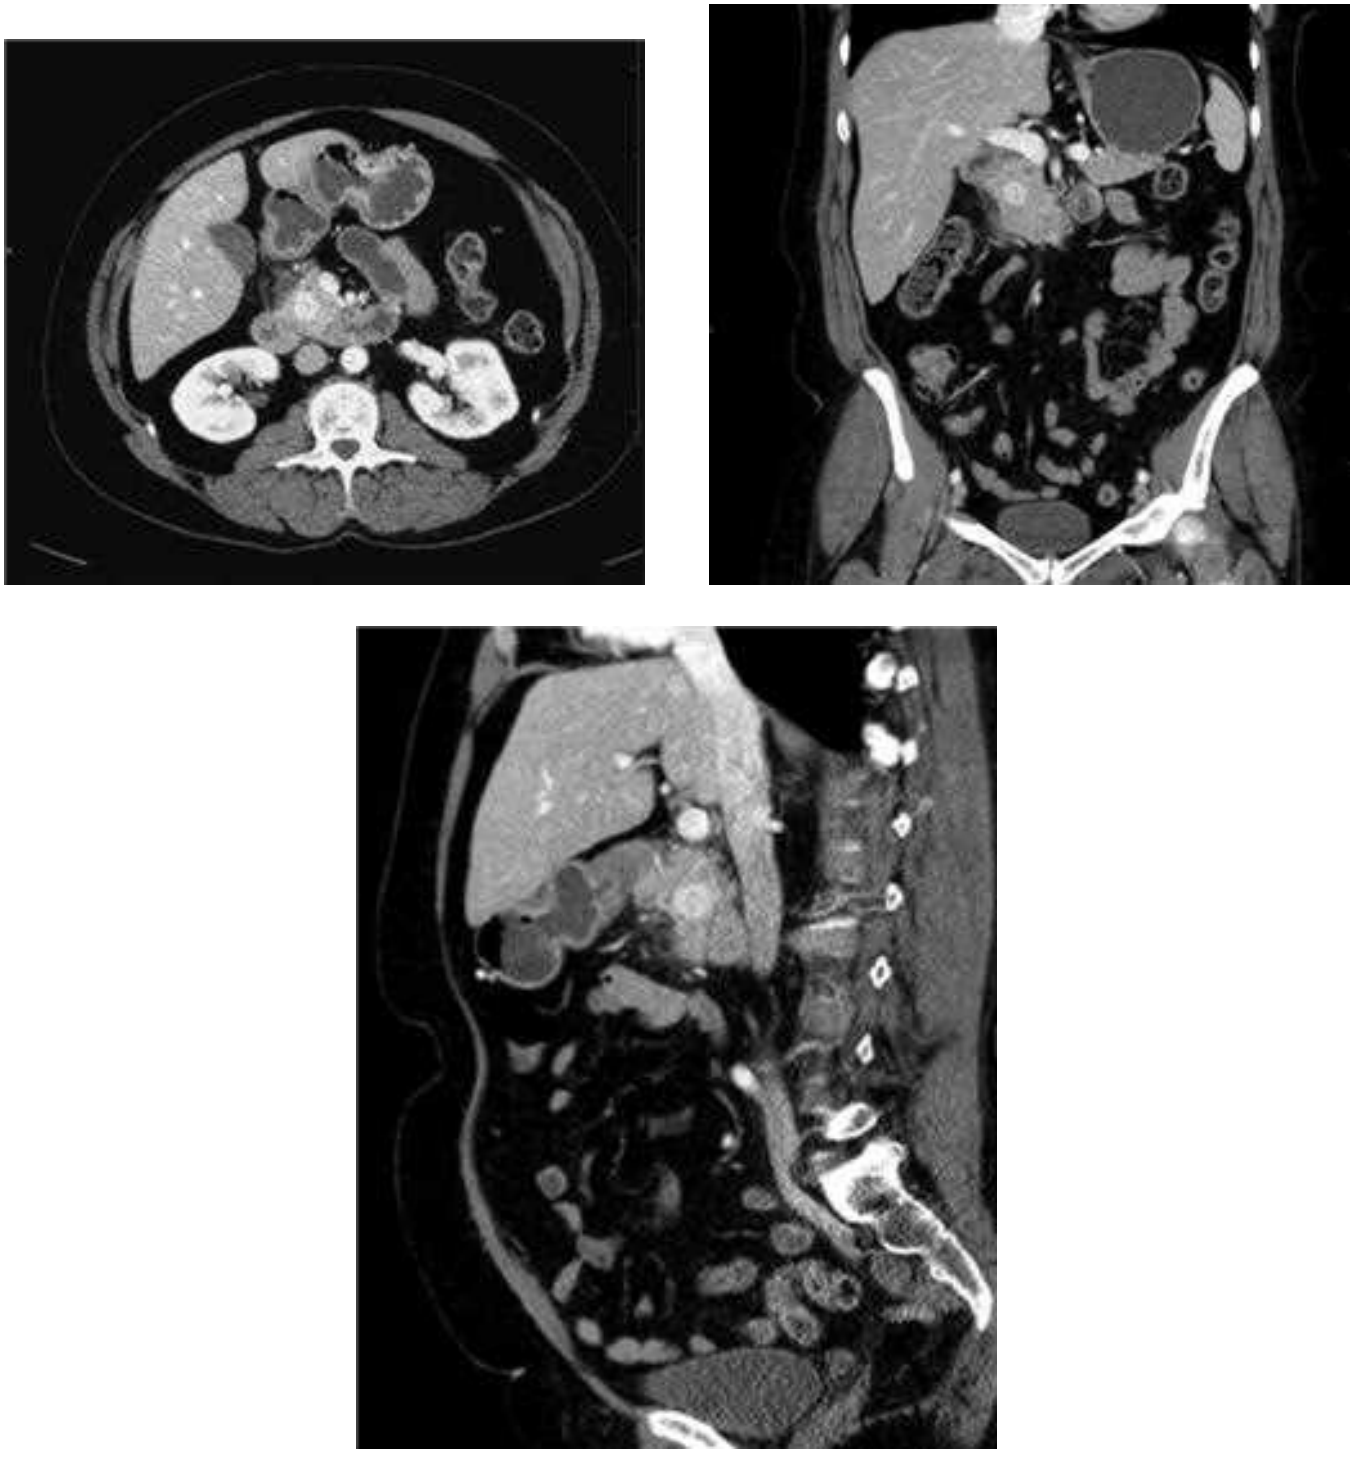

Figure 33-64. Pancreatic neuroendocrine tumor (PNET) demonstrating enhancement during arterial phase of CT scan. Pancreatic head PNET seen in (*left*) sagital, (*middle*) coronal, and (*right*) lateral views of the abdomen.

Diabetes has been known to be associated with pancreatic cancer for many years. In fact, glucose intolerance is present in 80% of patients with pancreatic cancer, and approximately 50% have overt diabetes, a much greater incidence than would be expected to occur by chance. Pre-existing type 2 diabetes increases the risk for development of pancreatic cancer by about twofold.[291] The new onset of diabetes also can be an early manifestation of otherwise occult pancreatic cancer. Thus, the new onset of diabetes, or a sudden increase in insulin requirement in an elderly patient with pre-existing diabetes, should provoke concern for the presence of pancreatic cancer.

Recent epidemiologic studies have confirmed the fact that patients with chronic pancreatitis, especially familial pancreatitis, have an increased risk of developing pancreatic cancer.[111,177,178] Large, retrospective cohort studies of patients with pancreatitis have revealed up to a 20-fold increase in risk for pancreatic cancer. This increased risk seems to be independent of the type of pancreatitis, a finding consistent with the fact that most studies have shown little effect of alcohol ingestion per se on the risk of pancreatic carcinoma. The mechanisms involved in carcinogenesis in patients with pre-existing pancreatitis are unknown. However, the mutated K-*ras* oncogene, which is present in most

cases of pancreatic cancer, has been detected in the ductal epithelium of some patients with chronic pancreatitis.

Genetics of Pancreatic Cancer. Pancreatic carcinogenesis probably involves multiple mutations that are inherited and acquired throughout aging. The K-*ras* oncogene is currently thought to be the most commonly mutated gene in pancreatic cancer, with approximately 90% of tumors having a mutation.[293] This prevalent mutation is present in precursor lesions and is therefore thought to occur early and be essential to pancreatic cancer development. K-*ras* mutations can be detected in DNA from serum, stool, pancreatic juice, and tissue aspirates of patients with pancreatic cancer, suggesting that the presence of this mutation may provide the basis for diagnostic testing in select individuals. The HER-2/*neu* oncogene, homologous to the epidermal growth factor receptor (EGFr), is overexpressed in pancreatic cancers.[292] This receptor is involved in signal transduction pathways that lead to cellular proliferation. Multiple tumor-suppressor genes are deleted and/or mutated in pancreatic cancer, including*p53, p16*, and *DPC4* (*Smad 4*), and in a minority of cases, *BRCA2*.[293] Most pancreatic cancers have three or more of the above mutations.

With the completion of the human genome project, comparison of the normal genome and the results of DNA sequencing of pancreatic and other cancers is an active area of research. The genetic landscape of pancreatic adenocarcinoma has recently been investigated using exome capture technology combined with the SOLiD or Illumina next generation sequencing platforms and copy number analysis. Detailed analysis of 99 tumors reaffirmed the importance of the already known mutations such as KRAS, TP53, CDKN2A, SMAD4, MLL3, TGFBR2, ARID1A, and SF3B1 in pancreatic cancer and identified 8 novel significantly mutated genes involved in chromatin modification (EPC1 and ARID2), DNA damage repair (ATM) and other mechanisms (ZIM2, MAP2K4, NALCN, SLC16A4, and MAGEA6). Pathway-based analysis of recurrently altered genes also revealed the involvement of axon-guidance genes, particularly SLIT/ROBO signaling, in pancreatic carcinogenesis.[294] Rapid and sensitive sequencing techniques will hopefully lead to better diagnostic and therapeutic approaches for pancreatic cancer. It is estimated that up to 10% of pancreatic cancers occur as a result of an inherited genetic predisposition. A family history of pancreatic cancer in a first-degree relative increases the risk of pancreatic cancer by about twofold.[293] Rare familial cancer syndromes that are associated with an increased risk of pancreatic cancer include *BRCA2*, the familial atypical multiple mole–melanoma syndrome, hereditary pancreatitis, familial adenomatous polyposis (FAP), hereditary nonpolyposis colorectal cancer, Peutz-Jeghers syndrome, and ataxia-telangiectasia.[293]

In addition to mutations in oncogenes and tumor-suppressor genes, pancreatic cancers also are known to have aberrations in the expression of growth factors and their receptors. These growth factors include epidermal growth factor, fibroblast growth factor, transforming growth factor beta, insulin-like growth factor, hepatocyte growth factor, and vascular endothelial growth factor.[292]

The fact that many GI hormones and growth factors affect the growth of the normal exocrine pancreas suggests that these peptides also could affect the growth of pancreatic cancer, and some studies in cell culture and laboratory animals have supported this hypothesis.[295] Newer drugs such as erlotinib (Tarceva) and cetuximab (Erbitux), EGFr inhibitors, and bevacizumab (Avastin), a vascular endothelial growth factor inhibitor, and other drugs aimed at manipulation of growth factors, their receptors, and secondary messengers are the subject of ongoing clinical research. However, the combination of these drugs with standard chemotherapy in recent trials has not resulted in dramatic improvements in overall survival in pancreatic cancer.

Pathology. Pancreatic cancer probably arises through a stepwise progression of cellular changes, just as colon cancer progresses by stages from hyperplastic polyp to invasive cancer. Systematic histologic evaluation of areas surrounding pancreatic cancers has revealed the presence of precursor lesions that have been named *pancreatic intraepithelial neoplasia* (Fig. 33-65). Three stages of pancreatic intraepithelial neoplasia have been defined. These lesions demonstrate the same oncogene mutations and loss of tumor-suppressor genes found in invasive cancers, the frequency of these abnormalities increasing with progressive cellular atypia and architectural disarray.[296] The ability to detect these precursor lesions in humans at a stage where the cancer can still be prevented or cured is an important goal of current pancreatic cancer research.

7▶ About two-thirds of pancreatic adenocarcinomas arise within the head or uncinate process of the pancreas; 15% are in the body, and 10% in the tail, with the remaining tumors demonstrating diffuse involvement of the gland. Tumors in the pancreatic body and tail are generally larger at the time of diagnosis, and therefore, less commonly resectable. Tumors in the head of the pancreas are typically diagnosed earlier because they cause obstructive jaundice. Ampullary carcinomas, carcinomas of the distal bile duct, and periampullary duodenal adenocarcinomas present in a similar fashion to pancreatic head cancer but have a slightly better prognosis, probably because early obstruction of the bile duct and jaundice leads to the diagnosis.

In addition to ductal adenocarcinoma, which makes up about 75% of nonendocrine cancers of the pancreas, there are a variety of less common types of pancreatic cancer. Adenosquamous carcinoma is a variant that has both glandular and squamous differentiation. The biologic behavior of this lesion is unfortunately no better than the typical ductal adenocarcinoma.[297] Acinar cell carcinoma is an uncommon type of pancreatic cancer that usually presents as a large tumor, often 10 cm in diameter or more, but the prognosis of patients with these tumors may be better than with ductal cancer.

Diagnosis and Staging. Exact pathologic staging of pancreatic cancer is important because it allows accurate quantitative assessment of results and comparisons between institutions. The *t*umor-node-*m*etastasis (TNM) staging of pancreatic cancer is shown in Table 33-21 .

T1 lesions are ≤2 cm in diameter and are limited to the pancreas. T2 lesions also are limited to the pancreas, but are >2 cm. T3 lesions extend beyond the pancreas but do not involve the celiac axis or superior mesenteric artery. T4 lesions involve the celiac axis or superior mesenteric artery and are not resectable. T1 and T2 tumors with no lymph node involvement are considered stage I disease (stage IA and IB). More extensive invasion, such as that associated with T3 tumors, indicates stage IIA disease. Any lymph node involvement indicates stage IIB disease. Locally advanced unresectable tumors (T4) without metastatic disease are considered stage III while patients with metastases to distant sites such as the liver or lungs are stage IV.

Eight percent of pancreas cancer cases are diagnosed while the cancer is still confined to the primary site (localized stage); 27% are diagnosed after the cancer has spread to regional lymph

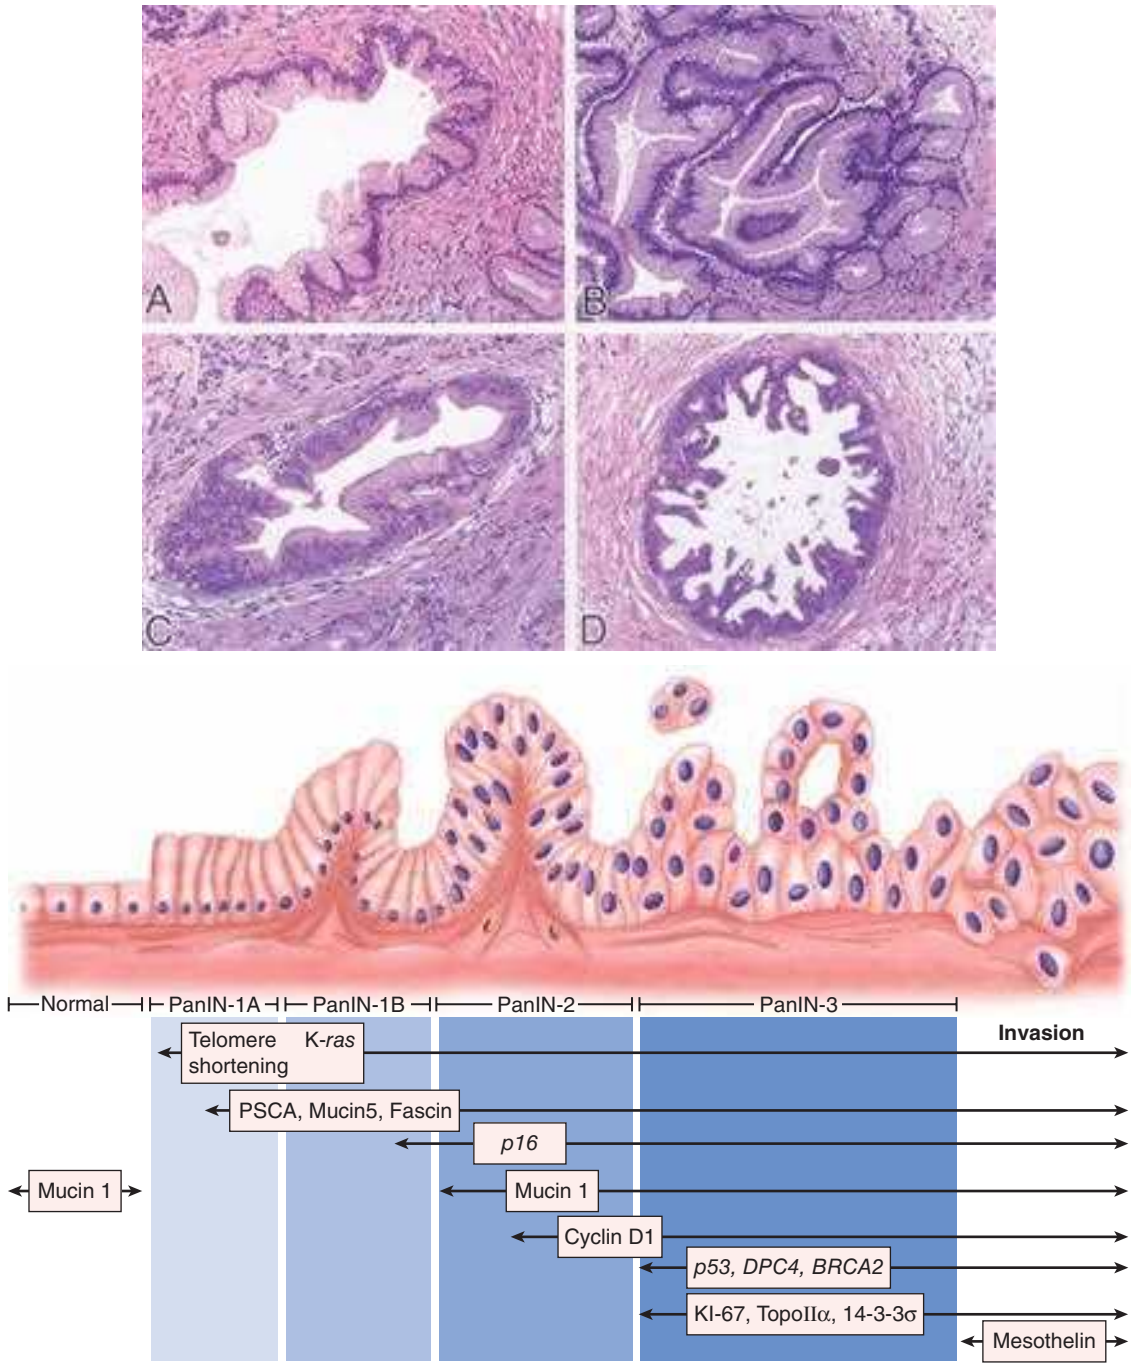

Figure 33-65. Pancreatic intraepithelial neoplasia (PanIN). Histology (*top panel*) showing grades PanIN-1A (**A**), PanIN-1B (**B**), PanIN-2 (**C**), and PanIN-3 (**D**), and schema of correlation of histology with mutational events (*bottom panel*) showing cumulative abnormalities of tumor-promoter and tumor suppressor factors such as kRAS, p53, etc, and their corresponding cellular phenotype. (*From Hruban RH, Takaori K, Klimstra DS, et al: An illustrated consensus on the classification of pancreatic intraepithelial neoplasia and intraductal papillary mucinous neoplasms. Am J Surg Pathol. 28:977, 2004.*)

nodes or directly beyond the primary site; 53% are diagnosed after the cancer has already metastasized (distant stage); and for the remaining 12%, the staging information was unknown. The corresponding 5-year relative survival rates were: 23.3% for localized, 8.9% for regional, 1.8% for distant, and 3.9% for unstaged. The overall 5-year relative survival rate for patients with pancreatic cancer for 2002 to 2008 from 18 Surveillance, Epidemiology and End Results (SEER) geographic areas was 5.8%.[298]

The most critical deficit in the ability to treat pancreatic cancer effectively is the lack of tools for early diagnosis. The pancreas is situated deep within the abdomen, and the early symptoms of pancreatic cancer often are too vague to raise suspicion of the disease. Ultimately, the majority of patients present with pain and jaundice. On physical examination, weight loss is evident and the skin is icteric; a distended gallbladder is palpable in about one-fourth of patients. More fortunate patients have tumors situated such that biliary obstruction and jaundice occurs early and prompts diagnostic tests. Unfortunately, however, the vast majority of patients are not diagnosed until weight loss has occurred—a sign of advanced disease.

Although it is often taught that carcinoma of the pancreas presents with painless jaundice (to help distinguish it

Table 33-21

Staging of pancreatic cancer

Tumor (T)
- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ
- T1: Tumor is limited to the pancreas and is ≤2 cm in greatest dimension
- T2: Tumor is limited to the pancreas and is >2 cm in greatest dimension
- T3: Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
- T4: Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)

Regional lymph nodes (N)
- NX: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Regional lymph node metastasis

Distant metastasis (M)
- MX: Distant metastasis cannot be assessed
- M0: No distant metastasis
- M1: Distant metastasis

Stage	T	N	M	Description
IA	1	0	0	Limited to pancreas ≤2 cm
IB	2	0	0	Limited to pancreas >2 cm
IIA	3	0	0	Extends beyond pancreas but does not involve arteries
IIB	1-3	1	0	Any tumor without artery involvement with lymph node involvement
III	4	Any	0	Tumor involves arteries (unresectable)
IV	Any	Any	1	Any tumor with distant metastases

from choledocholithiasis), this aphorism is not accurate. Most patients do experience pain as part of the symptom complex of pancreatic cancer, and it is often the first symptom. Therefore, awareness of the way pancreatic pain is perceived may help clinicians suspect pancreatic cancer. The pain associated with pancreatic cancer is usually perceived in the epigastrium but can occur in any part of the abdomen, and often, but not always, penetrates to the back. When questioned in retrospect, patients often recall mild and vague pain for many months before diagnosis. A low threshold for ordering a CT scan with "pancreatic protocol" should be maintained for elderly patients with unexplained, persistent, although vague, abdominal pain. As mentioned above, new-onset diabetes in an elderly patient, especially if combined with vague abdominal pain, should prompt a search for pancreatic cancer.

Unfortunately, at this time there is no sensitive and specific serum marker to assist in the timely diagnosis of pancreatic cancer. With jaundice, direct hyperbilirubinemia and elevated alkaline phosphatase are expected but do not serve much of a diagnostic role other than to confirm the obvious. With long-standing biliary obstruction, the prothrombin time will be prolonged due to a depletion of vitamin K, a fat-soluble vitamin dependent on bile flow for absorption. CA19-9 is a mucin-associated carbohydrate antigen that can be detected in the serum of patients with pancreatic cancer. Serum levels are elevated in about 75% of patients with pancreatic cancer. However, CA19-9 is also elevated in about 10% of patients with benign diseases of the pancreas, liver, and bile ducts.[299] CA19-9 is thus neither sufficiently sensitive nor specific to allow an early diagnosis of pancreatic cancer. Despite the fact that many tumor markers such as CA19-9 have been studied, there are still no effective screening tests for pancreatic cancer. Research taking advantage of recent advances in genomics, gene expression analysis, and proteomics has demonstrated thousands of genes and corresponding proteins that are differentially expressed in pancreatic tumors that have potential for early detection of pancreatic cancer.[300] Some of these proteins would be expected to be expressed at the cell surface or in pancreatic juice and may become useful as biomarkers for pancreatic cancer in the future.

In patients presenting with jaundice, a reasonable first diagnostic imaging study is abdominal ultrasound. If bile duct dilation is not seen, hepatocellular disease is likely. Demonstration of cholelithiasis and bile duct dilation suggests a diagnosis of choledocholithiasis, and the next logical step would be ERCP to clear the bile duct. In the absence of gallstones, malignant obstruction of the bile duct is likely, and a CT scan rather than ERCP would be the next logical step. For patients suspected of having pancreatic cancer who present without jaundice, a CT scan should be the first test.

The current diagnostic and staging test of choice for pancreatic cancer is a multidetector, dynamic, contrast-enhanced CT scan, and the techniques for obtaining high-quality images are constantly improving (Fig. 33-66). The accuracy of CT scanning for predicting unresectable disease is about 90% to 95%.[301] In contrast, CT scanning is less accurate in predicting resectable disease. CT scanning will miss small liver metastases, and predicting arterial involvement is sometimes difficult. CT findings that indicate a tumor is unresectable include involvement of ≥ 180 degrees of the celiac axis, hepatic or superior mesenteric artery, enlarged lymph nodes outside the boundaries of resection,

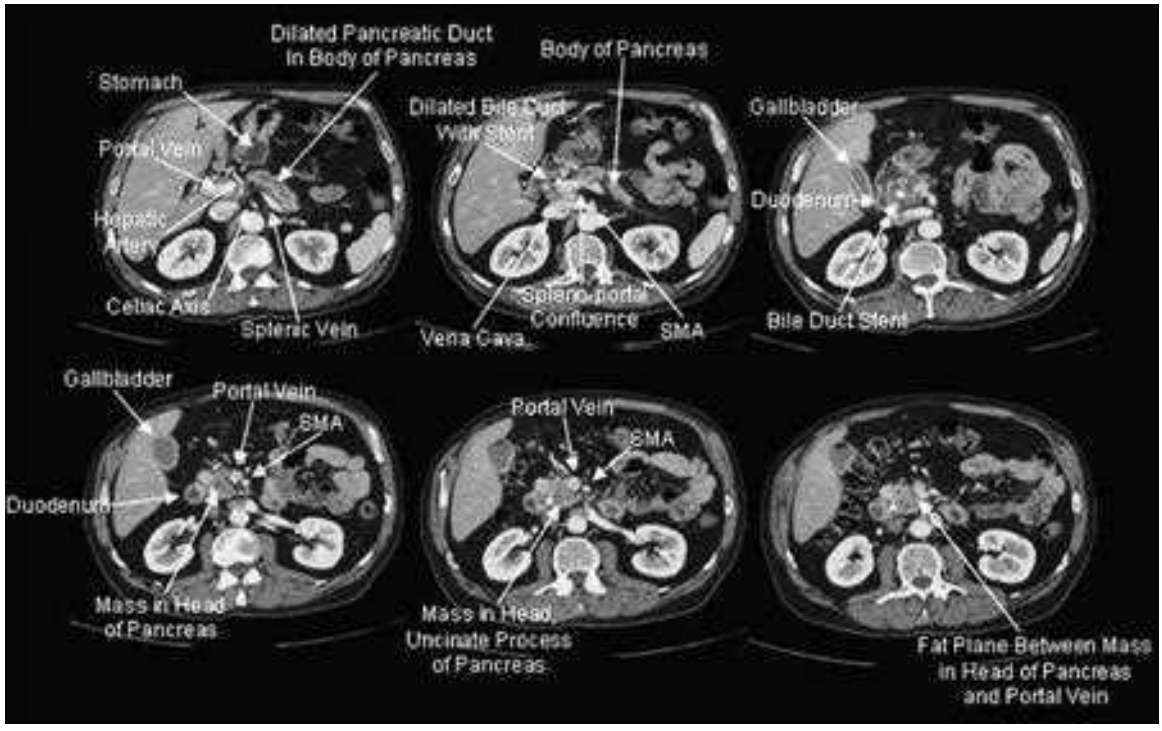

Figure 33-66. Computed tomography scan demonstrating resectable pancreatic cancer. SMA = superior mesenteric artery.

ascites, and distant metastases (e.g., liver). Invasion of the superior mesenteric vein or portal vein is not in itself a contraindication to resection as long as the veins are patent. Tumors are considered "borderline resectable" if there is abutment of ≤ 180 degrees of the circumference of the SMA, celiac axis, or hepatic artery or if there is a short segment of vein occlusion. Also, patients with CT findings suspicious for metastatic disease, like 1 mm liver lesions too small to characterize or biopsy, are considered "borderline resectable" as are patients with multiple comorbidities or marginal performance status. There is growing consensus that neoadjuvant treatment should be considered in all patients with any radiographic evidence of extension to adjacent vascular structures.

Currently, CT is probably the single most versatile and cost-effective tool for the diagnosis and staging of pancreatic cancer. Abdominal MRI is rapidly evolving but currently provides essentially the same information as CT scanning. Positron emission tomography scanning is becoming more widely available and may help distinguish chronic pancreatitis from pancreatic cancer. EUS can be used to detect small pancreatic masses that could be missed by CT scanning and is commonly used when there is a high suspicion for pancreatic cancer but no mass is identified by the CT scan. EUS has the added advantage of providing the opportunity for transluminal biopsy of pancreatic masses, although a tissue diagnosis before pancreaticoduodenectomy is not required. However, in specific patients a histologic diagnosis may be necessary such as for those in a neoadjuvant clinical trial or before chemotherapy in advanced tumors. EUS is a sensitive test for portal/superior mesenteric vein invasion, although it is somewhat less effective at detecting superior mesenteric artery invasion. When all of the current staging modalities are used, their accuracy in predicting resectability is reported to be about 80%, meaning that one in five patients brought to the operating room with the intent of a curative resection will be found at the time of surgery to have unresectable disease.[302]

In an attempt to avoid such futile laparotomies, preliminary laparoscopy has been advocated for patients with disease felt to be resectable by CT imaging (Fig. 33-67). Diagnostic laparoscopy with the use of US is reported to improve the accuracy of predicting resectability to about 98%.[302] The technique involves more than simple visualization with the scope and requires the placement of multiple ports and manipulation of the tissues. A general exploration of the peritoneal surfaces is carried out. The ligament of Treitz and the base of the transverse mesocolon are examined for tumor. The gastrocolic ligament is incised, and the lesser sac is examined. The US probe is used to examine the liver, porta hepatis, and the portal vein and superior mesenteric artery.

The percentage of patients in whom a positive laparoscopy helps avoid a nontherapeutic laparotomy varies from 10% to 30% in carcinoma of the head of the pancreas but may be as high as 50% in patients with tumors in the body and tail of the gland. As the quality of CT scanning has improved, the value

Figure 33-67. Liver metastases identified at diagnostic laparoscopy.

of routine diagnostic laparoscopy has decreased. However, the morbidity of diagnostic laparoscopy is less than that of laparotomy, and the procedure can be performed on an outpatient basis. Patients who are found to have unresectable disease recover more rapidly from a laparoscopy than a laparotomy and can receive palliative chemotherapy and radiation sooner. The potential immunosuppressive effects of a major surgical procedure also are avoided, as well as the negative psychologic impact of a major painful operation with little benefit.

Biliary obstruction can be relieved with an endoscopic approach in almost all cases. When large (10F) plastic stents are used, most patients do not require replacement for about 3 months. Metallic wall stents last about 5 months on average and usually fail only with tumor ingrowth.[303] Keeping in mind that patients with unresectable pancreatic cancer usually live <1 year, the requirement for numerous stent changes is unlikely.

Diagnostic laparoscopy is possibly best applied to patients with pancreatic cancer on a selective basis. Diagnostic laparoscopy will have a higher yield in patients with large tumors (>4 cm), tumors located in the body or tail, patients with equivocal findings of metastasis or ascites on CT scan, and patients with other indications of advanced disease such as marked weight loss or markedly elevated CA19-9 (>1000 U/mL). An algorithm for the diagnosis, staging, and treatment of pancreatic cancer is shown in Fig. 33-68.

Palliative Surgery and Endoscopy. For the 85% to 90% of patients with pancreatic cancer who have disease that precludes surgical resection, appropriate and effective palliative treatment is critical to the quality of their remaining life. Because of the poor prognosis of the disease, it is not appropriate to use invasive and toxic regimens in patients with extremely advanced disease and poor performance status. When patients do desire antineoplastic therapy, it is important to encourage them to enroll in clinical trials so that therapeutic advances can be made. In general, there are three clinical problems in advanced pancreatic cancer that require palliation: pain, jaundice, and duodenal obstruction. The mainstay of pain control is oral narcotics. Sustained-release preparations of morphine sulfate are frequently used. Invasion of retroperitoneal nerve trunks accounts for the severe pain experienced by patients with advanced pancreatic cancer. A celiac plexus nerve block can control pain effectively for a period of months, although the procedure sometimes needs to be repeated.[304]

Jaundice is present in the majority of patients with pancreatic cancer, and the most troublesome aspect for the patient is the accompanying pruritus. Biliary obstruction may also lead to cholangitis, coagulopathy, digestive symptoms, and hepatocellular failure. In the past, surgeons traditionally performed a biliary bypass when unresectable disease was found at laparotomy. As many patients today already have a bile duct stent in place by the time of operation, it is not clear that operative biliary bypass is required. If an operative bypass is performed, choledochojejunostomy is the preferred approach. Although an easy procedure to perform, choledochoduodenostomy is felt to be unwise because of the proximity of the duodenum to tumor. Some have discouraged the use of the gallbladder for biliary bypass[305]; however, it is suitable as long as the cystic duct clearly enters the common duct well above the tumor.

Duodenal obstruction is usually a late event in pancreatic cancer and occurs in only about 20% of patients.[305] Therefore, in the absence of signs or symptoms of obstruction, such as a tumor that is already encroaching on the duodenum at the time of surgery, the routine use of prophylactic gastrojejunostomy when exploration reveals unresectable tumor is controversial. Although anastomotic leaks are uncommon, gastrojejunostomy is sometimes associated with delayed gastric emptying, the very symptom the procedure is designed to treat.

Whether performing both a biliary and enteric bypass or just a biliary bypass, the jejunum is brought anterior to

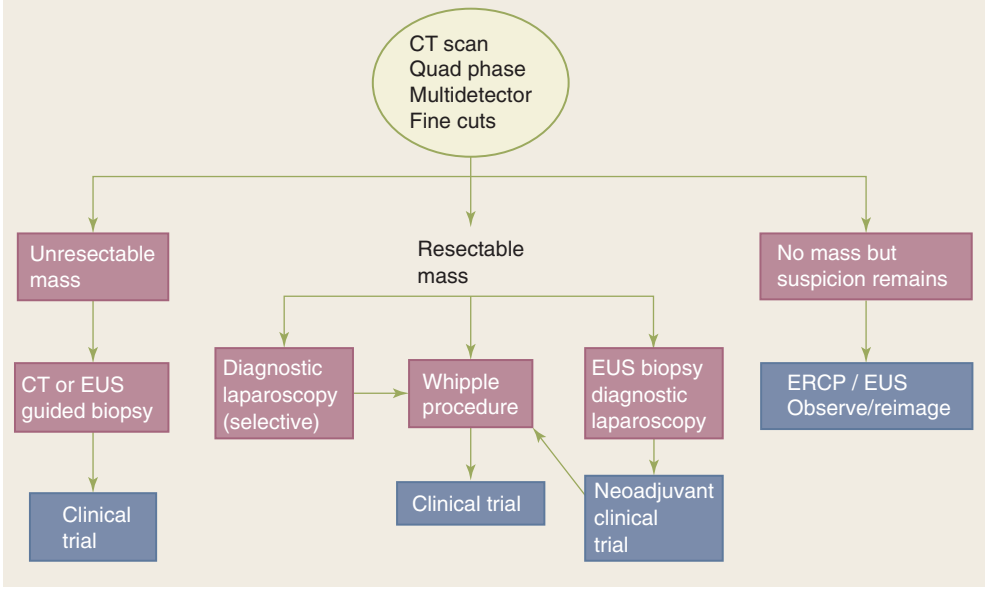

Figure 33-68. Diagnostic and treatment algorithm for pancreatic cancer. If computed tomography (CT) scan demonstrates a potentially resectable tumor, patients are offered participation in a clinical trial after histologic confirmation by CT or endoscopic ultrasound (EUS)-guided biopsy. If CT scan demonstrates resectable disease, diagnostic laparoscopy is used selectively in patients with tumors in the body/tail, equivocal findings of metastasis or CT scan, ascites, high CA19-9, or marked weight loss. Patients also have diagnostic laparoscopy if they elect to participate in a neoadjuvant clinical trial. In cases where no mass is demonstrated on CT scan, but suspicion of cancer remains, EUS or endoscopic retrograde cholangiopancreatography (ERCP) with brushings are performed, and the CT may be repeated after an interval of observation.

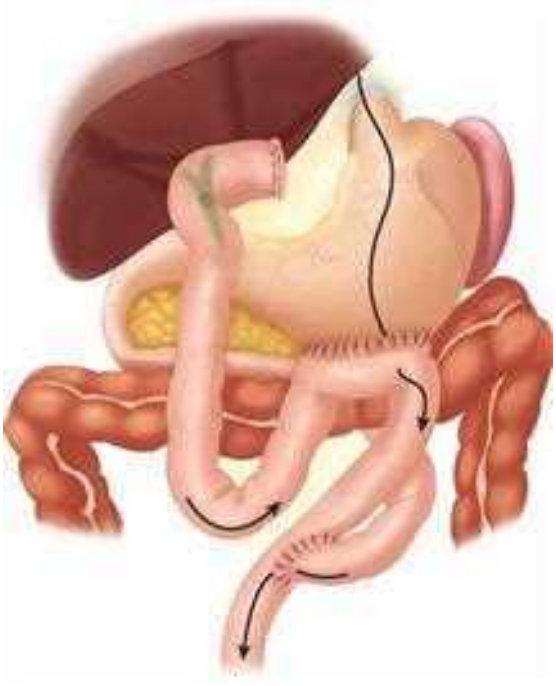

Figure 33-69. Biliary-enteric bypass to palliate unresectable pancreatic cancer. (*Reproduced with permission from Bell RH Jr: Atlas of pancreatic surgery, in Bell RH Jr, Rikkers LF, Mulholland MW (eds): Digestive Tract Surgery: A Text and Atlas. Philadelphia: Lippincott-Raven, 1996, p 1074.*)

the colon, if possible, rather than retrocolic, where the tumor potentially would invade the bowel sooner. Some surgeons use a loop of jejunum with a jejunojejunostomy to divert the enteric stream away from the biliary-enteric anastomosis. Others use a Roux-en-Y limb with the gastrojejunostomy located 50 cm downstream from the hepaticojejunostomy (Fig. 33-69). Potential advantages of the defunctionalized Roux-en-Y limb include the ease with which it will reach up to the hepatic hilum, probable decreased risk of cholangitis, and easier management of biliary anastomotic leaks. If a gastrojejunostomy is performed, it should be placed dependently and posterior along the greater curvature to improve gastric emptying, and a vagotomy should not be performed. If patients are explored laparoscopically and found to have unresectable disease, palliation of jaundice can be achieved in a minimally invasive fashion with ERCP and placement of a coated, expandable metallic endoscopic biliary stent (Fig. 33-70). Endoscopic stents are definitely not as durable as a surgical bypass. Recurrent obstruction and cholangitis is more common with stents and results in inferior palliation. However, this minimally invasive approach is associated with considerably less initial morbidity and mortality than surgical bypass. Newer, expandable metallic wall stents demonstrate improved patency and provide better palliation than plastic stents.

If an initial diagnostic laparoscopy reveals a contraindication to the Whipple procedure, such as liver metastases, it is not appropriate to perform a laparotomy simply to create a biliary bypass. In such a patient, it is better to place an endoscopic stent. In contrast, if a laparotomy has already been performed as part of the assessment of resectability and the Whipple procedure is not possible, a surgical bypass is usually performed. However, if the patient has a functioning endoscopic stent already in place, it may be reasonable to forego surgical bypass.

Palliative Chemotherapy and Radiation. For patients with locally advanced unresectable disease are treated with chemothearpy and possibly radiation and patients with Stage IV metastatic disease are treated with systemic chemotherapy. Gemcitabine (Gemzar®) was approved by the U.S. Food and Drug Administration (FDA) for use in pancreatic cancer in 1996. In patients with unresectable pancreatic cancer, gemcitabine results in symptomatic improvement, improved pain control and performance status, and weight gain.[306] However, survival is improved by only 1 to 2 months. Erlotinib (Tarceva®) was approved in 2005 based on very minimal improvement in overall survival in combination with gemcitabine. Frequently 5-fluorouracil (5-FU) and capecitabine (Xeloda®) are used as a radiosensitizer in patients receiving radiation therapy. FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan, and oxaliplatin) is an aggressive chemotherapy regimen that was recently shown to improve objective response rate from 9% to 32% and median overall survival of patients with metastatic pancreatic cancer from 7 to 11 months but the improvement is associated with increased toxicity so patient selection is important.[307]Although these results may warrant treatment in patients who understand the benefits and risks, the lack of significant survival advantage should encourage physicians to refer motivated patients for experimental protocols, because it is only through continued clinical research that more meaningful treatments for pancreatic cancer will be developed.

Ablation for Locally Advanced Unresectable Disease. Persistent arterial vascular encasement after neoadjuvant therapy contraindicates resection. Irreversible electroporation using

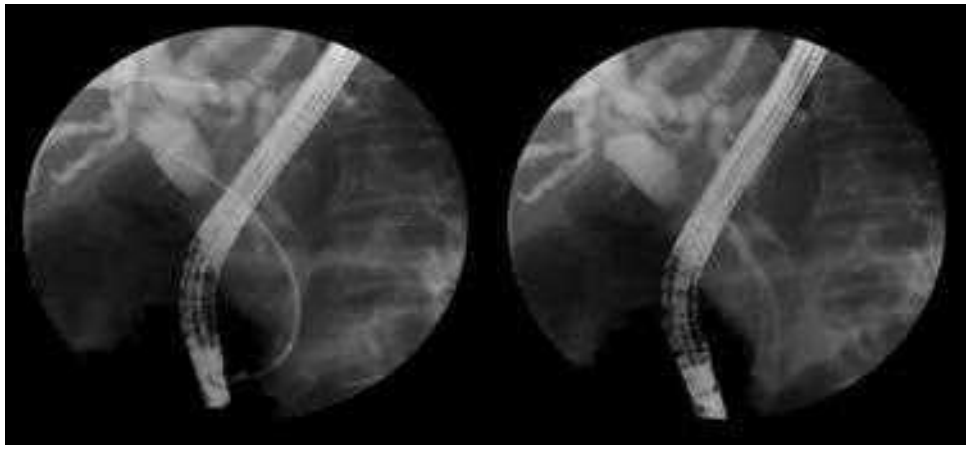

Figure 33-70. Expandable metallic biliary stent. After ERCP cannulation of the distal bile duct (*left*) the stent is advanced over the cannula and placed across the obstruction in the distal bile duct (*right*).

the Nanoknife® is reported to enable treatment of pancreatic tumors abutting vascular structures without compromise of the vessels or concern for the heat sink effect of nearby blood flow.[308] This modality is new but early reports with limited numbers of patients indicate it may be safe in combination with chemotherapy. Randomized prospective trials are needed. However, these early results are of particular interest because of the potential to down stage and offer surgery to patients initially diagnosed with locally advanced unresectable disease.

Surgical Resection: Pancreaticoduodenectomy. In a patient with appropriate clinical and/or imaging indications of pancreatic cancer, a tissue diagnosis before performing a pancreaticoduodenectomy is not essential. Although percutaneous CT-guided biopsy is usually safe, complications such as hemorrhage, pancreatitis, fistula, abscess, and even death can occur. Tumor seeding along the subcutaneous tract of the needle is uncommon. Likewise, FNA under EUS guidance is safe and well tolerated. The problem with preoperative or even intraoperative biopsy is that many pancreatic cancers are not very cellular and contain a significant amount of fibrous tissue, so a biopsy may be misinterpreted as showing chronic pancreatitis if it does not contain malignant glandular cells. In the face of clinical and radiologic preoperative indications of pancreatic cancer, a negative biopsy should not preclude resection. In patients who are not candidates for resection because of metastatic disease, biopsy for a tissue diagnosis becomes important because these patients may be candidates for palliative chemotherapy trials. It is especially important to make an aggressive attempt at tissue diagnosis before surgery in patients whose clinical presentation and imaging studies are more suggestive of alternative diagnoses such as pancreatic lymphoma or pancreatic islet cell tumors. These patients might avoid surgery altogether in the case of lymphoma or warrant an aggressive approach in the case of islet cell carcinoma.

Pancreaticoduodenectomy can be performed through a midline incision from xiphoid to umbilicus or through a bilateral subcostal incision. The initial portion of the procedure is an assessment of resectability. The liver and visceral and parietal peritoneal surfaces are thoroughly assessed. The gastrohepatic omentum is opened, and the celiac axis area is examined for enlarged lymph nodes. The base of the transverse mesocolon to the right of the middle colic vessels is examined for tumor involvement.

The ascending and hepatic flexure of the colon are mobilized off the duodenum and head of the pancreas and reflected medially. A Kocher maneuver is performed by dissecting behind the head of the pancreas. The superior mesenteric vein is identified early in the case and dissected up toward the inferior border of the neck of the pancreas. The gastroepiploic vein and artery are ligated to prevent any traction injury. The relation of the tumor to the superior mesenteric vein and artery cannot be accurately assessed by palpation at this point and is not completely determined until later in the operation when the neck of the pancreas is divided and the surgeon is committed to resection. Mesenteric vascular involvement is best determined by a high quality preoperative CT scan.

It is important to assess for an aberrant right hepatic artery, which is present in 20% of patients. The aberrant artery arises from the superior mesenteric artery posterior to the pancreas and ascends parallel and adjacent to the superior mesenteric and portal veins. The presence of an aberrant right hepatic artery should be apparent on the preoperative CT scan and can be identified intraoperatively by palpation on the back side of the hepatoduodenal ligament, where a prominent pulse will be felt posterior and to the right of the portal vein.

Table 33-22

Findings at exploration

Findings contraindicating resection
Liver metastases (any size)
Celiac lymph node involvement
Peritoneal implants
Hepatic hilar lymph node involvement
Findings not contraindicating resection
Invasion at duodenum or distal stomach
Involved peripancreatic lymph nodes
Involved lymph nodes along the porta hepatis that can be swept down with the specimen

The porta hepatis is examined. Enlarged or firm lymph nodes that can be swept down toward the head of the pancreas with the specimen do not preclude resection. If the assessment phase reveals no contraindications to the Whipple procedure (Table 33-22), the resection phase commences.

If the pylorus is to be preserved, the stomach and proximal duodenum are mobilized off the pancreas, preserving the gastroepiploic vessels down to the pylorus. The proximal hepatic artery is identified usually by removing a lymph node that commonly lies just anterior to the artery. The hepatic artery is dissected and traced toward the porta hepatis. Small vessels in this area can be ligated with 3-0 or 4-0 silk ligatures to prevent bothersome hemorrhage later in the case that makes subsequent dissection more tedious. The gastroduodenal branch of the hepatic artery is identified. A test clamping is performed to ensure that a strong pulse remains in the proper hepatic artery before division of the gastroduodenal artery. Once the gastroduodenal artery is divided, the hepatic artery is retracted medially and the common bile duct is retracted laterally to reveal the anterior surface of the portal vein behind them. Dissection is performed only on the anterior surface of the vein. If there is no tumor involvement, the neck of the pancreas will separate from the vein easily. A large, blunt-tipped clamp is a safe instrument to use for this dissection. The tunnel under the neck of the pancreas can then be completed mostly under direct vision from inferior and superior.

The gallbladder is then mobilized from the liver, the cystic duct and artery are ligated, and the gallbladder is removed. The common hepatic duct is circumferentially dissected. Either the duodenum is divided 2 cm distal to the pylorus (which defines the procedure as a pylorus-preserving pancreaticoduodenectomy, or PPPD) or the antrum is divided, as classically described by Whipple. The jejunum is divided beyond the ligament of Treitz, and the mesentery is ligated until the jejunum can be delivered posterior to the superior mesenteric vessels from left to right.

The common hepatic duct is then divided just above the entrance of the cystic duct, and the duct is dissected down to the superior margin of the duodenum. Inferior traction on the distal bile duct opens the plane to make visible the anterior portion of the portal vein. The pancreatic neck is divided anterior to the portal vein (Fig. 33-71). The pancreatic head and uncinate process then are dissected off of the right lateral aspect of the superior mesenteric vein, ligating the fragile branches draining the head and uncinate process into the portal vein (Fig. 33-72).

Figure 33-71. Division of the pancreatic neck. The pancreatic neck is separated from the anterior surface of the portal vein and then divided. If there is no tumor involvement, the neck of the pancreas will separate from the vein easily. A large, blunt-tipped clamp is a safe instrument to use for this dissection. (*Reproduced with permission from Bell RH Jr: Atlas of pancreatic surgery, in Bell RH Jr, Rikkers LF, Mulholland MW (eds): Digestive Tract Surgery: A Text and Atlas. Philadelphia: Lippincott-Raven, 1996, p 1054.*)

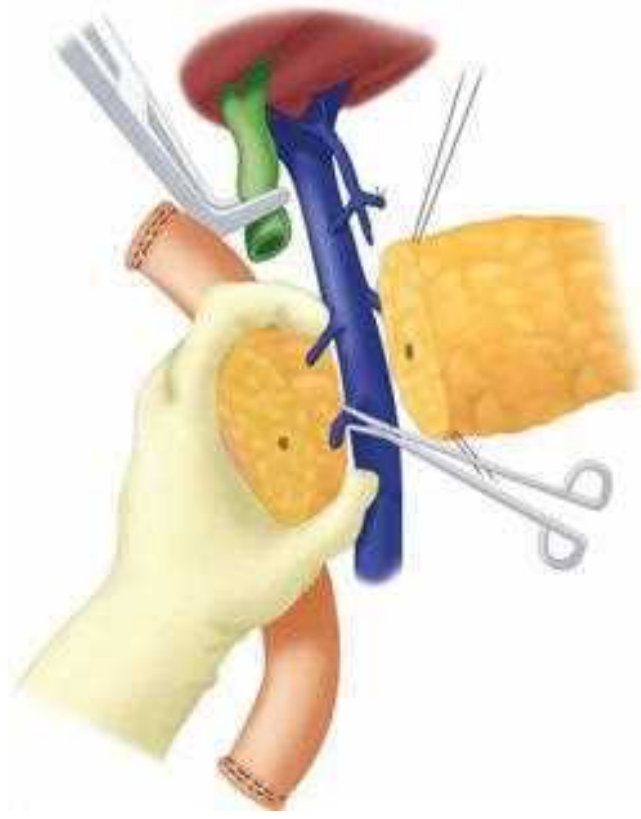

Figure 33-72. Dissection of the pancreatic head and uncinate process. The pancreatic head and uncinate process are dissected off of the right lateral aspect of the superior mesenteric vein and portal vein by ligating the fragile venous branches. (*Reproduced with permission from Bell RH Jr: Atlas of pancreatic surgery, in Bell RH Jr, Rikkers LF, Mulholland MW (eds): Digestive Tract Surgery: A Text and Atlas. Philadelphia: Lippincott-Raven, 1996, p 1056.*)

The uncinate process is then dissected off of the posterior and lateral aspect of the superior mesenteric artery. This can be the most tedious portion of the operation, but thoroughly clearing all tissue from the mesenteric vessels helps avoid incomplete resection. The wound is irrigated and meticulous hemostasis is assured at this point because the view of the portal vein area and retroperitoneum is more difficult after the reconstruction phase is completed.

The reconstruction involves anastomoses of the pancreas first, then the bile duct, and, finally, the duodenum or stomach. There are various techniques for the pancreatic anastomoses, and all have equivalent outcomes. After the pancreatic anastomosis is completed, the choledochojejunostomy is performed about 10 cm down the jejunal limb from the pancreatic anastomosis. This is usually performed in an end-to-side fashion with one layer of interrupted sutures. The duodenojejunostomy or gastrojejunostomy is performed another 10 to 15 cm downstream from the biliary anastomosis, using a two-layer technique.

Pancreaticoduodenectomy with Vascular Resection. Accurate staging of pancreatic cancer with a high-quality preoperative CT scan is extremely important. Involvement of the superior mesenteric artery, the celiac axis, or hepatic artery indicate a T4/Stage 3 tumor that is locally advanced and unresectable. However, involvement of the portal vein or superior mesenteric vein does not necessarily preclude resection as long as there is a patent superior mesenteric vein-portal vein confluence. Reconstruction can often be accomplished with a primary anastomosis of the vein. When resection of more than 2 cm of vein is required, an interposition graft such as the internal jugular vein, can be used for a tension-free reconstruction. During the last decade, studies have been published evaluating mortality rates and long-term survival after partial and segmental portal/mesenteric vein resection with mortality rates below 5%, similar to those of standard pancreaticoduodenectomy. When performed in expert centers, the surgical and oncologic outcome of pancreaticoduodenectomy without and with venous resection appear to be similar.[309,310]

Minimally Invasive Pancreatectomy. Laparoscopic distal pancreatectomy has been proven to be safe and is appropriate for essentially all indications for pancreatectomy. This approach is associated with decreased blood loss and quicker recovery. Centrally located lesions near the splenoportal confluence must be approached laparoscopically with caution. Robotic technology such as the da Vinci® Surgical System may make dissection and control of major vessels in this area easier and perhaps more safe. Interest in laparoscopic pancreaticoduodenectomy is increasing throughout the United States with some early adopters reporting excellent outcomes comparable to the open procedure in single-institution series.[311] Early results indicate this technique is feasible but considerable expertise is required in both open pancreatic resection as well as advanced laparoscopic techniques to achieve these outcomes. Whether the advantages seen in other areas of minimally invasive surgery apply to the Whipple procedure is an area of current investigation.

Variations and Controversies. The preservation of the pylorus has several theoretical advantages, including prevention of reflux of pancreaticobiliary secretions into the stomach, decreased incidence of marginal ulceration, normal gastric acid secretion and hormone release, and improved gastric function. Patients with pylorus-preserving resections have appeared to regain weight better than historic controls in some studies. Return of gastric emptying in the immediate postoperative period may take longer after the pylorus-preserving operation, and it is controversial whether there is any significant improvement in long-term quality of life with pyloric preservation.[312,313]

Techniques for the pancreaticojejunostomy include end-to-side or end-to-end and duct-to-mucosa sutures or invagination (Fig. 33-73). Pancreaticogastrostomy has also been investigated.

Some surgeons use stents, glue to seal the anastomosis, or octreotide to decrease pancreatic secretions. No matter what combination of these techniques is used, the pancreatic leakage rate is always about 10%. Therefore, the choice of techniques depends more on the surgeon's personal experience.

Traditionally, most surgeons place drains around the pancreatic and biliary anastomoses because disruption of

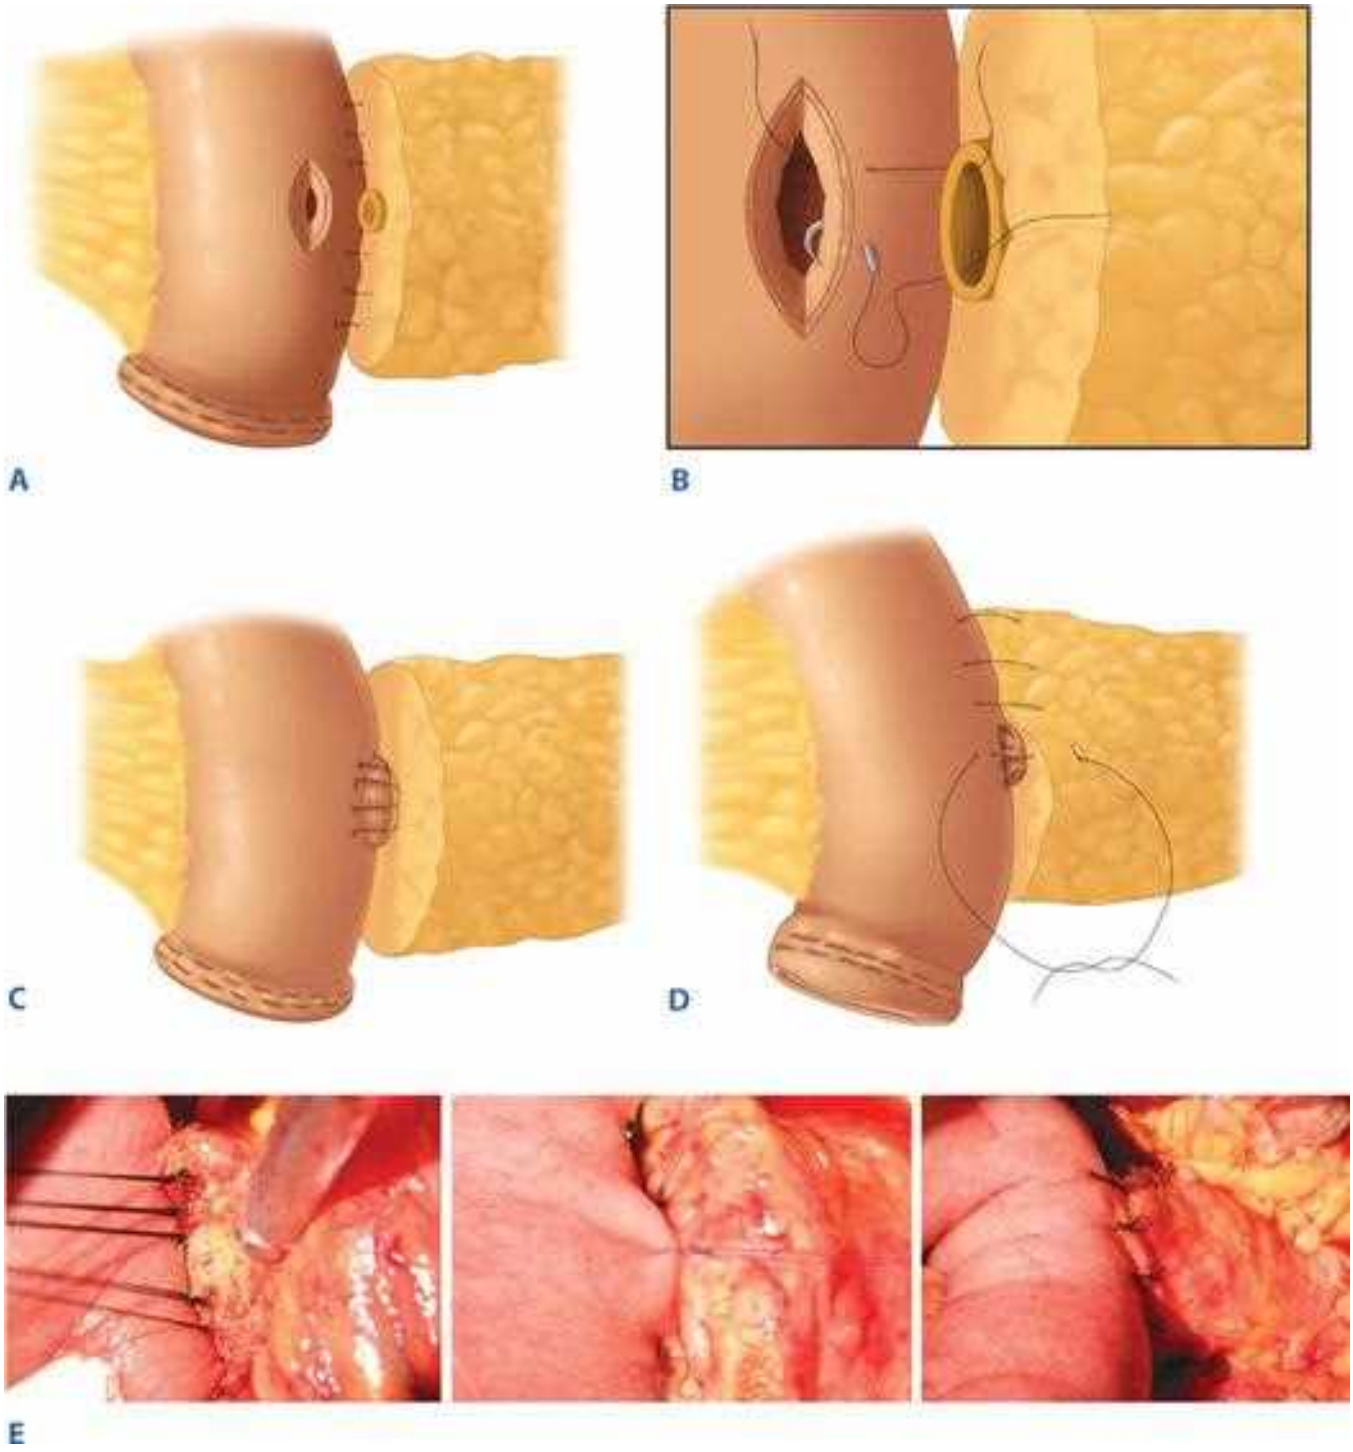

Figure 33-73. Techniques for pancreaticojejunostomy. **A** to **D.** Duct-to-mucosa, end-to-side **E.** Intraoperative photographs of end-to-side pancreaticojejunostomy. **F** to **J.** End-to-end invagination. **K** to **O.** End-to-side invagination.

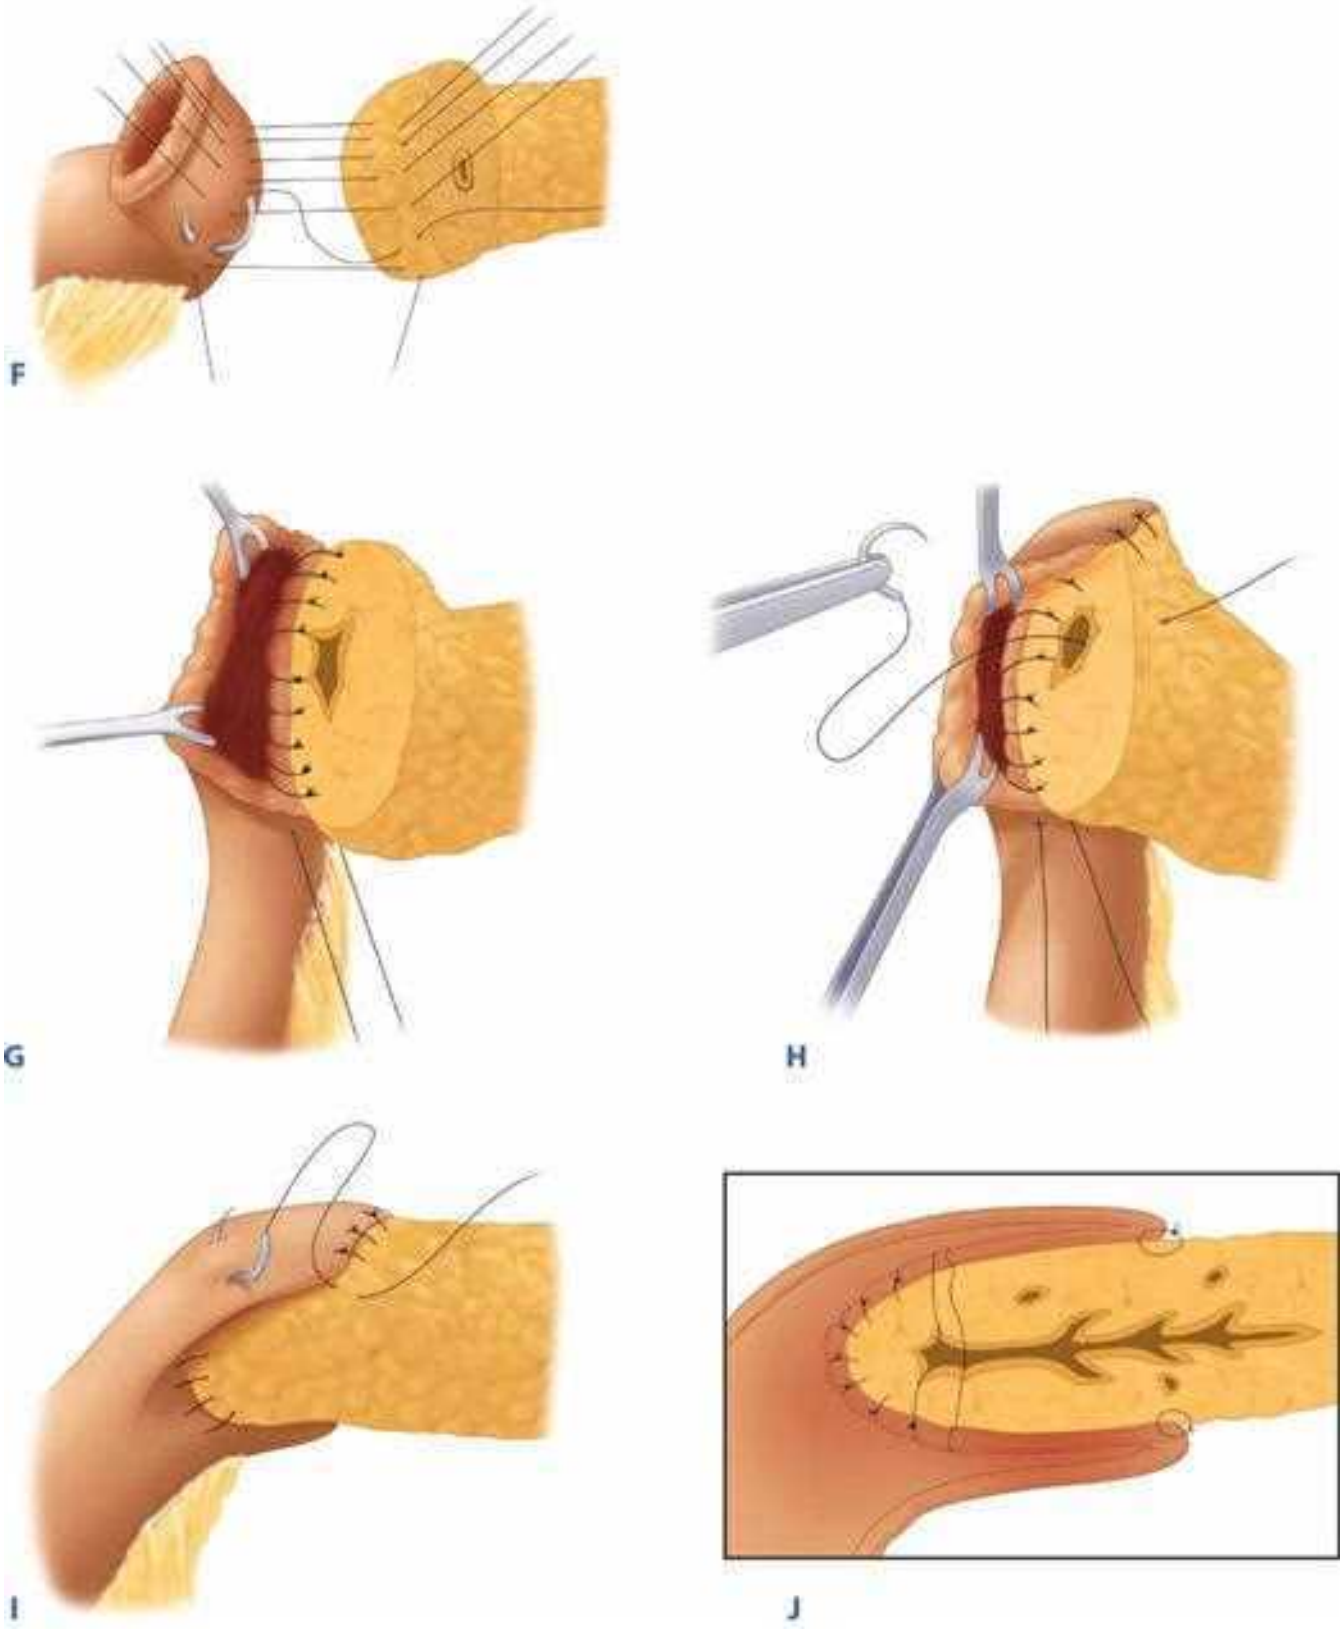

Figure 33-73. (*Continued*)

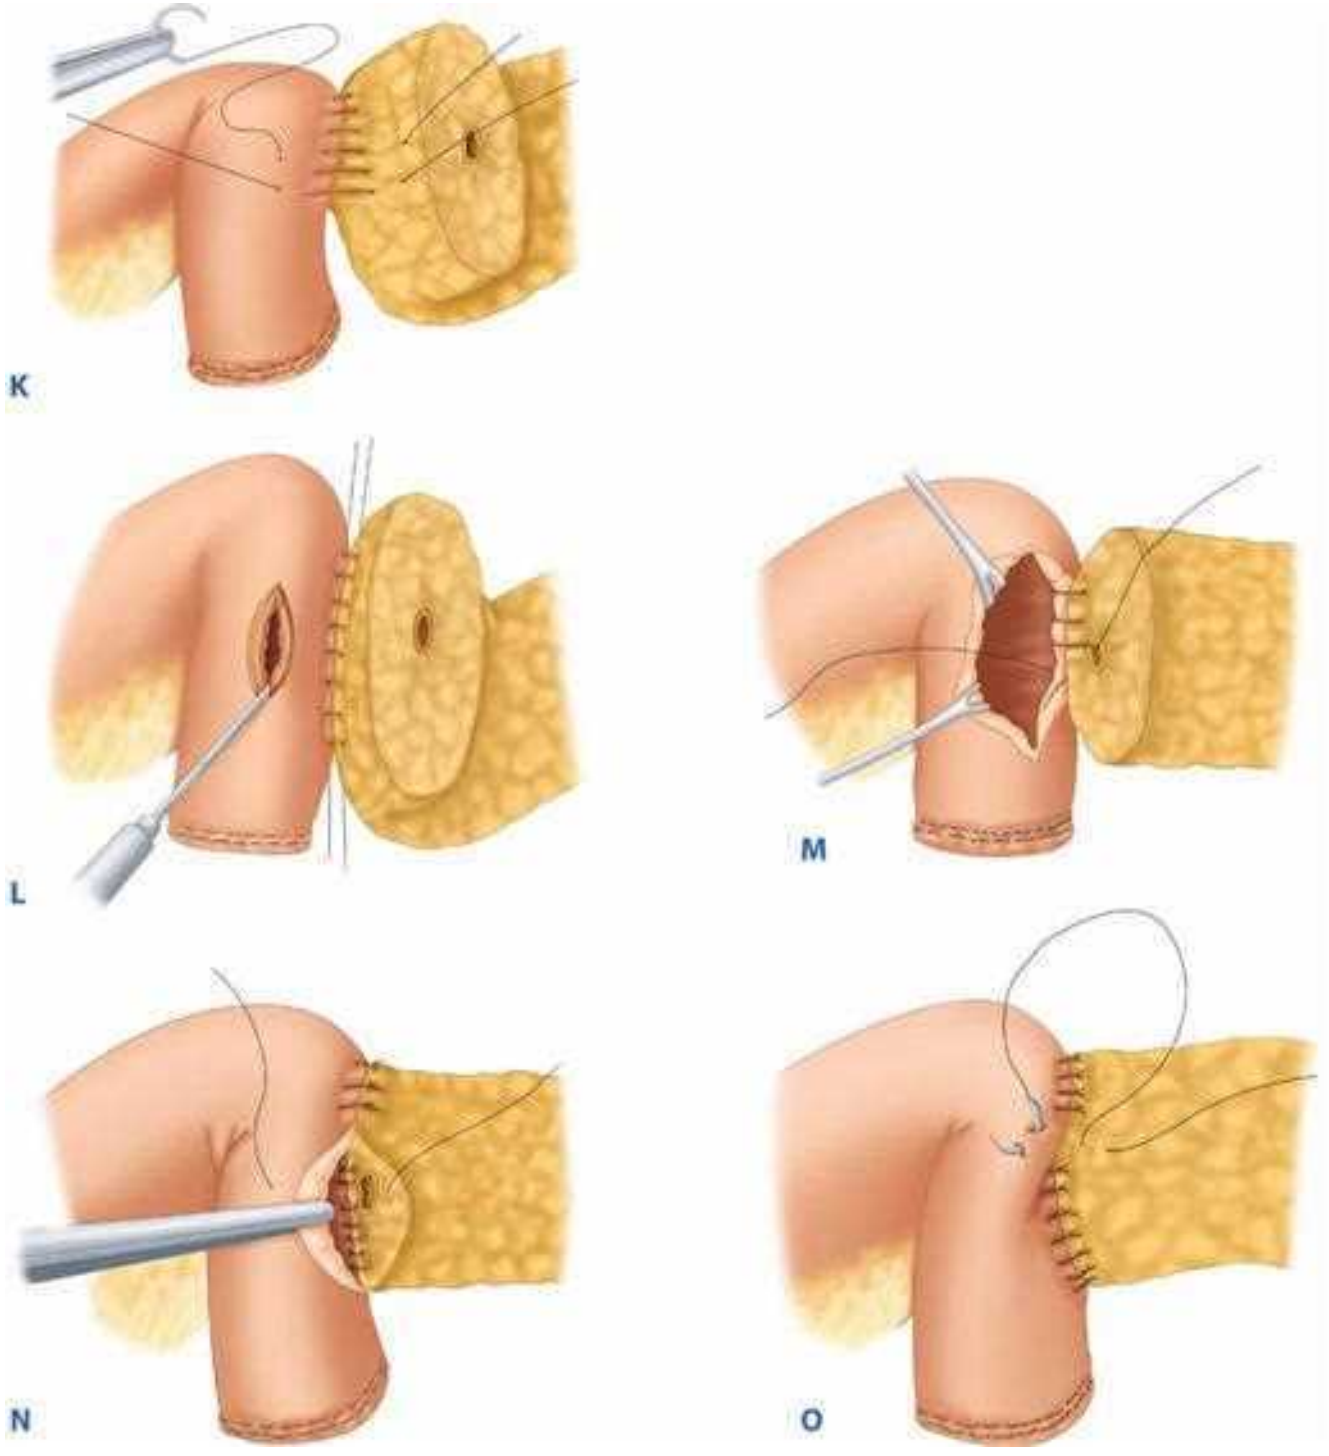

Figure 33-73. (*Continued*)

the pancreaticojejunostomy cannot be avoided in one out of 10 patients. This complication can lead to the development of an upper abdominal abscess or can present as an external pancreatic fistula. Usually, a pure pancreatic leak is controlled by the drains and will eventually seal spontaneously. Combined pancreatic and biliary leaks are cause for concern because bile will activate the pancreatic enzymes. In its most virulent form, disruption leads to necrotizing retroperitoneal infection, which can erode major arteries and veins of the upper abdomen, including the exposed portal vein and its branches or the stump of the gastroduodenal artery. Impending catastrophe is often preceded by a small herald bleed from the drain site. Depending on the clinical situation, such an event is an indication to perform an angiogram or return the patient to the operating room to widely drain the pancreaticojejunostomy and to repair the involved blood vessel. Open packing may be necessary to control diffuse necrosis and infection. Some studies have questioned the practice of routine drain placement after pancreaticoduodenectomy. These studies indicated that most pancreatic leaks can be managed with percutaneous drainage.[314] The practice of routine drainage after pancreatic resection is currently being investigated in a randomized multicenter clinical trial. Many patients with

pancreatic cancer are malnourished preoperatively and suffer from gastroparesis in the immediate postoperative period. Routine placement of a feeding jejunostomy tube and gastrostomy tube has become less common, and most surgeons use these tubes selectively. Gastrostomy tubes may decrease the length of stay in patients who might be predicted to have severe gastroparesis. Jejunostomy tubes are certainly not benign and can result in leaks and intestinal obstruction. However, parenteral nutrition is also associated with serious complications such as line sepsis, loss of gut mucosal integrity, and hepatic dysfunction.

Because of the high incidence of direct retroperitoneal invasion and regional lymph node metastasis at the time of surgery, it has been argued that the scope of resection for pancreatic cancer should be enlarged to include a radical regional lymphadenectomy and resection of areas of potential retroperitoneal invasion. The "radical pancreaticoduodenectomy" includes extension of the pancreatic resection to the middle body of the pancreas, segmental resection of the portal vein, if necessary, resection of retroperitoneal tissue along the right perinephric area, and lymphadenectomy to the region of the celiac plexus. In the hands of experienced surgeons, these techniques are associated with greater blood loss but no increase in mortality; however, improved survival has not been demonstrated. Total pancreatectomy has also been considered in the past. Although pancreatic leaks are eliminated, major morbidity from brittle diabetes and exocrine insufficiency outweigh any theoretical benefit.

Pancreatic cancer can recur locally after pancreaticoduodenectomy. Intraoperative radiotherapy (IORT) delivers a full therapeutic dose of radiation to the operative bed at the time of resection. Radiation to surrounding normal areas is minimized, but the radiation is delivered all in one setting, usually about 15 minutes, rather than in fractionated doses over time. IORT is best performed in a shielded, dedicated, operating room suite rather than by transporting the patient in the middle of an already long and complicated operation. IORT may improve local control and palliate symptoms after pancreaticoduodenectomy. However, IORT has not been shown to be superior to standard external beam radiation therapy, and further randomized trials are needed to determine how this modality should be utilized.[315]

Complications of Pancreaticoduodenectomy. The operative mortality rate for pancreaticoduodenectomy has decreased to <5% in "high volume" centers (where individual surgeons perform more than fifteen cases per year), suggesting that patients in rural areas would benefit from referral to large urban centers.[316,317] The most common causes of death are sepsis, hemorrhage, and cardiovascular events. Postoperative complications are unfortunately still very common, and include delayed gastric emptying, pancreatic fistula, and hemorrhage.

Delayed gastric emptying is common after pancreaticoduodenectomy and is treated conservatively as long as complete gastric outlet obstruction is ruled out by a contrast study. In the acute phase, IV erythromycin may help but the problem usually improves with time.

Considerable attention has been focused on the prevention of pancreatic leak after pancreas resection. Modifications of the anastomotic technique (end-to-side or end-to-end, duct-to-mucosa, or invaginated), the use of jejunum or the stomach for drainage, the use of pancreatic duct stents, the use of octreotide, and various sealants have all been evaluated. Octreotide, a synthetic analogue of somatostatin with a longer half-life, has been evaluated as a pharmacologic therapy to reduce pancreatic secretion and the rate of pancreatic fistula after pancreatic resection. European studies advocate the routine use of octreotide while North American trials conclude that octreotide is useless. European studies have demonstrated a significant reduction in the rate of postoperative pancreatic fistula with prophylactic preoperative octreotide injection.[318–320] However, randomized prospective studies in the United States showed that octreotide did not prevent postoperative pancreatic fistula when used following pancreatic resection.[321–325] However, a subgroup analysis done by Suc and colleagues[326] suggested that there may be a benefit to using octreotide in a high-risk group of patients undergoing pancreaticoduodenectomy who have a pancreatic duct measuring <3 mm. Some studies suggest a higher rate of complications[321,323] in patients who receive octreotide even though the difference was not statistically significant, while others report a significantly lower rate of complications with the use of octreotide.[319,320] Finally, the optimal dose, route (IV drip vs. subcutaneous injection), and timing (preoperative, intraoperative, or postoperative) of octreotide use is unclear.

Many technical modifications to the classic pancreaticoduodenectomy have been described. However, >70 technical variations to the pancreaticoenteric anastomosis have not clearly demonstrated an objective method to consistently decrease the rate of fistula, which varies from 0% to 40% depending on the definition of fistula.[321,322,327–335] Yeo compared the incidence of pancreatic fistula in patients who had a pancreaticoduodenectomy with reconstruction via a pancreaticogastrostomy or pancreaticojejunostomy.[335] There was no significant difference between the two techniques in the incidence of pancreatic fistula. A recent meta-analysis summarized the results of 16 trials comparing pancreaticogastrostomy to pancreaticojejunostomy. All of the observational clinical studies reported superiority of pancreaticogastrostomy over pancreaticojejunostomy, most likely influenced by publication bias. In contrast, all randomized prospective trials failed to show advantage of a particular technique, suggesting both techniques provide equally good results.[336]

Other options to consider when performing the pancreatic anastomosis are the duct-to-mucosa vs. the invagination techniques. Many surgeons choose the technique at the time of operation, depending on the size of the pancreatic duct and the texture of pancreas.[337] The duct-to-mucosa anastomosis results in a low pancreatic fistula rate[338] in patients with a large pancreatic duct and a fibrotic pancreas. However, the end-to-end invagination technique may be more secure in patients with a small duct and soft pancreas.

Even though there has been little convincing evidence for the use of a pancreatic duct stent, proponents suggest that a stent may discourage a pancreatic leak and aid in technical precision.[339,340] Both internal stenting as well as external stenting have been shown to reduce the incidence of pancreatic fistula in some clinical studies.[338]

Some studies[333,341] suggest that an isolated Roux-en-Y pancreaticoenteric anastomosis may be associated with a lower rate of postoperative pancreatic leak. The logic behind this technical modification is that the use of separate Roux-en-Y limbs for biliary and pancreatic secretions may protect the pancreatic anastomosis from activated pancreatic enzymes.

Avoiding the pancreatic anastomosis altogether by ductal ligation or occlusion has also been evaluated as a potential technique to reduce the rate of postoperative pancreatic fistula.[342] Ductal occlusion with neoprene or prolamine, which are nonresorbable glues, has been abandoned due to pancreatic atrophy

and loss of exocrine function.[343] Tran and associates examined duct occlusion in pancreaticojejunostomy and showed that duct occlusion significantly increases the risk of endocrine insufficiency without a decrease in the postoperative complication rate.[344] To avoid long-term loss of function, absorbable glues, such as fibrin glue, have been evaluated to limit the action of pancreatic enzymes until the anastomosis is healed. Fibrin glue has been used for both duct occlusion and has also been applied to the surface of the pancreatic stump and anastomotic site without clear improvement in pancreatic fistula rate. The effect of BioGlue® applied to the anastomotic surface after the Whipple procedure and pancreatic stump after distal pancreatectomy was recently evaluated in a retrospective cohort study. There were no statistically significant differences in the incidence or severity grades of postoperative pancreatic fistulas.[345]

If not combined with a biliary leak, pancreatic fistula, although serious, can usually be managed conservatively. In about 95% of cases, reoperation is not indicated and prolonged drainage, using drains placed in the original operation or percutaneously after resection, results in spontaneous closure of the fistula.[346]

Hemorrhage can occur either intraoperatively or postoperatively. Intraoperative hemorrhage typically occurs during the dissection of the portal vein. A major laceration of the portal vein can occur at a point in the operation at which the portal vein is not yet exposed. Temporary control of hemorrhage is generally possible in this situation by compressing the portal vein and superior mesenteric vein against the tumor with the surgeon's left hand behind the head of the pancreas. An experienced assistant is needed to divide the neck of the pancreas to the left of the portal vein and achieve proximal and distal control. Sometimes, the vein can be sutured closed with minimal narrowing. Other times, a segmental resection and interposition graft (internal jugular vein) may be needed.

Postoperative hemorrhage can occur from inadequate ligature of any one of numerous blood vessels during the procedure. Hemorrhage can also occur due to digestion of retroperitoneal blood vessels due to a combined biliary-pancreatic leak. Uncommonly, a stress ulcer, or later, a marginal ulcer, can result in GI hemorrhage. Typically, a vagotomy is not performed when pancreaticoduodenectomy is performed for pancreatic cancer, but patients are placed on proton pump inhibitors.

Outcome and Value of Pancreaticoduodenectomy for Cancer. Survival figures indicate that perhaps few patients are cured indefinitely of pancreatic cancer with pancreaticoduodenectomy. Survival rates vary according to the stage of disease at diagnosis, and most patients have evidence of locally advanced disease at the time of surgery. The tumor tends to recur locally with retroperitoneal and regional lymphatic disease. In addition, most patients also develop hematogenous metastases, usually in the liver. Malignant ascites, peritoneal implants, and malignant pleural effusions are all common. Median survival after pancreaticoduodenectomy is about 22 months. Even long-term (5-year) survivors often eventually die due to pancreatic cancer as late recurrence is common. Although pancreaticoduodenectomy may be performed with the hope of the rare cure in mind, the operation more importantly provides better palliation than any other treatment, and is the only modality that offers any meaningful improvement in survival. If the procedure is performed without major complications, many months of palliation are usually achieved. It is the surgeon's duty to make sure patients and their families have a realistic understanding of the true goals of pancreaticoduodenectomy in the setting of pancreatic cancer.

Adjuvant Chemotherapy and Radiation. Small studies in the 1980s suggested that adjuvant chemotherapy with 5-FU combined with radiation improves survival by about 9 months after pancreatic resection for pancreatic adenocarcinoma.[347] Subsequent, noncontrolled studies have reinforced that concept; however, the data have been criticized due to the low number of patients and low dose of radiation therapy that was given. In addition, gemcitabine has replaced 5-FU as standard therapy in pancreatic cancer but is thought to be too toxic when given with radiotherapy at current doses. However, a recent large European multicenter trial concluded that there was no value to chemoradiotherapy, although the study suggested the possibility that chemotherapy alone might have survival benefit.[348] In contrast to that study, remarkable results in adjuvant therapy have been reported by the Virginia Mason Clinic with combination 5-FU, cisplatinum, interferon-α, and external beam radiation. Although the toxicity is high (42% hospitalized for GI toxicity), the promising results prompted larger confirmatory studies. Unfortunately, one such study was stopped due to toxicity and this protocol has not been widely adopted. Results with FOLFIRINOX in the setting of metastatic disease have encouraged some oncologists, despite a lack of data, to offer this aggressive treatment in the adjuvant or neoadjuvant setting. Nevertheless, pending further study, it is typical in the United States for patients with acceptable functional status to receive some form of adjuvant chemotherapy and radiotherapy after surgery.

Neoadjuvant Treatment. There are several potential advantages to the use of chemoradiation before an attempt at surgical resection. For example, it avoids the risk that adjuvant treatment is delayed by complications of surgery. Neoadjuvant treatment also may decrease the tumor burden at operation, increasing the rate of resectability and killing some tumor cells before they can be spread intraoperatively. Another potential advantage is that it allows patients with occult metastatic disease to avoid the morbidity of pancreatic resection. As many as 20% of patients treated with neoadjuvant chemoradiation develop metastatic disease detected by restaging CT and do not go on to surgery. This approach may separate patients into a subset likely to benefit from resection and a subset in whom surgery would be unlikely to provide clinical benefit. Preoperative chemoradiation has been shown not to increase the perioperative morbidity or mortality of pancreaticoduodenectomy. It may even decrease the incidence of pancreatic fistula. Prospective randomized trials investigating this concept are ongoing but are difficult to complete due to the high number of patients who fail to complete or receive a full course of either therapy. Recent studies have shown that neoadjuvant therapy is associated with a lower rate of lymph node positivity and improved overall survival and should be considered an acceptable alternative to surgery followed by adjuvant therapy for resectable pancreatic cancer. Patients should be encouraged to consider available clinical trials of neoadjuvant therapy for resectable pancreatic cancer. [349]

Postoperative Surveillance. Recurrence after successful resection usually manifests as hepatic metastases. After adjuvant chemoradiation with 5-FU and external beam radiation, gemcitabine is usually administered on a weekly basis for 6

months. During this time period, patients are monitored with frequent physical examinations and laboratory tests, including CA19-9. CT scans are typically ordered every 3 months in the first two years after resection or when a rising CA19-9 or new symptoms suggest recurrence. Surgical therapy for recurrent disease is usually reserved for patients who remain reasonable operative candidates who develop symptomatic gastric outlet or bowel obstruction.

Future Therapy. The most needed advance in pancreatic cancer therapy is the ability to diagnose the disease at earlier stages. Recent developments in genomics and proteomics using high-throughput sequencing techniques and global expression methodologies may make this possible. Gene therapy is also under investigation using different strategies, including immunotherapeutic gene therapy, replacement of tumor suppressor gene function, inactivation of oncogenes, and suicide gene therapy.[350] With immunotherapeutic gene therapy, the goal is to assist the immune system in recognizing the cancer cells. Cancer cells have been forced to express tumor-specific antigens and cytokines that activate the immune system and that may have antitumor effects. Because pancreatic cancer is a disease with multiple genetic aberrations, inactivated tumor suppressor genes have been replaced, and mutated oncogenes have been inactivated with gene therapy. In suicide gene therapy, a transgene is introduced that converts an inactive nontoxic drug into an active cytotoxic agent. The herpes simplex virus-thymidine kinase system has been the most extensively studied.[350] Various delivery systems, including viral vectors, liposomes, and protein-conjugated DNA, exist. With each of these strategies and delivery systems, tumor cell–specific delivery would be extremely desirable but awaits the discovery of effective tumor-specific promoters. Cancer vaccines and immunotherapy are intriguing because immunotherapy has the potential to specifically target tumor cells and limit toxicities compared to chemotherapy. With recent sequencing of the pancreatic cancer genome, more candidate immune targets will be identified to serve as immunogens and insights into overcoming the immunosuppressive tumor microenvironment could possibly follow. Clinical trials for pancreatic cancer are ongoing and offer hope for more meaningful treatment.

Ampullary and Periampullary Cancer. Ampullary cancers need to be distinguished from periampullary cancers. The ampulla is the junction of the biliary and pancreatic ducts within the duodenum. Periampullary cancer includes tumors arising from the distal bile duct, duodenal mucosa, or pancreas just adjacent to the ampulla, and the ampulla can be overgrown by cancers that arise from these adjacent areas, making it impossible to determine the true site of origin. Clinically, the term *periampullary cancer* is, therefore, a nonspecific term used to refer to a variety of tumors arising at the intersection of these four sites. The term *ampullary cancer* is more specific and is reserved for tumors that arise at the ampulla. Based on their location, ampullary cancers are usually detected relatively early due to the appearance of jaundice and have a more favorable prognosis. The ampulla of Vater is lined by an epithelial layer that transitions from pancreatic and biliary ductal epithelium to duodenal mucosal epithelium. Ampullary adenocarcinomas can therefore have an intestinal and/or pancreaticobiliary histologic morphology, with the former having a better prognosis. Patients with ampullary cancer have a 10-year survival of about 35%, which is a much better prognosis than patients with pancreatic adenocarcinoma. The difference in survival is not entirely explained by an earlier presentation and lower incidence of lymph node metastases. There are probably biologic, particularly molecular, differences between ampullary and pancreatic adenocarcinoma of the pancreas. Intestinal type ampullary cancers have a lower incidence of EGFr and mutant p53 overexpression, and fewer activating K-*ras* mutations. These tumors are more likely to have genetic changes similar to colon cancer such as microsatellite instability and adenomatous polyposis coli mutations.

Management of Periampullary Adenomas. Benign tumors such as ampullary adenomas can also originate at the ampulla. The accuracy of endoscopic biopsy in distinguishing ampullary cancer from benign adenoma is poor with false-negative rates from 25% to 56% even if sphincterotomy precedes the biopsy. However, benign villous adenomas of the ampullary region can be excised locally. This technique is applicable only for small tumors (approximately 2 cm or less) with no evidence of malignancy upon biopsy. EUS may help to accurately determine if there is invasion into the duodenal wall. In the absence of invasion, adenomas may be amenable to an endoscopic or transduodenal excision. A longitudinal duodenotomy is made and the tumor is excised with a 2- to 3-mm margin of normal duodenal mucosa. In some centers, small periampullary adenomas can also be removed endoscopically. A preoperative diagnosis of cancer is a contraindication to transduodenal excision, and pancreaticoduodenectomy should be performed. Likewise, if final pathologic examination of a locally excised tumor reveals invasive cancer, the patient should be returned to the operating room for a pancreaticoduodenectomy. An important subset of patients are those with FAP, who develop periampullary or duodenal adenomas. These lesions have a high incidence of harboring carcinoma, and frequently recur unless the mucosa at risk is resected. A standard (not pylorus-sparing) Whipple is the procedure of choice in FAP patients with periampullary lesions.

Cystic Neoplasms of the Pancreas. A cystic neoplasm needs to be considered when a patient presents with a fluid-containing pancreatic lesion (Fig. 33-74). Cystic neoplasms of the pancreas may be more frequent than previously recognized and are being identified with increasing frequency as the use of abdominal

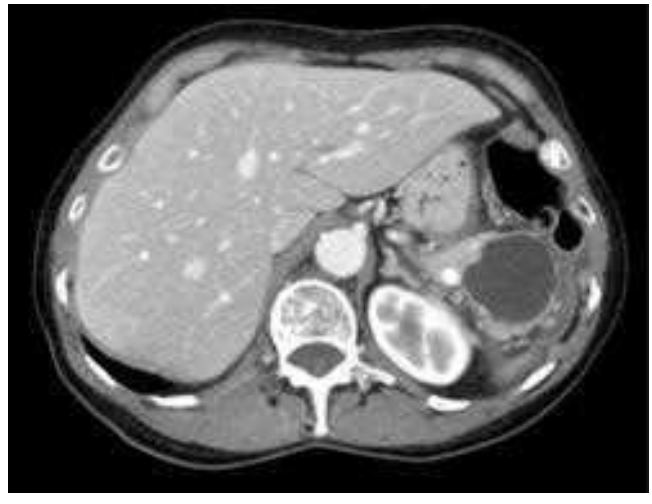

Figure 33-74. Mucinous cystic neoplasm in tail of pancreas.

CT scanning has increased. Most of these lesions are benign or slow growing, and the prognosis is significantly better than with pancreatic adenocarcinoma. However, some of these neoplasms slowly undergo malignant transformation and thus represent an opportunity for surgical cure, which is exceedingly uncommon in the setting of pancreatic adenocarcinoma. The dilemma for the surgeon is an accurate assessment of the risk-benefit ratio of resection vs. observation of these lesions in individual patients. Radiologic features including the size of the lesion and its growth rate, the density of the lesion, characteristics of the wall such as nodules, septations, or calcifications, and the relationship between the lesion and the pancreatic duct can help categorize these lesions. Although a thorough history and radiographic findings often suggest a particular diagnosis, EUS-guided FNA and analysis of cyst fluid or ERCP provide useful additional information to guide clinical decision making. Cysts that contain thick fluid with mucin, elevated carcinoembryonic antigen (CEA), or atypical cells must be treated as potentially malignant[351] (Fig. 33-75).

Pseudocysts. The most common cystic lesion of the pancreas is the pseudocyst, which, of course, has no epithelial lining and is a nonneoplastic complication of pancreatitis or pancreatic duct injury. As discussed in "Complications of Chronic Pancreatitis," the diagnosis is usually straightforward from the clinical history. Although not usually necessary, analysis of pseudocyst fluid would reveal a high amylase content. The danger comes in mistaking a cystic pancreatic neoplasm for a pseudocyst and incorrectly draining a cystic neoplasm into the GI tract rather than resecting the neoplasm. For this reason, biopsy of the pseudocyst wall is a common step in the management of pancreatic pseudocysts.

Cystadenoma. Serous cystadenomas are essentially considered benign tumors without malignant potential. Serous cystadenocarcinoma has been reported very rarely (<1%). Therefore, malignant potential should not be used as an argument for surgical resection, and the majority of these lesions can be safely observed in the absence of symptoms due to mass effect or rapid growth. The average rate of growth is about 0.45 cm/year. About 50% of cystadenomas are asymptomatic and detected as an incidental finding. Most symptomatic patients have mild upper abdominal pain, epigastric fullness, or

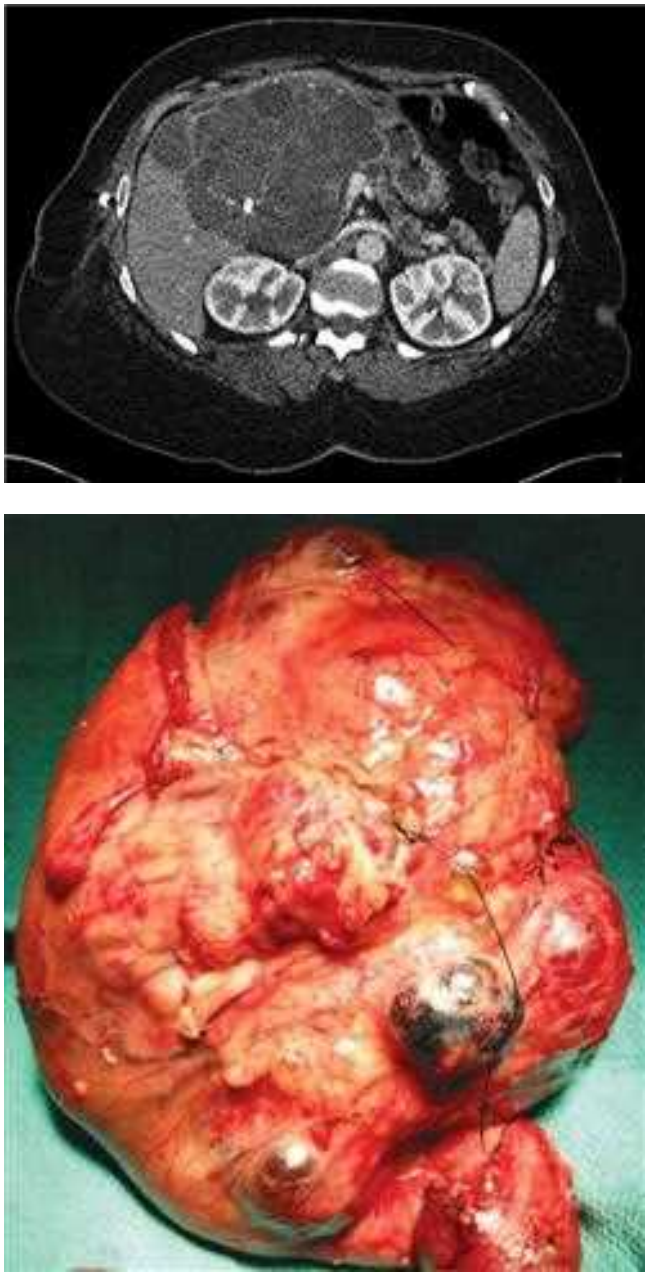

Figure 33-76. Computed tomography appearance of massive multiseptated serous cystadenoma in head of pancreas with central stellate scar (*left*) and resected specimen (*right*).

moderate weight loss. Occasionally, cystadenomas can grow to a size capable of producing jaundice or GI obstruction due to mass effect (Fig. 33-76). For symptomatic patients with serous cystadenoma, surgical resection is indicated. For lesions in the tail, splenectomy is not necessary, given the benign nature of the tumor. In appropriate candidates, a laparoscopic approach to distal pancreatectomy can be considered.[352] These cysts are frequently found in older women in which pancreatic resection for a benign neoplasm should be avoided in the absence of significant symptoms. All regions of the pancreas are affected, with half in the head/uncinate process, and half in the neck, body, or tail of the pancreas. They have a spongy appearance, and multiple small cysts (microcystic) are more common than

Table 33-23.

World Health Organization classification of primary tumors of the exocrine pancreas

A. Benign
1. Serous cystadenoma (16%)
2. Mucinous cystadenoma (45%)
3. Intraductal papillary-mucinous adenoma (32%)
4. Mature cystic teratoma
B. Borderline
1. Mucinous cystic tumor with moderate dysplasia
2. Intraductal papillary mucinous tumor with moderate dysplasia
3. Solid pseudopapillary tumor
C. Malignant
1. Ductal adenocarcinoma
2. Serous/mucinous cystadenocarcinoma (29%)
3. Intraductal mucinous papillary tumor

larger cysts (macrocystic or oligocystic). These lesions contain thin serous fluid that does not stain positive for mucin and is low in CEA (<200 ng/mL). Typical imaging characteristics include a well-circumscribed cystic mass, small septations, fluid close to water density, and sometimes, a central scar with calcification. If a conservative management is adopted, it is important to be sure of the diagnosis. EUS-FNA should yield nonviscous fluid with low CEA and amylase levels, and if cells are obtained, which is rare, they are cuboidal and have a clear cytoplasm.

Mucinous Cystadenoma and Cystadenocarcinoma. Mucinous cystic neoplasms (MCNs) encompass a spectrum ranging from benign but potentially malignant to carcinoma with a very aggressive behavior (Table 33-23). There is often heterogeneity within the lesions with benign and malignant-appearing regions, making it impossible to exclude malignancy with biopsy. MCNs are commonly seen in perimenopausal women, and about two-thirds are located in the body or tail of the pancreas. Like cystadenomas, most MCNs are now incidental findings identified during imaging performed for other reasons. When symptoms are present, they are usually nonspecific and include upper abdominal discomfort or pain, early satiety, and weight loss. On imaging studies, the cysts have thick walls and do not communicate with the main pancreatic duct (see Fig. 33-74). There may be nodules or calcifications within the wall of the cyst. The cysts are lined by tall columnar epithelium that fills the cyst with viscous mucin. The submucosal layer consists of a highly cellular stroma of spindle cells with elongated nuclei similar to the "ovarian stroma," which is a key pathologic feature distinguishing these lesions. Elevated CEA levels in the fluid (>200 ng/mL) may suggest malignant transformation. Solid areas may contain atypical cells or invasive cancer, and extensive sampling of the specimen is necessary to accurately predict prognosis. Resection is the treatment of choice for most mucin-producing cystic tumors. Malignancy cannot be ruled out without removal and extensive sampling of the tumor. Malignancy has been reported in 6% to 36% of MCNs. Current thinking is that all of these tumors will eventually evolve into cancer if left untreated. Malignant transformation is more common with larger tumors, and older

patients, and there appears to be a stepwise accumulation of mutations (K-*ras*, p53). Because most MCNs are located in the body and tail of the pancreas, distal pancreatectomy is the most common treatment. For small lesions, it may be appropriate to preserve the spleen but splenectomy ensures removal of the lymph node basin that can potentially be involved. It is very important not to rupture the cyst during resection and the tumor should be removed intact, not morselized. Therefore, a laparoscopic approach may not be appropriate for larger lesions. Completely resected MCNs without atypia are usually cured especially if small (<3 cm). Even patients with moderate dysplasia or carcinoma in situ are usually cured by complete resection. In the presence of invasive carcinoma, mucinous cystadenocarcinoma, the prognosis is dismal, similar to typical ductal adenocarcinoma of the pancreas.

Intraductal Papillary Mucinous Neoplasm. Intraductal papillary mucinous neoplasms (IPMNs) usually occur within the head of the pancreas and arise within the pancreatic ducts. The ductal epithelium forms a papillary projection into the duct, and mucin production causes intraluminal cystic dilation of the pancreatic ducts. (Fig. 33-77). Imaging studies demonstrate diffuse dilation of the pancreatic duct, and the pancreatic parenchyma is often atrophic due to chronic duct obstruction. However, classic features of chronic pancreatitis, such as calcification and a beaded appearance of the duct, are not present. At ERCP, mucin can be seen extruding from the ampulla of Vater, a so-called *fish-eye lesion* that is virtually diagnostic of IPMN (Fig. 33-78). Initial reports suggested a male predominance, but more recent series indicate an equal distribution. Patients are usually in their seventh to eighth decade of life and present with abdominal pain or recurrent pancreatitis, thought to be caused by obstruction of the pancreatic duct by thick mucin. Some patients (5%–10%) have steatorrhea, diabetes, and weight loss secondary to pancreatic insufficiency. Some IPMNs primarily involve the main pancreatic duct, while others involve the branch ducts (Fig. 33-79). Malignant transformation is found in main duct IPMNs in 57% to 92% of cases and all main duct IPMNs should be resected in fit surgical candidates. Branch-duct type IPMNs are often found in the uncinate process, are sometimes asymptomatic, and are less frequently associated with malignant transformation (6%–46%). Asymptomatic branch-duct IPMNs less than 1 cm can be observed with annual imaging.[353] Lesions 1 to 2 cm should be evaluated with EUS-FNA to rule out high-risk features such as mural nodules, a dilated main duct, positive cytology or cyst fluid CEA >200. In the absence of these features, continued observation with serial imaging (1–2 cm; every 6–12 months/2-3 cm; every 3–6 months) is appropriate. Branch-duct IPMNs >3cm should be resected[353].

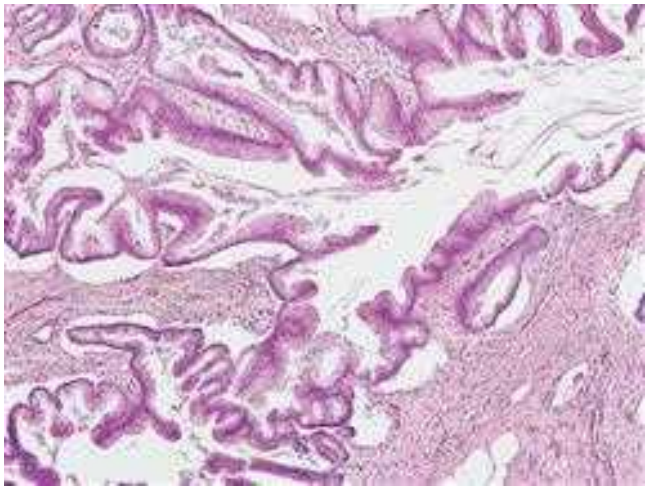

Figure 33-77. Intraductal papillary mucinous neoplasm histology. Papillary projections of ductal epithelium resemble villous morphology and contain mucin-filled vesicles. (*From Asiyanbola B, Andersen DK: IPMN. Editorial Update. Access Surgery, McGraw-Hill, 2008, with permission. Copyright © The McGraw-Hill Companies, Inc.*)

The surgical management of IPMNs is complicated by the fact that the lesion itself is small and preoperative imaging studies show a dilated pancreatic duct but not necessarily the mass. Mucus can dilate the duct proximal and distal to the lesion. Furthermore, these lesions can spread microscopically along the duct, and there can be skip areas of normal duct between the diseased portions. Therefore, thorough preoperative imaging including EUS, MRCP, or ERCP, and sometimes pancreatic ductoscopy, which can also be repeated intraoperatively, is useful (see Fig. 33-78). The surgeon needs to be prepared to extend the resection, if necessary, based on intraoperative findings and frozen section of the margin. Extending the resection to the point of total pancreatectomy is controversial due to the morbidity of this operation. Like MCNs, the IPMNs require careful histologic examination of the entire specimen for an invasive cancer, which if carefully sought, is found in 35% to 40% of cases.

Survival of patients with IPMN, even when malignant and invasive, can be quite good. As with MCN, patients with borderline tumors or carcinoma in situ are usually cured. In IPMN associated with invasive carcinoma, the 5- and 10-year survival is 60% and 50%, which is much better than typical pancreatic adenocarcinoma.[356]

For this reason, if recurrence occurs in the remaining pancreas, further resection is warranted because several series have shown that some of these cases are salvageable. Patients with IPMN are also at risk for other malignancies and should undergo colonoscopy and close surveillance.

Solid-Pseudopapillary Tumor. Solid-pseudopapillary tumors are rare and typically occur in young women. Previous names for this entity include, *solid and cystic, solid and papillary, cystic and papillary,* and *papillary-cystic tumor.* They are typically well circumscribed on CT (Fig. 33-80). The cysts are not true epithelial-lined cysts but rather represent a necrotic/degenerative process. Histology may be similar to neuroendocrine tumors, but they do not stain positive for neuroendocrine markers such as chromogranin. Most are cured by resection but liver and peritoneal metastasis has been reported.

Other Cystic Neoplasms. Rarely, typical ductal adenocarcinoma of the pancreas may undergo cystic degeneration due to central necrosis. Occasionally, this will create difficulty in the proper preoperative diagnosis and should be kept in mind when deciding to conservatively follow a cystic pancreatic neoplasm. It is more common, 5% to 10%, for neuroendocrine tumors of the pancreas to contain cysts. These cysts are filled with serosanguineous fluid rather than necrotic debris. Lymphoepithelial cysts of the pancreas usually occur in men in their fifth to sixth decade. These benign lesions may be unilocular or multilocular and vary widely in size. The contents of the cyst are also variable and may be thin serous fluid or cheesy/caseous

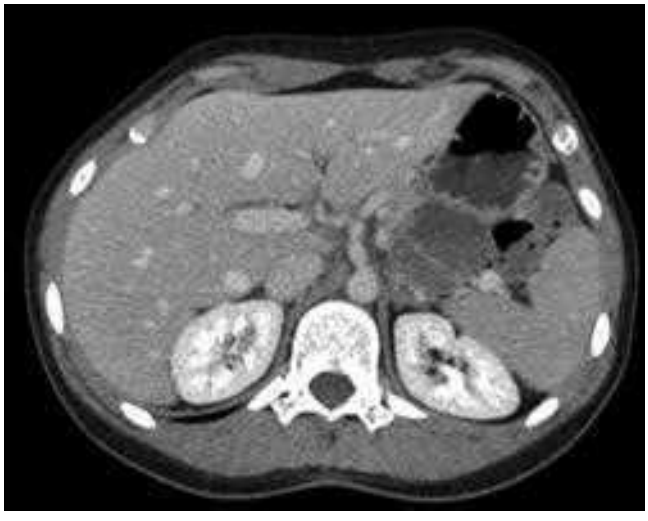
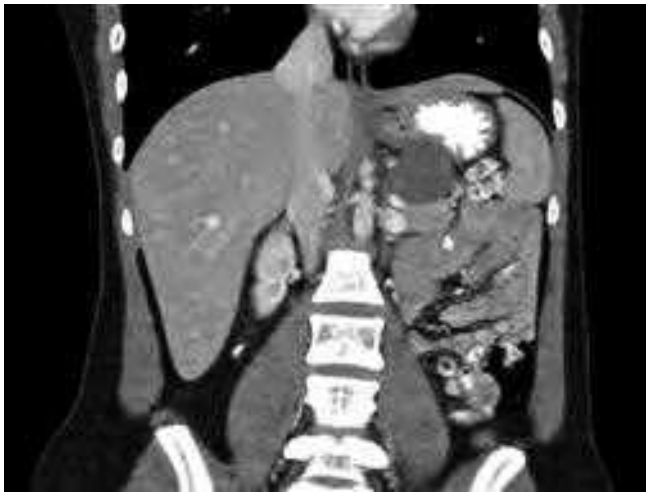
material if there is increased keratin formation. A substantial number of patients with von Hippel-Lindau syndrome develop pancreatic cysts that resemble serous cystadenomas. There may be multiple lesions scattered throughout the pancreas. Patients with polycystic kidney and hepatic disease may also develop benign pancreatic cysts (cystadenomas). With all of these rare cystic neoplasms, careful clinical history, high-quality pancreatic imaging, and sampling of the cyst fluid for analysis will guide proper treatment.

Pancreatic Lymphoma. Lymphoma can affect the pancreas. Primary involvement of the pancreas with no disease outside the pancreas also occurs. The clinical presentation often is similar to pancreatic adenocarcinoma, with vague abdominal pain and weight loss. Identification of a large mass often involving the head and body of the pancreas should raise suspicion. Percutaneous or EUS-guided biopsy will confirm the diagnosis in most cases. If the diagnosis cannot be confirmed preoperatively, laparoscopic exploration and biopsy are indicated.[354] There is no role for resection in the management of pancreatic lymphoma. Endoscopic stenting to relieve jaundice followed by chemotherapy is the standard treatment, and long-term remission is often achieved.





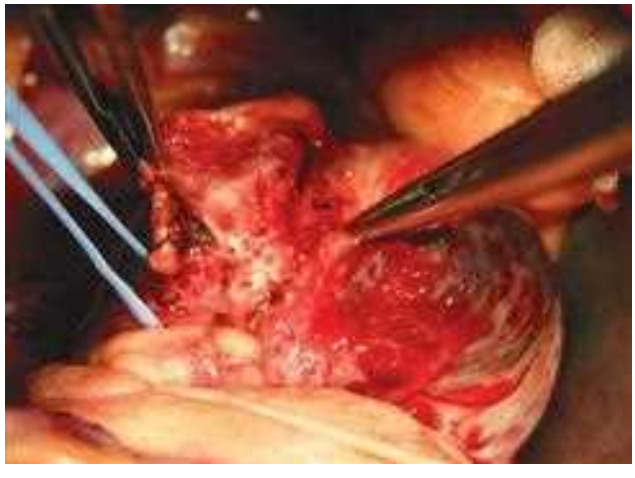


Figure 33-80. Abdominal computed tomographic scan of a 25-year-old woman demonstrating a well-circumscribed cystic lesion with septation in body/tail of pancreas. At surgery, the tumor was adherent to the splenic artery. Pathologic diagnosis was solid-pseudopapillary carcinoma.

chapter 34

Spleen

Adrian E. Park, Eduardo M. Targarona, and Igor Belyansky

HISTORICAL BACKGROUND

For more than two millennia, the spleen has perhaps been the least understood and most underappreciated major organ. The central role played by the spleen in regulating the immune system as well as influencing metabolic and endocrine functions has only become clear over the past few decades. Our previous notion of the spleen as an utterly dispensable filter of the blood has been dispelled, enlightening our surgical approach to this fascinating organ.

Many of the "founding fathers of medicine" have weighed in on the anatomy and function of the spleen over the centuries. Hippocrates[1-3] in the fourth century BC was one of the first to write on the spleen. He taught broadly on the need for balance and equilibrium between the patient and his environment. Illness arose from disharmony in nature, particularly among the patient's four humors: blood, phlegm, black bile (melancholia), and yellow bile. Hippocrates wrote of a direct connection between the brain and spleen and its particular association with the black bile. These ideas would influence thinking about the role of the spleen for more than 1000 years.[2]

Aristotle, later in the same era, famously stated that, "Nature makes nothing in vain," yet held the spleen to be an organ of minor importance whose main role was to counterbalance the liver.[4] He also described how the "hot character" of the spleen aided in digestion.

Galen, in the second century AD, engaged in more serious anatomic investigation espousing the early belief that function followed structure. His investigations, though pioneering, lacked sufficient rigor, evidenced by his contention that black bile or melancholia flowed from the liver to the spleen and then through the short gastric vessels into the stomach to be excreted. The influence of Galen's teaching endured for more than 1200 years.

In the early seventeenth century, several physician scientists, Malpighi being the most prominent, began testing hypotheses on splenic function by splenectomizing dogs. He reportedly followed several dogs 5 years postoperatively, noting their healthy survival though apparent ravenous hunger and enhanced sexual appetites. The spleen, still in the era of "balanced humors," was thus felt to play a role in balancing various appetites as well. In addition to melancholy, the spleen became associated with anger and, paradoxically, was also seen as the "seat of laughter."[5]

The claim for the first human splenectomy may have predated that of canine splenectomy. Andriano Zaccavello was credited in 1549 with having performed a splenectomy on a middle-aged woman. This claim remains shrouded in controversy, and the indication for the surgery and whether in fact splenectomy was performed have been called into question. The patient apparently survived. Most patients who underwent splenectomy in the three centuries that followed fared badly. The vast majority of splenectomies performed were partial. Most of these patients required surgery for left upper quadrant stab wounds sustained in battles or duels resulting in partial or complete splenic prolapse.[6]

It was in the early eighteenth century that the growing body of anatomic microstructural knowledge began to turn the tide on the long-held theory of health and disease deriving from a balance of the four humors. William Henson believed the spleen to be a ductless vascular gland similar to the thyroid and adrenals. In 1777, he wrote of the lymphatic nature of the spleen and its filtering function and even suggested its role in hematopoiesis.[13]

Rudolf Virchow, one of the first to discover leukemia, implicated the spleen as figuring prominently in all leukemia patients. He suspected that the spleen was responsible for

Key Points

1. The human spleen plays a key immunologic role in defense against a number of organisms, particularly encapsulated bacteria.
2. The spleen can cause significant morbidity and/or hematologic disturbance if it becomes hyperfunctioning (hypersplenism) or hypertrophied (splenomegaly).
3. There is a broad spectrum of nontraumatic diseases for which elective splenectomy can be curative or palliative. They can be broadly categorized as red blood cell disorders and hemoglobinopathies, white blood cell disorders, platelet disorders, bone marrow disorders, infections and abscesses, cysts and tumors, storage diseases and infiltrative disorders, and miscellaneous conditions.
4. Partial splenectomy may be a suitable alternative to total splenectomy for certain conditions of hypersplenism or splenomegaly, particularly in children in whom preservation of splenic immunologic function is especially important.
5. Preoperative splenic artery embolization for elective splenectomy has benefits and disadvantages. It may be most suitable in cases of enlarged spleen. Conclusive evidence is lacking.
6. Laparoscopic splenectomy provides equal hematologic outcomes with decreased morbidity compared with the open operation. The laparoscopic approach has emerged as the standard for elective, nontraumatic splenectomy.
7. Inadvertent intraoperative splenic injury is a scenario for which every abdominal surgeon should be prepared. Availability of a predetermined algorithm, with emphasis on the patient's condition, facilitates intraoperative decision making.
8. Overwhelming postsplenectomy infection (OPSI) is an uncommon but potentially grave disease. Children and those undergoing splenectomy for hematologic malignancy are at elevated risk.
9. Antibiotic prophylactic strategies against OPSI vary widely. Data regarding their use are lacking.
10. Vaccination of the splenectomized patient remains the most effective prevention strategy against OPSI. Preoperative vaccination before elective splenectomy is most prudent.

generating the leukocytes in large quantities in these patients. There soon followed an enthusiastic effort by surgeons to cure leukemia by splenectomy. Dr. Thomas Bryant performed the first splenectomy in 1866 in a patient with leukemia. The patient died, as did all 14 patients who underwent splenectomy for leukemia over the next 15 years. After his second consecutive mortality in this setting, Bryant declared that "the operation is physiologically unsound & surgically unsafe for leukemia and should not be performed."[7] In 1908, Johnson reported a series of 99 splenectomies for leukemia with an 85% mortality rate. Unfortunately, it took several decades for his words to be heeded.

In 1916, a medical student from Prague named Paul Kaznelson wrote on the key role played by the spleen in the destruction of platelets leading to the first reported (and successful) splenectomy for a patient with idiopathic thrombocytopenia purpura.[2]

As surgeons' experience with the procedure grew, the associated morbidity and mortality decreased. By 1920, the Mayo Clinic experience with splenectomy reported a reduced mortality rate of 11%.[1]

O'Donnell in 1929 was the first to describe fatal postsplenectomy sepsis in a child who had undergone the surgery for hemolytic anemia.[3] It took Springer's 1973 review of almost 2800 postsplenectomy patients and the 2.5% incidence of sepsis-induced mortality (vs. 0.01% in the general population) to reorient surgeons to more conservative splenic procedures.[2,3]

The advent of minimally invasive surgery and laparoscopic splenectomy in the early 1990s represented a clear advance, benefitting the patient through this evolution of surgical technique. Most large series of laparoscopic splenectomy for benign and malignant indication now report a mortality rate of <1%.[9,10] As even more contemporary research reveals the spleen to play a central role in immune, metabolic, and endocrine function, it follows that the surgeon's role going forward will be to preserve this organ and its functions whenever possible.

EMBRYOLOGY AND ANATOMY

Consisting of an encapsulated mass of vascular and lymphoid tissue, the spleen is the largest reticuloendothelial organ in the body. Arising from the primitive mesoderm as an outgrowth of the left side of the dorsal mesogastrium, by the fifth week of gestation, the spleen is evident in an embryo 8 mm long.

Development begins through the formation of the splanchnic mesodermal plate, derived from the mesoderm, at embryonic day 12. The embryonic spleen is first colonized by erythroid and myeloid progenitor cells at 2 weeks of gestation. Following soon thereafter, the hematopoietic stem cells take up residence in the forming spleen.[11] The spleen assumes an important hematopoietic role until the fifth month of gestation. After birth, splenic erythropoietic function may persist in some hematologic disorders.[12]

The organ continues its differentiation and migration to the left upper quadrant, where it comes to rest with its smooth, diaphragmatic surface facing posterosuperiorly.[8]

The most common anomaly of splenic embryology is the accessory spleen. Present in up to 20% of the population, one or more accessory spleens may also occur in up to 30% of patients with hematologic disease. Over 80% of accessory spleens are found in the region of the splenic hilum and vascular pedicle. Other locations for accessory spleens in descending order of frequency are the gastrocolic ligament, the pancreas tail, the greater omentum, the stomach's greater curve, the splenocolic ligament, the small and large bowel mesentery, the left broad ligament in women, and the left spermatic cord in men (Fig. 34-1).[8,13]

The abdominal surface of the diaphragm separates the spleen from the lower left lung and pleura and the ninth to

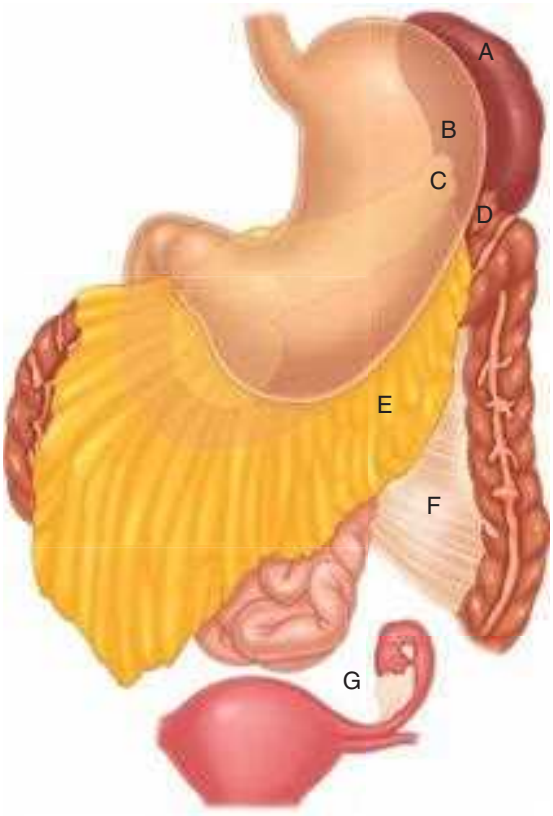

Figure 34-1. Sites where accessory spleens are found in order of importance. *A.* Hilar region, 54%; *B.* pedicle, 25%; *C.* tail of pancreas, 6%; *D.* splenocolic ligament, 2%; *E.* greater omentum, 12%; *F.* mesentery, 0.5%; *G.* left ovary, 0.5%.

eleventh ribs. The visceral surface faces the abdominal cavity and contains gastric, colic, renal, and pancreatic impressions. Spleen size and weight vary with age, with both diminishing in the elderly and in those with underlying pathologic conditions. The average adult spleen is 7 to 11 cm in length and weighs 150 g (range, 70 to 250 g).

The spleen's superior border separates the diaphragmatic surface from the gastric impression of the visceral surface and often contains one or two notches, which are particularly pronounced when the spleen is greatly enlarged.

Of particular clinical relevance, the spleen is suspended in position by several ligaments and peritoneal folds to the colon (splenocolic ligament), the stomach (gastrosplenic ligament), the diaphragm (phrenosplenic ligament), and the kidney, adrenal gland, and tail of the pancreas (splenorenal ligament) (Fig. 34-2). The gastrosplenic ligament contains the short gastric vessels; the remaining ligaments are avascular, with rare exceptions, such as in patients with portal hypertension. The relationship of the pancreas to the spleen also has important clinical implications. In cadaveric anatomic series, the tail of the pancreas has been demonstrated to lie within 1 cm of the splenic hilum 75% of the time and to actually abut the spleen in 30% of patients.[2]

The spleen derives most of its blood from the splenic artery, the longest and most tortuous of the three main branches of the celiac artery. The splenic artery can be characterized by the pattern of its terminal branches. The *distributed type* of splenic artery is the most common (70%) and is distinguished by a short trunk with many long branches entering over three-fourths of the spleen's medial surface. The less common *magistral type* of splenic artery (30%) has a long main trunk dividing near the hilum into short terminal branches, and these enter over 25% to 30% of the spleen's medial surface. The spleen also receives some of its blood supply from the short gastric vessels that branch from the left gastroepiploic artery running within the gastrosplenic ligament. The splenic vein joins the superior mesenteric vein to form the portal vein and accommodates the major venous drainage of the spleen.

When a normal, freshly excised spleen is sectioned, the cut surface is finely granular and predominantly dark red with whitish nodules distributed liberally across its expanse. This gross observation reflects the spleen's microstructure. The splenic parenchyma is composed of two main elements: the red pulp, constituting approximately 75% of total splenic volume, and the white pulp (Fig. 34-3). At the interface between the red and white pulp is the narrow marginal zone.

Blood enters the red pulp through cords comprised of fibroblasts and reticular fibers, which contain many macrophages and lack an endothelial lining. The blood then passes from these "open" cords to venous sinuses, which are surrounded and separated by the same reticulum, and ultimately drains into tributaries of the splenic vein. An understanding of the microanatomy of these sinuses has elucidated the mechanical filtration function of the spleen. Unlike the cords of the red pulp, the sinuses of the red pulp are lined by endothelial cells. These cells contain unique stress fibers that connect the endothelial cells and that contain actin and myosin–like filaments capable of producing a sliding action. When activated, these filaments can create slits or gaps between the endothelial cells through which blood can then pass from the cords.[11] Aging erythrocytes with stiffer membranes get stuck trying to pass into the sinus and are phagocytized by macrophages within the red pulp.[12]

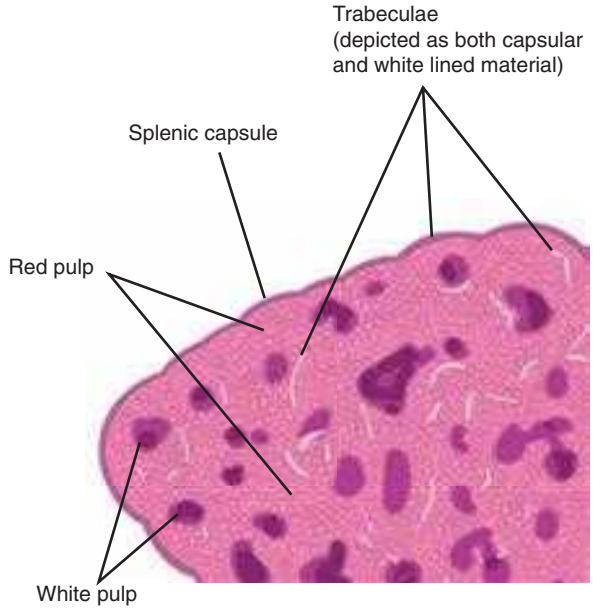

Figure 34-3. Splenic architecture. *(Used with permission of Ivan George, University of Maryland School of Medicine.)*

The red pulp thus serves as a dynamic filtration system, enabling macrophages to remove microorganisms, cellular debris, antigen-antibody complexes, and senescent erythrocytes from the circulation.

Around the terminal millimeters of splenic arterioles, a *periarticular lymphatic sheath* replaces the native adventitia of the vessel. The sheath is comprised of T lymphocytes and intermittent aggregations of B lymphocytes or lymphoid follicles. When antigenically stimulated, the follicles, serving as centers of lymphocyte proliferation, develop germinal centers, which regress as the stimulus or infection subsides. This white pulp consists of nodules that normally are ≤1 mm in size but can increase to several centimeters when nodules coalesce, as occurs in certain lymphoproliferative disorders. At the junction between the white and red pulp is the marginal zone, where lymphocytes are more loosely aggregated.

As well as serving as a transit area, the marginal zone is home to its own unique population of cells. Notably two specific types of macrophages reside there, marginal zone macrophages and marginal zone metallophilic macrophages. The former play an important role in the targeting and clearance of certain bacterial pathogens. The latter have been shown to be the main producers of interferons A and B in response to a viral challenge.[11]

1▶

PHYSIOLOGY AND PATHOPHYSIOLOGY

The spleen is contained by a 1- to 2-mm thick capsule. In humans, the capsule is rich in collagen and contains some elastin fibers. Many mammals have splenic capsules and trabeculae with abundant smooth muscle cells, which upon autonomic stimulation contract to expel large volumes of stored blood into the general circulation. The human splenic capsule and trabeculae, by contrast, contain few or no smooth muscle cells.

Total splenic inflow of blood is approximately 250 to 300 mL/min. Blood flows through successively tapering arteries to arterioles, traverses the white pulp, crosses the marginal zone, and enters the red pulp. From that entry, the flow rate through the spleen may vary greatly. Animal studies measuring the transit times of isotopically labeled blood through the spleen have revealed three distinct velocities of flow. Humans have long been recognized to have both a fast or closed circulation—with blood passing directly from arterioles into venous sinuses—and a slower or open circulation. Most of the spleen's filtration function occurs via the slower circulation. During open circulation, blood percolates through the reticular space and splenic cords, thus gaining access through gaps or slits in the endothelial cell lining to the sinuses as previously described. Flowing into and out of the venous sinuses through these gaps, the blood is exposed to extensive contact with splenic macrophages. These are responsible for the innate immune response of the spleen, which occurs largely within the marginal zone. The white pulp, by contrast, is involved only in adaptive immunity. In addition, because the passage of plasma through these spaces does not slow in a similar manner, a temporary and unique adhesive contact between blood cells and components of the splenic cord may occur. That there is a selective slowing of blood cell flow versus plasma flow is further evidenced by the fact that within the spleen, the erythrocyte concentration (hematocrit) is twice that of the general circulation. During this contact with splenic macrophages, it is likely that the removal of both cellular debris and senescent blood cells occurs.[14]

The process by which the spleen removes erythrocyte inclusions, such as Heinz bodies (intracellular altered hemoglobin), without cell lysis while red blood cells travel through the spleen is not well understood. The spleen acts as the major site for clearance from the blood of damaged or aged red blood cells and, in addition, has a part in the removal of abnormal white blood cells and platelets. A minimum of 2 days of the erythrocyte's 120-day life cycle is spent sequestered in the spleen. Daily, approximately 20 mL of aged red blood cells are removed. Evidence suggests that, as erythrocytes age, previously undetected antigens on their surfaces may attach to autoantibodies in the circulation; then macrophages may bind to the antibodies and initiate phagocytosis. It is probable that the erythrocyte is damaged over time by multiple passages through the spleen as well as delayed transit through the congested and relatively hypoxic and acidotic environment of the splenic cords.

The spleen can also serve as an extra medullary site for hematopoiesis, if required. Another role played by the spleen is in recycling iron. Erythrocytes in large numbers are destroyed intravascularly throughout the body. The released hemoglobin is then bound to haptoglobin, which is ultimately scavenged from the circulation in the spleen.[15]

The spleen plays a vital, although not indispensable, role in host defense evidenced by the healthy survival of splenectomized patients. Both innate and adaptive immune responses (historically categorized as cell-mediated and humoral immunity) occur within the spleen.

In addition to the previously noted activities of the marginal zone macrophages, marginal zone B cells serve to detect circulating pathogens and respond quickly to either differentiate into immunoglobulin M (IgM)–producing plasma cells or to function as antigen-presenting cells (APCs), which facilitate pathogen removal and destruction.

It is APC entry in the white pulp in particular that is key to the initiation of the adaptive immune response. Antigens are thus presented to immunocompetent centers within the lymphoid

follicles. This gives rise to the elaboration of immunoglobulins (predominantly IgM). After an antigen challenge, such an acute IgM response results in the release of opsonic antibodies from the white pulp of the spleen. Antigen clearance is then facilitated by the splenic and hepatic reticuloendothelial systems.

The structure and immunophysiology of the white pulp is very similar to that of lymph nodes, with the notable difference being that material enters the lymph node in the lymph whereas it is delivered to the white pulp in the blood.[16]

The spleen also produces opsonins, tuftsin, and properdin. Circulating monocytes are converted within the red pulp into fixed macrophages that account for the spleen's remarkable phagocytic activity.

The spleen also appears to be a major source of the protein properdin, important in the initiation of the alternate pathway of complement activation. The splenic reticuloendothelial system is better able to clear bacteria that are poorly or inadequately opsonized from the circulation than is the hepatic reticuloendothelial system. Encapsulated bacteria generally fit such a profile, hence the risk posed by pneumococcus and *Haemophilus influenzae* to an asplenic patient. There appears to be sufficient physiologic capacity within the complement cascade to withstand the loss of tuftsin and properdin production without an increase in patient vulnerability after splenectomy.[17-19]

In patients with chronic hemolytic disorders, splenic tissue may become permanently hypertrophied. The reticular spaces of the red pulp become distended with macrophages engorged with the products of erythrocyte breakdown, and splenomegaly can result. It is important to distinguish between *splenomegaly* and *hypersplenism*, two similar but distinct terms that are critical to understand when discussing splenic pathology. *Splenomegaly* refers simply to abnormal enlargement of the spleen. Splenomegaly is described variably within the surgical literature as *moderate, massive*, and *hyper*, which reflects a lack of consensus. Most would agree, however, that *splenomegaly* applies to organs weighing ≥500 g and/or averaging ≥15 cm in length.

2▶

Massive splenomegaly similarly lacks a consensus definition but has been described variably as spleens >1 kg in mass or >22 cm in length (Fig. 34-4).[6] Spleens palpable below the left costal margin are thought to be at least double normal size, with an estimated weight of ≥750 g.[20]

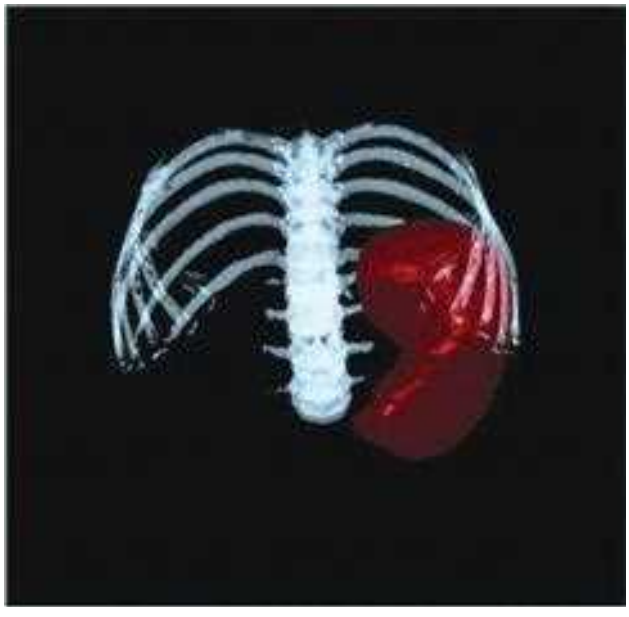
There is not a single, universally accepted standard, but most would agree that an ex vivo mass of >1 kg or a pole-to-pole length of >15 cm generally qualifies as splenomegaly. Hypersplenism often is found in association with splenomegaly but is not synonymous with it. Hypersplenism is defined as the presence of one or more cytopenias in the context of a normally functioning bone marrow.

Disorders causing hypersplenism can be categorized as either (a) those in which increased destruction of abnormal blood cells occurs in an intrinsically normal spleen (e.g., hemolytic anemias) or (b) primary disorders of the spleen resulting in increased sequestration and destruction of normal blood cells (e.g., infiltrative disorders).

3▶

The life cycles of cellular elements vary widely in human blood. A neutrophil in circulation has a normal half-life of approximately 6 hours. The spleen's role in the normal clearance of neutrophils is not well established. It is clear that hypersplenism may result in neutropenia through sequestration of normal white blood cells or the removal of abnormal ones. Platelets, on the other hand, generally survive in the circulation for 10 days.

A



B

C

Figure 34-4. Splenomegaly. **A.** Computed tomography (CT) scan. **B.** Three-dimensional reconstruction of CT scan. **C.** Postoperative specimen.

Under normal circumstances, a third of the total platelet pool is sequestered in the spleen. Thrombocytopenia may result from excessive sequestration of platelets as well as accelerated platelet destruction in the spleen. Splenomegaly may result in sequestration of up to 80% of the platelet pool. The spleen may also contribute to the immunologic alteration of platelets, which leads to thrombocytopenia in the absence of splenomegaly (e.g., idiopathic thrombocytopenic purpura [ITP]).[21]

The immunologic functions of the spleen are consistent with those of other lymphoid organs. It is a site of bloodborne antigen presentation and the initiation of T- and B-lymphocyte activities involved in humoral and cellular immune responses. Alteration of splenic immune function often gives rise to antibody production, which results in blood cell destruction.

Although the spleen contributes to the process of erythrocyte maturation, in adult humans there is little evidence of normal hematopoietic function. The spleen does have a minor role in hematopoiesis in the fourth month in the human fetus, and reactivation can occur in childhood if the bone marrow fails to meet the hematologic needs. Splenic hematopoiesis giving rise to abnormal red blood cells is seen in adults with myeloproliferative disorders. In addition, in response to some anemias, elements of the red pulp may revert to hematopoiesis.

IMAGING FOR EVALUATION OF SIZE AND PATHOLOGY

Prior to operation, thorough assessment of anatomic detail and functional status of the spleen is essential for surgical planning. Special preoperative consideration needs to be given to patients with splenomegaly because minimally invasive methods increase in difficulty with increasing size of the spleen. Other indications for splenic imaging include trauma, investigations of left upper quadrant pain, characterization of splenic lesions such as tumors, cysts, and abscesses, and guidance for percutaneous procedures.[22,23]

Preoperative imaging of the spleen is primarily performed to obtain an accurate assessment of the splenic volume in order to confirm and document splenomegaly as well as to exclude any large splenic lesion that could affect the surgical resection plane. Identification of the presence of accessory spleens in the preoperative setting is also important, although lack of accessory tissue on the imaging should not preclude a thorough intraoperative search.

The guidelines of the European Association for Endoscopic Surgery suggest that all patients should undergo preoperative imaging.[20] Some of the common imaging modalities include ultrasound and computed tomography (CT), both enabling measurement of splenic size and volume. When desired, the splenic volume may be calculated using a formula for the volume of a prolate ellipsoid: Volume (cc) = Length (cm) × Width (cm) × Height (cm) × 0.52.[43] Other imaging modalities, although not as commonly used, include nuclear medicine studies and magnetic resonance imaging (MRI).

Ultrasound

Ultrasound is the least invasive mode of splenic imaging. It is rapid, easy to perform, and does not expose the patient to ionizing radiation. It is often the first imaging modality applied to the spleen during evaluation and resuscitation of the trauma patient, although questions of sensitivity and specificity remain.[24,25] In the elective setting, such as for routine diagnostic purposes or for preoperative planning, it is the least costly modality available, and the sensitivity of ultrasound for detecting textural lesions of the spleen can be quite good in experienced hands.[26]

When examining a normal spleen, differentiation between red and white pulp is not possible, and a homogeneous acoustic echotexture should be visualized. Splenic artery and vein patency may be assessed using Doppler imaging. Splenic artery anatomy has been classified commonly into two patterns: distributed and magistral. This variability in vascular distribution visualized by Doppler imaging becomes important when there is consideration of performing a partial splenectomy.

Percutaneous ultrasound-guided procedures for splenic disease (e.g., cyst aspiration, biopsy), historically avoided due to the risk of hemorrhage and other complications, are becoming more common as the safety of these procedures is being increasingly demonstrated.[22,23]

Computed Tomography

CT affords a high degree of resolution and detail of the splenic parenchyma, vasculature, and its relationship to neighboring structures. Modern-day CT is more automated and thus less operator dependent than ultrasound, which makes it the preferred imaging modality for many practitioners. Furthermore, CT has become an invaluable tool in the evaluation and management of the blunt trauma patient, and standardized scoring systems for splenic trauma based on CT images now aid in management decisions.[27] In the nontrauma setting, CT is extremely useful for assessment of splenomegaly, identification of solid and cystic lesions, and guidance of percutaneous procedures.[3] The use of iodinated contrast material adds diagnostic clarity to CT imaging of the spleen, although at the cost of the small but real risks of renal impairment or allergic reaction. Three-dimensional reconstruction after CT scan may help to predict the difficulty of the procedure and to choose the best surgical approach: open or laparoscopic.[29,30]

The appearance of normal splenic tissue on a noncontrast CT is uniform parenchymal attenuation. On a contrast-enhanced CT, the appearance of the spleen depends largely on the timing of the intravenous bolus administration of contrast material. Due to the different rates of flow through the red and white pulp, the spleen appears heterogeneously enhancing during the first minute after initiation of intravenous administration of contrast material. The frequency of these artifacts increases with advancing patient age. When evaluating a splenic abscess, a contrast-enhanced CT should be considered.[28,43]

Three-dimensional CT volumetry is a novel modality that measures the volume of the spleen. This tool may be of some benefit in planning technically challenging cases involving splenomegaly. A recent retrospective review of laparoscopic splenectomy patients who underwent CT volumetry preoperatively demonstrated a higher conversion rate when the spleen was measured to be greater than 2700 cc.[29] This information may aid in preoperative planning in determining which patients may benefit from a hand-assisted laparoscopic surgery approach or open approach.[97]

Plain Radiography

Rarely is plain radiography used for primary splenic imaging. Plain films can indirectly provide an outline of the spleen in the left upper quadrant or suggest splenomegaly by revealing displacement of adjacent air-filled structures (e.g., the stomach or splenic flexure of the colon). Plain films may also demonstrate

splenic calcifications. Splenic calcifications often are found in association with splenomegaly but are otherwise a nonspecific finding. Splenic calcifications can indicate a number of benign, neoplastic, or infectious processes, including phlebolith, splenic artery aneurysm, sickle cell changes, tumors (e.g., hemangioma, hemangiosarcoma, lymphoma), echinococcosis, or tuberculosis.[26]

Magnetic Resonance Imaging

Although MRI offers excellent detail and versatility in abdominal imaging, it is more expensive than CT scanning or ultrasound and offers no obvious advantage for primary imaging of the spleen. MRI can be a valuable adjunct to the more commonly used imaging techniques when splenic disease is suspected but not definitively diagnosed.[26,28]

Magnetic resonance (MR) signal characteristics of the spleen are related to the relative ratio of red and white pulp and the relationship of the timing of the intravenous (IV) contrast bolus and the time of image acquisition. The spleen will generally have a homogeneous MR signal on noncontrast images. On contrast MRI, the spleen appears to have heterogeneous enhancement during the arterial phase of contrast enhancement.

Angiography

Angiography of the spleen most commonly refers to invasive arterial imaging, and when it is combined with therapeutic splenic arterial embolization (SAE), there are multiple applications for this procedure: localization and treatment of hemorrhage in select trauma patients[31]; delivery of a variety of therapies in patients with cirrhosis or portal and sinistral hypertension and in transplant patients[32]; and adjunct (or, more controversially, as an alternative) to splenectomy for treatment of hematologic disorders such as ITP or hypersplenism.[33] Preoperative or intraoperative SAE for elective splenectomy is also a common, although not universal, practice. Few prospective data have been published in the last 5 years on preoperative SAE.[34] Preoperative SAE is purported not only to facilitate operation but also possibly to allow a laparoscopic approach in patients whose spleens had previously been considered too large for, or otherwise not amenable to, laparoscopic resection. Limited success in using partial SAE as an alternative to therapeutic splenectomy in chronic ITP has been previously reported.[35] Its detractors argue that the need for increased analgesics and occasional extended hospital stay preoperatively, the possibility of pancreatitis, and the well-described risks of invasive arteriography negate any presumed benefits of preoperative SAE.

Nuclear Imaging

Radioscintigraphy with technetium-99m sulfur colloid demonstrates splenic location and size. It may be especially helpful in locating accessory spleens after unsuccessful splenectomy for ITP and has recently proven useful in diagnosing splenosis.[36,37] Unfortunately, no conclusive outcome benefit has been shown for preoperative technetium scanning before splenectomy.[38,39] When dealing with diseases of platelet sequestration, indium-labeled autologous platelet scanning (ILAPS) demonstrates whether platelet sequestration is predominantly in the spleen, liver, or both. This becomes important in deciding whether or not a patient will benefit from a splenectomy. ILAPS is a nuclear imaging modality in which autologous platelets are reinfused into the patient after ex vivo labeling. Subsequent scintigraphy demonstrates the site(s) of platelet sequestration and clearance. It has been proposed that patients with purely or predominantly splenic sequestration determined by ILAPS may be more likely to respond to splenectomy than those exhibiting hepatic, mixed, or diffuse patterns.[33]

An emerging and novel application for spleen scintigraphy may be as a noninvasive method to diagnose nonalcoholic steatohepatitis (NASH). NASH, which may lead to cirrhosis, can result from nonalcoholic fatty liver disease (NAFLD), the most common cause of steatosis. With the rising prevalence of obesity in the United States, NAFLD is also increasingly prevalent.[12] The diagnosis of progression from NAFLD to NASH has been dependent on histologic assessment of tissue obtained from liver biopsy. Characteristics unique to NASH have been reported, among them the association of splenic enlargement, not seen to a similar degree in NAFLD.[10]

In addition, the ratio of liver-to-spleen uptake determined by scintigraphy has been found to be predictably altered in NASH patients. The liver-to-spleen uptake ratio is significantly decreased in NASH patients, but not NAFLD patients, leading some to conclude that technetium-99m-phytate scintigraphy is a reliable tool to differentiate NASH from NAFLD.[40]

INDICATIONS FOR SPLENECTOMY

Splenectomy is therapeutic for a large host of conditions, which can be divided into the following broad categories: (a) benign, including red blood cell disorders, hemoglobinopathies, and platelet disorders; (b) malignant, including white blood cell disorders and bone marrow disorders (myeloproliferative disorders); and (c) other, including cysts and tumors, infections and abscesses, splenic rupture, and a number of miscellaneous disorders and lesions (Table 34-1).

Overall, the most common indication for splenectomy is trauma to the spleen, whether external trauma (blunt or penetrating) or iatrogenic injury (e.g., during operative procedures for other reasons). Inadvertent intraoperative injury to the spleen in the nontrauma patient is discussed in a later section. Management of splenic injury in the trauma patient is beyond the scope of this chapter. The most common indication for elective splenectomy is ITP.

Benign Disorders

Red Blood Cell Disorders

Congenital

Hereditary Spherocytosis. Hereditary spherocytosis (HS) results from an inherited dysfunction or deficiency in one of the erythrocyte membrane proteins (*spectrin, ankyrin, band 3 protein,* or *protein 4.2*). The resulting destabilization of the membrane lipid bilayer allows a pathologic release of membrane lipids. The red blood cell assumes a more spherical, less deformable shape, and the spherocytic erythrocytes are sequestered and destroyed in the spleen. Hemolytic anemia ensues; in fact, HS is the most common hemolytic anemia for which splenectomy is indicated. HS is inherited primarily in an autosomal dominant fashion; the estimated prevalence in Western populations is 1 in 5000.[41-43]

Patients with typical HS forms may have mild jaundice. Splenomegaly usually is present on physical examination. Laboratory examination reveals varying degrees of anemia: patients with mild forms of the disease may have no anemia; patients with severe forms may have hemoglobin levels as low as 4 to 6 g/dL. The mean corpuscular volume is typically low to normal or slightly decreased. For screening, a combined elevated

Table 34-1

Indications for and expected response to splenectomy in various diseases and conditions

DISEASE/CONDITION	INDICATIONS FOR SPLENECTOMY	RESPONSE TO SPLENECTOMY
Hereditary spherocytosis	Hemolytic anemia, recurrent transfusions, intractable leg ulcers	Improves or eliminates anemia
Hereditary elliptocytosis	Limited role for splenectomy	—
Pyruvate kinase deficiency	Only in severe cases, recurrent transfusions	Decreased transfusion requirement, palliative only
Glucose-6-phosphate dehydrogenase deficiency	None	—
Warm-antibody autoimmune hemolytic anemia	Failure of medical (steroid) therapy	60%–80% response rate, recurrences common
Sickle cell disease	History of acute sequestration crisis, splenic symptoms, or infarction (consider concomitant cholecystectomy)	Palliative, variable response
Thalassemia	Excessive transfusion requirements, symptomatic splenomegaly, or infarction	Diminished transfusion requirements, relief of symptoms
Acute myeloid leukemia (AML)	Intolerable symptomatic splenomegaly	Relief of abdominal pain and early satiety
Chronic myeloid leukemia	Symptomatic splenomegaly	Relief of abdominal pain and early satiety
Chronic myelomonocytic leukemia	Symptomatic splenomegaly	Relief of abdominal pain and early satiety
Essential thrombocythemia	Only for advanced disease (i.e., transformation to myeloid metaplasia or AML) with severe symptomatic splenomegaly	Relief of abdominal pain and early satiety
Polycythemia vera	Only for advanced disease (i.e., transformation to myeloid metaplasia or AML) with severe symptomatic splenomegaly	Relief of abdominal pain and early satiety
Myelofibrosis (agnogenic myeloid metaplasia)	Severe symptomatic splenomegaly	76% clinical response at 1 y, high risk of hemorrhagic, thrombotic, and infectious complications (26%)
Chronic lymphocytic leukemia	Cytopenias and anemia	75% response rate
Hodgkin's disease	Surgical staging in selected cases	—
Non-Hodgkin's lymphoma	Cytopenias, symptomatic splenomegaly	Improved complete blood count values, relief of symptoms
Idiopathic thrombocytopenic purpura	Failure of medical therapy, recurrent disease	75%–85% rate of long-term response
Thrombotic thrombocytopenic purpura	Excessive plasma exchange requirement	Typically curative
Abscesses of the spleen	Therapy of choice	Curative
Symptomatic parasitic cysts	Therapy of choice	Curative; exercise caution not to spill cyst contents
Symptomatic nonparasitic cysts	Partial splenectomy for small cysts; unroofing for large cysts	Curative
Gaucher's disease	Hypersplenism	Improves cytopenias; does not correct underlying disease
Niemann-Pick disease	Symptomatic splenomegaly	Improves symptoms; does not correct underlying disease
Amyloidosis	Symptomatic splenomegaly	Improves symptoms; does not correct underlying disease
Sarcoidosis	Hypersplenism or symptomatic splenomegaly	Improves symptoms and cytopenias; does not correct underlying disease
Felty's syndrome	Neutropenia	80% durable response rate
Splenic artery aneurysm	Splenectomy best for distal lesions near splenic hilum	Curative
Portal hypertension	Portal or sinistral hypertension due to splenic vein thrombosis	Palliative

mean corpuscular hemoglobin concentration and an elevated erythrocyte distribution width are an excellent predictor. Other laboratory indicators of HS include those providing evidence of rapid red blood cell destruction, including elevated reticulocyte count, elevated lactate dehydrogenase level, and increased level of unconjugated bilirubin. Spherocytes are readily apparent on peripheral blood film.

Risks and benefits should be assessed carefully before splenectomy and cholecystectomy are performed for HS.[41] The main indications are symptomatic hemolytic anemia, growth retardation, skeletal changes, leg ulcers, and extramedullary hemopoietic tumors in young patients. If gallstones coexist with spherocytosis, the gallbladder should be removed, but prophylactic cholecystectomy without gallstones is not recommended. Near total splenectomy is advocated in children. Dramatic clinical improvement—despite persistent hemolysis—usually occurs after splenectomy in patients with severe disease. Because children can be affected with HS, the timing of splenectomy is important and is aimed at reducing the quite small possibility of overwhelming postsplenectomy sepsis. Delaying such an operation until the patient is between the ages of 4 and 6—unless the anemia and hemolysis accelerate—is recommended by most experts.[44]

Hereditary elliptocytosis (HE) merits brief discussion to distinguish it from HS. Both HS and HE are conditions of the red blood cell membrane that result from genetic defects in skeletal membrane proteins. With the HE defect, the red blood cell elongates as it circulates, so that far fewer red blood cells are sequestered or destroyed when transiting the splenic parenchyma. Unless more than 50% of red blood cells are affected (a scenario that could permit development of a clinical syndrome like HS), HE may be considered harmless.

Red Blood Cell Enzyme Deficiencies. Red blood cell enzyme deficiencies associated with hemolytic anemia may be classified into two groups: deficiencies of enzymes involved in glycolytic pathways, such as pyruvate kinase (PK) deficiency, and deficiencies of enzymes needed to maintain a high ratio of reduced to oxidized glutathione in the red blood cell, protecting it from oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency.[45]

Pyruvate Kinase Deficiency The most common red blood cell enzyme deficiency to cause congenital chronic hemolytic anemia is PK deficiency.[45] Its pathophysiology is unclear. PK deficiency affects people worldwide, with a slight preponderance among those of northern European or Chinese descent. Clinical manifestations of the disease vary widely, from transfusion-dependent severe anemia in early childhood to well-compensated mild anemia in adolescents or adults. Diagnosis is made either by a screening test or by detection of specific mutations at the complementary DNA or genomic level. Splenomegaly is common, and in severe cases, splenectomy can alleviate transfusion requirements.[5] As with other disorders that cause hemolytic anemia in children, splenectomy should be delayed if possible to at least 4 years of age to reduce the risk of postsplenectomy infection.

Glucose-6-Phosphate Dehydrogenase Deficiency The most common red blood cell enzyme deficiency overall is G6PD deficiency. It is far more prevalent than PK deficiency with more than 400 million people affected worldwide, although most experience only moderate health risks and no longevity reduction.[46] Clinical manifestations—chronic hemolytic anemia, acute intermittent hemolytic episodes, or no hemolysis—depend on the variant of G6PD deficiency. The mainstay of therapy is avoidance of drugs known to precipitate hemolysis in patients with G6PD deficiency. Transfusions are given in cases of symptomatic anemia. Conventional wisdom is that splenectomy is not indicated in this disease, and certainly the overwhelming majority of patients with G6PD deficiency will neither require nor benefit from splenectomy. However, one report described a small collection of cases of six symptomatic G6PD deficiency patients who had severe hemolytic anemia and required transfusion, all of whom were identified to share a common mutation at exon 10. All underwent splenectomy. A complete response occurred in four patients (transfusion requirement eliminated), and a partial response occurred in one patient (transfusion requirement reduced); no follow-up data were provided for the remaining patient. This study indicates that for a carefully select group of patients with severe hemolytic anemia attributable to G6PD deficiency, splenectomy may be of benefit, although more data must be collected before such a recommendation can be made.[46]

Acquired

Warm-Antibody Autoimmune Hemolytic Anemia. Autoimmune hemolytic anemias (AIHAs) are characterized by the destruction of red blood cells, whose erythrocyte life span is diminished by autoantibodies leveled against antigens. AIHA is classified as either primary or secondary, depending on whether an underlying cause, such as a disease or toxin, is identified. AIHA is also divided into "warm" and "cold" categories, based on the temperature at which the autoantibodies exert their effect.[47] In cold-agglutinin disease, severe symptoms are uncommon and splenectomy is almost never indicated; therefore, this entity is not discussed further in this section. However, warm-antibody AIHA has clinical consequences with which the surgeon should be familiar.

Warm-antibody AIHA, although occurring primarily in midlife, can affect individuals at all ages. The disorder is more common among women, and fully half of warm-antibody AIHA cases are idiopathic. Clinical presentation may be acute or gradual. Findings include mild jaundice and symptoms and signs of anemia. One-third to one-half of patients present with splenomegaly. Sometimes in such cases the spleen is palpable on physical examination. The diagnosis relies on demonstrating hemolysis as indicated by anemia, reticulocytosis, and/or products of red blood cell destruction, including bilirubin, in the blood, urine, and stool. A positive result on direct Coombs' test confirms the AIHA diagnosis by distinguishing autoimmune from other forms of hemolytic anemia.

Treatment of AIHA depends on the severity of the disease and whether it is primary or secondary. Severe symptomatic anemia demands prompt attention, often requiring red blood cell transfusion. The mainstay treatment for both primary and secondary forms of symptomatic, unstable AIHA is corticosteroids. Therapy should continue until a response is noted by a rise in hematocrit and fall in reticulocyte count, which generally occurs within 3 weeks.

Clinical response to splenectomy for AIHA varies, and the evidence from a number of small case series is conflicting. For example, one 2004 series reported a favorable response to splenectomy in patients with AIHA secondary to chronic lymphocytic leukemia,[48] whereas more recent series found no benefit from splenectomy in patients with AIHA secondary to systemic lupus erythematosus or inflammatory bowel disease.[49]

Favorable responses to splenectomy have been reported in patients with warm-antibody AIHA. Transient responses are more common, however, and many patients eventually experience hemolysis again despite splenectomy.[48,49] The decision regarding splenectomy in the case of AIHA should be individualized based on careful consideration of the clinical history and frank discussion with the patient. It is considered as a third-line therapy after failure of steroids or anti-CD20 antibody administration.[50]

Hemoglobinopathies. Sickle cell disease is an inherited chronic hemolytic anemia that results from the mutant sickle cell hemoglobin (HbS) within the red blood cell and is inherited in an autosomal codominant fashion. Persons who inherit an *HbS* gene from one parent (heterozygous) are carriers; those who inherit an *HbS* gene from both parents (homozygous) have sickle cell anemia.[51]

In sickle cell disease, the underlying abnormality is the mutation of adenine to thymine in the sixth codon of the β-globin gene, which results in the substitution of valine for glutamic acid as the sixth amino acid of the β-globin chain. Mutant β chains included in the hemoglobin tetramer create HbS. Deoxygenated HbS is insoluble and becomes polymerized and sickled. The subsequent lack of deformability of the red blood cell, in addition to other processes, results in microvascular congestion, which may lead to thrombosis, ischemia, and tissue necrosis. The disorder is characterized by painful intermittent episodes.

Sequestration occurs in the spleen, with splenomegaly resulting early in the disease course. In most patients, subsequent infarction of the spleen and autosplenectomy occur at some later time. The most frequent indications for splenectomy in sickle cell disease are recurrent acute sequestration crises, hypersplenism, and splenic abscess. The occurrence of one major acute sequestration crisis, characterized by rapid painful enlargement of the spleen and circulatory collapse, generally is considered sufficient grounds for splenectomy. Preoperative preparation should include special attention to adequate hydration and avoidance of hypothermia.

Splenectomy does not affect the sickling process, and therapy for sickle cell anemia remains largely palliative. It is only indicated in cases of massive splenomegaly or frequent sequestration crisis. The patients often have a functional asplenia. Transfusions are indicated for anemia, for moderately severe episodes of acute chest syndrome (i.e., a new infiltrate on chest radiograph associated with new symptoms, such as fever, cough, sputum production, or hypoxia), and preoperatively before splenectomy. Patients experiencing stroke or a severe crisis may require hydration and an exchange transfusion, which may be performed manually or with automated apheresis equipment. Hydroxyurea is an oral chemotherapeutic agent that upregulates fetal hemoglobin, which interferes with polymerization of HbS and thus reduces the sickling process.[52]

Thalassemia. *Thalassemia* is the term for a group of inherited disorders of hemoglobin synthesis prevalent among people of Mediterranean extraction and classified according to the hemoglobin chain (α, β, or γ) affected. As a group, the thalassemias are the most common genetic diseases known to arise from a single gene defect.[53,54] Most forms of this disorder are inherited in Mendelian recessive fashion from asymptomatic carrier parents. In the so-called thalassemia belt that extends throughout the shores of the Mediterranean as well as through the Arabian Peninsula, Turkey, Iran, India, and southeastern Asia, the incidence of thalassemia is between 2.5% and 15%. However, thalassemias have been found in people of all ethnic origins.[54]

In all forms of thalassemia, the primary defect is absent or reduced production of hemoglobin chains. From this abnormality, two significant consequences arise: (a) reduced functioning of hemoglobin tetramers, yielding hypochromia and microcytosis; and (b) unbalanced biosynthesis of individual α and β subunits, which results in insoluble red blood cells that cannot release oxygen normally and may precipitate with cell aging. Both underproduction of hemoglobin and excess production of unpaired hemoglobin subunits contribute to thalassemia-associated morbidity and mortality.

A diagnosis of thalassemia major (homozygous form) is made by demonstrating hypochromic microcytic anemia associated with randomly distorted red blood cells and nucleated erythrocytes (target cells) on peripheral blood smear.[5] Elevated reticulocyte count and white blood cell count are among the associated findings. Because α chains are needed to form both fetal hemoglobin and adult hemoglobin, α-thalassemia becomes symptomatic in utero or at birth. By contrast, β-thalassemia becomes symptomatic at 4 to 6 months, because β chains are involved only in adult hemoglobin synthesis.

The clinical spectrum of the thalassemias is wide. Heterozygous carriers of the disease are usually asymptomatic. Homozygous individuals, on the other hand, typically present before 2 years of age with pallor, growth retardation, jaundice, and abdominal swelling due to liver and spleen enlargement. Among other characteristics of thalassemia major are intractable leg ulcers, head enlargement, frequent infections, and the need for periodic blood transfusions. Untreated individuals usually die in late infancy or early childhood from severe anemia.[5]

Treatment for thalassemia involves red blood cell transfusions to maintain a hemoglobin level of >9 mg/dL, along with intensive parenteral chelation therapy with deferoxamine. Splenectomy is indicated for patients with excessive transfusion requirements (>200 mL/kg per year), discomfort due to splenomegaly, or painful splenic infarction. Careful assessment of the risk-benefit ratio is essential. Thalassemia patients are at high risk for pulmonary hypertension after splenectomy; the precise etiology of this sequela is under investigation.[55] The increase in infectious complications is likely to be due to a coexisting immune deficiency, in large part brought about by iron overload, which may be associated both with the thalassemia itself and with transfusions. The disproportionately high rate of overwhelming postsplenectomy infection in thalassemia patients 4▶ has led some investigators to consider partial splenectomy in children; some success in reducing mortality has been reported.[56] However, splenectomy should be delayed until after the age of 4 years unless it is absolutely necessary.

Platelet Disorders

Idiopathic Thrombocytopenic Purpura Idiopathic thrombocytopenic purpura (ITP), also called *immune thrombocytopenic purpura*, is an autoimmune disorder characterized by a low platelet count and mucocutaneous and petechial bleeding. The low platelet count stems from premature removal of platelets opsonized by antiplatelet immunoglobulin G autoantibodies produced in the spleen. This clearance occurs through the interaction of platelet autoantibodies with Fc receptors expressed on tissue macrophages, predominantly in the spleen and liver. The estimated incidence of ITP is 100 persons per million annually, about one-half of whom are children.[57] Adult-onset and

childhood-onset ITP are strikingly different in their clinical course and management.

Patients with ITP typically present with petechiae or ecchymoses, although some experience major bleeding from the outset. Bleeding may occur from mucosal surfaces in the form of gingival bleeding, epistaxis, menorrhagia, hematuria, or even melena. The severity of bleeding frequently corresponds to the deficiency in platelets: Patients with counts greater than 50,000/mm^3 usually present with incidental findings; those with counts between 30,000 and 50,000/mm^3 often have easy bruising; those with platelet counts between 10,000 and 30,000/mm^3 may develop spontaneous petechiae or ecchymoses; and those with counts less than 10,000/mm^3 are at risk for internal bleeding.[57] The incidence of major intracranial hemorrhage is approximately 1%, and it usually occurs early in the disease course. The duration of the bleeding helps to distinguish acute from chronic forms of ITP. Children often present at a young age (peak age of approximately 5 years) with sudden onset of petechiae or purpura several days to weeks after an infectious illness. In contrast, adults experience a more chronic form of disease with an insidious onset. Splenomegaly is uncommon with ITP in both adults and children, and its occurrence should prompt a search for a separate cause of thrombocytopenia. Up to 10% of children, however, have a palpable spleen tip.

Diagnosis of ITP is based on exclusion of other possibilities in the presence of a low platelet count and mucocutaneous bleeding. Other diseases resulting in secondary forms of ITP, such as systemic lupus erythematosus, antiphospholipid syndrome, lymphoproliferative disorders, human immunodeficiency virus (HIV) infection, and hepatitis C, should be identified and treated when present. In addition, any history of use of a drug known to cause thrombocytopenia, such as certain antimicrobials, anti-inflammatories, antihypertensives, and antidepressants, should be sought. In addition to low platelet count, another laboratory finding characteristic of ITP is the presence of large, immature platelets (megakaryocytes) on peripheral blood smear.

The usual first line of therapy is oral prednisone at a dosage of 1.0 to 1.5 mg/kg per day.[58,59] No consensus exists as to the optimal duration of steroid therapy, but most responses occur within the first 3 weeks. Response rates range from 50% to 75%, but relapses are common. IV immunoglobulin, given at 1.0 g/kg per day for 2 to 3 days, is indicated for internal bleeding when platelet counts remain less than 5000/mm^3, when extensive purpura exists, or to preoperatively boost platelets. IV immunoglobulin is thought to impair clearance of immunoglobulin G–coated platelets by competing for binding to tissue macrophage receptors. An immediate response is common, but a sustained remission is not. The medical approach to ITP has been modified with the advent of rituximab[60] and thrombopoietin receptor agonists. Therapeutic recommendations are summarized in Table 34-2. Splenectomy is selectively indicated for failure of medical therapy, for prolonged use of steroids with undesirable effects, and in selected cases after first relapse.[5] Prolonged use of steroids can be defined in various ways, but a persistent need for more than 10 to 20 mg/d for 3 to 6 months to maintain a platelet count of greater than 30,000/mm^3 generally prompts referral for splenectomy. Splenectomy is an effective option for refractory ITP and provides a permanent response without subsequent need for steroids in 75% to 85% of patients. Two recent reviews and meta-analyses have assessed the global results of splenectomy for ITP, specifically after the use of laparoscopic techniques.

Table 34-2

Second-line treatment options for immune thrombocytopenia

Splenectomy
Advantages
• Effective, time-honored treatment
• Most effective response (overall 88%, partial 22%, complete 66%)
Disadvantages
• Surgical procedure with associated morbidity and mortality
• Risk of overwhelming postsplenectomy infection
• Increased risk of thrombotic events
Rituximab
Advantages
• Nonsurgical
• Good experience since 1999
• Initial response 63%, 31% at 2 years
Disadvantages
• Short follow-up
• Severe toxicity 2%–6%
Thrombopoietin Receptor Agonist
Advantages
• Nonsurgical
• Oral agent self-administered weekly
• 80% response rate
Disadvantages
• Long-term treatment required
• Long-term risk not well known
• Potential toxicity

In 2004, Kojouri and colleagues[60] reviewed 135 case series from 1966 to 2004, pooling 4955 patients. The long-term platelet count response was assessed, as was the ability to predict response and the incidence of complications. Complete response was achieved in 66% of cases with a follow-up ranging from 1 to 153 months, and complete and partial responses occurred in as many as 88% of patients, regardless of the duration of follow-up. They also analyzed 12 preoperative demographic, clinical, and laboratory parameters and found no predictive capability of platelet response in any of them. Mortality was very low (1%), and morbidity was 10%. Limitations of this review included old case series and a low percentage of laparoscopic splenectomies. In a 2009 systemic review involving 1223 patients, Mikhael and colleagues[61] evaluated the short- and long-term outcomes after laparoscopic splenectomy. The conversion rate to open surgery was 5.6%, and the immediate nonresponder rate was 8.2%; however, eventually a clinical response was achieved in 72% of the patients on long-term follow-up (5 years). The initial concerns regarding the potential for missing accessory spleens, longer operative times, and increased cost related to laparoscopic versus open splenectomy have been resolved. Laparoscopy is now the approach of choice for elective splenectomy for ITP.[62,63]

In children with ITP, the course is self-limited, with durable and complete remission in greater than 70% of patients regardless of therapy. Because of the good prognosis without treatment, the decision to intervene surgically is controversial and is largely to obviate intracranial hemorrhage discussed

earlier. Thus, children with typical ITP—and certainly those without hemorrhage—are managed principally by observation, with short-term therapy in select cases. Urgent splenectomy, in conjunction with aggressive medical therapy, may play a role in the rare circumstance of severe, life-threatening bleeding in both children and adults.

Thrombotic Thrombocytopenic Purpura. Thrombotic thrombocytopenic purpura (TTP) is a serious disorder characterized by thrombocytopenia, microangiopathic hemolytic anemia, and neurologic complications. Abnormal platelet clumping occurs in arterioles and capillaries, reducing the lumen of these vessels and predisposing the patient to microvascular thrombotic episodes. The reduced lumen size also causes shearing stresses on erythrocytes, which leads to deformed red blood cells subject to hemolysis. Hemolysis may also be due in part to sequestration and destruction of erythrocytes in the spleen. Research has demonstrated that the underlying abnormality is likely related to the persistence of unusually large multimers of von Willebrand factor associated with platelet clumping in the patient's blood.[64,65]

TTP occurs in approximately 3.7 individuals per million, but this rare disorder's dramatic clinical sequelae and favorable response to early therapy demand an understanding of its clinical presentation to ensure an early diagnosis. Clinical features of the disorder include petechiae, fever, neurologic symptoms, renal failure, and, infrequently, cardiac symptoms such as heart failure or arrhythmias. Petechial hemorrhages in the lower extremities are the most common presenting sign. Along with fever, patients may experience flu-like symptoms, malaise, or fatigue. Neurologic changes range from generalized headaches to altered mental status, seizures, and even coma. Generally, however, the mere presence of petechiae and thrombocytopenia is sufficient to lead to the diagnosis of TTP and consideration of treatment.

The diagnosis is confirmed by the peripheral blood smear, which shows schistocytes, nucleated red blood cells, and basophilic stippling. Although other conditions such as tight aortic stenosis or prosthetic valves may lead to the presence of schistocytes, these conditions generally are not accompanied by thrombocytopenia. TTP may be distinguished from autoimmune causes of thrombocytopenia, such as Evans' syndrome (ITP and autoimmune hemolytic anemia) or systemic lupus erythematosus, by a negative result on Coombs' test.

Plasma exchange is the first-line therapy for TTP. This treatment consists of the daily removal of a single volume of the patient's plasma and its replacement with fresh-frozen plasma until the thrombocytopenia, anemia, and associated symptoms are corrected. Therapy is then tapered over 1 to 2 weeks.[51] Splenectomy plays a key role for patients who experience relapse or who require multiple plasma exchanges to control symptoms, and generally is well tolerated without significant morbidity.[65]

Malignant Conditions

White Blood Cell Disorders. The role of splenectomy in patients with white blood cell disorders varies. As for the myelogenous diseases mentioned previously, splenectomy for white blood cell disorders can be effective therapy for symptomatic splenomegaly and hypersplenism, improving some clinical parameters but generally not altering the course of the underlying disease. Historically, splenectomy has played a role during surgical staging for Hodgkin's disease, although this practice has become obsolete with the advent of imaging technologies (CT scan and 18F-fluorodeoxyglucose positron emission tomography [18F-FDG PET]).[66-68] Careful consideration of the intended benefits of splenectomy must be weighed against the significant perioperative and postsplenectomy risks in this often complex patient population.[43]

Hairy Cell Leukemia Hairy cell leukemia (HCL) is an uncommon blood disorder, representing only 2% of all adult leukemias. HCL is characterized by splenomegaly, pancytopenia, and large numbers of abnormal lymphocytes in the bone marrow. These lymphocytes contain irregular hair-like cytoplasmic projections identifiable on the peripheral smear. Many HCL patients have few symptoms and require no specific therapy. Splenectomy does not correct the underlying disorder but does return cell counts to normal in 40% to 70% of patients and alleviates symptoms of splenomegaly. However, with the advent of diverse new drugs (e.g., rituximab, pentostatin, cladribine), splenectomy has become rarely indicated.[69]

Hodgkin's Disease Hodgkin's disease (HD) is a disorder of the lymphoid system characterized by the presence of Reed-Sternberg cells (which actually form the minority of the Hodgkin's tumor). More than 90% of patients with HD present with lymphadenopathy above the diaphragm. Lymph nodes can become particularly bulky in the mediastinum, which may result in shortness of breath, cough, or obstructive pneumonia. Lymphadenopathy below the diaphragm is rare on presentation but can arise with disease progression. The spleen is often an occult site of spread, but massive splenomegaly is not common. In addition, large spleens do not necessarily signify involvement.[67]

Four major histologic types exist: lymphocyte predominance type, nodular sclerosis type, mixed cellularity type, and lymphocyte depletion type. The histologic type, along with location of disease and symptomatology, influence survival for patients with HD. Stage I disease is limited to one anatomic region; stage II disease is defined by the presence of two or more contiguous or noncontiguous regions on the same side of the diaphragm; stage III disease involves disease on both sides of the diaphragm, but limited to lymph nodes, spleen, and Waldeyer's ring (the ring of lymphoid tissue formed by the lingual, palatine, and nasopharyngeal tonsils); and stage IV disease includes involvement of the bone marrow, lung, liver, skin, gastrointestinal tract, or any organ or tissue other than the lymph nodes or Waldeyer's ring.[67]

Staging laparotomy for HD is less commonly performed in the current era of minimally invasive surgery and advanced imaging techniques. More liberal use of diagnostic tools (CT scan and 18F-FDG PET) and chemotherapy for patients with HD has drastically reduced the indications for surgical staging. Current indications for surgical staging include clinical suspicion of lymphoma without evidence of peripheral disease or patients requiring restaging for suspicion of failure after chemotherapy.[67,70]

Non-Hodgkin's Lymphoma Non-Hodgkin's lymphoma (NHL) encompasses all malignancies derived from the lymphoid system except classic HD.[68] A proliferation of any one of the three predominant lymph cell types—natural killer cells, T cells, or B cells—may be included in the category of NHL. Because of the wide net cast by NHL, the clinical presentations of the disorders under its umbrella vary. The subentities of NHL may be clinically classified into nodal or extranodal, as well as indolent, aggressive, and very aggressive groups. Patients with indolent lymphomas may present with mild or no symptoms and seek medical attention for a swollen lymph node, whereas

the aggressive and very aggressive lymphomas create easily noticeable symptoms, such as pain, swelling due to obstruction of vessels, fever, and night sweats. Surgical staging is no longer indicated for NHL, because the combination of history and physical examination, chest radiograph and abdominal/pelvic CT scan, biopsy of involved lymph nodes (including laparoscopically directed nodal and liver biopsies), and bone marrow biopsy is sufficient.[68] Splenomegaly exists in some, but not all, forms of NHL. Splenectomy is indicated in cases where a diagnosis cannot be established by obtaining peripheral tissue and clinical suspicion remains[71,72] or for management of symptoms related to an enlarged spleen as well as for improvement of cytopenias. Splenectomy does not alter the natural history of the disease, but related thrombocytopenia may improve in up to 75% of patients.

5▶

Chronic Lymphocytic Leukemia Chronic lymphocytic leukemia (CCL) is currently considered a subtype of NHL. The main characteristic of CLL is a progressive accumulation of old and nonfunctional lymphocytes.[68,73] Symptoms of CLL are nonspecific and include weakness, fatigue, fever without illness, night sweats, and frequent bacterial and viral infections. The most frequent finding is lymphadenopathy. When the spleen is enlarged, it may be massive or barely palpable below the costal margin. Splenectomy is indicated to improve cytopenias and was shown to be 75% effective in a combined group of patients who had either CLL or nonmalignant HD.[44] Splenectomy may facilitate chemotherapy in patients whose cell counts were prohibitively low before spleen removal. Palliative splenectomy also is indicated for symptomatic splenomegaly.

Bone Marrow Disorders (Myeloproliferative Disorders). The myeloproliferative disorders are characterized by an abnormal growth of cell lines in the bone marrow. They include chronic myeloid leukemia, acute myeloid leukemia, chronic myelomonocytic leukemia, essential thrombocythemia, polycythemia vera, and myelofibrosis, also known as *agnogenic myeloid metaplasia* (see "Myelofibrosis [Agnogenic Myeloid Metaplasia]" later in this chapter). The common underlying problem leading to splenectomy in these disorders is symptomatic splenomegaly. Symptoms due to splenomegaly consist of early satiety, poor gastric emptying, heaviness or pain in the left upper quadrant, and even diarrhea. Hypersplenism, when it occurs in these conditions, usually is associated with splenomegaly. Splenectomy performed in the setting of the myeloproliferative disorders is generally for treatment of the pain, early satiety, and other symptoms of splenomegaly.

Splenomegaly can sometimes be treated nonsurgically by chemotherapeutic agents (busulfan, hydroxyurea, interferon-α) to achieve mild to moderate size reductions and some relief of symptoms, but discontinuation of treatment may result in rapid splenic regrowth. Radiation has been used since 1903 to treat symptomatic splenomegaly, but today it is principally used in situations in which splenectomy is not an option.

Chronic Myeloid Leukemia Chronic myeloid leukemia (CML) is a disorder of the primitive pluripotent stem cells in the bone marrow that results in a significant increase in erythroid, megakaryotic, and pluripotent progenitors in the peripheral blood smear. The genetic hallmark is a transposition between the *bcr* gene on chromosome 9 and the *abl* gene on chromosome 22. CML accounts for 7% to 15% of all leukemias, with an incidence of 1.5 in 100,000 in the United States.[54] It is often asymptomatic, but CML can cause fatigue, anorexia, sweating, and left upper quadrant pain and early satiety secondary to splenomegaly. Enlargement of the spleen is found in roughly one-half of patients with CML. Current therapy includes imatinib or allogeneic stem cell transplantation. Splenectomy is indicated to ease pain and early satiety and does not prevent blast crisis.[55]

Acute Myeloid Leukemia Like CML, acute myeloid leukemia (AML) involves the abnormal growth of stem cells in the bone marrow. Unlike CML, AML has a presentation that is more rapid and dramatic. The proliferation and accumulation of hematopoietic stem cells in the bone marrow and blood inhibit the growth and maturation of normal red blood cells, white blood cells, and platelets. Death usually results within weeks to months if AML goes untreated. The incidence of AML is approximately 9200 new cases each year in the United States, and it accounts for 1.2% of all cancer deaths.[74] Patients with other myeloproliferative disorders, such as polycythemia vera, primary thrombocytosis, or myeloid metaplasia, are at increased risk for leukemic transformation to AML. Presenting signs and symptoms of AML include a viral-like illness with fever, malaise, and frequently bone pain due to the expansion of the medullary space. Standard treatment is combined induction therapy with daunorubicin, cytarabine, and stem cell transplantation. Splenectomy is indicated in AML only in the uncommon circumstance that left upper quadrant pain and early satiety become unbearable. The benefit must be weighed against the heightened risk of postsplenectomy infection in AML patients immunocompromised due to neutropenia and chemotherapy.[74]

Chronic Myelomonocytic Leukemia Like CML and AML, chronic myelomonocytic leukemia (CMML) is characterized by a proliferation of hematopoietic elements in the bone marrow and blood. CMML differs from CML in that it is associated with monocytosis in the peripheral smear ($>1 \times 10^3$ monocytes/mm^3) and in the bone marrow. Splenomegaly occurs in one-half of these patients, and splenectomy can result in symptomatic relief.[75]

Essential Thrombocythemia Essential thrombocythemia (ET) represents abnormal growth of the megakaryocyte cell line, resulting in increased levels of platelets in the bloodstream. The diagnosis is made after the exclusion of other chronic myeloid disorders such as CML, polycythemia vera, and myelofibrosis that may also present with thrombocytosis.[76] Clinical manifestations of ET include vasomotor symptoms, thrombohemorrhagic events, recurrent fetal loss, and the transformation to myelofibrosis with myeloid metaplasia or AML. Hydroxyurea is used to reduce thrombotic events in ET but does not alter transformation to myelofibrosis or leukemia. Splenomegaly occurs in one-third to one-half of patients with ET. Splenectomy is not felt to be helpful in the early stages of ET and is best reserved for the later stages of disease, when myeloid metaplasia has developed.[72] Even in these circumstances, candidates should be chosen selectively, because significant bleeding has been reported to complicate splenectomy in these patients.

Polycythemia Vera Polycythemia vera (PV) is a clonal, chronic, progressive myeloproliferative disorder characterized by an increase in red blood cell mass, frequently accompanied by leukocytosis, thrombocytosis, and splenomegaly. Patients with PV typically enjoy longer survival than those affected by hematologic malignancies but remain at risk for transformation to myelofibrosis or AML. The disease is rare, with an annual incidence of 5 to 17 cases per million population.[76,77] Physical findings include ruddy cyanosis, conjunctival plethora,

hepatomegaly, splenomegaly, and hypertension. Treatment should be tailored to the risk status of the patient and ranges from phlebotomy and aspirin administration to the use of chemotherapeutic agents. As in ET, splenectomy is not helpful in the early stages of disease and is best reserved for patients with late-stage disease in whom myeloid metaplasia has developed and splenomegaly-related symptoms are severe.[76,77]

Myelofibrosis (Agnogenic Myeloid Metaplasia) The term *myelofibrosis* may be used to describe either the generic condition of fibrosis of the bone marrow (which may be associated with a number of benign and malignant disorders) or a specific, chronic, malignant hematologic disease associated with splenomegaly, the presence of red blood cell and white blood cell progenitors in the bloodstream, marrow fibrosis, and extramedullary hematopoiesis, otherwise known as *agnogenic myeloid metaplasia (AMM).* AMM also can be referred to as *myelosclerosis, idiopathic myeloid metaplasia,* and *osteosclerosis.* In this chapter, the term *myelofibrosis* is synonymous with AMM.

In AMM, fibrosis of the bone marrow is believed to be a response to a clonal proliferation of hematopoietic stem cells. Marrow failure is common. The true incidence of AMM is unknown due to the scarcity of epidemiologic data, but one study estimated its U.S. incidence at 1.46 per 100,000 population.[78-80] The diagnosis is made by a careful examination of the peripheral blood smear and bone marrow. Nucleated red blood cells and immature myeloid elements in the blood are present in 96% of cases and strongly suggest the diagnosis. Teardrop poikilocytosis is another frequent finding. Care must be taken, however, to exclude a history of a primary neoplasm (such as lymphoma or adenocarcinoma of the stomach, lung, prostate, or breast) or tuberculosis, because patients with these conditions may develop secondary myelofibrosis.

Treatment depends on symptoms: Asymptomatic patients are closely followed, whereas symptomatic patients undergo therapeutic intervention targeted to their symptoms. The only curative therapy is allogeneic bone marrow transplantation in younger, high-risk patients. Supportive therapy for clinically symptomatic anemia includes steroids, danazol, erythropoietin, or blood transfusion.[78,80] Splenomegaly-related symptoms are best treated with splenectomy. Although some chemotherapeutic agents (busulfan, hydroxyurea, interferon-α) and low-dose radiation can reduce splenic size, their discontinuation usually results in rapid splenic regrowth.

A thorough preoperative workup must precede splenectomy in patients with AMM. The candidate must possess acceptable cardiac, pulmonary, hepatic, and renal reserve for the operation. The coagulation system should be examined; testing should include measurement of coagulation factors V and VIII and fibrin split products, platelet count, and bleeding time. Low platelet counts may require administration of steroids and/or platelet transfusion at the time of surgery. Splenectomy provides durable, effective palliation for nearly all patients with AMM, although postoperative complications are more common in patients with AMM than in those with other hematologic indications. The Mayo Clinic recently published its 30-year experience with 314 myelofibrosis patients who underwent splenectomy. Nearly half of the operations (49%) were performed to alleviate the mechanical symptoms of splenomegaly; the remainder were undertaken to manage anemia, thrombocytopenia, or portal hypertension. Response to splenectomy was 76% overall at 1 year; overall complication rate was 28%, including 21 perioperative deaths.[81] Thrombosis, hemorrhage, and infection complications were common, with preoperative thrombocytopenia an independent predictor of mortality risk. These data underscore the severity of this malignancy and emphasize need for careful patient selection when considering splenectomy in AMM.[79]

Other Diseases of the Spleen

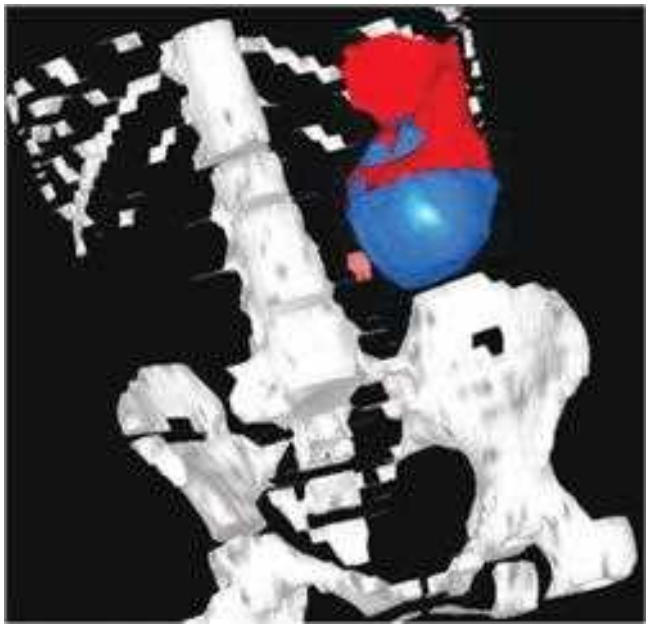
Infections and Abscesses. Primary infections of the spleen are infrequently reported. However, the potential effects of certain systemic infections on the spleen merit close attention, mostly because of the potential risk of spontaneous splenic rupture. Infectious mononucleosis due to either Epstein-Barr virus or cytomegalovirus infection imparts a small but often-discussed risk of spontaneous splenic rupture in both adults and children. The true incidence may be underreported, however. Recent case reports abound in the literature regarding spontaneous splenic rupture due to a variety of infectious causes (malaria, *Listeria* infection, fungal infections, dengue, and Q fever, to name a few) as well as a variety of neoplastic and other noninfectious causes (lymphoma, angiosarcoma, amyloidosis, pregnancy). The presumed pathophysiologic mechanism is infiltration of the splenic parenchyma with inflammatory cells, which distorts the architecture and fibrous support system of the spleen and thins the splenic capsule.[82] In this setting, splenic rupture can occur spontaneously or after a seemingly minor external trauma or even a Valsalva maneuver.

Abscesses of the spleen are uncommon, with an incidence of 0.14% to 0.7% based on autopsy findings.[82] They occur more frequently in tropical locations, where they are associated with thrombosed splenic vessels and infarction in patients with sickle cell anemia. Five distinct mechanisms of splenic abscess formation have been described: (a) hematogenous infection; (b) contiguous infection; (c) hemoglobinopathy; (d) immunosuppression, including HIV infection and chemotherapy; and (e) trauma. Presentation frequently is delayed, with most patients enduring symptoms for 16 to 22 days before diagnosis. Clinical manifestations include fever, left upper quadrant pain, leukocytosis, and splenomegaly in about one-third of patients. The diagnosis is confirmed by ultrasound or CT scan, which has a 95% sensitivity and specificity. The most common organisms in most series are aerobic microbes (streptococci and *Escherichia coli*), but other microorganisms have also been isolated (*Mycobacterium tuberculosis* and *Salmonella typhi*). Upon discovery of a splenic abscess, broad-spectrum antibiotics should be started, with adjustment to more specific therapy based on culture results and continuation of treatment for 14 days. Splenectomy is the operation of choice, but percutaneous and open drainage are options for patients who cannot tolerate splenectomy. Percutaneous drainage is successful for patients with unilocular disease.

Cysts. Splenic cysts (Fig. 34-5) can be categorized according to a number of criteria; one clinically relevant scheme is to characterize splenic cysts as either parasitic or nonparasitic.

Parasitic infection is the most common cause of splenic cysts worldwide, and the majority is due to *Echinococcus* species. Such cysts are more commonly found in areas where the pathogen is endemic. Symptoms, when present, generally are related to the presence of a mass lesion in the left upper quadrant or a lesion that impinges on the stomach. Ultrasound can establish the presence of a cystic lesion and occasionally incidentally detect asymptomatic lesions as well. Serologic testing for echinococcal antibodies can confirm or exclude the cystic lesion as

A



B

C

D

Figure 34-5. **A.** Computed tomography (CT) scan of giant splenic cyst. **B.** Three-dimensional CT reconstruction of splenic cyst. **C and D.** Macroscopic aspect of a multicystic spleen lesion.

parasitic, an important piece of information when planning operative therapy. Symptomatic parasitic cysts are best treated with splenectomy. Avoidance of spillage of parasitic cyst contents into the peritoneal cavity to avoid the possibility of anaphylactic shock is an important principle in surgical management.

Cysts resulting from trauma are termed *pseudocysts* due to their lack of cellular lining. Less common examples of nonparasitic cysts are dermoid, epidermoid, and epithelial cysts.[66] The treatment of nonparasitic cysts depends on whether or not they produce symptoms. Asymptomatic nonparasitic cysts may be observed with close follow-up by ultrasound to exclude significant expansion. Patients should be advised of the risk of cyst rupture with even minor abdominal trauma if they elect nonoperative management for large cysts. Small symptomatic nonparasitic cysts may be excised with splenic preservation, and large symptomatic nonparasitic cysts may be unroofed. Both of these operations may be performed laparoscopically.[66]

Tumors and Metastasis. The most common primary tumor of the spleen is sarcoma. Autopsy studies reveal an approximately 0.6% rate of tumor metastasis to the spleen; most of these metastases are carcinomas. Lung cancer is the tumor that most commonly spreads to the spleen.[83-85]

The spleen is an infrequent site for metastatic deposits and usually appears in cases of widely disseminated disease. In some circumstances, colorectal, ovary, and melanoma metastases can be isolated to the spleen. If after a thorough examination, the isolated splenic metastasis is confirmed, a laparoscopic splenectomy with intact spleen retrieval should be considered.[84,85]

Storage Diseases and Infiltrative Disorders

Gaucher's Disease Gaucher's disease is an inherited lipid storage disorder characterized by the deposition of glucocerebroside in cells of the macrophage-monocyte system. The underlying abnormality is a deficiency in the activity of a lysosomal hydrolase. Abnormal glycolipid storage results in organomegaly, particularly hepatomegaly and splenomegaly.[86,87] Patients with Gaucher's disease frequently experience symptoms related to splenomegaly, including early satiety and abdominal discomfort, and to hypersplenism, including thrombocytopenia, normocytic anemia, and mild leukopenia. These latter findings occur as a result of excessive sequestration of formed blood elements

in the spleen. Other symptoms in patients with Gaucher's disease include bone pain, pathologic fractures, and jaundice. Splenectomy alleviates hematologic abnormalities in patients with hypersplenism, but it does not correct the underlying disease process. Partial splenectomy has been shown to be effective in children to correct both hematologic problems and symptoms due to splenomegaly without incurring the risk of overwhelming postsplenectomy sepsis.

Niemann-Pick Disease Niemann-Pick disease is an inherited disorder of abnormal lysosomal storage of sphingomyelin and cholesterol in cells of the macrophage-monocyte system. Four types of the disease (A, B, C, and D) exist, with unique clinical presentations. Types A and B result from a deficiency in lysosomal hydrolase and are the forms most likely to demonstrate splenomegaly with its concomitant symptoms.

Amyloidosis Amyloidosis is a disorder of abnormal extracellular protein deposition. There are multiple forms of amyloidosis, each with its own individual clinical presentation, and the severity of disease may range from asymptomatic to multiorgan failure. Patients with primary amyloidosis, associated with plasma cell dyscrasia, have splenic involvement in approximately 5% of cases. Secondary amyloidosis, associated with chronic inflammatory conditions, also may present with an enlarged spleen. Symptoms of splenomegaly are relieved by splenectomy.

Sarcoidosis Sarcoidosis is an inflammatory disease of young adults characterized by noncaseating granulomas in affected tissues. Signs and symptoms of the disease range in severity and typically are nonspecific, such as fatigue and malaise. Any organ system may be involved. The most commonly involved organ is the lung, followed by the spleen. Splenomegaly occurs in approximately 25% of patients. Massive splenomegaly (>1 kg) is rare.[69] Other affected tissues include the lymph nodes, eyes, joints, liver, spleen, and heart. When splenomegaly occurs and causes symptoms related to size or hypersplenism, splenectomy effectively relieves symptoms and corrects hematologic abnormalities such as anemia and thrombocytopenia. Spontaneous splenic rupture has been reported in sarcoidosis.[88]

Miscellaneous Disorders and Lesions

Splenic Artery Aneurysm Although splenic artery aneurysm is rare, it is the most common visceral artery aneurysm. Women are four times more likely to be affected than men. The aneurysm usually arises in the middle to distal portion of the splenic artery.[89,90] Indications for treatment include presence of symptoms, pregnancy, intention to become pregnant, and presence of pseudoaneurysms associated with inflammatory processes. Aneurysm resection or ligation alone is acceptable for amenable lesions in the mid-splenic artery, but distal lesions in close proximity to the splenic hilum should be treated with concomitant splenectomy. An excellent prognosis follows elective treatment. Splenic artery embolization has been used to treat splenic artery aneurysm, but painful splenic infarction and abscess may follow.

Portal Hypertension Portal hypertension can result from numerous causes but is usually due to cirrhosis. Splenomegaly and splenic congestion often accompany portal hypertension, which leads to sequestration and destruction of circulating cells in the spleen. Splenectomy is not indicated for hypersplenism per se in patients with portal as there is no correlation between the degree of pancytopenia and long-term survival in these patients.[5] In rare circumstances in which splenectomy is required to reduce bleeding from esophageal varices exacerbated by thrombocytopenia, a concomitant splenorenal shunt procedure should be performed to decompress the portal system.

Portal hypertension secondary to splenic vein thrombosis is potentially curable with splenectomy. Patients with bleeding from isolated gastric varices who have normal liver function test results, especially those with a history of pancreatic disease, should be examined for splenic vein thrombosis and treated with splenectomy if findings are positive.

Felty's Syndrome The triad of rheumatoid arthritis, splenomegaly, and neutropenia is called *Felty's syndrome.* It exists in approximately 3% of all patients with rheumatoid arthritis, two-thirds of whom are women. Immune complexes coat the surface of white blood cells, which leads to their sequestration and clearance in the spleen with subsequent neutropenia. This neutropenia (<2000 neutrophils/mm^3) increases the risk for recurrent infections and often drives the decision for splenectomy. The size of the spleen is variable, from nonpalpable in 5% to 10% of patients to massively enlarged in others. In Felty's syndrome the spleen is four times heavier than normal. Corticosteroids, hematopoietic growth factors, methotrexate, and splenectomy have all been used to treat the neutropenia of Felty's syndrome. Responses to splenectomy have been excellent, with >80% of patients showing a durable increase in white blood cell count. More than one-half of patients who had infections before surgery did not have any infections after splenectomy.[91] Besides symptomatic neutropenia, other indications for splenectomy include transfusion-dependent anemia and profound thrombocytopenia.

Wandering Spleen A very uncommon anatomic abnormality is the "wandering spleen." The spleen "floats" inside the abdominal cavity due to an anomaly of embryogenesis. The wandering spleen is not normally attached to adjacent viscera in the splenic fossa. This may lead to splenic torsion and infarction. Spleen removal or splenopexy is indicated.[92]

PREOPERATIVE CONSIDERATIONS

As part of preoperative discussion prior to splenectomy, patients should be consulted on potential complications associated with this procedure, including overwhelming postsplenectomy sepsis, splenic vein thrombosis, bleeding, arteriothombosis (myocardial infarction, stroke), deep vein thrombosis, and pulmonary hypertension.

Vaccination and Patient Education

Considering that infection is the most common complication, patient education and vaccinations against encapsulated pathogens are the mainstay of preventive therapy.[93,61] Although rare, the most feared and extreme infectious complication is overwhelming postsplenectomy sepsis (OPSS). (See later section, "Overwhelming Postsplenectomy Infection," for detailed discussion.) Patients undergoing splenectomy for hematologic or malignant indications have the greatest risk, whereas patients who undergo splenectomy for trauma or iatrogenic injury have the lowest risk. OPSS is more common in the pediatric population, with 4.4% of children less than 16 years of age versus 0.9% of adults developing this life-threatening condition. The risk has been observed to be the greatest in the first 2 years after splenectomy; however, asplenic patients remain at lifelong risk.[108,109,110] Considering that the spleen is the site for special adaptation of macrophages that target encapsulated organisms, asplenic patients are at higher risk of infection caused by *Streptococcus pneumoniae* (responsible for >50% of OPSS), *H. influenzae* type b, *Neisseria meningitidis,* and *Capnocytophaga canimorsus* (transmitted by dog bites).[111]

In the setting of elective splenectomy, patients should be vaccinated 2 weeks prior to surgery to optimize antigen recognition and processing. If splenectomy is performed emergently, vaccinations can be administered postoperatively and consideration should be given to delaying administration for 2 weeks to avoid the transient immunosuppression associated with surgery. Preoperative and postoperative patient education regarding OPSS is paramount because patients with OPSS may rapidly progress from a febrile illness to circulatory collapse and death within a matter of hours. In one study, 28% of asplenic patients were unaware of the potential infection risks and the main reasons were that correct advice was not given or that that advice was forgotten.[107,108]

The use of currently available vaccines against pneumococcus and other encapsulated organisms has led to a drop in the overall incidence of OPSI to <1%. The mechanism by which vaccination protects asplenic patients is not entirely understood. Serum antibody titers do not necessarily correspond to clinical immunity. Moreover, antibody levels after pneumococcus vaccination decline steadily within 5 to 10 years. Revaccination is reasonably recommended for these patients, although the efficacy of this measure is not proven.[107–111]

Deep Vein Thrombosis Prophylaxis

Deep vein thrombosis (DVT) after splenectomy is not infrequent, especially in cases involving splenomegaly and myeloproliferative disorders.[76] The risk of portal vein thrombosis (PVT) may reach 40% for patients presenting with both splenomegaly and myeloproliferative disorders. Postsplenectomy PVT typically presents with anorexia, abdominal pain, leukocytosis, and thrombocytosis. Effective PVT treatment is possible by maintaining a high index of suspicion, achieving early diagnosis with contrast-enhanced CT, and starting anticoagulation immediately. DVT prophylaxis, including use of sequential compression devices and subcutaneous administration of heparin (5000 U), should be initiated for patients undergoing splenectomy.[8,77] Each patient's risk factors for DVT should be evaluated, and when elevated risk exists (obesity, history of prior venous thromboembolism, known hypercoagulable state, older age), an antithrombotic regimen, including low-molecular-weight heparin, should be pursued.

SPLENECTOMY TECHNIQUES

Patient Preparation

All patients undergoing elective splenectomy should be vaccinated at least 1 week preoperatively with polyvalent pneumococcal, meningococcal, and *Haemophilus* vaccines.[93] Assessment of the potential need for transfusion of blood products and optimization of preoperative coagulation status are necessary. It is the authors' practice to order blood typing and antibody screening tests for normosplenic patients undergoing elective splenectomy. Anemic patients should be transfused before surgery to a hemoglobin level of 10 g/dL. In more complex cases, including patients with splenomegaly, at least 2 to 4 units of cross-matched blood should be available at the time of surgery. Thrombocytopenia may be transiently corrected with platelet transfusions. Thrombocytopenic patients preferably should not undergo transfusion before the day of surgery and ideally not before the intraoperative ligation of the splenic artery.

Patients who have been maintained on corticosteroid therapy preoperatively should receive parenteral corticosteroid therapy perioperatively. Bowel preparation is not routinely performed for patients undergoing elective splenectomy. All splenectomy patients do receive DVT prophylaxis, as discussed previously. After endotracheal intubation, a nasogastric (NG) tube is inserted for stomach decompression.

Open Splenectomy

Although laparoscopic surgery increasingly has achieved acceptance as the standard approach for normosplenic patients requiring splenectomy, open splenectomy (OS) is still widely practiced. Traumatic rupture of the spleen continues as the most common indication for OS. Several other clinical scenarios favor an OS approach, including massive splenomegaly, ascites, portal hypertension, multiple prior operations, extensive splenic irradiation, and possible splenic abscess.

During OS, the patient is placed in the supine position with the surgeon situated at the patient's right. A left subcostal incision paralleling the left costal margin and lying two fingerbreadths below it is preferred for most elective splenectomies. A midline incision is optimal for exposure when the spleen is ruptured or massively enlarged. The spleen is mobilized by dividing ligamentous attachments, usually beginning with the splenocolic ligament (Fig. 34-6). In patients with significant splenomegaly, once lesser sac access has been achieved through either the gastrosplenic or gastrohepatic attachments, ligating the splenic artery in continuity along the superior border of the pancreas may be preferable. This maneuver may serve several purposes: allowing safer manipulation of the spleen and dissection of the splenic hilum, facilitating some shrinkage of the spleen, and providing an autotransfusion of erythrocytes and platelets. Further medial mobilization of the spleen is achieved by incising its lateral peritoneal attachments, most notably the splenophrenic ligament. Then follows individual ligation and sequential division of the short gastric vessels, steps that if carefully executed reduce the risk of these vessels' retracting and bleeding. Splenic hilar dissection then takes place. Whenever possible, care should be taken to dissect and individually ligate the splenic artery and vein (in that order) before dividing

Figure 34-6. Splenocolic ligament is divided at the beginning of open splenectomy.

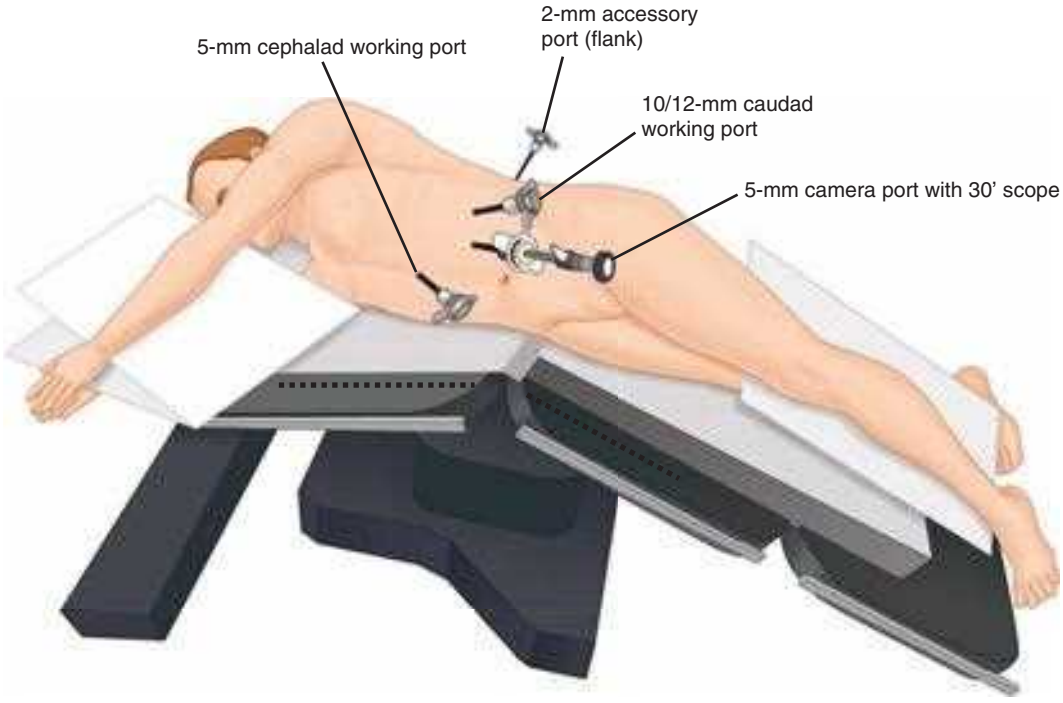


Figure 34-7. Patient positioning and trocar placement for laparoscopic splenectomy.

them. As noted in the discussion of splenic anatomy, the tail of the pancreas lies within 1 cm of the splenic hilum in 75% of patients; therefore, during hilar dissection, great care must be taken to avoid injuring the pancreas.

Once the spleen is excised, hemostasis is secured by irrigating, suctioning, and scrupulously inspecting the bed of dissection. The splenic bed is not routinely drained. A thorough search for accessory spleens must be undertaken when a hematologic disorder has occasioned splenectomy. At the completion of surgery, the nasogastric tube is removed.

Laparoscopic Splenectomy

Laparoscopic splenectomy (LS) has become the procedure of choice over the last two decades, since it has been first described Delaitre and Maignien in 1991.[25] In fact, LS is now the gold standard for elective splenectomy in patients with normal-sized spleens. In experienced hands, LS is associated with decreased intraoperative blood loss, shorter hospital length of stay, and lower morbidity rates when compared to OS.[112,113]

Since the introduction of the lateral approach,[94] most LS procedures are now performed with the patient in the right lateral decubitus position (Fig. 34-7). A midway "double-access" technique in which the patient is in a 45° right lateral decubitus position has also been advocated. This positioning permits concomitant surgery, such as laparoscopic cholecystectomy, more easily than does the lateral approach. The double-access technique requires the placement of five or six trocars. The lateral approach routinely involves the use of three or four trocars positioned as shown in Fig. 34-7. Use of an angled (30° or 45°) laparoscope (2, 5, or 10 mm) greatly facilitates the procedure. Exposure of the vital anatomy in a manner that allows for a more intuitive sequence of dissection, paralleling that of OS, may be considered an additional advantage of the lateral approach.

Placement of trocars in the left upper quadrant should be performed under laparoscopic visualization, particularly if any degree of splenomegaly exists, because the latter can significantly reduce the available operating space. As with OS, the splenocolic ligament and the lateral peritoneal attachments are divided with resultant medial mobilization of the spleen. The short gastric vessels may be divided usually with hemostatic energy sources such as ultrasonic dissection, diathermy, or radiofrequency ablation. With the lower pole of the spleen gently retracted, the splenic hilum is accessible to further applications of clips or an endovascular stapling device. The splenic artery and vein are divided separately when possible. Good long-term outcomes, however, are increasingly being achieved with mass hilar stapling (Fig. 34-8). Using the lateral approach with the spleen thus elevated, the surgeon can easily visualize the tail of the pancreas and avoid injury when placing the endovascular stapler.

Figure 34-8. Splenic hilum can be divided laparoscopically en masse once the spleen has been rotated medially having been mobilized from its lateral attachments.

Once excised, the spleen is placed in a durable ripstop nylon sack (Fig. 34-9), the neck of which is drawn through one of the 10-mm trocar sites. Morcellation of the spleen takes place within the sack and allows piecemeal extraction; a blunt instrument should be used to disrupt and remove the spleen to avoid the risk of sack rupture, spillage of contents, and subsequent splenosis (Fig. 34-10).

Hand-Assisted Splenectomy

When LS is performed in patients with splenomegaly, there have been reports of high rates of both complications and conversion to open splenectomy.[96] Hand-assisted laparoscopic surgery (HALS) has been described as an alternative to the LS approach.[20,95,97] Spleens greater than 22 cm in craniocaudal length or 19 cm in width may benefit from HALS over a purely laparoscopic approach.[97] It has been reported that the use of this technique has resulted in a marked reduction in average operative time for patients with massive splenomegaly (146 vs. 295 minutes). Although HALS does require a small incision (7–8 cm) for hand insertion and specimen extraction, no differences in length of stay were observed when comparing these patients to those managed purely laparoscopically.[97]

When performing HALS splenectomy, patient positioning is similar to that of LS (Fig. 34-11). For patients with massive spleens, lateral positioning is altered slightly, such that the patient is placed supine with the left side elevated at 45°. Depending on the hand dominance of the surgeon, the hand-assist device can be placed in either a midline position for right-hand dominant or a subcostal position for left-hand dominant surgeons. A 7- to 8-cm incision should be made 2 to 4 cm caudal to the inferior pole of the enlarged spleen. The hand-assisted technique allows for a tactile feedback and atraumatic manipulation of the enlarged spleen.

C

Figure 34-11. **A.** Patient table placement for hand-assisted laparoscopic splenectomy (HALS) in case of splenomegaly. **B and C.** Intraoperative images of HALS.

The nondominant hand provides medial retraction and rotation of the spleen through a hand-assist port, while the dominant hand carries out the dissection using laparoscopic instruments. The anterior and posterior attachments of the spleen are taken down as in the laparoscopic approach, and the hilar pedicle is ligated using an endoscopic vascular stapler.

Single-Incision Laparoscopic Surgery Splenectomy

Single-incision laparoscopic surgery (SILS) splenectomy emphasizes the concept of surgery through one small transabdominal incision rather than the standard multiple trocar sites, with theoretical benefits of less pain and better cosmetics. The incision can be hidden periumbilically and is used as the specimen extraction site at the end of the case. This approach for solid organs poses several technical challenges. Since all instruments are closely aligned together, "fencing" of instruments and the laparoscope and limited degrees of movement are commonly encountered. The spleen, being a solid organ, cannot be grasped, and thus retraction may be more challenging in these cases. Furthermore, it has been reported that periumbilical port position may result in technical challenges when dealing with high body mass index or tall patients, precluding the surgeon from adequately reaching the spleen. Other alternatives to single port placements have been reported, although to date, no proven benefits of SILS splenectomy have been demonstrated.[98,114,115]

Robotic Splenectomy

The robotic approach does offer a unique three-dimensional visualization of the surgical field. It is also debated that robotic intervention facilitates movement with higher precision than standard laparoscopy. Otherwise the overall surgical approach to splenectomy is very similar to standard laparoscopy, although not as cost effective. To date, no randomized prospective data are available that show a clear benefit of robotic versus laparoscopic splenectomy.[99,100]

Partial Splenectomy

The past few decades have witnessed ever-widening endorsement for and practice of partial splenectomy. This technique, initially reported in the early eighteenth century, is particularly indicated to minimize the risk of postsplenectomy sepsis in children. Certain lipid storage disorders leading to splenomegaly (e.g., Gaucher's disease) and some forms of traumatic splenic injury (blunt and penetrating) and spherocytosis in children are amenable to treatment with partial splenectomy. Both the laparoscopic and open approaches for partial splenectomy have been well described. The spleen must be adequately mobilized, and the splenic hilar vessels attached to the targeted segment, ligated, and divided. The devascularized segment of spleen is transected along an obvious line of demarcation. Bleeding from the cut surface of the spleen usually is limited and can be controlled by various methods, including cauterization, argon coagulation, or application of direct hemostatic agents such as cellulose gauze and fibrin glue.

Inadvertent Intraoperative Splenic Injury

Inadvertent intraoperative injury to the spleen is a noted occurrence in the surgical literature, familiar to and dreaded by the abdominal surgeon. The true incidence is unknown. The gravity of such injury is not to be underestimated. Significant short-term morbidity is associated with injury to the spleen, including increased blood loss, need for transfusion, and prolonged hospital stay.[102]

7▶

Intraoperative injury to the spleen has been linked with numerous operations, such as gastric fundoplication, colectomy, paraesophageal hernia repair, nephrectomy, and abdominal and pelvic vascular surgery. There are also reports of splenic injuries after endoscopic procedures, such as colonoscopy.

Improper traction on the spleen against its peritoneal attachments is the most common mechanism of intraoperative injury. Capsular tears are the most common type of injury, but parenchymal lacerations and subcapsular hematomas also occur. The lower pole is more commonly injured, owing to its orientation and the greater concentration of peritoneal attachments found here.

As with all hemorrhage, prompt temporary control of bleeding should be obtained by direct compression of the spleen itself, packing of the left upper quadrant, compression of the vessels at the splenic hilum, or pressure on the splenic artery at the superior pancreatic margin. The spleen should then be mobilized from its peritoneal attachments and the nature of the injury assessed. Overall, the patient's condition is the primary determinant of whether splenic salvage can be attempted, although hilar injury is best managed by splenectomy. When dealing with capsular tears (most common injury), strong consideration should be given to splenorrhaphy techniques: application of topical hemostatics, suture plication of disrupted parenchyma with or without omental buttress, and the use of bioabsorbable mesh sheets.

The time-honored surgical tenets of liberal exposure and visualization are particularly germane to the avoidance of splenic injury. Incisions and approaches must be tailored to both patient circumstances and surgeon experience. There is some evidence to support the assertion that use of the laparoscopic approach may reduce the incidence of splenic injury for certain operations. As with all hemorrhage, prompt temporary control of bleeding is required. Direct compression of the spleen itself, packing of the left upper quadrant, compression of the vessels at the splenic hilum, or pressure on the splenic artery at the superior pancreatic margin can slow or stop hemorrhage and allow more deliberate consideration of management options.

The spleen is mobilized from its peritoneal attachments and the nature of the injury assessed. Overall, the patient's condition is the primary determinant of whether splenic salvage can be attempted. The type of injury plays a role as well; it has been suggested that hilar injury is best managed by splenectomy.[80] Barring these unfavorable circumstances, however, and recalling that the majority of intraoperative splenic injuries are capsular tears, it is reasonable to expect that splenic preservation can be achieved in many appropriately selected situations. Presented with one of these situations, the surgeon has at his or her disposal a number of useful and well-described splenorrhaphy techniques: application of topical hemostatics, suture plication of disrupted parenchyma with or without omental buttress, and the use of bioabsorbable mesh sheets.

SPLENECTOMY OUTCOMES

Changes in blood composition resulting from splenectomy include the appearance of Howell-Jolly bodies and siderocytes. After splenectomy, leukocytosis and increased platelet counts are common as well. Although platelet counts most often rise within 2 days, they may not peak for several weeks in patients

with preoperative thrombocytopenia (see "Hematologic Outcomes" later). Similarly, within 1 day after splenectomy, the white blood cell count typically rises, and such elevation may continue for several months.

Complications

Complications of splenectomy may be classified as pulmonary, hemorrhagic, infectious, pancreatic, and thromboembolic.[9,103] Left lower lobe atelectasis is the most common complication after OS; pleural effusion and pneumonia also can occur. Hemorrhage can occur intraoperatively or postoperatively, presenting as subphrenic hematoma. Transfusions have become less common since the advent of LS, although the indication for operation influences the likelihood of transfusion as well. Subphrenic abscess and wound infection are among the perioperative infectious complications. The placement of a drain in the left upper quadrant may be associated with postoperative subphrenic abscess and is not routinely recommended. Pancreatitis, pseudocyst, and pancreatic fistula are among the pancreatic complications that may result from intraoperative trauma to the pancreas during dissection of the splenic hilum.

Hematologic Outcomes

The results of splenectomy may be appraised according to the level of hematologic response (e.g., rise in platelet and hemoglobin levels) in those disorders in which the spleen contributes to the hematologic problem. Hematologic responses may be divided into initial and long-term responses. For thrombocytopenia, an initial response typically is defined as a rise in platelet count within several days of splenectomy. Reported series demonstrate the effectiveness of LS in providing a long-term platelet response in approximately 80% of individuals with ITP (Table 34-3). These results are consistent with the long-term success rate associated with OS.

For chronic hemolytic anemias, a rise in hemoglobin levels to >10 g/dL without the need for transfusion signifies a successful response to splenectomy. By this criterion, splenectomy has been reported to be successful for the vast majority of patients with chronic hemolytic anemia. For hemolytic anemia due to spherocytosis, the success rate is usually higher, ranging from 90% to 100%.

Splenectomy results also may be examined in terms of surgical and postsurgical characteristics, including operative time, recovery time, and morbidity and mortality rates, all of which tend to vary according to hematologic indication[9] (Tables 34-3 and 34-4).

Results of few prospective, randomized trials comparing LS and OS have been published. However, several recent meta-analyses[9,94] of published comparative series including 38 papers with more than 2914 patients indicate that the laparoscopic approach typically results in longer operative times, shorter hospital stays, lower morbidity rates, similar blood loss, and similar mortality rates compared with OS. Questions of the cost effectiveness of LS persist, although analysis of this issue is hindered by a lack of universally accepted metrics as well as a paucity of recent objective data. Proponents of LS argue that the generally higher operating room charges are offset by the reduced hospital stay and presumably shorter time of lost productivity. For those institutions with experienced personnel and technical capability, the laparoscopic approach has emerged as the standard for elective, nontraumatic splenectomy.

Overwhelming Postsplenectomy Infection

Asplenic patients bear an increased susceptibility to infection for the remainder of their lives. Although the overwhelming majority of splenectomized patients experience no ill consequence from the absence of the spleen, the potentially catastrophic consequences of overwhelming postsplenectomy infection (OPSI) demand lifelong vigilance and intimate knowledge of the appropriate precautions and preventative measures. All involved—patients, family members, and physicians—need to play an active role.[17]

Clinical Features. Sepsis in splenectomized patients is a medical emergency. Therefore, any clinical suggestion of infection, including seemingly isolated fevers, must be viewed with a high index of suspicion and treated empirically as thorough investigation proceeds. OPSI may begin with a relatively

Table 34-3

Outcome after splenectomy

mild-appearing prodrome with nonspecific symptoms. In addition to fever, nonspecific symptoms such as malaise, myalgias, headache, vomiting, diarrhea, abdominal pain, and others should be viewed with alarm in the asplenic patient. Absent the spleen, the infectious process signaled by such symptoms can progress rapidly to fulminant bacteremic septic shock, with hypotension, anuria, and disseminated intravascular coagulation. The need for a high index of suspicion, prompt action, and aggressive education of the patient, family, and medical provider cannot be overstated.

The true incidence of OPSI is not precisely known, because defining criteria vary among published series. Overall lifetime risk remains low, ranging from <1% to 5%.[9,17,106,107] Among those who develop OPSI, some characteristics can be identified that impart greater risk. Reason for splenectomy is the single most influential determinant of OPSI risk. Case series demonstrate that those who undergo splenectomy for hematologic disease (malignancy, myelodysplasia, or hemoglobinopathy) are far more susceptible to OPSI than patients who undergo splenectomy for trauma or iatrogenic reasons. Age is also an important consideration, with children 5 years of age or less
8▶ and adults 50 years or older being at elevated risk. Finally, time interval from spleen removal must be considered. A large number of OPSI cases occur many years to decades later. This observation underscores both the threat of this lethal disease and the need for lifelong vigilance.

Microbiology and Pathogenesis. Life-threatening infection in the asplenic patient is attributable to three factors: loss of splenic macrophages, diminished tuftsin production, and loss of the spleen's reticuloendothelial screening function. In the normal host, these three factors work in concert to eliminate opsonized bacteria from the bloodstream. This system is particularly suited to the removal of encapsulated bacteria, whose polysaccharide coating is a natural defense against opsonization (*S. pneumoniae, H. influenzae*, and *N. meningitidis* are classic examples). Infections with protozoa that invade the red blood cell, such as *Babesia microti* (transmitted by tick bites), *Ehrlichia*, and *Plasmodium*, occur more frequently in splenectomized individuals than in normal hosts. Other potential infectious bacterial sources include group A streptococci, *C. canimorsus* (transmitted by dog bites), group B streptococci, *Enterococcus* species, *Bacteroides* species, *Salmonella* species, and *Bartonella* species.[111] In the absence of the spleen, elimination of these pathogens from the bloodstream falls solely to the liver, a process that has been demonstrated to be less effective.[9,107]

Antibiotics and the Asplenic Patient. Antibiotic therapy for the asplenic patient can be considered in three contexts: deliberate therapy for established or presumed infections, prophylaxis in anticipation of invasive procedures (e.g., dental procedures), and general prophylaxis. For the latter two indications, unfortunately, evidence supporting efficacy is scant, and guidelines for antibiotic prophylaxis are not uniform. Optimal
9▶ duration of chemoprophylaxis in children is unclear. Daily doses of antibiotics until 5 years of age or at least 5 years after splenectomy are commonly recommended,[108,109] although some advocate continuation into at least young adulthood. Concerns regarding compliance and bacterial resistance have been raised, which have led some authors to suggest that lifelong daily antibiotic prophylaxis be recommended only for those patients whose antibody titers fail to respond appropriately to vaccination or, alternately, that asplenic patients be advised to carry at all times a reserve supply of antibiotic to be self-admin-
10▶ istered at the earliest sign of infection.[109] Considering the grave consequences of OPSI and its relatively low incidence, controlled trials resulting in meaningful data on this issue seem unlikely to be performed.

Several risk management strategies are commonly recommended to asplenic patients, including wearing a medical bracelet, carrying a laminated medical alert card, possessing a medical letter with specific empiric therapy instructions (including drug names and dosages), and keeping a 5-day supply of standby antibiotics, particularly when travel is anticipated.

chapter 35

Abdominal Wall, Omentum, Mesentery, and Retroperitoneum

Neal E. Seymour and Robert L. Bell

ABDOMINAL WALL

General Considerations

The abdominal wall provides structure, protection, and support for abdominal and retroperitoneal structures and is defined superiorly by the costal margins, inferiorly by the pelvic ring, and posteriorly by the vertebral column. Knowledge of its specific anatomic features is required for management of abdominal wall diseases or during entry into the peritoneal cavity.

Surgical Anatomy

The abdominal wall is an anatomically complex, layered structure with segmentally derived blood supply and innervation (Fig. 35-1). It is mesodermal in origin and develops as bilateral migrating sheets, which originate in the paravertebral region and envelop the future abdominal area. The leading edges of these structures develop into the rectus abdominis muscles, which eventually meet in the anterior midline. The rectus abdominis is longitudinally oriented and encased within an aponeurotic sheath, the layers of which are fused in the midline at the *linea alba.* The rectus insertions are on the pubic bones inferiorly and on the fifth and sixth ribs, as well as the seventh costal cartilages and the xiphoid process superiorly. The lateral border of the rectus muscles has a curved shape identifiable as the surface landmark, the *linea semilunaris.* Three tendinous intersections cross the rectus muscles at the level of the xiphoid process, umbilicus, and about halfway between the xiphoid process and the umbilicus (see Fig. 35-1).

Lateral to the rectus sheath are three muscular layers with oblique fiber orientations relative to one another (Fig. 35-2). These layers are derived from laterally migrating mesodermal tissues during the sixth to seventh week of fetal development. The external oblique muscle runs inferiorly and medially, arising from the margins of the lowest eight ribs and costal cartilages. The external oblique muscles originate on the latissimus dorsi and serratus anterior muscles, as well as on the iliac crest. Medially, the external obliques form a tendinous aponeurosis, which is contiguous with the anterior rectus sheath. The *inguinal ligament* is the inferior-most edge of the external oblique aponeurosis, reflected posteriorly in the area between the anterior superior iliac spine and pubic tubercle. The internal oblique muscle lies deep to the external oblique and arises from the lateral aspect of the inguinal ligament, the iliac crest, and the thoracolumbar fascia. Its fibers course superiorly and medially and form a tendinous aponeurosis that contributes components to both the anterior and posterior rectus sheath. The lower medial and inferior-most fibers of the internal oblique may fuse with the lower fibers of the transversus abdominis muscle (the *conjoined area*). The inferior-most fibers of the internal oblique muscle are contiguous with the cremasteric muscle in the inguinal canal. These relationships are of critical significance in the management of inguinal hernias. The transversus abdominis muscle is the deepest of the three lateral muscles and runs transversely from the lowest six ribs, the lumbosacral fascia, and the iliac crest, to the lateral border of the rectus abdominis. The *arcuate line* (semicircular line of Douglas) lies roughly at the level of the anterior superior iliac spines (Fig. 35-3). Above the arcuate line, the anterior rectus sheath is formed by the external oblique aponeurosis and the external lamina of the internal oblique aponeurosis, whereas the posterior rectus sheath is formed by the internal lamina of the internal oblique aponeurosis and the transversus abdominis aponeurosis. Below the arcuate line, the anterior rectus sheath is formed by the external oblique aponeurosis, the laminae of the internal oblique aponeurosis, and the transversus abdominis aponeurosis. There is no aponeurotic posterior covering of this lower portion of the rectus muscles, although the endoabdominal, or *transversalis*, fascia provides contiguous coverage of the posterior aspect of the abdominal above and below the arcuate line.

1▶

The blood supply to the muscles of the anterior abdominal wall is derived mainly from the superior and inferior epigastric arteries (Fig. 35-4). The superior epigastric artery arises from

Key Points

1. There are important anatomic differences in the rectus sheath structures above and below the arcuate line. The laminae of the internal oblique, which contribute to both the anterior and (along with the transversus abdominis) posterior rectus above the arcuate line, only contribute to the anterior sheath below the arcuate line. There is no aponeurotic posterior covering on the lower portion of the rectus muscles.
2. Rectus diastasis is associated with abdominal wall bulging consequent to separation of the rectus abdominis muscles in the midline. It does not represent a hernia, and surgical interventions for this condition are of questionable, if any, clinical benefit.
3. When resection of abdominal wall desmoid tumors is undertaken, it must be recognized that failure to achieve negative margins is associated with an extremely high risk of local recurrence of the tumor.
4. Primary repair of ventral incisional hernias is associated with unacceptably high failure rates, and repair using other approaches, such as use of prosthetic mesh, is preferred.
5. The addition of the closed videoscopic technique to components separation procedures has been associated with a significant decrease in the incidence of local wound complications.
6. Potential benefits of laparoscopic incisional hernia repairs compared to open repairs with mesh include shorter hospitalization, lower risk of wound complications, and better abdominal wall function. A lower recurrence rate benefit remains controversial.
7. Surgical treatment of sclerosing mesenteritis is most often undertaken to confirm diagnosis and to rule out neoplasm as the cause of a mesenteric mass. Resection possibilities are limited by the extensiveness of the process as well as by the questionable benefit in most cases.
8. Potential surgical interventions in retroperitoneal fibrosis include operative biopsy to rule out neoplasm, ureteral stent placement, open or laparoscopic ureterolysis, and endovascular interventions for iliocaval occlusion.

the internal thoracic artery, while the inferior epigastric artery arises from the external iliac artery. A collateral network of branches of the subcostal and lumbar arteries also contributes the abdominal wall blood supply. The lymphatic drainage of the abdominal wall is predominantly to the major nodal basins in the superficial inguinal and axillary areas.

Anterior abdominal wall innervation is segmental. Motor nerves to the rectus, oblique, and transversus abdominis muscles run from the anterior rami of spinal nerves at the T6 to T12 levels. The overlying skin is innervated by afferent branches of the T4 through L1 nerve roots, with T10 nerve roots providing sensation around the umbilicus (Fig. 35-5).

Physiology

The rectus muscles, external obliques, and internal obliques work as a unit to flex the trunk anteriorly or laterally. Trunk rotation is achieved by simultaneous contraction of a unilateral external oblique and the contralateral internal oblique (e.g.,

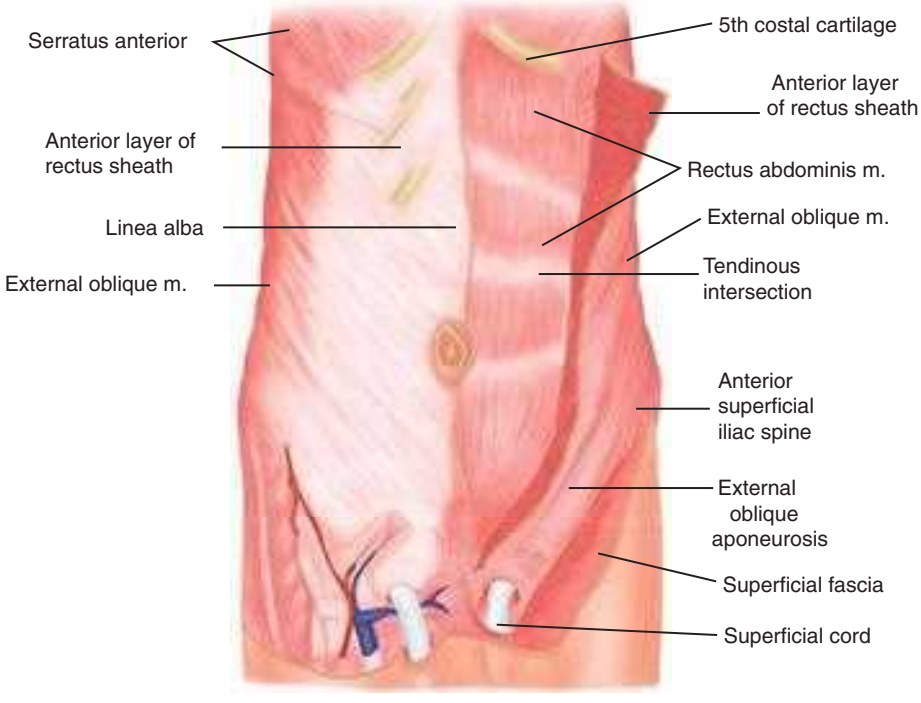

Figure 35-1. Anterior abdominal wall. *Linea alba* is the midline aponeurotic demarcation between the bellies of the rectus abdominis muscles. The rectus abdominis muscle and its tendinous intersections on the left are shown deep to the reflected anterior rectus sheath. *(Reproduced with permission from Moore KL, Dalley AF, eds.* Clinically Oriented Anatomy. *4th ed. Philadelphia: Lippincott Williams & Wilkins; 1999:181.)*

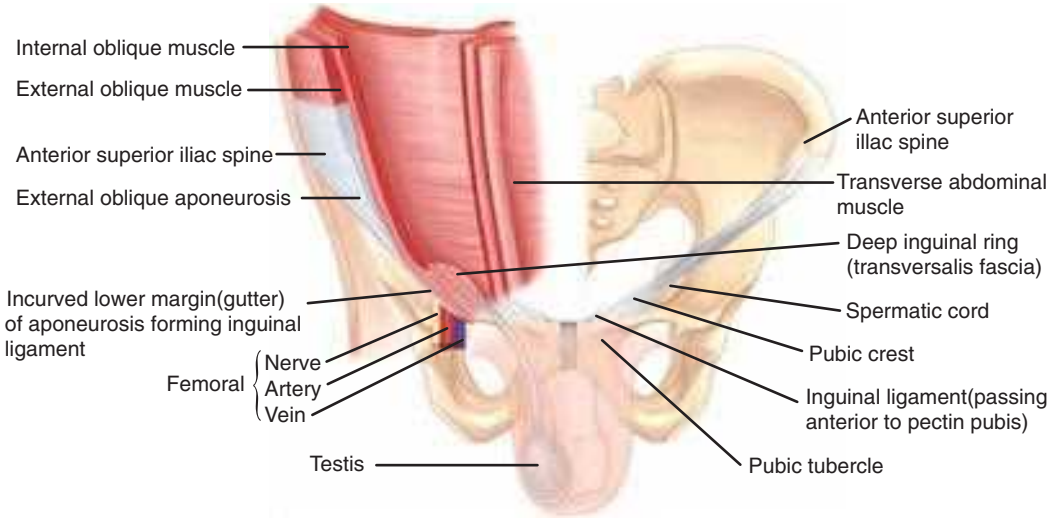

Figure 35-2. The three muscular layers of the abdominal wall lateral to the rectus abdominis are the *external oblique, internal oblique,* and *transversus abdominis* muscles, shown here on the low abdomen, where the lower margin of the external oblique reflects posteriorly as the inguinal ligament. *(Reproduced with permission from Moore KL, Dalley AF, eds.* Clinically Oriented Anatomy. *4th ed. Philadelphia: Lippincott Williams & Wilkins; 1999:181.)*

rotation to the right is produced by contraction of the left external oblique muscle and the right internal oblique). All of the truncal muscles are involved in raising intra-abdominal pressure. Abdominal musculature contraction that occurs when the diaphragm is relaxed will result in expiration of air from the lungs, or a cough if this contraction is forceful. If the diaphragm is contracted when the abdominal musculature is contracted (*Valsalva maneuver*), the increased abdominal pressure aids in processes such as micturition, defecation, and childbirth.

Abdominal Anatomy and Surgical Incisions

Surgeons must deal with the abdominal wall to access pre-, intra-, and retroperitoneal sites. This begs practical questions of where and how to make incisions. Incisions for open surgery are generally located in proximity to the principal operative targets. Laparoscopic port site incisions might be remote from the site of interest and are carefully planned based on the instrument approach angles and working distances both to the operative site and between ports. Orientation of any incision may be determined based on expected quality of exposure, closure considerations including cosmesis, avoidance of previous incision sites, and surgeon preference. In general, incisions for open peritoneal access can be longitudinal (in or off the midline), transverse (lateral to or crossing midline), or oblique (directed either upward or downward toward the flank) (Fig. 35-6). Modifications are numerous and can consist of various extensions to optimize exposure in specific clinical situations. Midline incisions are used for the majority of nonlaparoscopic

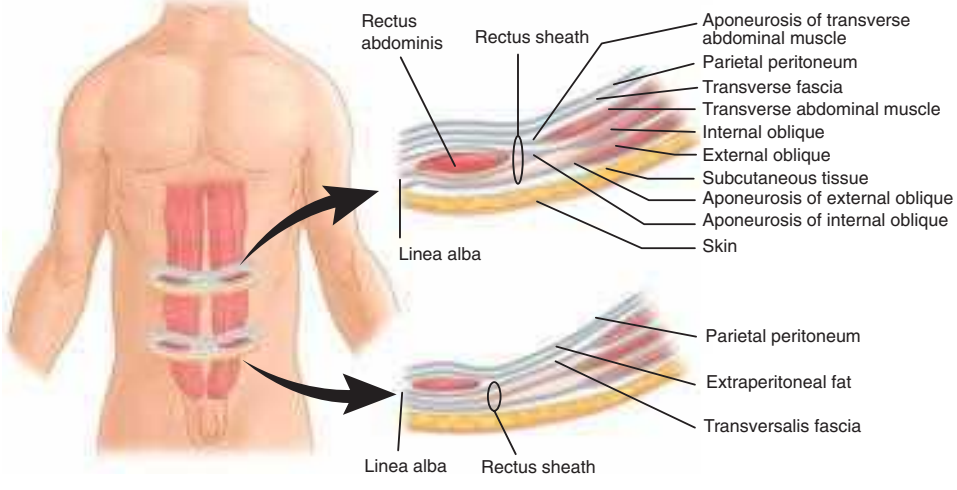

Figure 35-3. Cross-sectional anatomy of the abdominal wall above and below the arcuate line of Douglas. The lower right abdominal wall segment shows clearly the absence of an aponeurotic covering of the posterior aspect of the rectus abdominis muscle inferior to the arcuate line. Superior to the arcuate line, there are both internal oblique and transversus abdominis aponeurotic contributions to the posterior rectus sheath. *(Reproduced with permission from Moore KL, Dalley AF, eds.* Clinically Oriented Anatomy. *4th ed. Philadelphia: Lippincott Williams & Wilkins; 1999:185.)*

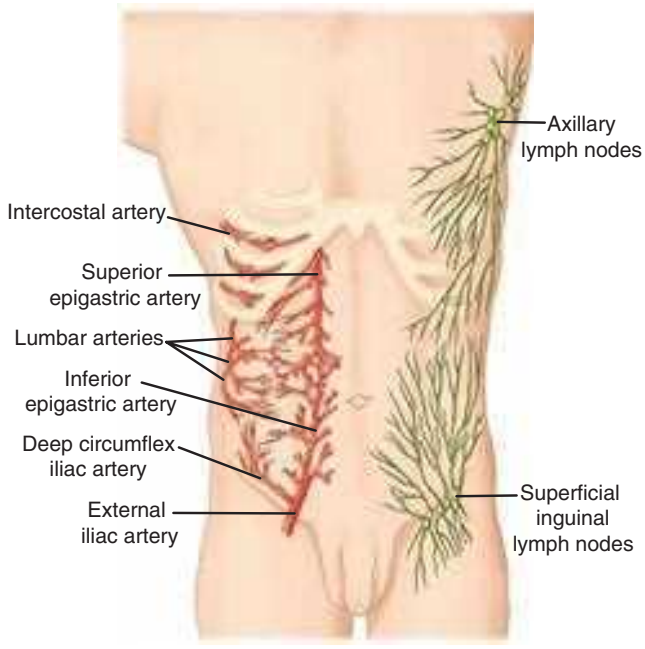

Figure 35-4. The superior and inferior epigastric arteries form an anastomosing network of vessels in and around the rectus sheath, with collateralization to subcostal and lumbar vessels situated more laterally on the abdominal wall. Lymphatic drainage is via axillary or inguinal nodal basins. *(Reproduced with permission from Moore KL, Dalley AF, eds.* Clinically Oriented Anatomy. *4th ed. Philadelphia: Lippincott Williams & Wilkins; 1999:188.)*

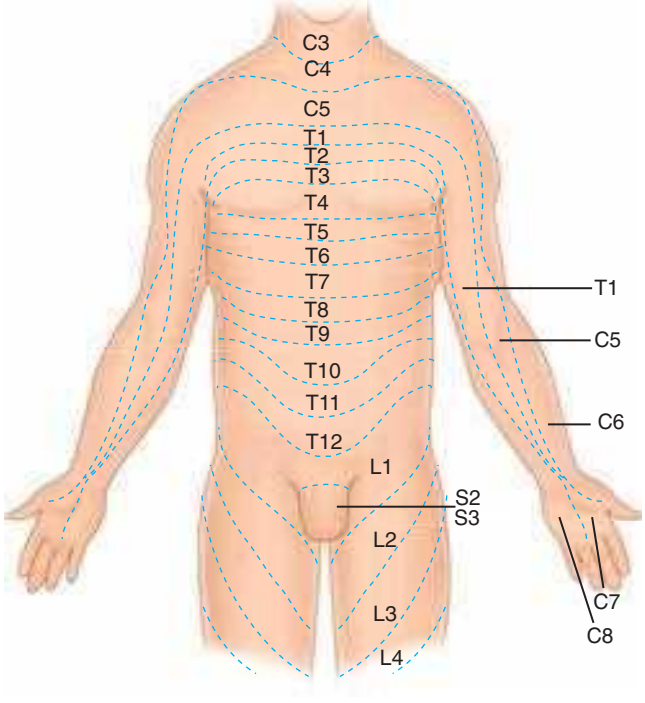

Figure 35-5. Dermatomal sensory innervation of the abdominal wall. *(Reproduced with permission from Moore KL, Dalley AF, eds.* Clinically Oriented Anatomy. *4th ed. Philadelphia: Lippincott Williams & Wilkins; 1999:86.)*

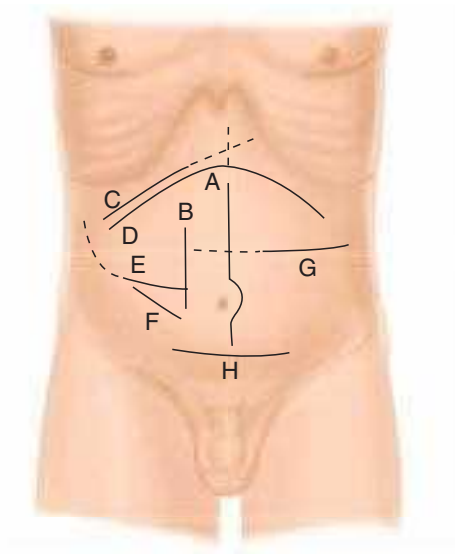

Figure 35-6. Various anterior abdominal wall incisions for exposure of peritoneal structures. *A.* Midline incision; *B.* paramedian incision; *C.* right subcostal incision and "saber slash" extension to costal margin (*dashed line*); *D.* bilateral subcostal (also bucket-handle, chevron, gable) incision and "Mercedes Benz" extension (*dashed line*); *E.* Rocky-Davis incision and Weir extension (*dashed line*); *F.* McBurney incision; *G.* transverse incision and extension across midline (*dashed line*); and *H.* Pfannenstiel incision.

procedures on the gastrointestinal tract. Incising the fused midline aponeurotic tissue of the linea alba is simple and does not injure skeletal muscle. Paramedian incisions through the rectus abdominis sheath structures have largely been abandoned in favor of midline or nonlongitudinal incisions. Incisions lateral to the midline made with transverse or oblique orientations can either divide the successive muscular layers or bluntly separate the fibers. This latter muscle-splitting approach, exemplified by the classic McBurney incision for appendectomy, may be less destructive to tissue but offers more limited exposure. Subcostal incisions on the right (Kocher incision for cholecystectomy) or left (for splenectomy) are archetypal muscle-dividing incisions that result in transection of intervening musculoaponeurotic tissues, including a portion of the rectus abdominis. These incisions are closed in two layers, the more superficial one incorporating the anterior aponeurotic sheath of the rectus medially, transitioning to external oblique muscle and aponeurosis laterally. The posterior, deeper layer consists of internal oblique and transversus abdominis muscle. Similar anatomic considerations are guide closure of transversely oriented muscle-dividing incisions. The Pfannenstiel incision, used commonly for pelvic procedures, is distinguished by transverse skin and anterior rectus sheath incisions, followed by rectus muscle retraction and longitudinal incision of the peritoneum. Irrespective of the incision type, suture apposition of abdominal wall tissues during closure is accomplished without significant tension and with great precision.

Abdominal incisions can lead to short- and long-term complications and patient disability. The question of how large an incision ought to be has no simple answer. In general, it is prudent to make incisions no larger than necessary to safely accomplish the operative goals. Laparoscopic and other minimally invasive surgical methods owe their development in large

Figure 35-7. Bookwalter™ retractor in use for exposure of peritoneal structures during abdominal surgery. Devices of this type are valuable exposure aids that reduce the physical demands on personnel in the operating room and allow more complete focus on the surgical site of interest.

part to the belief that minimizing surgical injury to the abdominal wall is of significant benefit to the patient. For open surgery, a variety of devices are available to retract the abdominal wall and facilitate peritoneal exposure without subjecting the patient to excessively large incisions or surgical personnel to exhausting retraction tasks (Fig. 35-7). Examples include the Bookwalter™, Omni-Tract®, and Thompson retractors.

Congenital Abnormalities

The abdominal wall layers begin to form within in first weeks following conception. In early embryonic development, there is a large central defect through which pass the vitelline (omphalomesenteric) duct and allantois. The vitelline duct connects the embryonic and fetal midgut to the yolk sac. During the sixth week of development, the abdominal contents grow too large for the abdominal wall to completely contain them, and the embryonic midgut herniates into the umbilical cord. While outside the developing abdomen, it undergoes a 270-degree counterclockwise rotation on the developing mesentery. At the end of the twelfth week, it returns to the abdominal cavity. Defects in abdominal wall closure may lead to omphalocele or gastroschisis. In omphalocele, viscera protrude through an open umbilical ring and are covered by a sac derived from the amnion. In gastroschisis, the viscera protrude through a defect lateral to the umbilicus and no sac is present.

During the third trimester, the vitelline duct regresses. Persistence of a vitelline duct remnant on the ileal border results in a *Meckel's diverticulum.* Complete failure of the vitelline duct to regress results in a *vitelline duct fistula,* which is associated with drainage of small intestinal contents from the umbilicus. If both the intestinal and umbilical ends of the vitelline duct regress into fibrous cords, a central *vitelline duct (omphalomesenteric) cyst* may occur. Persistent vitelline duct remnants between the gastrointestinal tract and the anterior abdominal wall may be associated with small intestinal volvulus in neonates. When diagnosed, vitelline duct fistulas and cysts should be excised along with any accompanying fibrous cord.

The urachus is a fibromuscular tubular extension of the allantois that develops with the descent of the bladder to its pelvic position. Persistence of urachal remnants can result in cysts as well as fistulas to the urinary bladder with drainage of urine from the umbilicus. These are treated by urachal excision and closure of any bladder defect that may be present.

Acquired Abnormalities

Rectus Abdominis Diastasis. Rectus abdominis diastasis (or diastasis recti) results from a separation of the two rectus abdominis muscle pillars. This results in the characteristic bulging of the abdominal wall in the epigastrium that is sometimes mistaken for a ventral hernia despite the fact that the midline aponeurosis is intact and no hernia defect is present. Diastasis may be congenital, as a result of a more lateral insertion of the rectus muscles to the ribs and costochondral junctions, but is more typically an acquired condition with advancing age, obesity, or following pregnancy. In the postpartum setting, rectus diastasis tends to occur in women of advanced maternal age, after multiple or twin pregnancies, or in women who deliver high-birth-weight infants. Diastasis is usually easily identified on physical examination (Fig. 35-8). Computed tomography (CT) scanning can provide an accurate measure of the distance between the rectus pillars and will differentiate rectus diastasis from a true ventral hernia if clarification is required. Surgical correction of rectus diastasis by plication of the broad midline aponeurosis has been described for cosmetic indications and for disability of abdominal wall muscular function. However, these approaches introduce the risk of an actual ventral hernia and are of questionable value in addressing any actual pathology.

2▶

Rectus Sheath Hematoma. Hemorrhage from the network of collateralizing vessels within the rectus sheath and muscles can result in a rectus sheath hematoma. Although a history of trauma might be elicited, other less obvious events including sudden contraction of the rectus muscles with coughing, sneezing, or any vigorous physical activity may also cause this condition. Spontaneous rectus sheath hematomas occur most frequently in the elderly and in those on anticoagulation therapy. Patients frequently describe the sudden onset of unilateral abdominal pain that may be confused with lateralized peritoneal disorders such as appendicitis.

Figure 35-8. Diastasis recti visible in the midepigastrium with Valsalva maneuver. The edges of the rectus abdominis muscle, rigid with voluntary contraction, are palpable along the entire length of the bulging area. This should not be mistaken for a ventral hernia.

Figure 35-9. Computed tomography scan showing a medium-sized right rectus sheath hematoma. This occurred in an elderly, anticoagulated patient without a clear history of trauma. Because of its size and the patient's slender body habitus, this hematoma was palpable and could be followed clinically.

History and physical examination alone may be diagnostic. Pain typically increases with contraction of the rectus muscles, and a tender mass may be palpated. The ability to appreciate an intra-abdominal mass is ordinarily degraded with contraction of the rectus muscles. *Fothergill's sign* is a palpable abdominal mass that remains unchanged with contraction of the rectus muscles and is classically associated with rectus hematoma. A hemoglobin/hematocrit level and coagulation studies should be obtained. Both ultrasonography and CT (Fig. 35-9) can provide confirmatory imaging information and exclude other disorders.

Specific treatment depends on the severity of the hemorrhage. Small, unilateral, and stable hematomas may be observed without hospitalization. Bilateral or large hematomas will likely require hospitalization, as well as potential resuscitation. Transfusion or coagulation factor replacement may be indicated in some situations. Angiographic embolization is required infrequently, but may be necessary if hematoma enlargement, free bleeding, or clinical deterioration occurs. Surgical therapy is used in the rare situations of failed angiographic treatment or hemodynamic instability that precludes any other options. The operative goals are evacuation of the hematoma and ligation of any bleeding vessel identified. Mortality in this condition is rare, but has been reported in patients requiring surgical treatment and in the elderly.

Desmoid Tumors. Desmoid tumors of the abdominal wall are fibrous neoplasms originating from the musculoaponeurotic structures of the anterior abdomen. They are also referred to collectively as *aggressive fibrosis*, a term that describes their aggressive and infiltrative local behavior. They do not have metastatic potential, and although there is marked cellularity in biopsy specimens, there are no specific histologic characteristics that suggest malignancy, per se. Desmoid tumors of the abdominal wall have a slight female predominance and occur either sporadically or in the setting of familial adenomatous polyposis (FAP), with the greatest risk incurred in Gardner's syndrome. As many as 10% to 15% of FAP patients develop desmoid tumors of the abdominal wall, abdomen, or retroperitoneum, and this condition can account for patient mortality from complications of aggressive local growth. In non-FAP settings, abdominal wall desmoids occur most frequently in postpartum women or in surgical scars. Radical resection with frozen section margins and immediate mesh reconstruction of any consequent abdominal wall defect is the most commonly recommended treatment. Involvement of margins is associated with recurrence rates as high as 80%. Extensive infiltration and involvement of peritoneal structures frequently makes desmoid resection technically unfeasible. Medical treatment with an antineoplastic agent such as doxorubicin, dacarbazine, or carboplatin can produce remission for variable periods in up to 50% of patients, although the prognosis of advanced desmoids, particularly in FAP, is poor, with a 5-year mortality rate as high as 50% reported. Combined medical treatments and the addition of imatinib have been used with some success in small numbers of patients; radiation therapy has been used in both adjuvant and palliative roles with high response rates.

3▶

Other Abdominal Wall Tumors. The abdominal wall may be the site of various benign neoplasms including lipomas and neurofibromas. Surgical treatment is not always mandatory, but local excision is recommended for symptomatic or enlarging lesions. Primary abdominal wall malignancies are exceedingly rare and include subtypes of sarcomas (leiomyosarcoma, malignant fibrous histiocytoma, fibrosarcoma, liposarcoma, and rhabdomyosarcoma), dermatofibrosarcoma protuberans, schwannoma, and melanoma. Magnetic resonance imaging (MRI) or CT is used for tumor staging, and chest CT should be included to rule out pulmonary metastases. These studies define the extent of the tumor and involvement of contiguous structures in anticipation of surgical treatment. Prior to surgery for abdominal wall sarcomas, a core needle biopsy is generally obtained (with image guidance if needed). Once the diagnosis is established, treatment consists of resection with tumor-free margins, applying the same general principles used for extremity sarcoma resection. Meticulous dissection avoiding violation of tumor capsule and maintaining margins greater than 2 cm, if possible, are essential considerations. Extensive resection may leave a considerable abdominal wall defect that will have to be reconstructed. Immediate reconstruction with mesh and/or wound coverage with rotational or free myocutaneous flaps are the best options if primary closure is not feasible. Although these tumors are frequently described as radiation- and chemotherapy-resistant, both modalities have been used in advanced cases in both adjuvant and palliative settings. The very limited experience in these rare conditions makes commentary on the effectiveness of these therapies difficult.

Abdominal wall resection may also be required with contiguous involvement of gastrointestinal or gynecologic malignancies. Primary closure may be feasible, but prosthetic mesh use (even in the setting of bowel resection), absorbable or biologic mesh reinforcement, and myocutaneous flap reconstruction are also options.

Abdominal Wall Hernias. Hernias of the anterior abdominal wall, or *ventral* hernias, represent defects in the parietal abdominal wall fascia and muscle through which intra-abdominal or preperitoneal contents can protrude. Ventral hernias may be congenital or acquired. Acquired hernias may develop via slow architectural deterioration of the musculoaponeurotic tissues, or they may develop from failed healing of an anterior abdominal

wall incision (*incisional hernia*). The most common finding is a mass or bulge, which may increase in size with Valsalva. Ventral hernias may be asymptomatic or cause a considerable degree of discomfort and will generally enlarge over time. Physical examination reveals a bulge on the anterior abdominal wall that may reduce spontaneously, with recumbency, or with manual pressure. A hernia that cannot be reduced is described as *incarcerated* and generally requires surgical correction. Incarceration of an intestinal segment may be accompanied by nausea, vomiting, and significant pain, and is a true surgical emergency. If the blood supply to the incarcerated bowel is compromised, the hernia is described as *strangulated,* and the localized ischemia may lead to infarction and perforation.

Primary ventral hernias (nonincisional) are generally named according to their anatomic location. *Epigastric* hernias are located in the midline between the xiphoid process and the umbilicus. They are generally small and may be multiple, and at elective repair, they are usually found to contain omentum or a portion of the falciform ligament. These may be congenital and due to defective midline fusion of developing lateral abdominal wall elements.

Umbilical hernias occur at the umbilical ring and may be present at birth or develop later in life. Umbilical hernias are present in approximately 10% of all newborns and are more common in premature infants. Most congenital umbilical hernias close spontaneously by 5 years. If closure does not occur, elective surgical repair is usually advised. Adults with small, asymptomatic umbilical hernias should be followed clinically. Surgical treatment is offered if a hernia is observed to enlarge or is associated with symptoms, or if incarceration occurs. Surgical treatment can consist of primary sutured repair or placement of prosthetic mesh for larger defects (>2 cm) using open or laparoscopic methods.

Patients with advanced liver disease, ascites, and umbilical hernia require special consideration. Enlargement of the umbilical ring usually occurs in this clinical situation as a result of increased intra-abdominal pressure from uncontrolled ascites. First line of therapy is aggressive medical correction of the ascites and paracentesis for tense ascites with respiratory compromise. These hernias are usually filled with ascitic fluid, but omentum or bowel may enter the defect after large-volume paracentesis. Uncontrolled ascites may lead to skin breakdown on the protuberant hernia and eventual ascitic leak, which can predispose the patient to bacterial peritonitis. Patients with refractory ascites may be candidates for transjugular intrahepatic portocaval shunt (TIPS) or eventual liver transplantation. Umbilical hernia repair should be deferred until after the ascites is controlled.

Spigelian hernias can occur anywhere along the length of the Spigelian line or zone—an aponeurotic band of variable width at the lateral border of the rectus abdominis. However, the most frequent location of these rare hernias is at or slightly above the level of the arcuate line. These are not always clinically evident as a bulge and may come to medical attention because of pain or incarceration. The largest review of surgical management of these hernias suggests that the risk of incarceration is as high as 17% at the time of diagnosis. This has been cited as a justification for mandatory repair of Spigelian hernias after they have been diagnosed. Repair may be accomplished with either open or laparoscopic procedures.

Incisional Hernias. As many as 10% to 20% of patients may eventually develop hernias at incision sites following open abdominal surgery. The etiology of any given case of incisional hernia can be difficult to determine. Obesity, primary wound healing defects, multiple prior procedures, prior incisional hernias, and technical errors during repair may all be contributory. Repair of incisional hernias can be technically challenging, and a myriad of methods have been described. The most important distinctions in surgical management of incisional hernias are primary versus mesh repair and open versus laparoscopic repair.

Primary repairs of incisional hernia include both simple suture closure and components separation. Primary repair by simple suture approximation, even for small hernias (defects <3 cm), is associated with high reported hernia recurrence rates. In a randomized prospective study of open primary and open mesh incisional hernia repairs in 200 patients, investigators from the Netherlands found that after 3 years, recurrence rates were 43% and 24%, respectively. Risk factors for recurrence were primary suture repair, postoperative wound infection, prostate problems, and surgery for abdominal aortic aneurysm.

4▶

In an effort to decrease suture line tension associated with primary repair, Ramirez described the components separation technique in 1990. This procedure entailed creation of large subcutaneous flaps lateral to the fascial defect followed by bilateral incision of the external oblique aponeuroses and, if necessary, incision of the posterior rectus sheaths bilaterally. The net effect is up to 10 cm of medial mobilization of the rectus muscles allowing for primary apposition of the fascia. Early reports of components separation demonstrated a high wound infection rate (20%) and an 18.2% hernia recurrence rate at 1 year. However, as the technique evolved, an improved understanding of key operative elements, including maximal preservation of the rectus perforator vessels and minimal dissection of the subcutaneous tissues, has led to fewer postoperative wound complications. In recent years, further modifications have included the endoscopic components separation technique as well as the addition of mesh reinforcement to primary fascial edge closure. Using the former closed technique with videoscopic control, effective external oblique division is achieved without creation of extensive subcutaneous flaps. This has been shown to dramatically decrease wound complications associated with the open procedure. The use of either permanent implant or biologic materials with components separation may lead to a hernia recurrence rate as low as 4% at 1 year of follow-up.

5▶

Mesh repair has become the standard in the elective management of most incisional hernias. Mesh can be placed as an *underlay* deep to the fascial defect (intra- or preperitoneal), an *interlay* either bridging the gap between the defect edges or within the abdominal wall musculoaponeurotic layers (intraparietal), or an *onlay* (superficial to the fascial defect). Laparoscopic repairs use an underlay technique. Each mesh material type has specific density, porosity, and strength characteristics. Some of the commercially available meshes for incisional hernia repair are listed in Table 35-1. Permanent mesh implants are made of prosthetic materials that do not degrade over time. Their principal advantages are ease of use, relatively low cost, and durability. Absorbable meshes are degraded and eliminated from tissues, gradually losing the structural integrity needed for tissue support. They can be useful for temporary abdominal wall closure in contaminated or infected fields but will eventually leave patients with an incisional hernia. Biologic meshes are prepared from collagen-rich porcine, bovine, or human tissues from which all antigenic cellular materials have been removed. These can also be chemically treated to crosslink collagen molecules, increasing strength and durability at the cost of some

Table 35-1

Commercially available meshes for incisional hernia repair

PROPRIETARY NAME	COMPOSITION
Prosthetic meshes	
Parietex	Polyester/collagen film
Composix	Polypropylene/ePTFE
DualMesh, Dulex, MotifMESH	ePTFE
Prolene, Surgipro, ProLite	Polypropylene
Proceed, Physiomesh	Polypropylene/polydioxanone
Sepramesh IP	Polypropylene/hyaluronate gel
C-Qur	Polypropylene/omega-3 fatty acid
TiMESH	Polypropylene/titanium
Biologic meshes	
Surgisis Gold	Porcine small intestine submucosa
AlloDerm	Human dermis
SurgiMend	Fetal bovine dermis
CollaMend	Porcine dermis
AlloMax	Human dermis
Strattice	Porcine dermis
Veritas	Bovine pericardium
Absorbable meshes	
Gore Bio-A	Polyglycolide/trimethylene carbonate
Vicryl	Polyglactin 910
Dexon	Polyglycolic acid

ePTFE = expanded polytetrafluoroethylene.

impairment in host cellular ingrowth. Over time, biologic mesh-derived collagen is incorporated into the host tissue, remodeled, and eventually replaced by host collagen. These characteristics may be useful in the setting of contaminated or infected fields. However, when used to bridge ventral hernia defects, biologic meshes are associated with excessively high hernia recurrence rates and ought to be reserved for tissue reinforcement rather than replacement. Newer prosthetic absorbable mesh materials are now available that share some of the characteristics of biologics (e.g., host tissue ingrowth and replacement with collagen) and can also be used for reinforcement of primary closure at a considerably lower cost.

In recent years, the trend toward use of minimally invasive surgical methods has exerted a great influence on incisional hernia management. However, open repairs continue to be performed extensively, mostly using a mesh underlay technique, often with extensive dissection of a preperitoneal space to accommodate a large sheet of polypropylene or woven polyester mesh. This method isolates mesh from the peritoneal contents. Although the implications of direct mesh contact with peritoneal structures is somewhat controversial, dense adhesions to intestine may complicate reoperation, and at least anecdotally may predispose to erosion and fistulization even without a concomitant bowel resection. Meshes with adhesion barrier coatings of fish oil, oxidized cellulose, or hyaluronic acid have been offered as solutions for this concern. Expanded polytetrafluoroethylene (ePTFE) prostheses are also used if contact with peritoneal structures is unavoidable because this material tends not to be associated with development of dense adhesions.

Laparoscopic incisional hernia repair was first described by LeBlanc and Booth in 1993. Since that time, numerous studies have examined early and late results compared to open repair. In 2000, data from 407 patients undergoing laparoscopic incisional hernia as part of a multicenter trial revealed a recurrence rate of only 3.4%, with a mean follow-up of more than 2 years. Of the recurrences noted, the vast majority were felt to be secondary to technical errors committed early in the surgeons' experience that were avoided during the later cases. Studies using pooled multicenter data or meta-analyses of published reports have tended to strongly favor laparoscopic incisional hernia repairs based on fewer wound complications, fewer overall complications, and lower recurrence rates when compared to the open technique. Authors speculate that these benefits are achieved by eliminating repeated abdominal incisions and improving detection of unsuspected secondary defects that might not otherwise be appreciated during open repair. However, a recent Cochrane database review of studies totaling 880 cases and including the results from 10 randomized controlled trials concluded that short-term recurrence rates did not differ significantly and laparoscopic repairs were associated with higher in-hospital costs despite generally shorter lengths of stay. The major benefit for laparoscopic repairs compared to open repairs was a consistently lower risk of wound infections. In a recent multicenter randomized trial, in addition to lower infection rates, superior early physical function was also demonstrated very early after laparoscopic repairs compared to open repair.

6▶

The technique of laparoscopic incisional hernia repair generally involves laterally placed ports for midline defects and contralaterally placed ports for lateral defects. All adhesions to the anterior abdominal wall are divided, taking great care not to injure the intestine either directly or with thermal or electrical energy. The contents of the hernia sac are completely reduced, but in contrast to open repairs, the sac itself is left in situ. Once the area encompassing all fascial defects is defined, a mesh is fashioned to allow for sufficient overlap (at least 4 cm) under the healthy abdominal wall. After insertion into the abdomen, the mesh is fixed into position with transfascial sutures, placed circumferentially around the mesh, and spiral tacks are placed according to surgeon preference (Fig. 35-10). It has been proposed that transfascial sutures contribute to excessive postoperative pain, and some surgeons have eliminated them from the aforementioned technique, relying solely on spiral tacks for the strength of the repair. LeBlanc reviewed the utility of transfascial sutures and recommended a minimum 5-cm overlap of mesh from defect edge if transfascial sutures are not used.

OMENTUM

Surgical Anatomy

The greater omentum and lesser omentum are fibrofatty aprons that provide support, coverage, and protection of peritoneal contents.

Figure 35-10. Intraperitoneal view of expanded polytetrafluoroethylene mesh used for laparoscopic ventral incisional hernia repair. The mesh is in place on the posterior aspect of the abdominal wall without apparent laxity due to the ongoing carbon dioxide insufflation. Once pneumoperitoneum is released, sufficient laxity is introduced to relieve any pull at the fixation points and to permit good apposition of mesh to the abdominal wall surface.

These structures begin to develop during the fourth week of gestation. The greater omentum develops from the dorsal mesogastrium, which begins as a double-layered structure. The spleen develops in between the two layers, and later in development, the two layers fuse, giving rise to the intraperitoneal spleen and the gastrosplenic ligament. The fused layers then hang from the greater curvature of the stomach and drape over the transverse colon, to which its posterior surface becomes fixed. The gastrocolic ligament and the gastrosplenic ligament are those segments of the greater omental apron that connect the named structures. In the adult, the greater omentum lies in between the anterior abdominal wall and the hollow viscera and usually extends into the pelvis.

The lesser omentum, otherwise known as the hepatoduodenal and hepatogastric ligaments, develops from the mesoderm of the septum transversum, which connects the embryonic liver to the foregut. The common bile duct, portal vein, and hepatic artery are located in the inferolateral margin of the lesser omentum, which also forms the anterior border of the foramen of Winslow.

The blood supply to the greater omentum is derived from the right and left gastroepiploic arteries. The venous drainage parallels the arterial supply to a great extent, with the left and right gastroepiploic veins ultimately draining into the portal system.

Physiology

In the early twentieth century, the British surgeon Rutherford Morison noted that the omentum tended to wall off areas of infection and limit the spread of intraperitoneal contamination. He termed the omentum the "abdominal policeman." Shortly after his description was published, several reports suggested intrinsic hemostatic characteristics of the omentum. In 1996, researchers from the Netherlands demonstrated that the concentration of tissue factor in omentum is over twice the amount per gram of that found in muscle. This facilitates activation of coagulation at sites of inflammation, ischemia, infection, or trauma within the peritoneal cavity. The consequent local production of fibrin contributes to the ability of the omentum to adhere to areas of injury or inflammation.

Omental Infarction

Interruption of the blood supply to the omentum is a rare cause of an acute abdomen that may be secondary to torsion of the omentum around its vascular pedicle, thrombosis or vasculitis of the omental vessels, or omental venous outflow obstruction. Fewer than 100 cases have been reported, and the diagnosis is most likely to be made in male adults. Depending on the location of the infarcted omental tissue, this disease process may mimic appendicitis, cholecystitis, diverticulitis, perforated peptic ulcer, or ruptured ovarian cyst, with abdominal pain and tenderness typical at locations typical for these conditions. Abdominal examination may reveal a tender, palpable mass. The diagnosis is generally inferred from abdominal CT or ultrasonography, which shows a localized inflammatory mass of fat density. In patients with convincing imaging who are clinically stable without signs of worsening peritonitis, supportive care is sufficient. However, some cases may be indistinguishable from more worrisome surgical conditions. In these instances, laparoscopic exploration can establish an accurate diagnosis and permit resection of the infarcted tissue, which should result in rapid resolution of symptoms.

Omental Cysts

Cystic lesions of the omentum and mesentery are related disorders, likely resulting from either peritoneal inclusions or degeneration of lymphatic structures. Omental cysts are far less common than mesenteric cysts. Omental cysts may present as an asymptomatic abdominal mass or may cause abdominal pain with or without appreciable mass or distention. Physical examination may reveal a freely mobile intra-abdominal mass. Both CT and abdominal ultrasound reveal a well-circumscribed, cystic-mass lesion arising from the greater omentum. Treatment involves resection of all symptomatic omental cysts. Resection of these benign lesions is readily accomplished using laparoscopic techniques.

Omental Neoplasms

Primary tumors of the omentum are rare. Benign tumors of the omentum include lipomas, myxomas, and desmoid tumors. Primary malignant tumors of the omentum are usually mesodermally derived and may share immunohistochemical characteristics of gastrointestinal stromal tumors including c-kit immunopositivity. Metastatic tumors of the omentum are common, with metastatic ovarian cancer having the highest preponderance of omental involvement. Cancers of any portion of the gastrointestinal tract, as well as melanoma, uterus, and kidney cancer, may also metastasize to the omentum.

MESENTERY

Surgical Anatomy

The small and large intestinal mesenteries serve as the major pathways for arterial, venous, lymphatic, and neural structures to course to and from the bowel. Mesenteric tissues develop from embryonic dorsal mesentery that attaches the foregut, midgut, and hindgut to the posterior abdominal wall. The dorsal mesentery becomes the greater omentum proximally, the small intestinal mesentery in the region of the jejunum and ileum, and

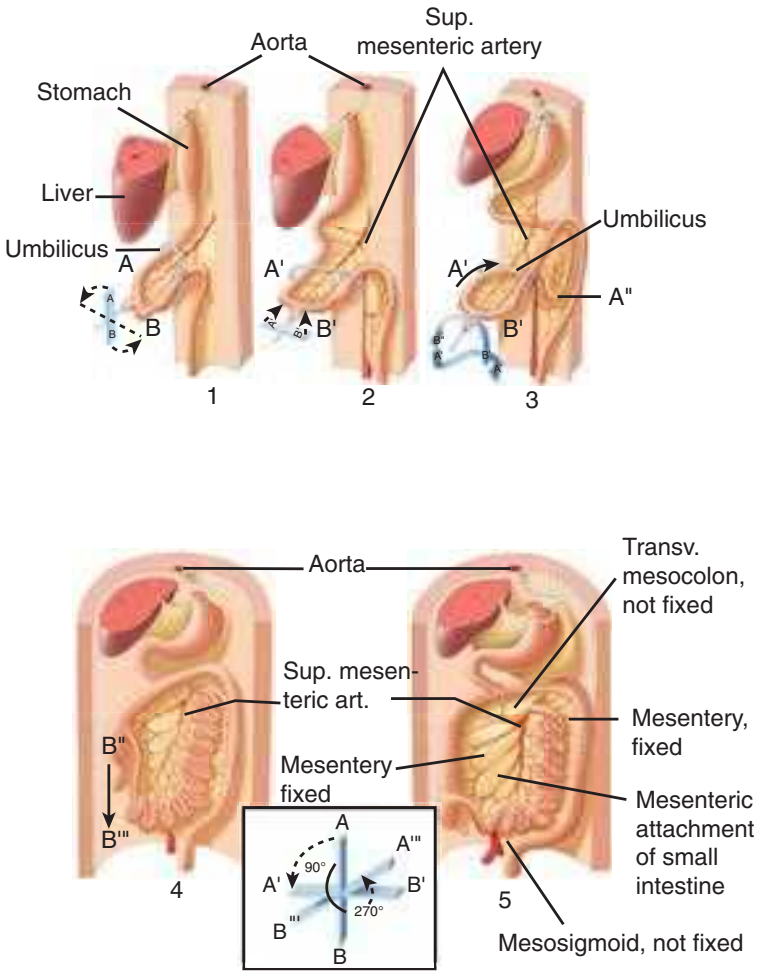

Figure 35-11. Rotational events during gastrointestinal (GI) tract development in the fetus result in the final positioning of the GI tract segments and anatomic relationships of intestinal mesentery to the retroperitoneum. The cecum, designated "B," can be followed during the course of the 270-degree counterclockwise rotation of the mesentery to its right lower quadrant position. During the course of these events, the duodenum and right and left colon segments and their mesenteries become affixed to the retroperitoneum, leaving the small intestine and sigmoid colon mobile on their respective mesenteries. *(*Reproduced with permission from Healy JE, Hodge J (eds). *Surgical Anatomy, 2nd ed*. Toronto: BC Decker, 1990:151.*)*

the mesocolon in the region of the colon. During fetal development, after the herniated and 270-degree rotated midgut returns to its intraperitoneal location, the reduced mesentery achieves its final fixation state. The duodenum and lateral colon segments become fixed to the retroperitoneum, whereas the small intestinal mesentery, transverse colon mesentery, and sigmoid colon mesentery remain mobile (Fig. 35-11). Defects in these normal developmental steps starting with midgut rotation result in the spectrum of disorders associated with midgut malrotation. The related anatomic anomalies of the mesentery include paraduodenal or mesocolic hernias (Fig. 35-12), which can present as chronic or acute intestinal obstruction in children or adults.

Sclerosing Mesenteritis

Sclerosing mesenteritis, also referred to as retractile mesenteritis, mesenteric panniculitis, or mesenteric lipodystrophy, is an inflammatory and fibrotic process involving the intestinal mesentery. There is no gender or race predominance, but the condition is most commonly diagnosed in individuals older than 50 years of age.

The etiology of this process is unknown, but its cardinal feature is increased tissue density within the mesentery. This can be localized and associated with a discrete nonneoplastic mesenteric mass, or it can be more diffuse, sometimes involving large swaths of mesentery without well-defined borders. There may be varying relative degrees of fat tissue degeneration, inflammation, and fibrosis on histologic examination, giving rise to the various terms used to describe this condition. It is not clear if these variations represent stages in a sequential process or differences in basic pathobiology. Abdominal pain is the most frequent presenting symptom, followed by the presence of

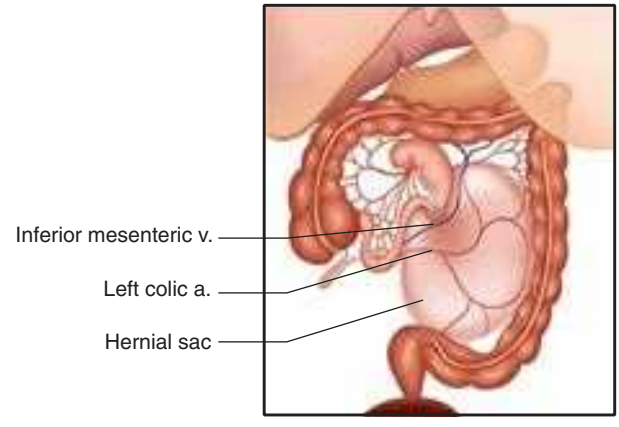

Figure 35-12. Mesocolic hernia of small bowel into a retrocolic hernia sac posterior to the descending colon mesentery. Hernias of this type, as well as hernias into paraduodenal recesses, result from abnormal fixation of mesenteric structures during the course of intestinal rotation. *(Reproduced with permission from Healy JE, Hodge J, eds.* Surgical Anatomy. *2nd ed. Toronto: BC Decker; 1990:153.)*

Figure 35-13. Computed tomography scan of sclerosing mesenteritis (mesenteric lipodystrophy). This condition cannot easily be distinguished from a neoplasm of the mesentery on radiologic study. In this case, the study showed "fatty mesenteric tumor with involvement of mesenteric vessels," and "mesenteric lipodystrophy" was demonstrated by biopsy at exploration. The finding of a "hyperattenuating stripe" around the lesion, as seen in this image, has been associated with the mesenteritis diagnosis.

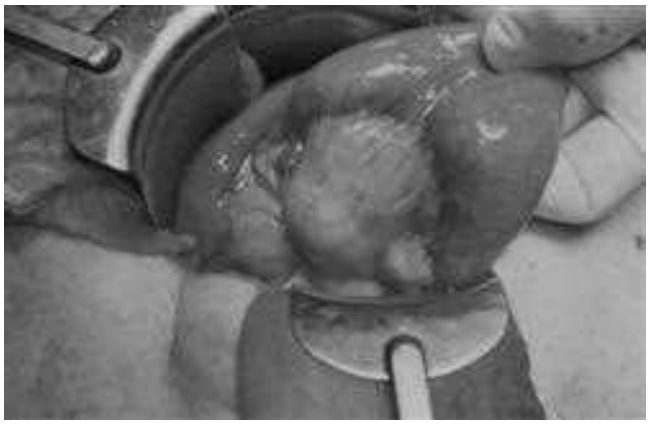

Figure 35-14. Operative findings at the time of resection of what was believed to be a mesenteric tumor but that proved to be a focus of mesenteric lipodystrophy. In this case, the relatively small site of involvement and the peripheral location in the small intestinal mesentery permitted management by resection en bloc with a segment of adjacent small bowel.

a mass or, much more rarely, intestinal obstruction. However, many cases are discovered incidentally when imaging studies, most frequently CT scan, are performed for unrelated reasons.

CT of the abdomen shows a mass lesion or an area of the mesentery with a higher density than normal mesenteric tissue. Vascular structures are seen coursing through the affected areas, which sometimes involve in the mesenteric root (Fig. 35-13). Although CT cannot definitively distinguish sclerosing mesenteritis from a mesenteric tumor, identification of a "fat ring sign" or hypodense zone around the mass area has been suggested as a means of distinguishing sclerosing mesenteritis from lymphoma. The presence of a hyperattenuating stripe has also been suggested as radiologic finding that would favor the mesenteritis diagnosis.

Operative findings range from a discrete mesenteric mass (Fig. 35-14) to broad areas of mesenteric nodularity and thickening. Surgical biopsy has frequently been used to confirm the diagnosis and to rule out a neoplastic process. The extent and location of mesenteric involvement define and, in some cases, limit the options for surgical intervention. In addition to simple biopsy, bowel and mesenteric resection can be considered, particularly in cases where this is technically feasible based on mass size and the ability to avoid injury to small intestinal blood supply. Often, however, the involvement of the vascular structures at the mesenteric root makes resection unfeasible. Rarely, an ostomy of some type for fecal diversion in the face of obstruction can be considered. Positron emission tomography with CT scanning has proven effective in ruling out neoplasia for focal mesenteric masses, leaving the sclerosing mesenteritis diagnosis as one of exclusion.

7▶

In most cases of sclerosing mesenteritis, the process appears to be self-limited and may even demonstrate regression if followed with interval imaging studies. Clinical symptoms are very likely to improve without intervention, and therefore, aggressive surgical treatments are generally not indicated. In clinically problematic cases that are not amenable to resection because of widespread mesenteric involvement or unfavorable location, medical treatment has been given to alleviate severe symptoms. Among the agents that have been used are corticosteroids, colchicine, tamoxifen, and cyclophosphamide.

Mesenteric Cysts

Cysts of the mesentery are benign lesions with an incidence of less than 1 in 100,000. The etiology of such cysts remains unknown, but several theories regarding their development exist, including degeneration of the mesenteric lymphatics or peritoneal inclusions arising as congenital anomalies.

Mesenteric cysts may be asymptomatic or cause acute or chronic symptoms of a mass lesion. Acute pain is generally caused by rupture or torsion of the cyst or from acute hemorrhage into the cyst cavity. Mesenteric cysts may also cause intermittent abdominal pain secondary to compression of adjacent structures or reversible torsion of the cyst. Mesenteric cysts can also be the cause of nonspecific symptoms such as anorexia, nausea, vomiting, fatigue, and weight loss.

Physical examination may reveal a mass lesion that is mobile only from the patient's right to left or left to right (Tillaux's sign), in contrast to the findings with omental cysts, which should be freely mobile in all directions. Tillaux was the first to record this physical finding and, in 1850, the first to successfully remove a mesenteric cyst.

CT (Fig. 35-15), ultrasound, and MRI all have been used to evaluate patients with mesenteric cysts. Cysts generally appear unilocular without solid component on imaging. Less frequently, they may be multiple or multilocular or difficult to distinguish from solid mesenteric tumors with cystic components such as a cystic stromal tumor or mesothelioma. Mesenteric cystic lymphangioma may present as numerous, often large cysts in the setting of abdominal pain. These can be difficult to treat and almost invariably recur after excision.

When symptomatic, simple mesenteric cysts are surgically excised either openly or laparoscopically. Cyst unroofing or marsupialization is not recommended because mesenteric cysts

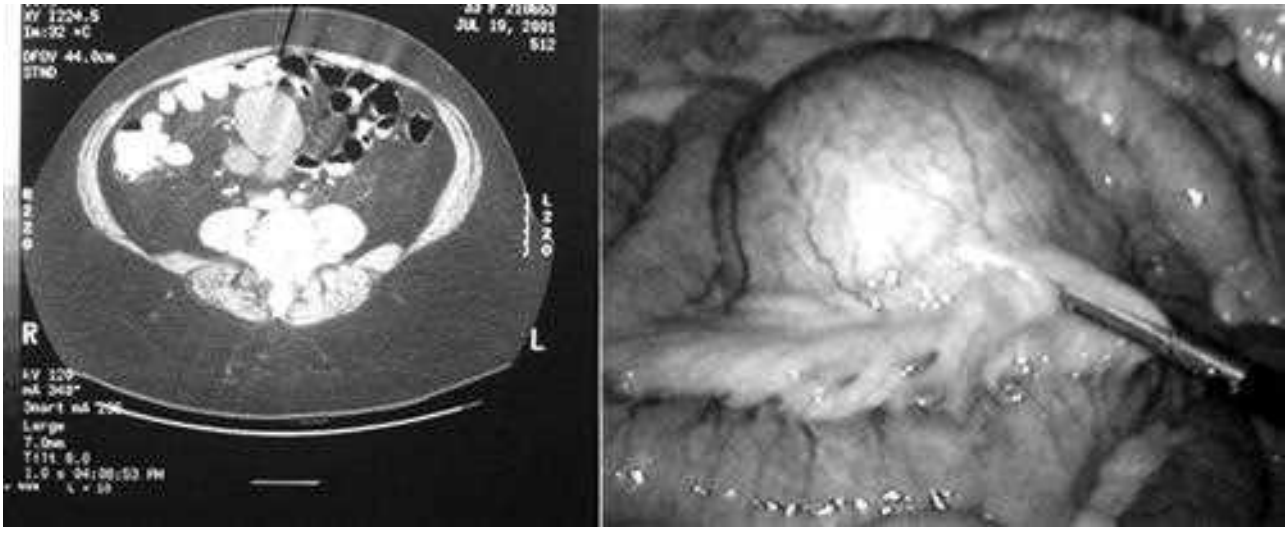

Figure 35-15. Computed tomography (CT) scan of a mesenteric cyst (*left panel*). Unilocular appearance without associated solid component strongly suggests the diagnosis of benign cyst. The operative findings during laparoscopic eploration (*right panel*) confirm the CT diagnosis of unilocular cyst, which is then enucleated from the mesentery in a relatively avascular plane adjacent to mesenteric vessels.

have a high propensity to recur after drainage alone. On rare occasion, adjacent mesentery or bowel may be densely adherent to the cyst, or mesenteric vessels must be sacrificed in order to achieve complete excision. In this case, segmental bowel resection inclusive of the adjacent mesentery is performed.

Mesenteric Tumors

Primary tumors of the mesentery are rare. Benign tumors of the mesentery include lipoma, cystic lymphangioma, and desmoid tumors. Primary malignant tumors of the mesentery are similar to those described for omentum. Liposarcomas, leiomyosarcomas, malignant fibrous histiocytomas, lipoblastomas, and lymphangiosarcomas have all been described. Metastatic small intestinal carcinoid in mesenteric lymph nodes may exceed the bulk of primary disease and compromise blood supply to the bowel. Treatment of mesenteric malignancies involves wide resection of the mass. Because of the proximity to the blood supply to the intestine, such resections may be technically unfeasible or involve loss of substantial lengths of bowel.

RETROPERITONEUM

Surgical Anatomy

The retroperitoneum is defined as the space between the posterior envelopment of the peritoneum and the posterior body wall (Fig. 35-16). The retroperitoneal space is bounded superiorly by the diaphragm, posteriorly by the spinal column and iliopsoas muscles, and inferiorly by the levator ani muscles. Although technically bounded anteriorly by the posterior reflection of the peritoneum, the anterior border of the retroperitoneum is quite convoluted, extending into the spaces in between the mesenteries of the small and large intestine. Because of the rigidity of the superior, posterior, and inferior boundaries, and the compliance of the anterior margin, retroperitoneal tumors tend to expand anteriorly toward the peritoneal cavity.

Retroperitoneal Infections

The posterior reflection of the peritoneum limits the spread of most intra-abdominal infections into the peritoneum. Accordingly, the source of retroperitoneal infections is usually an organ contained within or abutting the retroperitoneum. Retrocecal appendicitis, contained perforation of duodenal ulcers, iatrogenic perforation with esophagogastroduodenoscopy or endoscopic retrograde cholangiopancreatography, and complicated pancreatitis may all lead to retroperitoneal infection with or without abscess formation. The substantial space and rather nondiscrete boundaries of the retroperitoneum allow some retroperitoneal abscesses to become quite large prior to diagnosis.

Patients with a retroperitoneal abscess usually present with pain and fever, but more worrisome signs of sepsis may also be present depending on clinical severity. The site of pain may be variable and can include the back, pelvis, or thighs. Erythema may be observed around the umbilicus or flank. The diagnosis is best established by CT, which may demonstrate a unilocular or multilocular collection along with retroperitoneal soft tissue stranding (Fig. 35-17).

Management of retroperitoneal infections includes identification and treatment of the underlying condition, intravenous antibiotics, and drainage of all well-defined collections. Image-guided percutaneous drainage is strongly favored, but operative drainage may sometimes be needed for adequate drainage of complex or multiple collections. The mortality rate of retroperitoneal abscess has been reported to be as high as 25%, and even higher in rare cases of necrotizing fasciitis of the retroperitoneum.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is a class of disorders characterized by hyperproliferation of fibrous tissue in the retroperitoneum. This may be a primary disorder as in idiopathic retroperitoneal fibrosis, also known as Ormond's disease, or a secondary reaction to an inciting inflammatory process, malignancy, or medication. Idiopathic retroperitoneal fibrosis is a rare disorder, usually affecting 0.5 per 100,000 patients annually. Men are twice as likely to be affected as women, with no predilection for any particular ethnic group. The disease primarily affects individuals in the fourth to the sixth decades of life.

Although allergic or autoimmune mechanisms have been postulated, the pathogenesis of this condition remains uncertain.

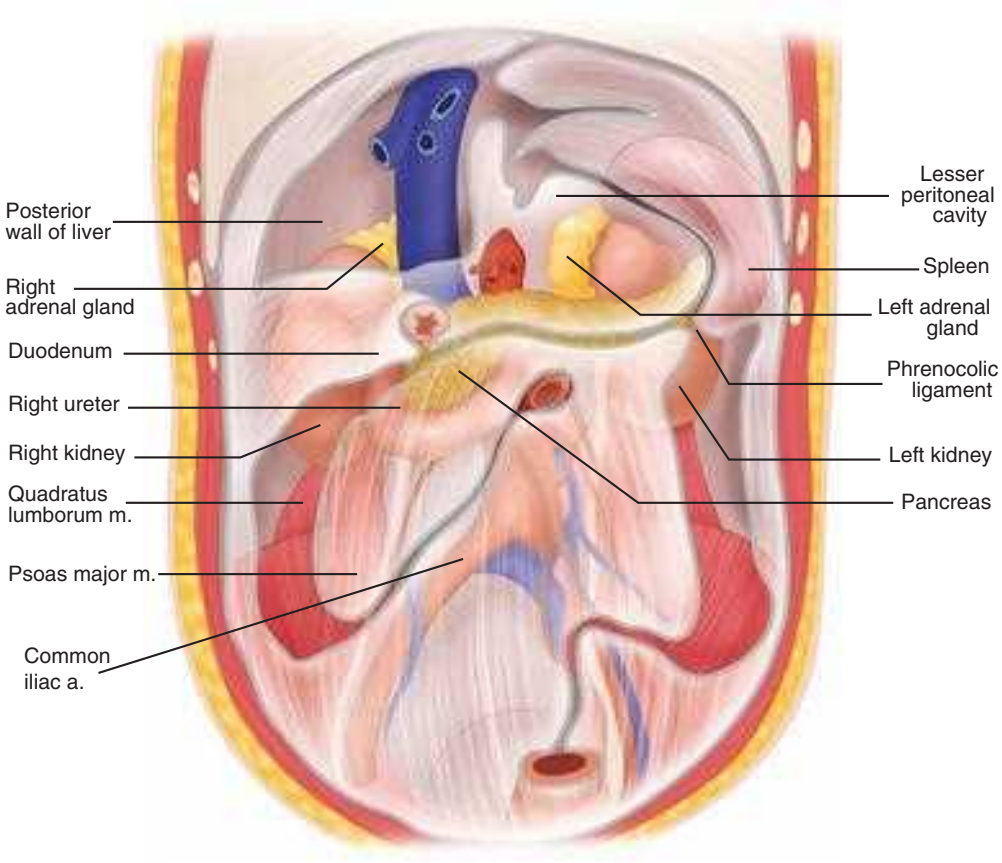

Figure 35-16. Anatomy of the retroperitoneum. *(Reproduced with permission from Healy JE, Hodge J, eds.* Surgical Anatomy. *2nd ed. Toronto: BC Decker; 1990:201.)*

In the closely related condition of chronic perioaortitis, an association with the HLA-DRB1*03 allele, which has been linked to autoimmune diseases such as systemic lupus erythematosus, type 1 diabetes mellitus, and myasthenia gravis, is of particular interest in defining an autoimmune cause of retroperitoneal fibrosis. Circulating antibodies to ceroid, a lipoproteinaceous by-product of vascular atheromatous plaque oxidation, are present in more than 90% of patients with retroperitoneal fibrosis. The relationship of these finding to the occurrence of fibrosis remains uncertain. The early inflammatory reaction is predominated by T-helper cells, plasma cells, and macrophages, but is subsequently replaced by collagen-synthesizing fibroblasts. Microscopically, the infiltrate is indistinguishable from the periadventitial involvement of aortic aneurysmal disease, Reidel's thyroiditis, sclerosing cholangitis, and Peyronie's disease. The fibrotic process begins in the retroperitoneum just below the level of the renal arteries. Fibrosis gradually expands, encasing the ureters, inferior vena cava, aorta, mesenteric vessels, or sympathetic nerves. Bilateral involvement is noted in 67% of cases.

Figure 35-17. Computed tomography scan of retroperitoneal abscess complicating complex, surgically treated retroperitoneal infection that had resulted from ampullary perforation at the time of endoscopic retrograde cholangiopancreatography. This pattern of infection may be difficult to treat and result in multiple interventions such as percutaneous drainage before resolution.

Retroperitoneal fibrosis may also appear secondarily with a variety of inflammatory conditions including abdominal aortic aneurysm, pancreatitis, histoplasmosis, tuberculosis, or actinomycosis. It also is associated with a variety of malignancies, including prostate, pancreas, and gastric cancer, as well as non-Hodgkin's lymphoma, stromal tumors, and carcinoid tumors. Retroperitoneal fibrosis has been described in association with autoimmune disorders including ankylosing spondylitis, systemic lupus erythematosus, Wegener's granulomatosis, and polyarteritis nodosa.

There is strong evidence that methysergide, a semisynthetic ergot alkaloid used in the treatment of migraine headaches, plays a causal role in some cases of retroperitoneal

fibrosis. Other medications that have been linked to retroperitoneal fibrosis include β-blockers, hydralazine, α-methyldopa, and entacapone, which inhibits catechol-*O*-methyltransferase and is used as an adjunct with levodopa in the treatment of Parkinson's disease. The retroperitoneal fibrosis regresses upon discontinuation of these medications.

Presenting symptoms depend on the structure or structures affected by the fibrotic process. Initially, patients complain of the insidious onset of dull, poorly localized abdominal pain. Sudden-onset or severe abdominal pain may signify acute mesenteric ischemia. Other symptoms of retroperitoneal fibrosis may include unilateral leg swelling, intermittent claudication, oliguria, hematuria, or dysuria.

As with the patient's symptomatology, findings on physical examination vary with the retroperitoneal structure involved. Consequently, findings may include hypertension, the palpation of an abdominal or flank mass, lower-extremity edema (unilateral or bilateral), or diminished lower-extremity pulses (unilateral or bilateral). Laboratory evaluation may reveal elevated blood urea nitrogen and/or creatinine levels. As with many autoimmune inflammatory processes, the erythrocyte sedimentation rate almost always is elevated in patients with retroperitoneal fibrosis.

Many imaging modalities have been used with various sensitivities to diagnose retroperitoneal fibrosis. Abdominal/lower-extremity ultrasonography is the least invasive imaging procedure but is technician dependent. It may be useful if iliocaval compressive or renal symptoms predominate. A lower-extremity ultrasound may show deep venous thrombosis, whereas abdominal ultrasonography may identify a mass lesion or hydronephrosis. Once the diagnostic procedure of choice, intravenous pyelography (IVP) is less commonly used today. If the ureters are involved, IVP findings include ureteral compression, ureteral deviation toward the midline, and hydronephrosis.

Abdominopelvic CT with oral and intravenous contrast is the imaging procedure of choice and will generally allow the extent of the fibrotic process to be determined. If there is diminished renal function, avoidance of the use of intravenous contrast will reduce the ability to characterize retroperitoneal tissue planes. In this case, MRI may be used, since the signal intensity of the fibrotic process is discrete from muscle or fat. Additionally, magnetic resonance angiography will generally provide a good assessment of the degree of iliocaval involvement. Once a mass lesion is identified, the mass should be biopsied to rule out a retroperitoneal malignancy. The specimen may be retrieved using image-guided techniques or surgical retroperitoneal biopsy, which may be performed laparoscopically or during open laparotomy.

Once malignancy, drug-induced, and infectious etiologies are ruled out, treatment of the retroperitoneal fibrotic process is instituted. Corticosteroids, with or without surgery, are the mainstay of medical therapy. Surgical treatment consists primarily of ureterolysis or ureteral stenting and is required in patients who present with significant hydronephrosis. Laparoscopic ureterolysis has been shown to be as efficacious as open the open procedure. Patients with iliocaval thrombosis require anticoagulation, although appropriate duration of therapy is uncertain. Endovascular interventions for iliocaval occlusion have also been shown to be effective in small numbers of patients. Prednisone is initially administered at a relatively high dose (60 mg every other day for 2 months), and then gradually tapered over the next 2 months. Therapeutic efficacy is assessed based on patient symptoms and interval imaging studies. Cyclosporin, tamoxifen, and azathioprine have also been used to treat patients who respond poorly to corticosteroids.

8▶

The overall prognosis in idiopathic retroperitoneal fibrosis is good, with 5-year survival rates of 90% to 100%. Because long-term recurrences have been described, lifelong follow-up is warranted.

chapter 36

Soft Tissue Sarcomas

Janice N. Cormier, Alessandro Gronchi, and Raphael E. Pollock

INTRODUCTION

Sarcomas are a heterogeneous group of neoplasms that arise predominantly from cells of the embryonic mesoderm. While the majority of sarcomas are soft tissue sarcomas, other types of sarcoma include bone sarcomas (osteosarcoma, chondrosarcoma, and rare bone tumors like chordoma, angiosarcoma, and leiomyosarcoma of bone) and Ewing's sarcoma/peripheral primitive neuroectodermal tumor, which can occur either in the bone or in the soft tissues. The primary focus of this chapter is soft tissue sarcomas. Most primary soft tissue sarcomas originate in an extremity (50%–60%); the next most common sites are the trunk (19%), retroperitoneum (15%), and head and neck (9%). The anatomic site of a primary sarcoma influences treatment and outcome.[1]

Soft tissue sarcomas include more than 50 histologic subtypes (Table 36-1). Historically, the most common subtypes in adults (excluding Kaposi's sarcoma) were malignant fibrous histiocytoma (28%), liposarcoma (15%), leiomyosarcoma (12%), synovial sarcoma (10%), and malignant peripheral nerve sheath tumor (6%).[2] Today, malignant fibrous histiocytoma is classified as either leiomyosarcoma, pleomorphic undifferentiated sarcoma, myxofibrosarcoma, or dedifferentiated liposarcoma based on cellular differentiation and genetics. Embryonal/alveolar rhabdomyosarcomas are the most common soft tissue sarcomas of childhood, whereas pleomorphic rhabdomyosarcoma occurs predominantly in adults, and although it shares part of the name, it has a different biology and should not be treated as a pediatric sarcoma.

During the past 25 years, patients with extremity sarcomas have been treated with a multimodality approach, which has led to some improvements in survival, local control, and quality of life.[3] However, patients with abdominal sarcomas continue to have high rates of recurrence and poor overall survival.[4] The overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50% to 60%. Of the patients who die of sarcoma, most succumb to lung metastasis, which 80% of the time occurs within 2 to 3 years after initial diagnosis.

INCIDENCE

In the United States in 2012, approximately 11,280 new cases of soft tissue sarcoma were diagnosed, and 3900 deaths were attributable to this disease.[5] The true incidence of sarcoma is thought to be higher than reported, and gastrointestinal stromal tumors (GISTs) likely account for an additional 5000 new sarcoma cases per year.[1] Overall, sarcomas affect 5 to 6 individuals per 100,000 inhabitants per year,[6] accounting for less than 1% of all malignancies in adults and 15% of malignancies in children.[7]

Key Points

1. Sarcomas are a heterogeneous group of tumors that can occur throughout the body and encompass more than 50 subtypes with distinct histologic lines of differentiation.
2. Approximately two thirds of soft tissue sarcomas arise in the extremities; the remaining one third is distributed between the retroperitoneum, trunk, abdomen, head, and neck.
3. Multimodality treatment, including surgical resection, radiation therapy, and, in selected cases, systemic chemotherapy, has been applied to patients with locally advanced, high-grade, extremity sarcomas.
4. Overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50% to 60%.
5. These rare tumors account for less than 1% of cancer in adults (estimated 10,000 cases per year in the United States) and represent 15% of cancers in children.
6. The treatment algorithm for soft tissue sarcomas depends on tumor stage, site, and histology.
7. Of the patients who die of sarcoma, most will succumb to metastatic disease in the lungs, which 80% of the time occurs within 2 to 3 years of the initial diagnosis.
8. Progress in the understanding of soft tissue sarcoma biology is crucial for the development of new treatments.

EPIDEMIOLOGY

Except for malignant peripheral nerve sheath tumors in patients with neurofibromatosis, sarcomas do not seem to result from progression or dedifferentiation of a benign soft tissue tumor. While most sarcomas are of unknown cause, a few sarcoma subtypes have been observed in settings suggesting etiology.

Radiation Exposure

External radiation therapy is a rare but well-established risk factor for soft tissue sarcoma that may be associated with radiation-induced mutations of the *p53* gene.[8] The incidence of sarcoma among patients who are often treated with radiation for cancer of the breast, cervix, ovary, testes, or lymphatic system is 8 to 50 times the general-population risk.[9,10] In a review of 160 patients with postirradiation sarcomas, the most common histologic types were osteogenic sarcoma, malignant fibrous histiocytoma, angiosarcoma, and lymphangiosarcoma.[9] The risk of developing a sarcoma increased with radiation dose, and the median time between radiation therapy and diagnosis of sarcoma was 10 years.[9] A recent review of 44 patients with radiation-induced sarcomas identified between 1989 and 2009 noted that the average period from initial radiation treatment to diagnosis was 16 years and that radiation-induced sarcomas occurred most commonly in patients treated for breast cancer (36% of the patients in the series) and lymphoma (34% of the patients in the series).[11] The 5-year overall survival rate for patients presenting without metastasis was 44%.

Table 36-1

Relative frequency of histologic subtypes of soft tissue sarcoma

HISTOLOGIC SUBTYPES	NO.	%
Liposarcoma	188	15
Leiomyosarcoma	148	12
Unclassified sarcoma	140	11
Synovial sarcoma	125	10
Malignant peripheral nerve sheath tumor	72	6
Rhabdomyosarcoma	60	5
Fibrosarcoma	38	3
Ewing sarcoma	25	2
Angiosarcoma	25	2
Osteosarcoma	14	1
Epithelioid sarcoma	14	1
Chondrosarcoma	13	1
Clear cell sarcoma	12	1
Alveolar soft part sarcoma	7	1
Malignant hemangiopericytoma	5	0.4

Source: Data from Coindre et al.[2]

Occupational Chemical Exposure

Exposure to herbicides such as phenoxyacetic acids and to wood preservatives containing chlorophenols has been linked to an increased risk of soft tissue sarcoma.[12] Several chemical carcinogens, including thorium oxide (Thorotrast), vinyl chloride, and arsenic, have been associated with hepatic angiosarcomas.[13]

Trauma

Although patients with sarcoma often report a history of trauma, no causal relationship has been established. More often, a minor injury calls attention to a pre-existing tumor.

Chronic Lymphedema

In 1948, Stewart and Treves first described the association between chronic lymphedema after axillary dissection and subsequent lymphangiosarcoma (Fig. 36-1).[14] Lymphangiosarcoma has been estimated to occur in 0.07% of patients who undergo axillary node dissection.[15] It also has been reported to occur after filarial infections and in the lower extremities of patients with congenital lymphedema.[16,17] Lymphangiosarcoma is generally an aggressive tumor; average survival of patients with lymphangiosarcoma is 19 months.[18]

MOLECULAR PATHOGENESIS

Sarcomas can be broadly classified into three groups according to the genetic events underlying their development: specific translocations or gene amplification, defining oncogenic mutations, and complex genomic rearrangements.[19] In general, sarcomas resulting from identifiable molecular events tend to occur in younger patients with histology suggesting a clear line of differentiation. The identifiable molecular events include point

Figure 36-1. A 57-year-old with a chronic, progressive lymphedema of the left upper extremity developed lymphangiosarcoma 10 years after breast cancer treatment.

mutations, translocations causing overexpression of an autocrine grow factor, and oncogenic fusion transcription factor producing a cellular environment prone to malignant transformation. In contrast, sarcomas without identifiable genetic changes or expression profile signatures tend to occur in older patients and exhibit pleomorphic cytology and *p53* dysfunction.[20] Improved understanding of the molecular pathogenesis of sarcomas has revealed several potential targets against which investigators are working to develop subtype-specific targeted therapy.

Translocation-Associated Sarcomas

To date, translocations have been identified in 14 subtypes of soft tissue sarcoma, accounting for 20% to 30% of all sarcomas[21] (Table 36-2). Translocations result in in-frame gene fusion, which in turn results in fused products encoding oncoproteins that function as transcriptional activators or repressors.[22,23] The best characterized gene fusions are in Ewing's sarcoma (*EWS-FLI1*), clear cell sarcoma (*EWS-ATF1*), myxoid/round cell liposarcoma (*TLS-CHOP*), alveolar rhabdomyosarcoma (*PAX3-FHKR*), desmoplastic small round cell tumor (*EWS-WT1*), and synovial sarcoma (*SS18-SSX*). Fusion gene–related sarcomas have been estimated to account for 30% or more of all sarcomas.[24]

Direct or indirect interactions between fusion transcripts and cell cycle regulators have been elucidated by several investigators and identify these transcripts as potentially promising molecular therapeutic targets.[25] However, fusion genes in sarcoma have been successfully targeted in only a few cases, in which fusion resulted in overexpression of a growth factor or growth factor receptor. Several growth factors and their receptors (e.g., epidermal growth factor receptor) previously reported to play an important role in autocrine or paracrine stimulation of carcinoma growth have been associated with high histologic grade and poor prognosis in soft tissue sarcomas.

Amplification-Associated Sarcomas

Oncogenes are genes that can induce malignant transformation and tend to drive cell proliferation. Several oncogenes have been associated with soft tissue sarcomas, including *MDM2,* N-*myc*, c-*erbB2*, and members of the *ras* family. These oncogenes produce specific oncoproteins that either play a role in nuclear function and cellular signal transduction or function as growth factors or growth factor receptors. This typically occurs in dedifferentiated liposarcoma, where the amplification of *MDM2* drives the neoplastic process. Amplification of these genes has been shown to correlate with adverse outcome in several types of soft tissue sarcoma.[22]

Table 36-2

Fusion transcripts in soft tissue sarcoma

Oncogenic Mutations

GISTs are the classic example of sarcomas in which tumorigenesis is primarily driven by a single activating mutation, in the gene encoding KIT receptor tyrosine kinase or platelet-derived growth factor receptor-α (PDGFRA).[19] The majority of GISTs have mutations in exon 11 of *KIT* and respond dramatically to the tyrosine kinase inhibitor imatinib mesylate, although this treatment rarely produces cure.

Complex Genomic Rearrangements

The largest group of sarcomas is the group with complex cytogenetic alterations, which includes high-grade spindle cell sarcomas and pleomorphic sarcomas.[19] Many sarcomas in this group exhibit inactivation of tumor suppressor genes. The two genes most relevant to soft tissue sarcoma are retinoblastoma (*Rb*) and

p53. Mutations or deletions in *Rb* can lead to retinoblastoma, the most common malignant ocular neoplasm of childhood. Survivors of retinoblastoma are at risk for developing soft tissue and bone sarcomas later in life. Patients with germline mutations in *p53* (Li-Fraumeni syndrome) have a high incidence of soft tissue sarcomas Mutant *p53* expression is thought to correlate with poor overall survival.[22] Strategies to target *p53* mutation are being investigated for treatment of some sarcomas.

Neurofibromatosis type 1 (von Recklinghausen's disease) occurs in approximately 1 of every 3000 people and is due to various mutations in the *NF-1* tumor suppressor gene, located on chromosome 17. Patients with neurofibromatosis type 1 have an estimated 3% to 15% additional risk of malignant disease compared with the general population lifetime risk, including malignant peripheral nerve sheath tumors (MPNST) and GIST. In turn, 25% to 50% of patients with MPNST have a mutation in *NF-1*.[26]

INITIAL ASSESSMENT

The clinical behavior of most soft tissue sarcomas is determined by anatomic location (depth in relation to the investing fascia), histologic subtype and grade of aggressiveness, and size. The dominant pattern of metastasis is hematogenous, primarily to the lungs. Lymph node metastasis is rare (affecting <5% of patients) except in a few histologic subtypes, including epithelioid sarcoma, pediatric rhabdomyosarcoma, clear cell sarcoma, angiosarcoma, and, more rarely, synovial sarcoma and myxofibrosarcoma,.[27]

Clinical Presentation

Soft tissue sarcomas most commonly present as an asymptomatic mass. Extremity sarcomas may present as a deep venous thrombosis, particularly in patients without significant risk factors for thrombosis.[28] Tumors in the distal extremities are generally smaller, whereas tumors in the proximal extremities and retroperitoneum can grow quite large before becoming apparent. Tumors often grow centrifugally and can compress surrounding normal structures. Infrequently, tumor impingement on bone or neurovascular bundles produces pain, edema, and swelling. Less frequently, tumors cause obstructive gastrointestinal symptoms or neurologic symptoms related to compression of lumbar or pelvic nerves. Often an extremity mass is discovered after a traumatic event that draws attention to a pre-existing lesion.

The differential diagnosis of a soft tissue mass should include consideration of lipoma (which is 100 times more common than sarcoma), lymphangioma, leiomyoma, neurinoma, primary or metastatic carcinoma, melanoma, and lymphoma. Superficial small lesions (<5 cm) that are new or that are not enlarging as indicated by clinical history can be observed. Enlarging masses and masses larger than 5 cm or deep to the fascia should be evaluated with a history, imaging, and biopsy.[29]

Diagnostic Imaging

Diagnostic imaging should be performed before any invasive procedure to avoid the possibility of soft tissue swelling or hemorrhage complicating the image interpretation. Pretreatment diagnostic imaging is helpful for defining the size and anatomic location of a tumor and its proximity to adjacent structures; staging disease with respect to regional or metastatic spread; guiding percutaneous biopsy; and establishing whether a tumor is benign or malignant and low grade or high grade.

Radiographs are useful in the evaluation of primary bone tumors but not in the evaluation of soft tissue sarcomas of the extremities unless there is underlying bone involvement from an adjacent soft tissue tumor. Magnetic resonance imaging (MRI) is the preferred imaging technique for soft tissue sarcomas of the extremities, whereas computed tomography (CT) is most useful for evaluating retroperitoneal, intra-abdominal, and truncal sarcomas.[30] CT of the chest should be performed to assess for lung metastases in patients with high-grade tumors larger than 5 cm. Abdominal/pelvic CT should be performed in patients with myxoid round cell liposarcomas, leiomyosarcomas, epithelioid sarcomas, or angiosarcomas because of their propensity to metastasize to the abdomen and/or pelvis.[1] MRI of the brain should be considered for patients with alveolar soft part sarcomas and angiosarcomas because of their propensity to metastasize to the brain.

Ultrasonography. Ultrasonography may have a diagnostic role in patients with soft tissue sarcoma who cannot undergo MRI. Ultrasonography can also be a useful adjunct to MRI when findings on MRI are indeterminate and for delineating adjacent vascular structures. Finally, ultrasonography can be used for postoperative surveillance and to guide biopsies.

Computed Tomography. Chest CT should be performed to evaluate for lung metastasis at presentation and before any radical treatment. CT is also the preferred imaging technique for evaluating retroperitoneal sarcomas (Fig. 36-2).[30] Current CT techniques can provide a detailed image of the abdomen and pelvis and can delineate adjacent organs and vascular structures. For extremity sarcomas, CT may be useful if MRI is not available or cannot be used. When histologic assessment of an extremity sarcoma reveals a myxoid liposarcoma, CT of the abdomen and pelvis should be done because this subtype is known to metastasize to the abdomen.[31]

Magnetic Resonance Imaging. MRI is the most useful imaging modality for extremity sarcomas because of its superior soft tissue contrast resolution and multiplanar capabilities. MRI accurately delineates muscle groups and distinguishes among bone, vascular structures, and tumor. Sagittal and coronal views allow evaluation of anatomic compartments in three dimensions (Fig. 36-3). Soft tissue sarcomas of the extremities usually present on MRI as a heterogeneous mass. Their signal intensity tends

to be equal to or slightly higher than that of adjacent skeletal muscle on T1-weighted images and heterogeneous and high on T2-weighted images. Hemorrhagic, cystic, or necrotic changes may also be observed in the tumor. If adjacent vascular structures must be delineated, special MRI techniques may be performed, including magnetic resonance angiography. MRI may also be an important adjunct to cytologic analysis in distinguishing benign lesions such as lipomas, hemangiomas, schwannomas, neurofibromas, and intramuscular myxomas from their malignant counterparts. In patients undergoing preoperative chemotherapy, contrast-enhanced T1-weighted MRI can be useful in evaluating intratumoral necrosis.

MRI is also valuable for assessing tumor recurrence after surgery. A baseline image is usually obtained 3 months after surgery. Some clinicians forego routine postoperative imaging of the primary extremity tumor site in asymptomatic patients, citing the difficulties in detecting early recurrence in scarred, irradiated tissue.[30] Others advocate routine imaging every 3 to 4 months for the first 2 years, every 6 months in years 3 through 5, and then annually.

Positron Emission Tomography. Positron emission tomography (PET) is a functional imaging modality that measures tumor uptake of the glucose analog [^{18}F] fluorodeoxyglucose (FDG). PET imaging allows evaluation of the entire body. Although PET/CT may be useful in specific circumstances, FDG-PET is not currently recommended for the initial staging of patients with soft tissue sarcoma.

Roberge and colleagues compared FDG-PET/CT versus chest CT alone in the initial staging of 75 patients with soft tissue sarcoma and found that only one patient had disease upstaged as a result of PET, whereas two had false-positive findings and three had indeterminate findings with no subsequent development of metastasis.[32] Previous studies that reported a marginal benefit of PET/CT for detecting metastasis at the time of sarcoma staging included patients with more heterogeneous tumors, such as osseous tumors, soft tissue osteosarcomas, Ewing's sarcoma, and rhabdomyosarcoma.[33-35]

In patients with sarcoma, PET has primarily been used to assist with tumor grading and to assess response to chemotherapy.[36-39] In 50 patients with resectable high-grade soft tissue tumors scheduled for preoperative chemotherapy and tumor resection, a 35% or greater reduction in tumor FDG uptake following an initial cycle of chemotherapy was associated with histopathologic tumor response defined as pathologic necrosis in 95% or more of the resected specimen.[40]

Biopsy Techniques

Fine-Needle Aspiration. At centers where cytopathologists have experience with evaluation of mesenchymal tumors, fine-needle aspiration is an acceptable method of diagnosing most soft tissue sarcomas, particularly when the results correlate closely with clinical and radiologic findings.[41] Fine-needle aspiration of primary tumors has a lower diagnostic accuracy rate (60%–90%) than core needle biopsy and is often not sufficient for establishing a specific histologic diagnosis and grade.[42] However, fine-needle aspiration is the procedure of choice to confirm or rule out the presence of a metastatic focus or local recurrence.[43]

Although fine-needle aspiration of superficial lesions can often be done in the clinic, fine-needle aspiration of deeper tumors may need to be done by an interventional radiologist under sonographic or CT guidance. Generally, a 21- to 23-gauge needle is introduced into the mass after appropriate cleansing of the skin and injection of local anesthetic. Negative pressure is applied, and the needle is moved back and forth several times in various directions. After the negative pressure is released, the needle is withdrawn, and the contents of the needle are used to prepare smears.[44] A cytopathologist then examines the slides to determine whether sufficient diagnostic material is present.

Core Needle Biopsy. Core needle biopsy is safe, accurate,[45,46] and economical[47] and has become the preferred technique for diagnosing soft tissue lesions. Dupuy and colleagues found that core needle biopsy had an accuracy of 93% in 221 patients with musculoskeletal neoplasms.[45]

Sonography/CT guidance can prevent sampling of nondiagnostic necrotic or cystic areas of the tumor and thus increase the positive yield rate. Sonography/CT guidance also permits biopsy of tumors in otherwise inaccessible locations and tumors located near vital structures.

The tissue sample obtained from core needle biopsy is usually sufficient for several diagnostic tests, such as electron microscopy, cytogenetic analysis, and flow cytometry. The reported complication rate for core needle biopsy is less than 1%.[45,46]

Incisional Biopsy. Historically, an open surgical biopsy was the gold standard for achieving adequate tissue for definitive and specific histologic diagnosis of bone or soft tissue sarcomas. Contemporary guidelines recommend incisional biopsy when core needle biopsy cannot produce adequate tissue for diagnosis or when findings on core needle biopsy are nondiagnostic.

The disadvantages of incisional biopsy include the need to schedule the procedure, the need for general anesthesia, and high costs. In addition, an inappropriately placed incisions can necessitate more extensive definitive resection to encompass the biopsy site. In a series of 107 patients with soft tissue sarcoma, planned surgical treatments had to be changed because of poorly oriented biopsies in 25% of cases.[48] Complication rates up to 17% have been reported after incisional biopsies.[44] Potential complications include hematoma, infection, wound dehiscence, and tumor fungation, any of which can delay definitive treatment.[44]

Incisional biopsies should be performed only by surgeons experienced in the management of soft tissue sarcoma, ideally in a center specializing in the treatment of sarcoma and by the surgeon who will perform the definitive surgery. The biopsy incision should be oriented longitudinally along the extremity to allow a subsequent wide local excision that encompasses the biopsy site, scar, and tumor en bloc. A poorly oriented biopsy incision often necessitates an excessively large surgical defect for a wide local excision, which in turn can result in a larger postoperative radiation therapy field to encompass all tissues at risk. Adequate hemostasis must be achieved at the time of biopsy to prevent dissemination of tumor cells into adjacent tissue planes by hematoma.

Excisional Biopsy. Excisional biopsy can be performed for easily accessible (superficial) extremity or truncal lesions smaller than 3 cm. However, excisional biopsy rarely provides benefits over other biopsy techniques. Excisional biopsies should not be performed for lesions involving the hands and feet because such biopsies may complicate definitive re-excision. For sarcomas with initial diagnosis confirmed with excisional biopsy, microscopic residual disease has been reported in up to 69% of re-excision specimens[49,50]; without re-excision, the reported rate of local recurrence is 30% to 40% when margins are positive or uncertain.

Wide en bloc excision is seldom performed as a diagnostic procedure. When en bloc excision is done for diagnosis, the margin status is often not adequately evaluated during pathologic assessment of the specimen. Unless detailed descriptions of the surgical procedure and the pathology specimen are provided, the margins should be classified as uncertain or unknown, a classification associated with the same prognosis as resection margins that are positive for tumor cells. In patients with uncertain or unknown margins, re-excision should be performed if possible to ensure negative margins. The biopsy site or tract (if applicable) should be included en bloc with the re-resected specimen.

Pathologic Assessment and Classification

Sarcoma is generally diagnosed by morphologic assessment based on microscopic examination of histologic sections by an experienced sarcoma pathologist. However, even expert sarcoma pathologists disagree on the specific histologic diagnosis and the tumor grade in 25% to 40% of cases.[51]

Morphologic assessment can be supported by ancillary techniques, including conventional cytogenetics; immunohistochemistry; and molecular genetic testing, which is useful for classifying soft tissue sarcoma subtypes with multiple genetic aberrations. Other molecular diagnostic techniques include cytogenetic analysis, fluorescence in situ hybridization, and polymerase chain reaction–based methods.[52] However, molecular genetic techniques are associated with significant technical limitations and should be interpreted in the context of the sarcoma's morphologic features.

Some experts have suggested that pathologic classification of soft tissue sarcomas has more prognostic significance than does tumor grade when other pretreatment variables are taken into account. Tumors with limited metastatic potential include desmoid, atypical lipomatous tumor (also called well-differentiated liposarcoma), dermatofibrosarcoma protuberans, and solitary fibrous tumor. Tumors with an intermediate risk of metastatic spread usually have a large myxoid component and include myxoid liposarcoma, myxofibrosarcoma, and extraskeletal myxoid chondrosarcoma. Among the highly aggressive tumors with substantial metastatic potential are angiosarcoma, clear cell sarcoma, pleomorphic and dedifferentiated liposarcoma, leiomyosarcoma, MPNST, rhabdomyosarcoma, and synovial sarcoma.

It has recently been noted that malignant fibrous histiocytoma is not associated with a distinct gene cluster, suggesting that malignant fibrous histiocytoma is not a separate tumor entity but rather a common morphologic appearance of various sarcoma subtypes.[53,54] For example, most tumors initially diagnosed as malignant fibrous histiocytoma in the retroperitoneum have been reclassified using genomic profiling as dedifferentiated liposarcomas,[55] whereas those in the extremities have been reclassified as leiomyosarcoma, myxofibrosarcoma, or pleomorphic undifferentiated sarcoma.

Guidelines for the pathologic reporting of sarcoma have been established.[1] Included in the report should be the primary diagnosis, anatomic site, depth, size, and histologic grade, presence or absence of necrosis, status of excision margins and lymph nodes, TNM stage, and additional features of the tumor (i.e., mitotic rate and presence or absence of vascular invasion).

Staging and Prognostic Factors

Soft tissue sarcoma is most commonly staged using either the American Joint Committee on Cancer (AJCC) system (generally used in the United States) or the World Health Organization system. A unique aspect of sarcoma staging is the inclusion of tumor grade, which is one of the most important prognostic factors.[56]

The seventh edition of the AJCC staging system for soft tissue sarcomas is based on histologic grade of aggressiveness, tumor size and depth, and the presence of nodal or distant metastases.[57] This system does not apply to GIST, fibromatosis (desmoid tumor), Kaposi's sarcoma, or infantile fibrosarcoma.

Histologic Grade of Aggressiveness. Histologic grade is the most important prognostic factor for patients with soft tissue sarcoma. For accurate determination of grade, an adequate tissue sample must be appropriately fixed, stained, and reviewed by an experienced sarcoma pathologist. The features that define grade are cellularity, differentiation (good, moderate, or poor/anaplastic), pleomorphism, necrosis (absent, <50%, or ≥50%), and number of mitoses per high-power field (<10, 10–19, or ≥20). Tumor grade has been shown to predict metastasis and overall survival.[58] Metastasis has been estimated to occur in 5% to 10% of low-grade lesions, 25% to 30% of intermediate-grade lesions, and 50% to 60% of high-grade lesions.

The number of grades varies according to the classification system used. The most common classification systems, those of the National Cancer Institute and the French Federation of Cancer Centers, use three-tier tumor grades.[59] The National Cancer Institute system is based primarily on histologic subtype, location, and amount of necrosis. The French Federation of Cancer Centers system is based on tumor differentiation (good, moderate, or poor/anaplastic), number of mitoses per high-power field (<10, 10–19, or ≥20), and amount of tumor necrosis (absent, <50%, or ≥50%). A comparative analysis of the two systems suggested that the French Federation of Cancer Centers system has better prognostic capability, predicting 5-year survival rates of 90%, 70%, and 40% for grade 1, 2, and 3 tumors, respectively.[59]

Following the recommendation of the College of American Pathologists, the committee that developed the 2008 AJCC staging system changed the system from a four-grade to a

three-grade system in which the grades are well differentiated (grade 1), moderately differentiated (grade 2), and poorly differentiated (grade 3).[60] Grade 1 is considered low grade, and grades 2 and 3 are considered high grade.

Tumor Size and Location. Tumor size is an important prognostic variable in soft tissue sarcomas. Sarcomas have classically been stratified into two size groups; T1 lesions are 5 cm or smaller, and T2 lesions are larger than 5 cm. Some authors have suggested adding a third group for tumors larger than 15 cm, because such tumors are associated with a worse prognosis than tumors measuring between 5 and 15 cm.[61,62]

Anatomic tumor location was incorporated into the AJCC staging system in 1998. Soft tissue sarcomas above the superficial investing fascia of the extremity or trunk are designated "a" lesions within the T category, whereas tumors invading or deep to the fascia and all retroperitoneal, mediastinal, and visceral tumors are designated "b" lesions.

Nodal Metastasis. Overall, lymph node metastases arising from soft tissue sarcomas are rare,[27] but the incidence of nodal involvement is higher for epithelioid sarcoma, pediatric rhabdomyosarcoma, clear cell sarcoma, synovial sarcoma, myxofibrosarcoma, and angiosarcoma. In the seventh edition of the AJCC staging system, sarcoma associated with nodal metastases was reclassified as stage III rather than stage IV because several studies reported better survival for patients with isolated regional lymph node metastases treated with radical lymphadenectomy than for patients with distant metastases.[27, 63-65] Patients with clinically or radiologically suspicious regional nodes should have metastases confirmed or ruled out by fine-needle aspiration before radical lymphadenectomy.

Distant Metastasis. Distant metastases occur most often in the lungs (Fig. 36-4). Selected patients with pulmonary metastases may survive for long periods after surgical resection and chemotherapy. Other potential sites of metastasis include bone (Fig. 36-5), brain (Fig. 36-6), and liver (Fig. 36-7). Visceral and

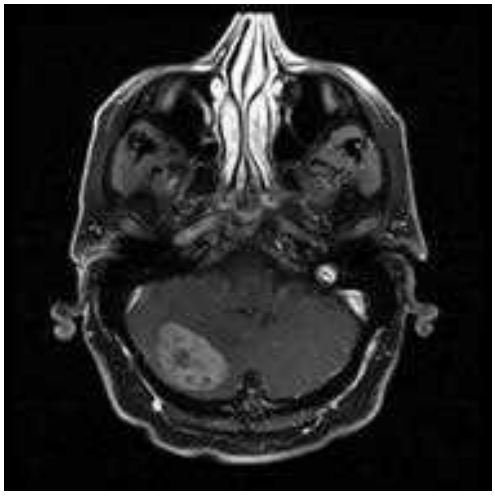

Figure 36-6. A 64-year-old man with a history of a T2 high-grade pleomorphic sarcoma of the thigh who developed brain metastases 14 months after diagnosis.

Figure 36-7. A 33-year-old woman with osteosarcoma of the sternum who presented with a liver metastasis 3 years after diagnosis.

retroperitoneal sarcomas have a higher incidence of liver and peritoneal metastases.

Prognostic Factors. Prognostic variables in soft tissue sarcoma include primary tumor size, grade, and depth, all of which are incorporated into the staging system, as well as histology, tumor site, and presentation (local recurrence or initial diagnosis). Patient factors such as older age and gender have also been associated with recurrence and mortality in several studies.[66] A positive microscopic margin and early recurrence after resection of an extremity sarcoma have been shown to be associated with decreased survival.[67]

Several groups have reported that Ki-67, a proliferation marker, is correlated with a poor clinical outcome in high-grade extremity sarcomas.[68,69] E-cadherin and catenins, proteins essential for intercellular junctions, have been associated with poor outcome in patients with soft tissue sarcoma.[68] Similarly, higher CD100 expression has been shown to correlate with higher proliferative potential and poorer outcome.[69]

Prognostic Nomograms. Prognostic nomograms for soft tissue sarcoma have been introduced for use in patient counseling, selecting appropriate surveillance strategies, and selecting patients for clinical trials.[70] One such nomogram, developed by Kattan and colleagues at Memorial Sloan-Kettering Cancer Center, considers age, histology, grade, location, depth, and size to determine the likelihood of 12-year sarcoma-specific survival.[70] Two validation studies using the nomogram demonstrated good predictive value.[71] More recently, the same group of investigators developed histology subtype-specific nomograms for patients with liposarcoma, synovial sarcoma, and GIST[72] and demonstrated that they were accurate in predicting disease-specific survival. Other investigators have just developed a site-specific nomogram for patients with retroperitoneal sarcoma, demonstrating an accurate prediction of survival and disease recurrence.[73]

TREATMENT OF EXTREMITY AND TRUNK WALL SARCOMA

The goals of treatment of soft tissue sarcoma are to maximize the likelihood of long-term recurrence-free survival while minimizing morbidity and maximizing function. In the past two decades, a multimodality treatment approach with optimal sequencing of treatments for individual patients has been shown to improve survival.[74] Furthermore, patients with soft tissue sarcoma treated at high-volume centers have been shown to have improved survival and functional outcomes.[75] Care at such centers is particularly important for patients with high-risk and advanced disease.

The overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50% to 60%. For patients with extremity sarcomas, a multidisciplinary treatment approach has resulted in local control rates exceeding 90% and 5-year survival rates exceeding 70%. Most patients who die of soft tissue sarcoma die of metastatic disease, which becomes evident within 2 to 3 years of initial diagnosis in 80% of cases.

Recommendations for evaluation and treatment of patients presenting with soft tissue masses are summarized in Table 36-3.

Surgery

Primary tumors with no evidence of distant metastasis are managed with surgery alone or, when wide pathologic margins cannot be achieved because of anatomic constraints and/or the grade is high, surgery plus radiation therapy. The type of surgical resection is determined by several factors, including tumor location, tumor size, depth of invasion, involvement of nearby structures, need for skin grafting or autogenous tissue reconstruction, and the patient's performance status. In 1985, the National Institutes of Health developed a consensus statement recommending limb-sparing surgery for most patients with high-grade extremity sarcomas.[76] However, for patients with primary or recurrent tumors that cannot be grossly resected with a limb-sparing procedure and preservation of function (<5% of patients), amputation remains the treatment of choice.

Table 36-3

Recommendations for the management of soft tissue masses

1. Soft tissue tumors that are enlarging or greater than 3 cm should be evaluated with radiologic imaging (ultrasonography or computed tomography [CT]), and a tissue diagnosis should be made using core needle biopsy.
2. Once a sarcoma diagnosis is established, obtain imaging (magnetic resonance imaging for extremity lesions and CT for other anatomic locations) and evaluate for metastatic disease with chest CT for intermediate- or high-grade (grade 2 or 3) or large (T2) tumors.
3. A wide local excision with 1- to 2-cm margins is adequate therapy for low-grade lesions and T1 tumors.
4. Radiation therapy plays a critical role in the management of large (T2), intermediate- or high-grade tumors.
5. Patients with locally advanced high-grade sarcomas or distant metastases should be evaluated for chemotherapy.
6. An aggressive surgical approach should be taken in the treatment of patients with an isolated local recurrence or resectable distant metastases.

Margin status after surgical resection has been shown to be an independent prognostic factor.[77,78] The goal of surgical resection is to achieve a complete resection because microscopically positive or grossly positive resection margins are associated with increased risk of local recurrence and death.[79] If an unexpected positive margin is found on pathologic examination of the resection specimen, re-excision should be performed. In patients with a positive margin, particularly in patients with macroscopic residual disease, local control is unlikely even with the addition of postoperative radiation therapy.[80]

Wide Local Excision. The preferred treatment for extremity sarcomas is wide local excision that includes resection of the biopsy site. The goal of wide local excision is to remove the tumor with approximately 1 to 2 cm of surrounding normal soft tissue,[77] but narrower margins may be necessary to preserve uninvolved critical neurovascular structures and may be adequate for patients undergoing radiation therapy.[81] Dissection should proceed through grossly normal tissue planes not abutting the tumor. Soft tissue sarcomas are generally surrounded by a zone of compressed reactive tissue that forms a pseudocapsule, but this pseudocapsule should not be used to guide resection (enucleation). If the tumor is adjacent to or displacing major neurovascular structures, these do not need to be resected, but the adventitia or perineurium should be removed.[1] For some massive tumors of the extremities, wide local excision entails a

radical or complete anatomic compartment resection. Surgical clips should be placed to delineate the extent of the resection bed for patients likely to require postoperative radiation therapy.

Recent reports demonstrate encouraging results following radical en bloc resection with vascular reconstruction in the lower extremities.[82,83] While en bloc resection with vascular reconstruction has been associated with increased rates of postoperative complications, reported local recurrence and 5-year survival rates are similar to those for patients not requiring vessel resection.[84,85] Similarly, studies have shown acceptable functional outcomes with resection of the sciatic, tibial, and peroneal nerves with appropriate reconstruction and rehabilitation.[86]

Bone invasion from extremity soft tissue sarcoma, which can generally be identified using high-quality cross-sectional imaging such as MRI, has been estimated to occur in about 5% of patients and is associated with reduced overall survival.[87] In cases of bone invasion, bone resection is required to obtain an adequate surgical margin and to achieve local control. Although tumor resection and repair of skeletal defects are possible, the likelihood of postoperative complications may be increased, and functional outcomes may be less favorable. Lin and colleagues[88] recently analyzed 55 patients with soft tissue sarcomas abutting bone and reported that in the absence of frank cortical bone penetration, periosteum was an adequate surgical margin in patients treated with wide local excision and radiation.

Soft tissue sarcomas arising in the distal extremities, particularly the hands and feet, present unique technical challenges. While distal-extremity tumors are often detected at a smaller size (<5 cm) than proximal-extremity tumors, resection and reconstruction techniques are often more complex for distal-extremity tumors, and preoperative planning is critical to obtain favorable functional outcomes. Identifying the proximity of the tumor to underlying critical structures (e.g., bone, tendon, or neurovascular structures) using MRI is essential for surgical planning. In a reported series of patients with sarcomas of the hands or feet treated with limited surgery only, 32% of patients had local recurrences.[89] Preservation of function and acceptable recurrence rates with limited surgery and adjuvant radiation therapy for soft tissue sarcomas of the distal extremities have been reported.[90] For locally advanced tumors, repair of bone defects, vascular reconstruction, tendon transfers, and soft tissue reconstruction using regional or free flaps have resulted in good functional outcomes.[91] Amputation remains a reasonable option for patients with soft tissue sarcomas of the distal extremities when acceptable oncologic or functional outcomes cannot be achieved using available limb salvage techniques.

In an interesting study conducted in Ontario and Quebec, investigators found patients expecting a difficult recovery and patients with uncertain expectations had worse functional outcomes than patients anticipating an easy recovery, indicating that preoperative education including consultation with rehabilitation services may optimize outcomes.[92] Furthermore, all patients undergoing resection of extremity sarcomas should undergo physical therapy beginning immediately after surgery and continuing until maximum function is achieved.[1]

Locoregional Lymphadenectomy. Several studies have reported improved survival for patients with isolated regional lymph node metastases treated with radical lymphadenectomy.[27, 63-65] Patients with clinically or radiologically suspicious regional nodes should have metastases confirmed before radical lymphadenectomy. At our institution, we perform ultrasound-guided fine-needle aspiration of lymph nodes in selected patients with suspicious clinical or radiologic findings. The utility of sentinel lymph node biopsy has remained controversial despite the recognition that several histologic subtypes of high-grade sarcoma are known to have a propensity for lymph node metastasis. However, there have been no prospective studies of the sensitivity and specificity of sentinel lymph node biopsy for such tumors.

Amputation. Amputation is the treatment of choice for the 5% of patients with primary or recurrent extremity tumors whose tumors cannot be grossly resected with limb-sparing procedures and preservation of function. Historically, local excision of large, high-grade soft tissue sarcomas resulted in local failure rates of 50% to 70%, even when a margin of normal tissue around the tumor was excised; consequently, radical resection or amputation was recommended. Today, however, the addition of radiation therapy to less radical surgical resection has made limb salvage possible in most cases.

A comparison of amputation versus limb-sparing surgery followed by adjuvant radiation therapy performed by the National Cancer Institute between 1975 and 1981 demonstrated no significant difference between the two groups in local recurrence or overall survival rate.[93] Potter and colleagues[49] later reviewed the entire National Cancer Institute experience with 123 patients treated with conservative surgery plus radiation therapy and 83 treated with amputation. The local recurrence rate was significantly higher in the surgery and adjuvant radiation therapy group: 8% versus 0% in the amputation group. However, survival rates did not differ between the groups. Several large single-institution studies have since also reported favorable local control rates with conservative resection plus radiation therapy.[94-96]

Isolated Regional Perfusion. Isolated regional perfusion is a limb-sparing technique in which a soft tissue sarcoma is perfused with high concentrations of tumor necrosis factor-α and melphalan under hyperthermic conditions. The technique is generally used for locally advanced, multifocal, or locally recurrent disease; it has also served as a palliative treatment to achieve local control for patients with distant metastases.

Limb perfusion requires isolating the main artery and vein of the perfused limb from the systemic circulation. The anatomic approach is determined by tumor site: external iliac vessels are used for thigh tumors, femoral or popliteal vessels for calf tumors, and axillary vessels for upper extremity tumors. The vessels are dissected, and all collateral vessels are ligated. The main artery and vein are then cannulated and connected to a pump oxygenator similar to that used in cardiopulmonary bypass. Either a tourniquet or an Esmarch band is applied to the limb to achieve complete vascular isolation. Chemotherapeutic agents are then added to the perfusion circuit and circulated for 90 minutes. Systemic leakage from the perfused limb is monitored continuously with ^{99}Tc-radiolabeled human serum albumin injected into the perfusate, and radioactivity above the precordial area is recorded with a Geiger counter. During the entire procedure, hyperthermia of the perfused limb is maintained by external heating and by warming the perfusate to 40°C. At the end of the procedure, the limb is washed out, the cannulas are extracted, and the blood vessels are repaired.

Despite the 40-year history of using isolated limb perfusion to treat extremity sarcomas, many questions about this technique remain to be answered. The optimal chemotherapeutic agent in

the perfusion circuit, the benefits of hyperthermia, and the effectiveness of hyperthermic perfusion as neoadjuvant or adjuvant treatment remain to be elucidated. Studies published to date have involved heterogeneous patient groups and various chemotherapeutic agents. Despite these limitations, response rates from 18% to 80% and overall 5-year survival rates from 50% to 70% have been reported.[97-101] However, survival outcomes following isolated limb perfusion have not yet been directly compared with survival outcomes after more conventional treatment approaches.

In the initial report of isolated regional perfusion for extremity sarcomas, published in 1974, McBride reported results in 79 patients with extremity sarcomas who had been treated with isolated limb perfusion during the previous 14 years.[97] All patients received melphalan and dactinomycin. The overall 5-year survival rate was 57%, and only 13 patients had subsequent amputation for recurrent disease. Over the next 20 years, isolated perfusion for treatment of extremity sarcoma fell out of favor for several reasons. Most notably, improved survival and decreased local recurrence rates could be obtained with less radical therapy, including conservative surgical excision combined with radiation to allow limb sparing in patients who were previously thought to require amputation.

A 1992 report by Lienard and colleagues[101] renewed interest in isolated limb perfusion for extremity tumors. Those investigators reported a 100% response rate among patients with extremity melanomas and sarcomas treated with high-dose recombinant tumor necrosis factor-α plus interferon-γ and melphalan in an isolated perfusion circuit. This report led to larger studies geared specifically to patients with sarcoma. The largest of these studies, the European Multicenter Study, was reported by Eggermont and colleagues in 1996.[99] In that study of 186 patients, the overall tumor response rate was 82%, and the clinical and pathologic complete response rate was 29%. Although all of the study participants were reported to initially be candidates for amputation, the rate of limb salvage following isolated limb perfusion was 82%.[99] Subsequent studies have shown high local response and limb salvage rates and acceptable local and systemic toxic effects.[102]

However, results in the United States have been inferior to those reported in Europe. In a study by Fraker and colleagues, the complete response rate was 26%, and an additional 30% of patients had a partial response. Fourteen patients (32%) underwent amputation for progressive tumors, while the remaining 30 patients (68%) were able to undergo limb-sparing surgery after isolated limb perfusion.[100] The inferior results in the U.S.-based studies are thought to be due to patient selection biases and the degree of treatment before limb perfusion.

Radiation Therapy

Radiation therapy is part of the standard treatment for high-grade extremity and trunk wall soft tissue sarcomas either in the pre- or postoperative setting. Patients with low-grade tumors or small, superficial high-grade tumors that have been resected with adequate margins may safely avoid radiation therapy.

The evidence supporting adjuvant radiation therapy for patients eligible for conservative surgical resection comes from two randomized trials[103,104] and three large single-institution reports.[105-107] In a randomized trial by the National Cancer Institute, 91 patients with high-grade extremity tumors were treated with limb-sparing surgery followed by chemotherapy alone or radiation therapy plus chemotherapy. The 10-year local control rate was 98% for patients receiving radiation therapy compared with 70% for those not receiving radiation therapy ($P = .0001$).[103] Similarly, in a randomized trial from Memorial Sloan-Kettering Cancer Center, 164 patients underwent conservative surgery followed by observation or brachytherapy. For patients with high-grade tumors, the 5-year local control rate was 66% in the observation group and 89% in the brachytherapy group ($P = .003$).[104] For patients with low-grade tumors, no significant difference was observed between treatment groups.[108]

Until recently, the standard treatment guidelines required radiation therapy after surgery for all patients with intermediate- or high-grade tumors of any size. However, small tumors (≤5 cm) have not generally been associated with local recurrence, and radiation therapy for such tumors may not be necessary.[104] In a series of 174 patients reported by Geer and colleagues, postoperative radiation therapy did not improve 5-year local recurrence or overall survival rates for patients with small soft tissue sarcomas.[109] Karakousis and colleagues reported a 5-year local recurrence rate of 6% for 80 patients with extremity sarcomas treated with wide local excision and observation, a rate similar to that for the 64 patients who underwent resection with narrower surgical margins and postoperative radiation therapy.[110]

The optimal mode of radiation therapy (external-beam radiation therapy, brachytherapy, or intensity-modulated radiation therapy [IMRT]) and timing of radiation therapy (preoperative, intraoperative, or postoperative) have yet to be defined. External-beam radiation therapy can be delivered using photons or particle beams (electrons, protons, pions, or neutrons). Conventional fractionation is usually 1.8 to 2 Gy per day. CT is an integral part of radiation therapy, used to define the gross tumor volume and to estimate the margin of tissue at risk for microscopic tumor involvement. The optimal radiation margin is not well defined: a margin of 5 to 7 cm is standard, but some centers advocate wider margins for tumors larger than 15 cm. At most institutions, the typical *preoperative* dose is 50 Gy given in 25 fractions, and resection is performed 4 to 8 weeks after completion of radiation therapy to allow acute radiation changes to subside. *Postoperative* radiation therapy planning is based on tumor site, tumor grade, surgical margins, and institutional preferences. The entire surgical scar and drain sites should be included in the field so that a near-full dose can be administered to the superficial skin. Metallic clips placed in the tumor bed during surgery can help define the limits of the resection and aid in radiation therapy planning. Doses of 60 to 70 Gy are usually necessary for postoperative treatment.

No consensus exists on the optimal sequence of radiation therapy and surgery. The available data come largely from single-institution, nonrandomized studies. Proponents of preoperative radiation therapy note that multidisciplinary planning with radiation oncologists, medical oncologists, and surgeons is easier early in the course of therapy. In addition, for some radiosensitive histologic subtypes, such as myxoid liposarcoma, preoperative radiation therapy may shrink the tumor, facilitating resection with negative margins. Furthermore, a tissue bed undisturbed by resection has better tissue oxygenation and can be successfully treated with lower doses of radiation. In addition, Nielsen and colleagues[111] demonstrated that preoperative radiation fields are smaller than postoperative radiation fields and that the average number of joints included in the field is lower with preoperative than postoperative radiation therapy, which may result in improved functional outcome. Critics of preoperative radiation therapy cite the difficulty of pathologic

assessment of margins and the increased rate of postoperative wound complications.[112] However, reconstructive surgical techniques with advanced tissue transfer procedures are being used more often in these high-risk wounds and reportedly result in better outcomes. The higher doses generally required for postoperative radiation therapy have also been shown to be associated with greater long-term functional impairment.

The only randomized comparison of preoperative and postoperative radiation therapy to date was performed by the National Cancer Institute of Canada Clinical Trials–Canadian Sarcoma Group.[113] This trial was designed to examine complications and functional outcome. The 190 patients enrolled from October 1994 to December 1997 were randomized to preoperative radiation therapy (50 Gy) or postoperative radiation therapy (66 Gy). With a median follow-up time of 3.3 years, the recurrence and progression-free survival rates were similar in the two groups. However, the incidence of wound complications was significantly lower with preoperative radiation therapy (3% vs. 17%), and the incidence of wound complications was significantly higher for tumors of the lower extremity (43%) than for those of the upper extremity (5%).[113] Late radiation toxic effects (e.g., fibrosis, joint stiffness, and edema) were more common with postoperative than preoperative radiation therapy (48% vs. 32%) because of higher postoperative radiation doses and larger treatment field sizes.[114]

Brachytherapy involves the placement of multiple radioactive seeds through catheters inserted in the tumor resection bed. The primary benefit of brachytherapy is the shorter overall treatment time of 4 to 6 days, compared to the 4 to 6 weeks generally required for preoperative or postoperative radiation therapy regimens. A cost-analysis comparison of adjuvant brachytherapy versus adjuvant external-beam irradiation for soft tissue sarcomas showed that costs were lower with brachytherapy.[115] Brachytherapy can also be used for recurrent disease previously treated with external-beam radiation. Guidelines established at Memorial Sloan-Kettering Cancer Center recommend spacing the afterloading catheters in 1-cm increments while leaving a 2-cm margin around the surgical bed.[104] After adequate wound healing is confirmed, usually after the fifth postoperative day, the catheters are loaded with seeds containing iridium-192 that deliver 42 to 45 Gy of radiation to the tumor bed over 4 to 6 days. The primary disadvantage of brachytherapy is that it requires significant expertise, extended inpatient hospital stays, and bed rest.

IMRT delivers radiation more precisely to the tumor than external-beam irradiation while minimizing the volume of surrounding tissues exposed to high radiation doses. The proposed benefits of preoperative IMRT include reduced risk of postoperative wound infections because of minimization of the dose to the skin[116] and protection of underlying bone (e.g., femur) as a result of concave dose distributions.[117] There have been no prospective randomized trials comparing the long-term outcomes following IMRT versus other types of radiation therapy. In a retrospective analysis of IMRT, patients with negative and positive/close (within 1 mm) margins were found to have 5-year local control rates of 94%.[118] In addition, the rates of posttreatment edema and joint stiffness with IMRT were lower than the expected rates with conventional radiation therapy.

Local toxic effects of radiation therapy vary according to radiation dose, field size, and timing (preoperative or postoperative). With preoperative radiation therapy, the most frequent wound complications are wound dehiscence, wound necrosis, persistent drainage, infection, seroma formation, ulceration, and cellulitis.[113] Postoperative irradiation of free flaps is often associated with wound complications, and patients should be advised that secondary surgical repair may be necessary. Wound complication rates of 13% to 37% have been reported for preoperative radiation therapy, compared to 5% to 20% for postoperative radiation therapy.[119] If catheters are loaded after the fifth postoperative day, rates of wound complications after brachytherapy are similar to those after postoperative radiation therapy.

Long-term (chronic) effects of radiation therapy (those occurring >1 year after completion of therapy) are generally related to fibrosis/contractures, lymphedema, neurologic injury, osteitis, and fractures, all of which can cause substantial functional impairment.[119] Variables associated with poorer functional outcome after radiation therapy include larger tumors, higher doses of radiation (>63 Gy), longer radiation fields (>35 cm), poor radiation technique, neural sacrifice, postoperative fractures, and wound complications.[114,120] Additionally, complications of any kind are less likely after treatment for upper extremity sarcoma than after treatment for lower extremity sarcoma.[112,113]

Definitive radiation therapy that delivers maximal-tissue-tolerance doses of radiation may be appropriate for selected patients with unresectable soft tissue sarcomas. In a study of 112 patients with unresectable soft tissue sarcomas, tumor size and radiation dose were found to influence local control and survival.[121] The local control rate was 51% for tumors smaller than 5 cm and 9% for tumors larger than 10 cm, and patients who received at least 64 Gy had better local control and survival.

Systemic Therapy

Despite improvements in local control rates, metastasis and death remain significant problems for patients with high-risk soft tissue sarcomas. Patients considered at high risk of death from sarcoma include those presenting with metastatic disease, localized sarcomas at nonextremity sites, or sarcomas of intermediate- or high-grade histology larger than 5 cm.[58,104]

Standard Chemotherapy. For most patients with sarcoma, results of conventional chemotherapy regimens have been poor. The chemosensitivity of soft tissue sarcoma varies by histologic subtype.[29] Synovial sarcoma, myxoid/round cell liposarcoma, and uterine leiomyosarcoma are sensitive to chemotherapy,[122] whereas pleomorphic liposarcoma, myxofibrosarcoma, epithelioid sarcoma, leiomyosarcoma, MPNSTs, angiosarcoma, and desmoplastic round cell tumors have intermediate sensitivity to chemotherapy. Relatively chemoresistant histologic subtypes include clear cell sarcoma, endometrial stromal sarcoma, alveolar soft part sarcoma, and extraskeletal myxoid chondrosarcoma. Considering the variability of responses by histologic subtype, it is not surprising that clinical trials of standard chemotherapy, which often include heterogeneous populations with respect to tumor grade and histology, have demonstrated no overall survival benefit.

Doxorubicin and ifosfamide are the two most active agents against soft tissue sarcoma, with consistently reported response rates of 20% or greater and positive dose-response curves.[123,124] The European guidelines recommend doxorubicin 75 mg/m^2 every 3 weeks as first-line treatment for advanced disease.[29] Treatment duration is based on response, but a maximum of six cycles is generally recommended because of the risk of cumulative cardiotoxicity. Ifosfamide is the recommended second-line treatment and is recommended for first-line treatment in patients

with cardiac morbidity. The standard dose of ifosfamide is 9 to 10 g/m^2; however, single-institution series using higher-dose regimens (>10 g/m^2) or standard-dose ifosfamide combined with doxorubicin have shown response rates of 20% to 60%.[124] Synovial sarcomas have been shown to be particularly sensitive to ifosfamide. Ifosfamide-associated toxic effects include hemorrhagic cystitis, neurotoxicity, and renal tubular acidosis. Historically, combination therapy with doxorubicin plus ifosfamide, dacarbazine, or both has resulted in increased response rates but no improvement in overall survival.[125] Dacarbazine as a single agent has also demonstrated activity in clinical trials.

Over the past decade, several additional chemotherapeutic agents, including gemcitabine, taxanes, and trabectedin, have been noted to be active against soft tissue sarcomas. Gemcitabine as a single agent was reported to produce responses in 18% of patients with advanced sarcoma.[126] Gemcitabine combined with docetaxel has been reported to produce response rates as high as 53% in patients with uterine leiomyosarcoma.[126,127] Gemcitabine combined with vinorelbine has also been associated with clinical benefit in patients with advanced sarcomas.[128] The taxanes (docetaxel and paclitaxel) have been found to be active against angiosarcomas, particularly of the face and scalp, likely because of their potent antiangiogenic effects.[129,130]

Novel Chemotherapeutic Agents. Trabectedin, a marine-derived alkaloid that binds DNA, affecting transcription and inducing the formation of DNA double-strand breaks, has shown benefit in the treatment of advanced soft tissue sarcomas, particularly leiomyosarcoma, myxoid liposarcoma, and other translocation-related sarcomas.[131] Trabectedin is generally well tolerated but can be associated with prolonged and severe neutropenia, thrombocytopenia, and hepatic toxic effects.

Palifosfamide is a stabilized formulation of the active metabolite of ifosfamide that has been reported to be better tolerated than ifosfamide.[132] Early trials have suggested antitumor activity comparable or superior to that of ifosfamide without nephrotoxicity.

Targeted Therapies. Several targeted agents are being investigated for the treatment of soft tissue sarcomas. Among these are tyrosine kinase inhibitors (e.g., imatinib, sunitinib, sorafenib, and dasatinib) that have been developed and approved for treatment of GIST. Clinical data accumulated in phase II trials also support the use of tyrosine kinase inhibitors (e.g., imatinib, sorafenib, and sunitinib) in the management of other advanced sarcomas.[125] Anti–vascular endothelial growth factor antibodies such as bevacizumab have demonstrated activity in patients with metastatic or unresectable angiosarcoma, solitary fibrous tumor, and epithelioid hemangioendothelioma.[133] Pazopanib is an oral angiogenesis inhibitor that targets vascular endothelial growth factor receptors, platelet-derived growth factor receptor (PDGFR), and c-kit. In a recent phase III study, pazopanib showed efficacy against placebo in second or further line of therapy in patients with advanced soft tissue sarcoma.[134] Inhibitors of the mammalian target of rapamycin pathway, including temsirolimus, everolimus, and ridaforolimus, have also shown activity against some soft tissue sarcomas (i.e., PEComas).[135]

Benefits of Systemic Therapy. The use of adjuvant and neoadjuvant chemotherapy for soft tissue sarcomas remains controversial. More than a dozen individual randomized trials of adjuvant chemotherapy have failed to demonstrate improvement in disease-free or overall survival for patients with soft tissue sarcoma. However, several limitations of these individual trials may explain the lack of observed improvement. First, the chemotherapy regimens used were suboptimal, consisting of single-agent therapy (most commonly with doxorubicin) and insufficiently intensive dosing schedules. Second, the patient groups were not large enough to reveal clinically significant differences in survival rates. Finally, most studies included patients at low risk of metastasis and death, namely those with small (<5 cm) and low-grade tumors.

The Sarcoma Meta-Analysis Collaboration analyzed 1568 patients from 14 trials of doxorubicin-based adjuvant chemotherapy to evaluate the effect of adjuvant chemotherapy on localized, resectable soft tissue sarcomas.[136] At a median follow-up time of 9.4 years, doxorubicin-based chemotherapy significantly improved the time to local and distant recurrence and recurrence-free survival rates. However, the absolute benefit in overall survival was only 4%, which was not significant ($P = .12$). In a subset analysis, patients with extremity tumors had a 7% benefit in terms of overall survival ($P = .029$).[136]

After this meta-analysis, randomized controlled trials of more contemporary anthracycline/ifosfamide dosing combinations with relatively small numbers of patients have yielded conflicting results. In an Italian cooperative trial, adjuvant chemotherapy improved median disease-free and overall survival times in patients with high-risk extremity soft tissue sarcomas.[137] In that study, 104 patients with high-grade tumors 5 cm or larger were randomized to definitive surgery or surgery plus adjuvant chemotherapy consisting of epirubicin (60 mg/m^2/d on days 1 and 2) and ifosfamide (1.8 g/m^2/d on days 1 through 5) for five cycles. With a median follow-up time of almost 5 years, disease-free survival times were 16 months in the surgery-alone group and 48 months in the combined-treatment group ($P = .04$), and median overall survival times were 46 months in the surgery-alone group and 75 months in the combined-treatment group ($P = .03$).[137] However, several years later, the surgery-alone and combined-treatment groups had equivalent relapse rates and deaths, which resulted in statistically similar overall survival.[138]

In an effort to further assess the role of chemotherapy in patients with stage III extremity sarcoma, a cohort analysis of the combined databases of The University of Texas MD Anderson Cancer Center and Memorial Sloan-Kettering Cancer Center was performed. Data on 674 patients with stage III extremity sarcoma who received either preoperative or postoperative doxorubicin-based chemotherapy were reviewed. The 5-year disease-specific survival rate was 61%.[139] Cox regression analysis showed a time-varying effect of chemotherapy with an associated benefit during the first year while receiving chemotherapy. However, the clinical benefits of chemotherapy in patients with stage III sarcomas were not sustained beyond 1 year. Grobmyer and colleagues compared the outcomes of patients treated at two institutions (1990–2001) with surgery only or surgery plus preoperative chemotherapy containing doxorubicin and ifosfamide. In this analysis, chemotherapy was associated with an improvement in the 3-year disease-specific survival rate that was most pronounced in patients with tumors larger than 10 cm (62% for surgery alone vs. 83% for neoadjuvant chemotherapy and surgery).[140]

More recently, the European Organization for Research and Treatment of Cancer (EORTC) completed a phase III randomized study (trial EORTC-62931; conducted from 1995 through 2003) comparing surgery alone versus surgery plus adjuvant ifosfamide (5 g/m^2) plus doxorubicin (75 mg/m^2) with growth factor support (lenograstim) every 21 days for five

cycles in 351 patients with resected grade II or III soft tissue sarcoma at any site. The estimated relapse-free survival rate was 52% in both arms, and the overall survival rate was better in the control arm (69% vs. 64%).[141] Although most individual studies are underpowered, data from all of these studies suggest that chemotherapy regimens that incorporate ifosfamide may provide some disease-free survival benefit but do not improve long-term overall survival for the majority of patients with soft tissue sarcoma.

In 2008, two updates to the 1997 Sarcoma Meta-Analysis Collaboration were published.[142,143] O'Connor and colleagues included all of the trials in the original meta-analysis and added data from four additional trials, for a total of 18 trials with 2170 patients.[142] The results showed a benefit of chemotherapy in terms of disease-free survival at 5 years and recurrence-free survival at 10 years but again failed to demonstrate a benefit in terms of long-term overall survival. The second update, by Pervaiz and colleagues, which did not include the EORTC-62931 trial, showed that adjuvant chemotherapy was associated with a significant decrease in the risk of death (hazard ratio, 0.77; $P = .01$).[143]

Because the evidence regarding adjuvant systemic therapy for stage III soft tissue sarcoma is inconclusive, considerable variation still exists in treatment recommendations even though patients with large, stage II or stage III soft tissue sarcomas are at high risk for recurrence and metastasis. Chemotherapy may be considered to downstage large tumors to enable limb-sparing procedures, particularly for tumors known to be chemosensitive. It is likely that subsets of high-risk patients with extremity soft tissue sarcoma defined on the basis of tumor size or histology derive significant benefit from systemic chemotherapy. For example, retrospective cohort analyses have noted a disease-specific survival benefit in patients with large, high-grade liposarcomas and synovial sarcomas of the extremity treated with ifosfamide plus doxorubicin versus no chemotherapy.[144]

Neoadjuvant (Preoperative) Chemotherapy. The use of neoadjuvant (preoperative) chemotherapy for soft tissue sarcomas is based on the belief that only 30% to 50% of patients respond to standard adjuvant (postoperative) chemotherapy. The rationale for using neoadjuvant chemotherapy is that it enables oncologists to identify patients whose disease is sensitive to a particular chemotherapy regimen by assessing response while the primary tumor is in situ. Patients whose tumors do not respond to short courses of neoadjuvant chemotherapy can thus be spared the toxic effects of prolonged adjuvant chemotherapy. Another advantage of neoadjuvant chemotherapy is that it may shrink tumors, enabling less morbid operations. The theoretical disadvantages of neoadjuvant chemotherapy are related to myelosuppression and potential postoperative wound healing complications.

A recent randomized study comparing three preoperative cycles of full-dose anthracycline-ifosfamide–based chemotherapy with three preoperative plus two postoperative cycles of the same regimen in high-risk extremity and trunk wall soft tissue sarcomas showed equivalence between the two approaches, suggesting the possibility of limiting chemotherapy administration to the three preoperative courses, improving the ratio between toxicity and expected benefit.[145]

A subanalysis on response showed how tumor attenuation on CT scan and MRI obtained by the administration of such preoperative treatment was associated with a higher percentage of pathologic necrosis[146] and better outcome.[147]

Eilber and colleagues examined treatment-induced pathologic necrosis in patients who received neoadjuvant therapy for high-grade extremity sarcomas.[148] The addition of ifosfamide to other agents (doxorubicin alone or doxorubicin and cisplatin) increased the rate of pathologic necrosis to 48% compared to 13% with other combinations. The 5- and 10-year local recurrence rates were significantly lower for patients with 95% or greater pathologic necrosis (6% and 11%, respectively) than for patients with less than 95% pathologic necrosis (17% and 23%, respectively).

Concurrent Chemoradiation Therapy

Treatment approaches that combine systemic chemotherapy with radiosensitizers and concurrent external-beam radiation therapy may improve disease-free survival by treating microscopic disease and enhancing the treatment of macroscopic disease. Concurrent chemoradiation therapy with doxorubicin-based regimens reportedly produces favorable local control rates for patients with sarcoma.[144] Since those findings were published, several groups have evaluated routes of administration, alternative chemotherapeutic agents, and the toxicity of combined therapies.

Theoretical advantages notwithstanding, concurrent chemoradiation therapy decreases the total treatment time for patients with high-risk sarcoma. This decrease represents a substantial advantage over current sequential combined-modality treatment approaches, for which the total duration of radiation therapy, chemotherapy, surgery, and rehabilitation frequently exceeds 6 to 9 months.

Posttreatment Surveillance

Currently, posttreatment surveillance is recommended for all patients with soft tissue sarcomas based on a few reports involving small numbers of patients indicating that local recurrence can be successfully treated with radical re-excision with or without radiation therapy.[149,150] Similarly, several groups have reported that survival can be prolonged by resection of pulmonary metastases.[151,152]

The National Comprehensive Cancer Network (NCCN) recommends a history and physical and chest CT or radiography every 3 to 6 months for 2 to 3 years after completion of treatment. Because most cases of distant metastasis occur within 2 to 3 years of initial diagnosis, the NCCN guidelines indicate that follow-up intervals can be lengthened to every 6 months and imaging can be done annually during years 2 through 5.[1] Consideration should also be given to imaging the primary tumor site; most experts recommend that the tumor site be evaluated every 6 months with MRI for extremity tumors or CT for intra-abdominal or retroperitoneal tumors. Guidelines have been established for using MRI to distinguish recurrences from typical postsurgical changes: a discrete nodule with low signal intensity on T1-weighted images and higher signal intensity on T2-weighted images that enhances after administration of intravenous contrast material is strongly suggestive of recurrence and should be biopsied. Ultrasonography may be an alternative to MRI or CT for assessing for recurrence in the extremities.

Recurrence is common after surgery for abdominal soft tissue sarcomas. CT is useful for detecting recurrences at primary and distant anatomic sites in the abdomen and pelvis. After surgery, CT every 3 to 6 months during the first 2 years and every 6 months for 3 years thereafter has been recommended. However, today many experienced surgeons are advocating less aggressive imaging for asymptomatic patients, particularly

after a second recurrence of retroperitoneal sarcoma, arguing that there is insufficient evidence to suggest that survival is improved by earlier detection.

Whooley and colleagues reviewed the efficacy of the surveillance strategy used at Roswell Park Cancer Institute for 174 patients with soft tissue sarcomas of the extremities.[153] Patients were evaluated every 3 months for the first 2 years, every 4 to 6 months during year 3, and every 6 months during years 4 and 5. Local recurrence occurred in 18% of patients at a median time after completion of treatment of 14 months, and all but one of the recurrences were detected with physical examination alone. Fifty-seven patients had distant recurrences (at a median of 18 months after treatment), of which 36 were asymptomatic and diagnosed by surveillance imaging. The investigators determined that the positive predictive value of chest radiography during follow-up was 92%.[153] However, evaluation of the primary tumor site by CT or MRI was ineffective in detecting recurrences. The authors recommended that patient characteristics, location of the primary tumor, previous treatment, and physician familiarity with changes after surgery and radiation therapy should all be considered in determining the need for radiographic imaging.

Management of Recurrent Sarcoma

Up to 20% of patients with extremity sarcoma develop locally recurrent disease, which is often accompanied by distant metastases; thus, all patients with recurrent extremity sarcoma should undergo a full staging assessment. Patients with microscopically positive surgical margins are at increased risk of local recurrence. In a series of 179 patients with locally recurrent extremity soft tissue sarcoma at Memorial Sloan-Kettering Cancer Center, the median interval to local recurrence was 16 months; 65% of patients developed a local recurrence by 2 years, and 90% by 4 years.[149] The majority of patients (89%) were treated with additional limb-sparing surgery, and 73% received additional adjuvant therapy; the disease-specific survival after treatment of first local recurrence was 55% at 4 years. Independent prognostic factors for disease-specific survival after local recurrence included tumor grade, local recurrence size, and local recurrence-free interval. These data indicate that an isolated local recurrence should be treated aggressively with resection with negative margins.

For patients with extremity sarcomas, achieving negative margins on resection of recurrent disease frequently requires amputation. However, in some patients with recurrent extremity sarcoma, function-preserving resection combined with additional radiation therapy, with or without chemotherapy, can produce acceptable rates of local control.[154-156] Nori and colleagues reported a local control rate of 69% among 40 patients with recurrent tumors treated with re-excision and brachytherapy to a median dose of 45 Gy.[156] In a similar series, Midis and colleagues reported that limb-sparing surgery was possible in 66% of patients, and the 5-year local recurrence-free survival rate was 72% in those patients.[154]

The primary determinant of survival in patients with soft tissue sarcoma is the development of distant metastases. Patients with extremity sarcomas generally develop pulmonary metastases.[153] Less common sites of metastasis for soft tissue sarcomas include bone (7%), liver (4%),[49] and lymph nodes (5%–7%).[27] Myxoid liposarcoma of the extremity is known to metastasize to the abdomen and pelvis; therefore, staging CT of these regions must be performed before definitive local therapy is administered.[31]

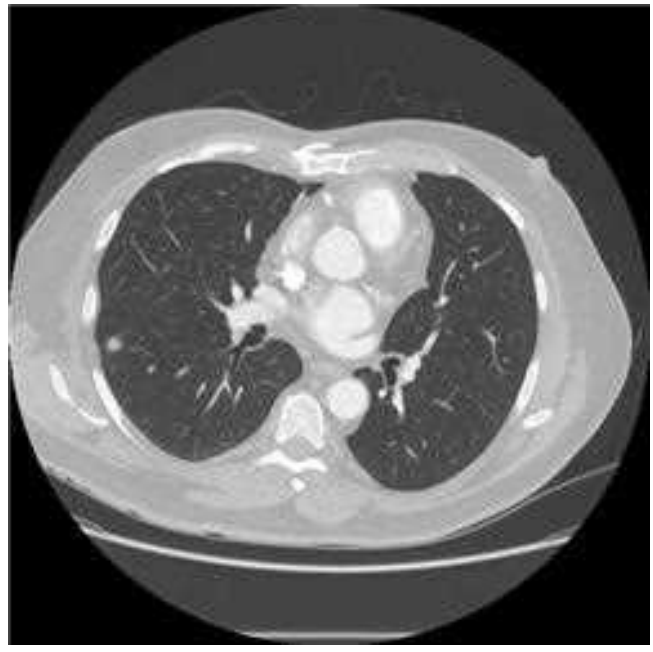

Figure 36-8. A 69-year-old patient with a history of a dedifferentiated liposarcoma of the retroperitoneum developed a solitary lung metastasis 6 years after surgical resection.

Management of Recurrent and Distant Metastatic Sarcoma. In selected individuals with distant metastatic disease, surgical resection of a primary soft tissue sarcoma may be appropriate as a palliative procedure. The decision should be based on the patient's symptoms, which often include pain; ability to achieve local tumor control; comorbidities; anticipated morbidity of the surgical procedure; and the extent of metastases.

The most common initial site of distant metastasis of soft tissue sarcomas is the lung. Selected patients with a limited number of pulmonary nodules (less than four nodules), long disease-free intervals, and no endobronchial invasion may become long-term survivors after pulmonary resection (Fig. 36-8); 15% to 40% of patients with complete resection of metastatic disease confined to the lung are long-term survivors.[153,157] In a retrospective multiinstitutional study of 255 patients with lung metastases, the 5-year overall survival rate after metastasectomy was 38%.[151] Favorable prognostic factors in that study included microscopically tumor-free margins, age younger than 40 years, and grade 1 or 2 tumor.[151] For patients who are surgical candidates, pulmonary resection alone can be more cost-effective than watchful waiting, chemotherapy, or chemotherapy plus surgery.[152]

Chemotherapy for Distant Metastatic Sarcoma. Doxorubicin, either alone or combined with other agents, has been the primary treatment modality for patients with advanced or distant metastatic sarcomas for several decades.[125] Although most patients with metastatic disease are not curable, some patients with limited disease experience stabilization of disease with multidisciplinary treatment, which often includes surgery and radiation therapy in addition to chemotherapy. Several factors predict better outcome for patients with recurrent metastatic sarcoma undergoing chemotherapy, including good performance status, previous response to chemotherapy, younger age, absence of hepatic metastases, low-grade tumor, and long disease-free interval.[158] Isolated liver metastases, if stable over several months, may be amenable to resection,[159] radiofrequency ablation,[160] or chemoembolization.[161]

As data accumulate regarding the sensitivity of sarcoma subtypes to particular chemotherapies, it is critical that histology-driven treatment approaches be used. New therapies are also being identified based on the unique molecular signatures of sarcomas.[125]

Palliative Radiation Therapy. Definitive radiation therapy can be considered when no acceptable surgical option is available (e.g., in patients with significant medical comorbidities). In this setting, radiation doses greater than 63 Gy yielded superior tumor control, but doses greater than 68 Gy resulted in increased rates of major complications.[162]

SPECIAL CLINICAL SITUATIONS

Myxoid Liposarcoma

Myxoid liposarcomas belong to the group of soft tissue sarcomas with lipomatous differentiation. However, myxoid liposarcomas differ from the other liposarcoma subtypes with respect to morphology (i.e., myxoid stroma and lipomatous differentiation) and clinical behavior. Myxoid liposarcomas frequently present as slow-growing, deep tumors in the lower extremity and can metastasize to other soft tissue locations, including the retroperitoneum and extremities.[163,164] For this reason, CT of the chest, abdomen, and pelvis is recommended for adequate staging and surveillance of myxoid liposarcoma.

Retroperitoneal Sarcoma

Most retroperitoneal tumors are malignant, and about one third are soft tissue sarcomas. Also to be considered in the differential diagnosis of a retroperitoneal tumor are primary germ cell tumors, lymphoma, and metastatic testicular cancer. Approximately 1000 new cases of retroperitoneal sarcoma are diagnosed annually in the United States, and these tumors account for 10% to 15% of all adult tissue sarcomas. Approximately two thirds of retroperitoneal sarcomas are high grade (either grade 2 or 3), and liposarcoma and leiomyosarcoma are the most common histologies.

Retroperitoneal sarcomas generally present as large masses: 70% are larger than 10 cm at diagnosis.[165] They typically do not produce symptoms until they grow large enough to compress or invade contiguous structures, although pain, early satiety, and obstructive gastrointestinal symptoms may occur early in the disease course in some patients. Evaluation of a patient with a retroperitoneal mass begins with an accurate history that should exclude signs and symptoms associated with lymphoma (e.g., fever and night sweats). A complete physical examination, with particular attention to all nodal basins and with a testicular examination in men, is critically important. Laboratory assessment can be helpful; elevated lactate dehydrogenase levels may suggest lymphoma, and elevated β-human chorionic gonadotropin levels or α-fetoprotein levels may indicate a germ cell tumor.

Although the general principles of evaluation and management for retroperitoneal sarcomas are similar to those for extremity sarcomas, there are some differences. Contrast-enhanced CT of the abdomen and pelvis is used to define the extent of the tumor and its relationship to surrounding structures, particularly vascular structures, for surgical planning; contrast-enhanced CT can also often distinguish between well-differentiated and dedifferentiated liposarcoma. CT imaging is also done to evaluate the liver for the evidence of metastases, the peritoneal cavity for evidence of discontiguous disease, and the kidneys for assessment of function. Angiography or magnetic resonance arteriography/venography can also be used to delineate vascular anatomy when involvement of critical vascular structures is suspected. Thoracic CT should be performed to evaluate for potential lung metastases because 11% of patients with retroperitoneal sarcoma present with synchronous metastatic disease. CT-guided core needle biopsy is appropriate to provide a tissue diagnosis; however, negative biopsy findings should not delay operative intervention.

Figure 36-9. A 45-year-old woman with a massive retroperitoneal atypical lipomatous tumor with displacement of the left kidney.

Complete surgical resection is the most effective treatment for primary or recurrent retroperitoneal sarcoma (Fig. 36-9). En bloc resection often necessitates sacrificing contiguous structures such as the colon, kidney, spleen, pancreas, psoas muscle, small bowel, inferior vena cava, and aorta.[166] In a review of 25 patients who underwent resection of retroperitoneal sarcoma with major blood vessel involvement in a 16-year time span, postoperative morbidity and mortality rates were 36% and 4%, respectively. Vessel patency rates were greater than 88% with a median follow-up time of 19.3 months.[83,167] Local control and survival rates were favorable in patients with tumor-free resection margins. The authors concluded that vascular resection is the treatment of choice in sarcomas that involve major blood vessels in the retroperitoneum.[83] Similar considerations were made by other groups reporting specifically on inferior vena cava resection in the context of multivisceral resection for retroperitoneal sarcoma and on surgical morbidity after extended surgical resection of retroperitoneal sarcoma. Extended procedures, including also vessels, are feasible and safe if carried out in experienced centers. While the goal of sarcoma resection is wide excision, this is unlikely to be achievable in most patients with retroperitoneal sarcomas. Surgery is considered marginal in most cases, even when macroscopically complete, but every attempt should be made to minimize this marginality by liberally resecting surrounding organs when needed. The extension of surgery should then take into consideration a trade-off between expected morbidity and benefit and should be best carried out at high-volume centers, where technical skills and knowledge of the natural history of this very rare disease can be found.

In an analysis of 500 patients with retroperitoneal soft tissue sarcoma treated at Memorial Sloan-Kettering Cancer Center, the median survival time was 103 months for those who underwent complete resection versus 18 months for those who underwent incomplete resection or observation without resection.[165] In general, surgical resection should not be offered unless radiographic evidence indicates the potential for complete resection; however, palliative surgical resection may be considered to reduce symptoms of intestinal obstruction, pain, or bleeding.[168] In particular, in patients with atypical lipomatous tumors, an aggressive surgical approach including incomplete resection or debulking is justified to palliate symptoms and may provide a potential survival benefit.[169] Such an approach is not justified for dedifferentiated liposarcomas or other high-grade retroperitoneal sarcomas because these tumors have high rates of distant metastasis and local recurrence.

Adjuvant Therapy. Most studies have failed to show a survival benefit from adjuvant chemotherapy for retroperitoneal sarcoma.[170-172] Because of the high rates of local recurrence, adjuvant radiation therapy has been proposed for treating microscopic residual disease following surgical resection. However, the optimal technique and timing of radiation therapy have not been established, and the potential benefits of radiation therapy must be weighed against the increased risk of treatment-related toxic effects.

Radiation treatment of retroperitoneal sarcomas is complex because tumors are usually large, which necessitates large treatment fields close to radiosensitive structures (e.g., bowel). Several techniques have been used, including preoperative and postoperative external-beam radiation therapy, intraoperative radiation therapy, and brachytherapy.[173] Preoperative radiation therapy is feasible and well tolerated. Toxic effects may be less severe with preoperative radiation therapy given that the tumor borders are definable, the tumor displaces radiosensitive viscera away from the treatment field, and effective doses of radiation may be lower preoperatively.[174]

Several studies have shown favorable local control rates for intermediate- and high-grade retroperitoneal sarcoma treated with preoperative radiation therapy and complete resection.[173] However, most studies have failed to show a survival benefit.[175] This situation prompted the initiation of a multicenter, randomized trial sponsored by the American College of Surgeons Oncology Group (ACOSOG) comparing surgery to surgery with preoperative radiation (ACOSOG Z9031). Unfortunately, the study was closed prematurely in 2006 because of low patient accrual. A similar study is now ongoing in Europe, sponsored by the Soft Tissue and Bone Sarcoma Group (STBSG) of the EORTC.

Current recommendations for radiation therapy for patients with retroperitoneal sarcoma at MD Anderson Cancer Center are based on disease characteristics at presentation.[176] For high-risk patients, defined as those with large, high-grade tumors or recurrent low-grade tumors, preoperative radiation therapy to a total dose of 50 Gy followed by surgical resection is considered. Postoperative radiation is discouraged unless the resected tumor bed is clearly away from dose-limiting structures.

Treatment of Recurrence. Retroperitoneal sarcomas recur more often than extremity and trunk wall ones. Retroperitoneal leiomyosarcomas, in addition to recurring locally in the tumor bed and metastasizing to the lungs, frequently spread to the liver. Retroperitoneal sarcomas can also recur diffusely throughout the peritoneal cavity (sarcomatosis). Resection of recurrent retroperitoneal sarcoma is similar to resection of recurrent extremity sarcoma. However, the likelihood that a recurrent retroperitoneal sarcoma will be resectable declines precipitously with each recurrence. In a large series of patients treated at Memorial Sloan-Kettering Cancer Center, the authors were able to resect recurrent tumors in 57% of patients with a first recurrence but only 20% of patients with a second recurrence and 10% of patients with a third recurrence.[68] In up to 25% of patients, well-differentiated retroperitoneal liposarcoma recurs in a poorly differentiated form or recurs with areas of dedifferentiation. Dedifferentiated retroperitoneal liposarcoma is more aggressive than its well-differentiated precursor and has a greater propensity for distant metastasis.

Gastrointestinal Sarcoma

Patients with gastrointestinal sarcoma most often present with nonspecific gastrointestinal symptoms that are determined by the site of the primary tumor. In a series from Memorial Sloan-Kettering Cancer Center, early satiety and dyspepsia were noted in patients with tumors of the upper gastrointestinal tract, whereas tenesmus and changes in bowel habits were common in patients with tumors of the lower gastrointestinal tract.[177] In a series of 80 patients with various smooth-muscle tumors of the gastrointestinal tract, Chou and colleagues[178] identified the most common presenting symptoms and signs as gastrointestinal bleeding (44%), abdominal mass (38%), and abdominal pain (21%).

Establishing the diagnosis of a gastrointestinal sarcoma preoperatively is often difficult. Radiologic assessment, including CT of the abdomen or pelvis, is sometimes useful to determine the anatomic location, size, and extent of disease. Patients with localized disease frequently present with a large intra-abdominal mass. However, there is no radiographic evidence of regional lymph node metastases, which would be typical of an adenocarcinoma of similar size and anatomic location. In patients with advanced gastrointestinal sarcoma, CT may demonstrate disseminated intra-abdominal masses with or without concomitant ascites and invasion of tissue planes.

Endoscopy (esophagoduodenoscopy or colonoscopy) has become the mainstay for evaluating symptoms related to the gastrointestinal tract. For tumors involving the stomach, upper endoscopy with endoscopic ultrasonography and biopsy are important diagnostic tests used to distinguish gastrointestinal sarcoma from adenocarcinoma of the stomach. This distinction is clinically significant because the extent of resection (local excision versus gastrectomy) and the role of regional lymphadenectomy differ for these two conditions. For gastrointestinal sarcomas, lymphatic spread is not the primary route of metastasis; consequently, lymphadenectomy is not routinely performed as part of resection. The general recommendation for gastrointestinal sarcoma, based on published data and the primary pattern of distant (vs. local) failure, is to resect the tumor with a 2- to 4-cm margin of normal tissue. However, some cases may be technically challenging because of the tumor's anatomic location or size. For example, for gastric tumors located near the gastroesophageal junction, achieving adequate surgical margins may not be possible without a total or proximal subtotal gastrectomy. Similarly, large leiomyosarcomas arising from the stomach with invasion of adjacent organs should be resected together with the adjacent involved viscera en bloc.

For sarcomas of the small or large intestine, segmental bowel resection is the standard treatment. For sarcomas of the

jejunum, ileum, and colon, the tumor is excised en bloc with the involved segment of intestine and its mesentery; radical mesenteric lymphadenectomy is not attempted. For sarcomas originating in the rectum, the tumor resection technique is based on the anatomic location and size of the tumor. For small, low rectal lesions, clear margins may be achievable with a transanal excision. Large or locally invasive lesions may require more extensive operations for complete tumor extirpation.[179,180]

Breast Sarcoma

Sarcomas of the breast are rare tumors, accounting for less than 1% of all breast malignancies and less than 5% of all soft tissue sarcomas. A variety of histologic subtypes have been reported within the breast, including angiosarcoma, stromal sarcoma, fibrosarcoma, and malignant fibrous histiocytoma.

Angiosarcoma of the breast accounts for about 50% of all sarcomas of the breast and has increasingly been associated with radiation therapy for treatment of primary breast cancer.[10] The period between radiation therapy and diagnosis of radiation-associated breast sarcoma has been reported to range from 3 to 20 years, with an incidence of 0.3% at 10 years and 0.5% at 15 years.[181] In a retrospective study of 55 patients with angiosarcoma of the breast, patients with radiation-associated angiosarcoma were on average 30 years older and were less likely to present with distant metastases than radiation-naïve patients. Clinically, radiation-associated angiosarcoma of the breast may occur in the irradiated chest wall after mastectomy or in the irradiated breast following segmental resection. The findings at presentation of a patient with cutaneous angiosarcoma often include an expanding erythematous patch, red papular eruptions, bluish-black lesions, or bruise-like discoloration overlying an area of induration. Mammography is often nonspecific, and diagnosis requires punch or incisional biopsy.

Cystosarcoma phyllodes are generally not considered to be sarcomas, because these tumors are thought to originate from hormonally responsive stromal cells of the breast and are usually benign. In patients with these tumors, infiltrating tumor margins, severe stromal overgrowth, atypia, and cellularity have all been identified as risk factors for metastases.[182]

As with sarcomas at other anatomic sites, histopathologic grade and tumor size are important prognostic factors for sarcomas of the breast. The likelihood of local recurrence increases as tumor size increases; tumors smaller than 5 cm are associated with better overall survival. Local and distant recurrences are more common in patients with high-grade lesions. Complete excision with negative margins is the primary therapy. Simple mastectomy confers no additional benefit if complete excision can be accomplished by segmental mastectomy. Because of low rates of regional lymphatic spread, axillary dissection is not routinely indicated. Neoadjuvant chemotherapy or radiation therapy may be considered for patients with large, high-risk tumors.

Uterine Sarcoma

Sarcomas account for less than 5% of uterine malignancies. Uterine sarcomas have been classified into four histologic subgroups: uterine leiomyosarcoma, endometrial stromal sarcoma, malignant mixed müllerian tumor (carcinosarcoma), and undifferentiated endometrial sarcoma. Five-year overall survival rates for patients with uterine sarcoma are 30% to 50%.[183] Total abdominal hysterectomy (TAH) is recommended for localized disease. Bilateral salpingo-oophorectomy is mandatory only in endometrial stromal sarcoma. Because uterine sarcomas are rare, the benefits of adjuvant therapy (e.g., chemotherapy, hormonal therapy) have not been adequately evaluated. Pelvic postoperative irradiation has been studied instead in a randomized fashion. The results of such study have been reported, showing no benefit in survival in favor of radiation therapy.[184]

Uterine leiomyosarcomas are smooth-muscle tumors and account for 35% to 40% of uterine sarcomas. Leiomyosarcoma can affect women in their twenties, although it is more commonly diagnosed between 50 and 60 years of age. Standard treatment is TAH with or without ovarian preservation depending on the patient's wishes and menopausal status. Lymph node metastasis is present in less than 5% of patients at diagnosis, and lymphadenectomy is not recommended. Adjuvant pelvic radiation therapy can be considered for selected high-risk patients. Adjuvant chemotherapy is controversial. Gemcitabine plus docetaxel has been noted to be well tolerated and highly active, with a response rate of 53% in patients with unresectable uterine leiomyosarcoma.[127] Doxorubicin and trabectedin have also demonstrated activity when used as first- or second-line therapy.

Endometrial stromal sarcomas account for approximately 7% to 10% of uterine sarcomas. Mitotic count is used to classify endometrial stromal sarcomas as low grade (<10 mitoses per 10 high-power fields) or high-grade (>10 mitoses per 10 high-power fields). In general, low-grade tumors demonstrate an indolent clinical course, while high-grade tumors are more aggressive with a poorer prognosis. Unlike other uterine sarcomas subtypes, endometrial stromal sarcomas express progesterone receptors and have been found to be responsive to hormonal manipulation as an adjuvant therapy or for treatment of recurrent disease.[185,186] Surgical treatment for these tumors includes TAH and bilateral salpingo-oophorectomy in premenopausal women; postoperative hormone replacement therapy is contraindicated.[187] Recurrent or advanced disease may respond to antiestrogen therapy. Tamoxifen is not recommended because it may be proestrogenic in this setting.

Malignant mixed müllerian tumor accounts for 50% of uterine sarcomas and arises predominantly in postmenopausal women. This tumor is regarded as epithelial and is treated not with agents typically used to treat sarcoma but with agents used to treat ovarian and endometrial cancers.

Undifferentiated endometrial sarcoma is an aggressive malignancy that does not express estrogen or progesterone receptors. It is associated with a poor prognosis even in patients presenting with localized disease. TAH with or without preservation of the ovaries is recommended; postoperative pelvic radiation therapy may also be administered. Systemic agents for other soft tissue sarcomas are used for recurrent and/or metastatic disease.

GASTROINTESTINAL STROMAL TUMORS

GISTs, which account for the majority of gastrointestinal sarcomas, have distinctive molecular features that have been characterized over the last decade. These tumors share phenotypic similarities with the intestinal pacemaker cells known as the interstitial cells of Cajal[188]; interstitial cells of Cajal and GIST cells express the hematopoietic progenitor cell marker CD34 and the growth factor receptor c-Kit.[189] Expression of the c-Kit gene protein product, CD117, has emerged as an important defining feature of GISTs. Using these diagnostic criteria, the incidence of GIST has been estimated to be 6 to 15 cases per million individuals per year.[190-192] Until recently, systemic

treatment for patients with unresectable or metastatic GIST was of little benefit because these tumors were resistant to conventional chemotherapy. Since the recognition that KIT activation occurs in most GISTs, KIT inhibition has emerged as the primary treatment modality along with surgery.

Approximately 80% of GISTs have a mutation in the gene encoding the KIT receptor tyrosine kinase, and 5% to 10% have a mutation in the gene encoding the related PDGFRA receptor tyrosine kinase; such mutations result in the expression of mutant proteins with constitutive tyrosine kinase activity.[1] The remaining GISTs do not have a detectable mutation, but lack of a mutation does not preclude a diagnosis of GIST if the tumor is morphologically typical of GIST. The presence and type of *KIT* (exon 11 or exon 9) or *PDGFRA* (exon 18) mutation has been found to predict tumor response to imatinib. In a phase II trial, patients with *KIT* exon 11 mutations had better response rates (83.5% vs. 47.8%) and survival than those with *KIT* exon 9 mutations or those without *KIT* or *PDGFRA* mutation.[193] These findings have subsequently been confirmed in two additional phase III trials conducted by the EORTC–Italian Sarcoma Group–Australasian Gastrointestinal Trials Group (EORTC-62005).[194,195]

The most common locations for GISTs are the stomach (60%) and small intestine (30%), but GISTs can arise anywhere along the gastrointestinal tract.[196] Gastric GISTs have been shown to be associated with a more favorable prognosis than GISTs at other sites.[197] GISTs are most commonly diagnosed by upper endoscopy and/or CT of the abdomen as an incidental finding in an asymptomatic patient or in a patient being evaluated for symptoms of early satiety, abdominal pain, or gastrointestinal bleeding. GIST most frequently metastasizes to the liver and/or abdominal cavity.

Radiologic Assessment

FDG-PET has been reported to be useful for preoperative staging of GISTs because it may reveal early metastases and establish baseline metabolic activity. PET has been shown to be highly sensitive in detecting early response to imatinib treatment and in predicting long-term response in patients with metastatic GIST. If PET is to be used for monitoring response to therapy, baseline PET should be performed before initiation of treatment. Because PET is still not widely available and because PET fails to detect some lesions because of poor glucose uptake, new CT-based criteria for detection of GIST and for predicting prognosis of GIST have also been proposed.[198]

Management of Localized Disease

Complete surgical resection with negative margins is the recommended treatment for localized GISTs. Extended anatomic resection and lymphadenectomy are not required. Resection of even locally advanced tumors is associated with improved survival.[199] The 5-year survival rate for all patients with GISTs ranges from 20% to 44%, and the 5-year survival rate for patients with completely excised early-stage tumors is up to 75%.[199] An analysis of 200 patients by DeMatteo and colleagues found a disease-specific survival rate of 54% for patients with grossly complete resection of primary GIST, and the median survival duration for patients with metastatic disease was only 20 months.[57]

As for other soft tissue sarcomas, tumor size has consistently been identified as an important prognostic factor for GIST. Mitotic activity has also been identified as an important prognostic factor and is generally categorized as fewer than 5, 5 to 10, or more than 10 mitoses per high-power field. The National Institutes of Health[200] and the Armed Forces Institute of Pathology[196] have proposed prognostic criteria for risk stratification of surgically treated, localized primary GIST. Both groups take into account tumor size and mitotic count; the Armed Forces Institute of Pathology also includes tumor site as a prognostic variable. Accurate risk stratification is essential for selecting patients most likely to benefit from adjuvant treatment.

Management of Locally Advanced or Metastatic Disease

Treatment with imatinib mesylate (Gleevec, ST1571), a selective inhibitor of the KIT protein tyrosine kinase, has resulted in impressive clinical responses in a large percentage of patients with unresectable or metastatic GISTs. On the basis of the initial results in a single patient with metastatic GIST, the EORTC Soft Tissue and Bone Sarcoma Group initiated a phase I study to test the safety and efficacy of imatinib.[201] In that study, 53% of patients with GISTs had confirmed partial responses; investigators concluded that imatinib is safe and effective against this disease.[201] A multicenter, international trial of imatinib for GIST was begun in July 2000 at four treatment centers: Dana-Farber Cancer Institute, Oregon Health Sciences University, Fox Chase Cancer Center, and University Hospital of Helsinki, Finland.[202] A total of 147 patients with unresectable or metastatic GISTs were randomized to 400 or 600 mg of imatinib daily for up to 24 months. Objective response was demonstrated in 79 patients (54%); all had partial responses, and there was no significant difference in response rate between imatinib doses.[203] Fourteen percent of patients experienced disease progression. The toxicity profile was acceptable; the predominant effects were gastrointestinal effects (diarrhea, nausea), periorbital edema, muscle cramps, and fatigue. However, 21% of patients experienced serious (grade 3 or 4) adverse events, including gastrointestinal bleeding in 5% of patients, most likely related to the rapid tumor response of mural lesions.

A phase III randomized Intergroup trial was simultaneously performed to assess the clinical activity of imatinib at two dose levels for patients with unresectable or metastatic GIST expressing the c-Kit tyrosine kinase.[204] From December 15, 2000, through September 1, 2001, 746 patients were accrued and randomized to low-dose (400 mg/d) or high-dose (800 mg/d) imatinib. The primary endpoint of the trial was survival. Preliminary toxicity data from 325 patients revealed a 23% incidence of grade 3 or 4 adverse events, including nausea and vomiting, gastrointestinal bleeding, abdominal pain, edema, fatigue, and rash.

In February 2002, the U.S. Food and Drug Administration approved imatinib for treatment of GIST based on the results of these promising clinical trials. Both the Intergroup trial mentioned in the preceding paragraph and a separate phase III trial compared the efficacy of low-dose (400 mg/d) and high-dose (800 mg/d) imatinib in patients with metastatic or unresectable GISTs.[205,206] Both studies showed equivalent response rates and overall survival for the two doses but increased toxicity for the 800-mg/d dose. Current recommendations include consideration of dose escalation to 800 mg/d for patients who experience disease progression at a dose of 400 mg/d and for patients with advanced GIST and *KIT* exon 9 mutations.[1,207]

The optimal duration of imatinib treatment, the duration of benefit from imatinib, and the long-term toxicity of imatinib

have not been established. When feasible, imatinib should be continued in the absence of disease progression. A randomized trial reported worse median progression-free survival in patients who stopped imatinib after 1 year than in patients who continued beyond 1 year (progression-free survival of 6 months vs. 18 months).[208] Less than 4% of patients with GISTs have experienced serious adverse events with imatinib. Mild gastrointestinal toxicity is the most frequently reported adverse event, but gastrointestinal tract hemorrhage, presumably from rapid tumor necrosis, has also been reported. Thus, all patients with GISTs treated on clinical protocols should be evaluated and followed by a team of medical professionals that includes a surgeon.

Many patients with GIST develop resistance to imatinib. Primary resistance is defined as clinical progression that develops during the first 6 months of treatment and is most commonly seen in patients with *KIT* exon 9 mutation, *PDGFRA* exon 18 mutation, or no mutations.[209] Secondary resistance is defined as progression that develops more than 6 months after the start of treatment in a patient with an initial response.[210] Imatinib resistance should be managed by either dose escalation or transition to treatment with sunitinib.[1]

In 2006, sunitinib malate (SU11248, Sutent, Pfizer) emerged as an alternative systemic treatment for patients unable to tolerate imatinib and patients with imatinib-refractory GIST. Sunitinib is a tyrosine kinase inhibitor that targets multiple kinases, including the vascular endothelial growth factor receptors, PDGFRA, KIT, and FLt3. Sunitinib has both antiangiogenic and antiproliferative activity. In a phase III randomized placebo-controlled trial, sunitinib was associated with a significant improvement in median time to progression (27.3 weeks vs. 6.4 weeks with placebo) in patients with imatinib-resistant GIST.[131] In addition, sunitinib therapy was well tolerated; diarrhea, fatigue, and nausea were the most common adverse effects. Sunitinib has also been associated with hand-foot skin reaction, hypertension, cardiotoxicity, and hypothyroidism.[211-213] In 2006, sunitinib was approved by the U.S. Food and Drug Administration for treatment of patients with resistance or intolerance to imatinib.

Other tyrosine kinase inhibitors are in development, many of which target more than one family of protein kinases.[214] Among these are sorafenib, dasatinib, and nilotinib, which are actively being investigated for the treatment of imatinib-resistant GIST.[215] Everolimus (RAD001) and protein kinase C are being investigated as agents that may maximize the extent and duration of response to imatinib by blocking potential pathways of resistance.

Multidisciplinary Treatment

Although imatinib has improved survival of patients with advanced GIST, most patients with advanced GIST are not cured with imatinib. Some patients develop secondary resistance to imatinib with one or more sites of disease progression after 6 months of clinical response (Fig. 36-10A [before imatinib], Fig. 36-10B [after imatinib]). The mechanisms of imatinib resistance are currently being investigated. Surgery has been shown to be beneficial for selected patients with isolated disease progression during imatinib therapy.[216-219] Surgical resection of residual metastatic disease responding to imatinib-sensitive GIST has also been shown to result in progression-free survival in 70% to 96% of patients with imatinib- or sunitinib-sensitive GISTs.[218-220] The optimal timing of surgery in relation to imatinib therapy for patients with metastatic disease remains to be determined. It is not possible to compare outcomes for patients treated with kinase inhibitors alone and patients treated with kinase inhibitors plus surgical resection outside the context of randomized trials given the heterogeneity of patients and biases associated with selection of patients for surgical resection.

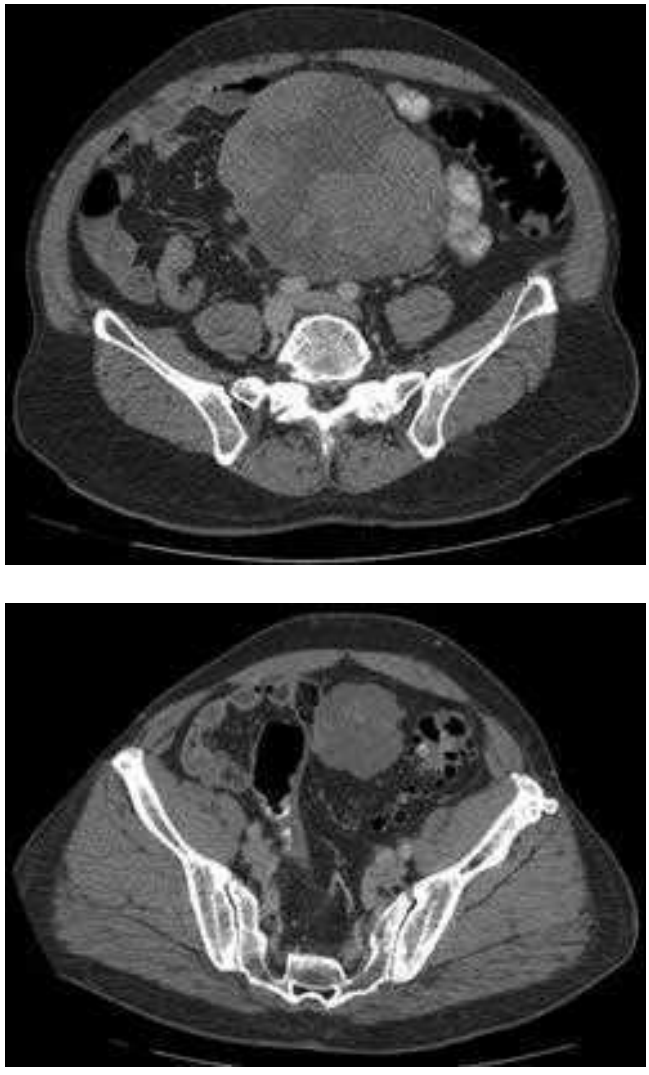

Figure 36-10. A 57-year-old man with a history of a pelvic gastrointestinal stromal tumor involving the small bowel mesentery treated preoperatively with 6 months of imatinib (Gleevec). **A.** Before imatinib. **B.** After imatinib.

Postoperative Imatinib

Given the promising results of imatinib therapy for metastatic and locally advanced GIST, the next step was to study the efficacy of imatinib as adjuvant (postoperative) treatment in patients with surgically resectable disease, particularly those at high risk for recurrence because of large tumor size or high mitotic count. The ACOSOG first evaluated the efficacy of 1 year of postoperative imatinib in a single-arm phase II trial with 106 patients with high-risk GIST and compared the results with historical controls. Adjuvant treatment with imatinib for GIST patients was then examined in two key trials. In the ACOSOG randomized, double-blind, phase III Z9001 study,[207] treatment with 12 months of imatinib was compared with placebo, following complete resection of a primary GIST >3 cm. Primary and secondary endpoints were recurrence-free survival (RFS) and overall survival (OS), respectively. Results showed a

significant benefit in RFS, but not OS, with 12 months of imatinib. Based on these results, imatinib for the adjuvant treatment of adult patients following resection of KIT-positive GIST was approved by the U.S. Food and Drug Administration in 2008 and by the European Medical Agency (EMA) in 2009.

A more recent study conducted by the Scandinavian Sarcoma Group (SSG) and the Sarcoma Group of the Arbeitsgemeinschaft Internistische Onkologie (AIO; SSGXVIII/AIO trial) compared 12 versus 36 months of adjuvant imatinib 400 mg/d in patients with GIST at high risk of recurrence (defined as a GIST tumor diameter >10 cm, or mitotic count >10 per 50 high-powered fields, or tumor diameter >5 cm and mitotic count >5 per 50 high-power fields, or tumor rupture).[208] Results showed that both RFS and OS significantly improved with 36 months of imatinib: the 5-year RFS rates for patients receiving 36 versus 12 months of imatinib were 65.6% versus 47.9%, respectively, and the 5-year OS rates were 92% versus 81.7%, respectively.

The NCCN and the European Society of Medical Oncology now recommend that imatinib be considered for patients at intermediate or high risk of recurrence after resection and that at least 36 months of adjuvant imatinib be considered for patients at high risk of recurrence.[221] Further, both the Food and Drug Administration and EMA updated the label, extending the duration of adjuvant therapy to at least 36 months in patients at high risk of recurrence.

Another study, sponsored by the EORTC (EORTC-62024), compared imatinib for 24 months versus no treatment.[209] Results will be soon communicated.

Whether longer treatment durations may be of further benefit is still an open question, which will be addressed by future studies. However, paralleling what is commonly done in the metastatic setting, many investigators believe that even adjuvant imatinib should become a chronic therapy. While moving toward more prolonged adjuvant treatment durations, it is all the more essential to identify the appropriate patients to treat to avoid the burden of adverse events or increased financial liability for patients who will not derive therapeutic benefit from imatinib. Risk stratification based on patients' risk of recurrence is a key component to optimizing adjuvant treatment. The most practical stratification scheme to use for making a decision for adjuvant therapy is the modified National Institutes of Health consensus criteria.[222] High-risk GIST patients, whose tumor harbors a sensitive genotype, should be treated by adjuvant imatinib, because they have a poor prognosis. On the contrary, neither low-risk nor intermediate-risk GIST patients need adjuvant therapy, even if their tumor carries a sensitive genotype. In fact, evidence has been provided that the outcome of these patients with intermediate- or low-risk GIST is good. When using other risk stratification schemes, such as the Armed Forces Institute of Pathology table, Memorial Sloan-Kettering Cancer Center nomogram, or the heat map,[197,223,224] there is a consensus to treat all patients having 30% or higher risk of recurrence, if their tumor carries a sensitive genotype. There is also a consensus not to treat patients having 10% or less risk of recurrence, even if their tumor carries a sensitive genotype. All patients having a risk between 10% and 30% should be evaluated on a case-by-case basis, and advantages/disadvantages of treatment should be made clear and discussed with the patient. Whenever a decision for adjuvant therapy is made, treatment duration of at least 36 months should be considered independently from the risk.

Beside the risk of recurrence, the other important factor to consider is the tumor genotype. In other words, as found in both the metastatic and adjuvant settings, GIST tumors with *KIT* exon 11 and *PDGFRA* non-D842V mutations are sensitive to imatinib. Patients with these mutations are suitable for adjuvant imatinib if the risk determined by stratification tools is significant. Patients with *KIT* exon 9 mutations should also be treated; a higher dose (800 mg/d) may be more appropriate but remains to be studied clinically. Patients with *PDGFRA* D842V–mutated tumors should not be treated with adjuvant imatinib, nor should patients with *KIT* and *PDGFRA* wild-type tumors associated with neurofibromatosis type 1 or the pediatric GIST/Carney-Stratakis syndromes, whatever the risk. Patients with sporadic wild-type GIST could be treated on an individual basis.

Preoperative Imatinib

Patients with marginally resectable GIST or at significant risk for operative morbidity should be considered for preoperative imatinib with close monitoring. Since the optimal duration of preoperative therapy is unknown, imatinib should be continued until maximal response is achieved or until there is evidence of progression.[225] Preoperative imatinib can be stopped immediately before surgery and resumed when oral medications are restarted.

Preoperative imatinib in patients with primary GIST or resectable metastatic GIST has been evaluated in the context of two randomized phase II studies. The Radiation Treatment Oncology Group (RTOG 0132/ACRIN 6665) evaluated the efficacy of preoperative imatinib (600 mg/d) for 8 to 10 weeks before surgery and 24 months after surgery in patients with primary (n = 30) or potentially resectable recurrent or metastatic (n = 22) tumors.[226] Primarily stable disease was noted during imatinib treatment, and the 2-year progression-free survival rates were 83% for primary GIST and 77% for recurrent or metastatic GIST.[227] In another study, 19 patients undergoing surgical resection at a single institution were randomized to preoperative imatinib (600 mg/d) for 3, 5, or 7 days followed by surgical resection and postoperative imatinib for 24 months. The response rate assessed using FDG-PET was 69%, and the median disease-free survival time following treatment with surgery and imatinib was 46 months.[228]

Similar results were observed in a prospective series of patients treated at a major institution.[229]

All these studies show that neoadjuvant treatment is feasible, but to maximize the benefit of preoperative therapy, the following factors need to be considered. First, the patient should in principle have a favorable mutational status; otherwise, the treatment would be in vane, allowing the tumor to continue growing. Fortunately. the majority of GISTs will respond, but it should not be forgotten that, especially in gastric location, the amount of insensitive mutations in the localized setting is less uncommon than what has been previously reported.[230] However, we do not absolutely need to know the mutational status in advance, but should be aware that mutation is an issue. Alternatively, if mutation status is not determined prior to treatment, we may also check response very early, either by CT, PET, or contrast-enhanced ultrasound. If a radiographic response is detected within a month, then the mutation status is likely favorable, and the treatment could be continued without necessarily pursuing mutation testing. If not, then mutation status should be investigated before continuing the treatment.

Second, the resectability of the tumor and the extent of resection necessary should be considered. Other than presentations of clearly inoperable tumors (which are usually treated with imatinib upfront) or symptomatic tumors requiring urgent intervention (hemorrhage, perforation, etc.), there are few reasons today to perform extended procedures (i.e., multivisceral resections or formal organ resections) without first attempting preoperative therapy. For instance, patients with large GISTs who may require a long midline incision for resection may benefit from neoadjuvant imatinib to downstage the operation, potentially converting an open laparotomy approach to a laparoscopic one. Another typical circumstance in which neoadjuvant therapy may be beneficial is in patients with GISTs arising in the esophagus, gastroesophageal junction, duodenum, or distal rectum. Preoperative treatment may shrink the tumor and allow a more conservative local excision. In general, such patients would normally undergo postoperative adjuvant treatment as well because of the expected recurrence risk. The chance of obtaining a response is high and the benefit for tumor shrinkage obvious, so this approach should always be discussed for patients affected by bulky and/or poorly located disease (esophagus, gastroesophageal junction, duodenum, distal rectum) as well as for those who would be candidates for an adjuvant treatment anyway.

Third, in the studies mentioned earlier, patients underwent surgery after a limited treatment duration (3 months at best). It is now well known that the preoperative treatment may result in sustained tumor shrinkage if given for a longer duration. Surgical resection may then be performed between 6 and 12 months or sooner if treatment effect plateaus. This allows for optimal tumor shrinkage, or at least shrinkage to the point where there is no further benefit to be gained by further neoadjuvant therapy without the risk of developing secondary resistance.

DESMOIDS

Desmoid tumors are not low-grade sarcomas but can be locally aggressive, although they do not metastasize. Approximately half of these tumors arise in the extremities; the remaining lesions are located on the trunk or in the retroperitoneum. Abdominal wall desmoids are associated with pregnancy and are thought to be the result of hormonal influence. Although usually sporadic, desmoids may occur in association with familial adenomatous polyposis, a presentation that is referred to as Gardner's syndrome and is linked to germline mutations in the *APC* gene. Sporadic cases of desmoid fibromatosis are commonly linked to mutations in *CTNNB1*, the gene for β-catenin.

The primary therapy for desmoid tumors has long been considered surgical resection with wide local excision to achieve negative margins. However, local recurrence occurs in up to one third of patients independently of the quality of surgical margins.[231-233] Up to two thirds of the patients operated on with positive margins do not recur. This is why there is growing evidence that the primary approach could be more conservative. Function-sparing operations should be the goal, even if a positive margin is left on a critical structure. Moreover, some authors advocate the possibility to observe patients at presentation, limiting surgery to those who progress or fail medical therapies. It has in fact been reported that by this approach, up to 50% of patients skip surgical resection.[234,235] Radiation therapy may be effective in patients with unresectable tumors or as adjuvant therapy following surgery for recurrent disease, although long-term side effects and the risk of radiation-induced sarcoma should always be considered. When used, a dose of 50 to 54 Gy is usually recommended. Systemic treatment is another option, when surgery is not indicated. Hormonal therapies such as tamoxifen have been reported to be beneficial, as have nonsteroidal anti-inflammatory drugs, which are known to affect the β-catenin signaling pathways. Chemotherapy is also effective, although usually reserved for patients with tumor-associated symptoms who have not responded to other interventions. Combinations of methotrexate and vinblastine have been shown to have activity, as have single-agent pegylated liposomal doxorubicin[236] and sorafenib.[237] Imatinib has also been studied with unconvincing results.[238-240]

DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans is a rare low-grade sarcoma arising in the dermis that rarely metastasizes but is locally aggressive. The overall annual incidence has been estimated at 4.2 cases per million individuals,[241] and the incidence is higher among blacks than whites (6.5 vs. 3.9 per million per year). Approximately 40% of cases arise on the trunk, and most of the remaining tumors are distributed between the head and neck and the extremities. Dermatofibrosarcoma protuberans presents as a nodular, cutaneous mass that grows slowly and persistently. Satellite lesions may be found in patients with larger tumors. Standard treatment is wide local excision, which generally results in local recurrence rates of less than 10%.[242] Although local recurrence rates as high as 30% to 50% have been reported in population-based series, the associated 5-year survival rate is greater than 99%.[241]

Dermatofibrosarcoma protuberans arises from a specific chromosomal translocation involving chromosomes 17 and 22, in which the collagen 1 α 1 gene is fused to the gene for PDGF β-chain (PDGFB).[243] The resultant deregulated expression of PDGFB leads to continuous activation of the PDGFR protein tyrosine kinase, which promotes tumor cell growth. The identification of this chromosomal translocation in more than 90% of cases of dermatofibrosarcoma protuberans has led to the development of targeted therapy. Inhibiting PDGFR with imatinib has been shown to induce clinical and radiologic improvement in patients with unresectable dermatofibrosarcoma protuberans.[20] These data have resulted in the approval by the U.S. Food and Drug Administration of imatinib for treatment of patients with locally advanced dermatofibrosarcoma protuberans.

PEDIATRIC SARCOMAS

Soft tissue sarcomas in children are relatively rare, accounting for 7% to 8% of all pediatric cancers and totaling approximately 600 new cases per year.[244] Pediatric sarcomas have traditionally been divided into two groups: rhabdomyosarcoma and nonrhabdomyosarcoma soft tissue sarcomas.

Rhabdomyosarcoma

Associated with skeletal muscle, rhabdomyosarcomas are the most common soft tissue tumors among children younger than 15 years and can occur at any site comprised of striated muscle. Patients with these tumors generally present with a painless enlarging mass; about 24% of tumors are located in the genitourinary system, 20% in the extremities, 20% in the head and neck, 16% in the parameningeal region, and 22% in other sites.[245]

Rhabdomyosarcoma is a small round cell tumor that demonstrates muscle differentiation upon light microscopy and immunohistochemical analysis. Two primary histologic subtypes account for 90% of cases: embryonal (70%) and alveolar (20%). Alveolar rhabdomyosarcoma is associated with cytogenetic translocation [t(2:13)(q35:q14)] in 85% to 90% of cases and [t(1:13)(p36:q14)] in 10% of cases.[246] These translocations affect biologic activity at the levels of protein function and gene expression, thereby affecting the control of cell growth, apoptosis, differentiation, and motility and ultimately contributing to tumorigenic behavior.[247] Whereas alveolar rhabdomyosarcomas often have translocations, most embryonal rhabdomyosarcomas have an allelic loss at chromosome 11p15.5 that is thought to inactivate a tumor suppressor gene.[247,248] Both of these distinct molecular subtypes of rhabdomyosarcoma are thought to have similar alterations in downstream targets such as the p53 and Rb pathways.[247] Further insight into these genetic alterations may lead to a better understanding of the pathogenesis of rhabdomyosarcoma and provide novel targets for therapeutic approaches.

Extent of disease is the strongest predictor of long-term outcome. Several staging systems for rhabdomyosarcoma are available. The Intergroup Rhabdomyosarcoma Study Group system is based on surgical-pathologic groupings. Multidisciplinary evaluation including pediatric oncologists, surgical subspecialists, and radiation oncologists is critical to plan the best treatment approach to maximize local tumor control while minimizing long-term treatment effects.

Complete surgical resection is the treatment of choice for rhabdomyosarcoma when function and cosmesis can be preserved. Patients who are able to undergo a complete tumor resection with negative (group I) or microscopic surgical margins (group II) are able to undergo less intensive systemic therapy and still have overall survival rates approaching 90%.[249] At some anatomic sites, in particular the head and neck and genitourinary system, surgery is often avoided because the associated morbidity would be substantial. Recent findings suggest that chemotherapy alone can adequately control many such tumors. In the second International Society of Paediatric Oncology study of rhabdomyosarcoma (MMT84), the choice of local treatment was based on response to initial chemotherapy such that radical surgery and radiation therapy were avoided in 66% of patients. Among the patients who subsequently developed local relapse, the 5-year overall survival rate after salvage therapy was 46%.[249]

Unlike other soft tissue sarcomas, rhabdomyosarcomas have a high propensity for lymph node metastasis, with rates up to 20% to 30% for sites such as the extremities, paratesticular nodes, and prostate. Lymph node sampling and, more recently, sentinel lymph node mapping have been used to evaluate regional node status in children with rhabdomyosarcoma.

About 15% to 20% of patients with rhabdomyosarcoma have distant metastasis at presentation, most commonly (40%–50% of cases) to the lungs, followed by bone marrow and bone. However, all patients with rhabdomyosarcoma are assumed to have micrometastatic disease at presentation. Therefore, multiagent chemotherapy is recommended for all patients with rhabdomyosarcoma. Combination regimens including vincristine, dactinomycin, and cyclophosphamide continue to be the basis of effective curative therapy.[245] Although various combinations including doxorubicin, ifosfamide, cisplatin, and etoposide have been shown to be active against rhabdomyosarcoma, they have not improved outcomes.[249,250] Radiation therapy is given to most patients with microscopic residual disease (group II) after resection.

The prognosis for children with rhabdomyosarcomas is related to tumor site, surgical-pathologic grouping, and tumor histology. The 5-year disease-free survival rate for all patients has been reported to be 65%. Five-year disease-free survival rates for patients in groups I, II, III, and IV have been reported to be 84%, 74%, 62%, and 23%, respectively (see Table 36-3).[251]

Nonrhabdomyosarcoma Soft Tissue Sarcomas

Approximately 60% of soft tissue sarcomas in children are nonrhabdomyosarcomas. These include numerous histologic subtypes, which are generally categorized into four groups: (a) fibrosarcoma, (b) Kaposi's sarcoma, (c) other "specified" soft tissue sarcomas (e.g., synovial, angiosarcoma, hemangiopericytoma, leiomyosarcoma, liposarcoma, and extraosseous Ewing's sarcoma), and (d) "unspecified" soft tissue sarcoma.[252] The most common subtypes are synovial sarcoma, MPNST, and fibrosarcoma. No single histology accounts for more than 15% of all cases.

As with adult tumors, the evaluation of the soft tissue mass begins with a history and physical examination followed by imaging, which usually includes MRI. A CT scan of the chest is important for evaluation of metastatic disease. A core needle biopsy is generally required to establish a diagnosis. Surgery remains the primary treatment of nonrhabdomyosarcoma, and local control of large, high-grade tumors is improved with radiation therapy. The prognostic factors for children with nonrhabdomyosarcoma are similar to those for adults, and the role of chemotherapy for high-risk tumors is unclear, as for adults.

RESEARCH PERSPECTIVES

As the molecular alterations associated with various sarcoma subtypes are elucidated, many new potential targets for therapeutic intervention will be identified. A wide variety of DNA alterations have been observed in sarcomas that result in mutated genes encoding proteins ranging from transcription factors to tyrosine kinases to cytokines.[215] The challenge in identifying therapeutic targets in sarcoma is to identify those that are specifically important to cellular function. The ideal therapeutic target has been described as a single molecule that is critical for pathogenesis, is expressed and active, is involved in a single pathway amenable to blockade (i.e., no alternative bypass pathways exist), and is critical for sarcoma cell survival.[24]

CONCLUSIONS

Soft tissue sarcomas are a heterogeneous family of rare tumors, accounting for approximately 1% of malignancies in adults. The etiology in the vast majority of patients is sporadic, and the management of such diverse tumors is complex. Diagnosis by light microscopy is inexact, but molecular diagnosis, although still in its infancy, holds great promise. The natural history of soft tissue sarcomas is well established. Approximately two thirds of cases arise in the extremities, and the remaining one third are distributed between the retroperitoneum, trunk, abdomen, and head and neck. The management algorithm for soft tissue sarcomas is
6▶ complex and depends on tumor stage, site, and histology.
7▶ The most common site of metastasis is the lungs, and metastasis generally occurs within 3 years of diagnosis.

Soft tissue sarcomas have unique molecular profiles that contribute to varying responses to systemic therapy. Doxorubicin-based regimens have been the mainstay of treatment for the past two decades; however, it is now clear that specific histologic

subtypes have increased sensitivity to specific agents. For example, angiosarcomas are more sensitive to paclitaxel, while leiomyosarcoma is sensitive to gemcitabine and docetaxel. Progress in understanding of soft tissue sarcoma biology is crucial for the development of additional therapeutic targets. Drug engineering will enable molecular-based therapies to become increasingly incorporated into clinical trials and, with success, into standard treatment strategies for soft tissue sarcomas in the near future.

chapter 37

Inguinal Hernias

Justin P. Wagner, F. Charles Brunicardi, Parviz K. Amid, and David C. Chen

INTRODUCTION

Inguinal hernia repair is the most commonly performed operation in the United States, owing to a significant lifetime incidence and variety of successful treatment modalities. Approximately 800,000 cases were performed in 2003, not including recurrent or bilateral hernias.[1] Advancements in perioperative anesthesia and operative technique have made this an outpatient ambulatory operation with low recurrence rates and morbidity. Given this success, quality of life and the avoidance of chronic pain have become the most important considerations in hernia repair.

Approximately 75% of abdominal wall hernias occur in the groin. The lifetime risk of inguinal hernia is 27% in men and 3% in women.[2] Of inguinal hernia repairs, 90% are performed in men and 10% in women. The incidence of inguinal hernias in males has a bimodal distribution, with peaks before the first year of age and after age 40. Abramson demonstrated the age dependence of inguinal hernias in 1978. Those age 25 to 34 years had a lifetime prevalence rate of 15%, whereas those age 75 years and over had a rate of 47% (Table 37-1).[3] Approximately 70% of femoral hernia repairs are performed in women; however, inguinal hernias are five times more common than femoral hernias. The most common subtype of groin hernia in men and women is the indirect inguinal hernia.[4]

History

Evidence of surgical repair of inguinal hernias can be traced back to ancient civilizations of Egypt and Greece.[5] Early management of inguinal hernias often involved a conservative approach with operative management reserved only for complications. Surgery often involved routine excision of the testicle, and wounds were closed with cauterization or left to granulate on their own. Considering these procedures were performed before the advent of the aseptic technique, it is safe to assume that mortality was quite high. For those that survived the operation, recurrence of the hernia was common.

1▶

From the late 1700s to the early 1800s, physicians including Hesselbach, Cooper, Camper, Scarpa, Richter, and Gimbernat identified vital components of the inguinal region, and their contributions are reflected in the current nomenclature. Improved understanding of the anatomy and pathophysiology of inguinal hernias, coupled with the development of aseptic technique, led surgeons such as Marcy, Kocher, and Lucas-Championnière to perform sac dissection, high ligation, and closure of the internal ring. Outcomes improved, but recurrence rates remained high with prolonged follow-up.

Based on a comprehensive understanding of inguinal anatomy, Bassini (1844–1924) transformed inguinal hernia repair into a successful venture with minimal morbidity. The success of the Bassini repair over its predecessors ushered in an era of tissue-based repairs. Modifications of the Bassini repair were manifest in the McVay and Shouldice repairs. All three of these techniques, as well as modern variations such as the Desarda operation, are currently practiced.[6]

In the early 1980s, Lichtenstein popularized the tension-free repair, supplanting tissue-based repairs with the widespread acceptance of prosthetic materials for inguinal floor reconstruction. This technique was superior to previous tissue-based repair in that mesh could restore the strength of the transversalis fascia, thereby avoiding tension in the defect closure. Superior results were reproducible regardless of hernia size and type, and they were achievable among expert and nonexpert hernia surgeons alike.[7]

With the advent of minimally invasive surgery, inguinal hernia repair underwent its most recent transformation. Laparoscopic inguinal hernia repair offers an alternative approach, minimizes postoperative pain, and improves recov-

Key Points

1▶ Conservative management of asymptomatic inguinal hernias is acceptable.
2▶ A proficient understanding of groin anatomy is essential to successful inguinal hernia treatment.
3▶ Elective repair of inguinal hernias can be undertaken using an laparoscopic or open approach.
4▶ The use of prosthetic mesh as a reinforcement significantly improves recurrence rates, whether the repair is open or laparoscopic.
5▶ Recurrence, pain, and quality of life are important outcome factors.
6▶ Laparoscopic inguinal hernia repair results in less pain and faster recovery, yet requires specialized training and equipment.

ery. Since the initial description by Ger, the laparoscopic method has become significantly more sophisticated. Refinements in approach and technique have led to the development of the intraperitoneal onlay mesh, the transabdominal preperitoneal (TAPP) repair, and the totally extraperitoneal (TEP) repair. Furthermore, an array of prosthetic materials has been introduced to minimize recurrence and improve quality of life. Irrespective of the approach, successful surgical treatment of inguinal hernias depends on a sound grasp of inguinal anatomy.

2▶

Anatomy

The inguinal canal is an approximately 4- to 6 cm-long cone-shaped region situated in the anterior portion of the pelvic basin (Fig. 37-1). The canal begins on the posterior abdominal wall, where the spermatic cord passes through the deep (internal) inguinal ring, a hiatus in the transversalis fascia. The canal concludes medially at the superficial (external) inguinal ring, the point at which the spermatic cord crosses a defect in the external oblique aponeurosis. The boundaries of the inguinal canal are comprised of the external oblique aponeurosis anteriorly, the internal oblique muscle laterally, the transversalis fascia and transversus abdominis muscle posteriorly, the internal oblique muscle superiorly, and the inguinal (Poupart's) ligament inferiorly. The spermatic cord traverses the inguinal canal, and it contains three arteries, three veins, two nerves, the pampiniform venous plexus, and the vas deferens. It is enveloped in three layers of spermatic fascia.

Additional important structures surrounding the inguinal canal include the iliopubic tract, the lacunar ligament, Cooper's ligament, and the conjoined tendon (Fig. 37-2). The iliopubic tract is an aponeurotic band that begins at the anterior superior iliac spine and inserts into Cooper's ligament from above. It forms on the deep inferior margin of the transversus abdominis and transversalis fascia. The shelving edge of the inguinal ligament is a structure that connects the iliopubic tract to the inguinal ligament. The iliopubic tract helps form the inferior margin of the internal inguinal ring as it courses medially, where it continues as the anteromedial border of the femoral canal. The lacunar ligament, or ligament of Gimbernat, is the triangular fanning of the inguinal ligament as it joins the pubic tubercle. Cooper's (pectineal) ligament is the lateral portion of the lacunar ligament that is fused to the periosteum of the pubic tubercle. The conjoined tendon is commonly described as the fusion of the inferior fibers of the internal oblique and transversus abdominis aponeurosis at the point where they insert on the pubic tubercle.

Inguinal hernias are generally classified as indirect, direct, and femoral based on the site of herniation relative to surrounding structures. Indirect hernias protrude lateral to the inferior epigastric vessels, through the deep inguinal ring. Direct hernias protrude medial to the inferior epigastric vessels, within Hesselbach's triangle. The borders of the triangle are the inguinal ligament inferiorly, the lateral edge of rectus sheath medially, and the inferior epigastric vessels superolaterally. Femoral hernias protrude through the small and inflexible femoral ring. The borders of the femoral ring include the iliopubic tract and inguinal ligament anteriorly, Cooper's ligament posteriorly, the lacunar ligament medially, and the femoral vein laterally. The Nyhus classification categorizes hernia defects by location, size, and type (Table 37-2).

Table 37-1

Inguinal hernia prevalence by age

AGE (Y)	25–34	35–44	45–54	55–64	65–74	75+
Current prevalence (%)	12	15	20	26	29	34
Lifetime prevalence (%)	15	19	28	34	40	47

Current = repaired hernias excluded; lifetime = repaired hernias included.

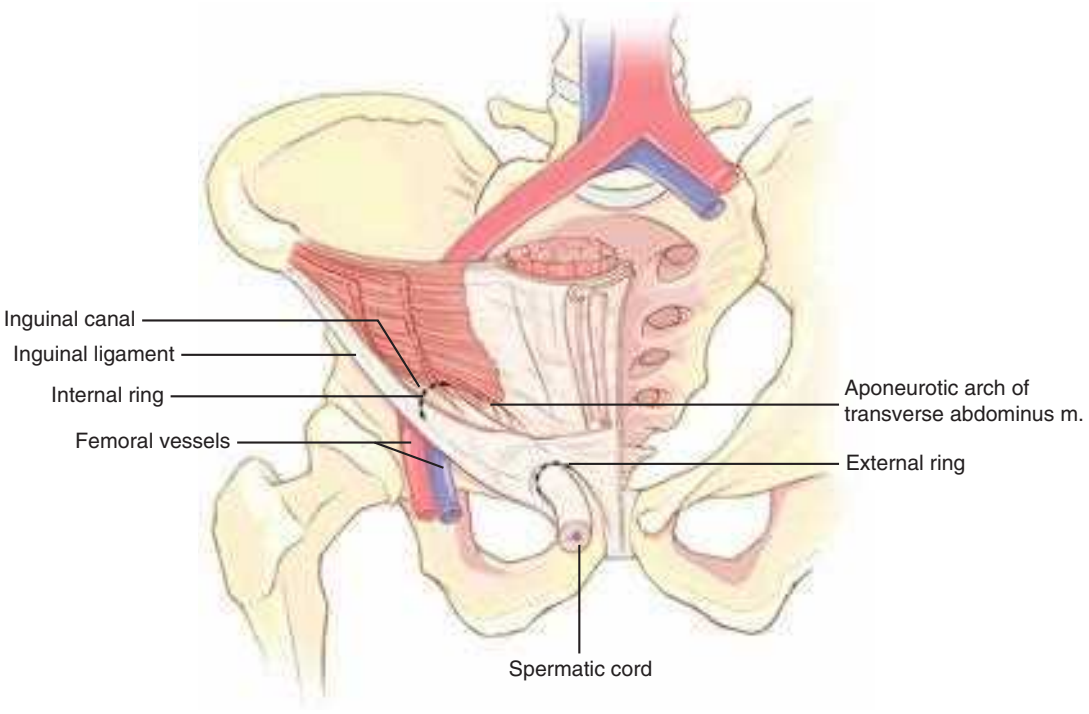

Figure 37-1. Location and orientation of the inguinal canal within the pelvic basin. Boundaries of the canal include: transversus abdominus and transversalis fascia posterior; internal oblique muscle superior; external oblique aponeurosis anterior; inguinal ligament inferior. m. = muscle.

The laparoscopic approach to hernia repair provides a posterior perspective to the peritoneal and preperitoneal spaces (Fig. 37-3). Intraperitoneal points of reference are the five peritoneal folds, bladder, inferior epigastric vessels, and psoas muscle (Fig. 37-4). Two potential spaces exist within the preperitoneum. Between the peritoneum and the posterior lamina of the transversalis fascia is Bogros's (preperitoneal) space. This area contains preperitoneal fat and areolar tissue. The most medial aspect of the preperitoneal space, that which lies superior to the bladder, is known as the space of Retzius. The posterior perspective also allows visualization of the myopectineal orifice of Fruchaud, a relatively weak portion of the abdominal wall that is divided by the inguinal ligament (Fig. 37-5).

The *vascular space* is situated between the posterior and anterior laminae of the transversalis fascia, and it houses the inferior epigastric vessels. The inferior epigastric artery supplies the rectus abdominis. It is derived from the external iliac artery, and it anastomoses with the superior epigastric, a continuation of the internal thoracic artery. The epigastric veins course parallel to the arteries within the rectus sheath, posterior to the rectus muscles. Inspection of the internal inguinal ring will reveal the deep location of the inferior epigastric vessels.

Nerves of interest in the inguinal region are the ilioinguinal, iliohypogastric, genitofemoral, and lateral femoral cutaneous nerves (Figs. 37-6 and 37-7). The ilioinguinal and iliohypogastric nerves arise together from the first lumbar nerve (L1). The

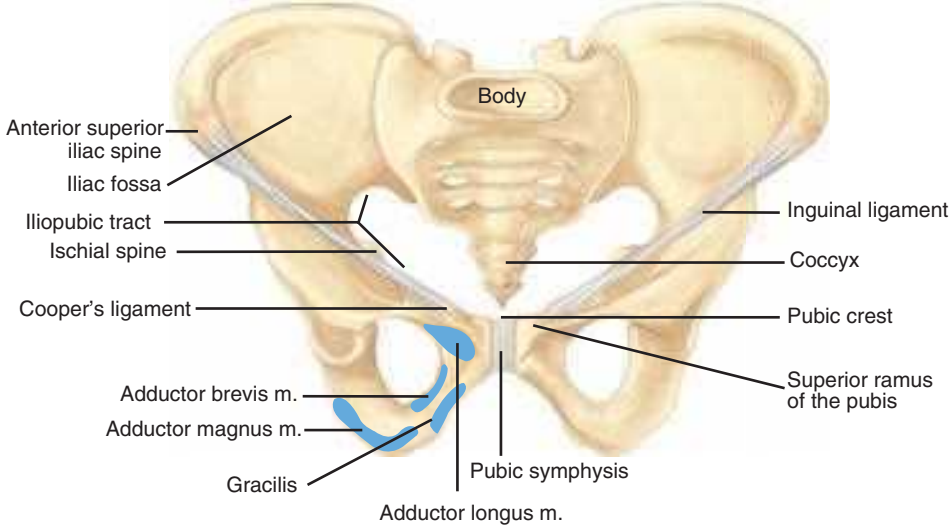

Figure 37-2. Ligaments that contribute to the inguinal canal include the inguinal ligament, Cooper's ligament, and the lacunar ligament. The iliopubic tract originates and inserts in a similar fashion to the inguinal ligament, but in a deeper position. m. = muscle.

Table 37-2

Nyhus classification system

Type I	Indirect hernia; internal abdominal ring normal; typically in infants, children, small adults
Type II	Indirect hernia; internal ring enlarged without impingement on the floor of the inguinal canal; does not extend to the scrotum
Type IIIA	Direct hernia; size is not taken into account
Type IIIB	Indirect hernia that has enlarged enough to encroach upon the posterior inguinal wall; indirect sliding or scrotal hernias are usually placed in this category because they are commonly associated with extension to the direct space; also includes pantaloon hernias
Type IIIC	Femoral hernia
Type IV	Recurrent hernia; modifiers A–D are sometimes added, which correspond to indirect, direct, femoral, and mixed, respectively

Figure 37-4. ilioinguinal nerve emerges from the lateral border of the psoas major and passes obliquely across the quadratus lumborum. At a point just medial to the anterior superior iliac spine, it pierces the transversus and internal oblique muscles to enter the inguinal canal and exits through the superficial inguinal ring. It supplies somatic sensation to the skin of the upper and medial thigh. In males, it also innervates the base of the penis and upper scrotum. In females, it innervates the mons pubis and labium majus. The iliohypogastric nerve arises from T12–L1. After it pierces the deep abdominal wall, it courses between the internal oblique and transversus abdominis, supplying both. It then divides into lateral and anterior cutaneous branches. A common variant is for the iliohypogastric and ilioinguinal nerves to exit around the superficial inguinal ring as a single entity. The genitofemoral nerve arises from L1–L2, courses along the retroperitoneum, and emerges on the anterior aspect of the psoas. It then divides into genital and femoral branches. The genital branch enters the inguinal canal lateral to the inferior epigastric vessels, and it courses ventral to the iliac vessels and iliopubic tract. In males, it travels through

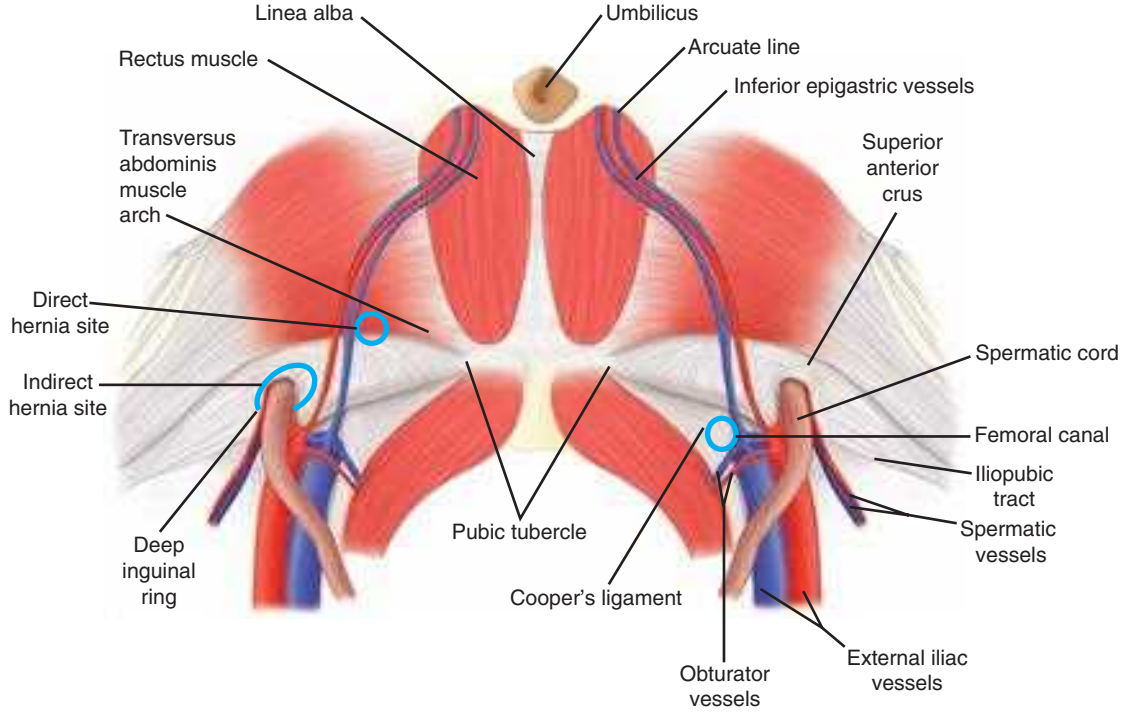

Figure 37-3. Anatomy of the groin region from the posterior perspective.

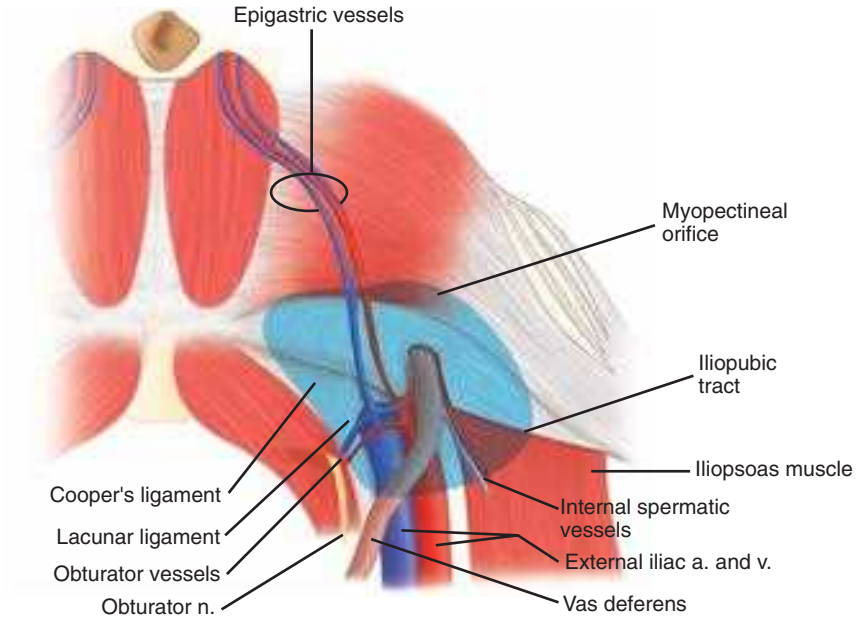

Figure 37-5. Posterior view of the myopectineal orifice of Fruchaud. a. = artery; n. = nerve; v. = vein.

the superficial inguinal ring and supplies the ipsilateral scrotum and cremaster muscle. In females, it supplies the ipsilateral mons pubis and labium majus. The femoral branch courses along the femoral sheath, supplying the skin of the upper anterior thigh. The lateral femoral cutaneous nerve arises from L2–L3, emerges lateral to the psoas muscle at the level of L4, and crosses the iliacus muscle obliquely toward the anterior superior iliac spine. It then passes inferior to the inguinal ligament where it divides to supply the lateral thigh (Fig. 37-8).

The preperitoneal anatomy seen in laparoscopic hernia repair led to characterization of important anatomic areas of interest, known as the *triangle of doom*, the *triangle of pain*, and the *circle of death* (Fig. 37-9).[8] The triangle of doom is bordered medially by the vas deferens and laterally by the vessels of the spermatic cord. The contents of the space include the external iliac vessels, deep circumflex iliac vein, femoral nerve, and genital branch of the genitofemoral nerve. The triangle of pain is a region bordered by the iliopubic tract and gonadal vessels, and it encompasses the lateral femoral cutaneous, femoral branch of the genitofemoral, and femoral nerves. The circle of death is a vascular continuation formed by the common iliac, internal iliac, obturator, inferior epigastric, and external iliac vessels.

Pathophysiology

Inguinal hernias may be congenital or acquired. Most adult inguinal hernias are considered acquired defects in the abdominal wall although collagen studies have demonstrated a heritable predisposition. A number of studies have attempted to delineate the precise causes of inguinal hernia formation; however, the best-characterized risk factor is weakness in the abdominal wall musculature (Table 37-3). Congenital hernias, which make up the majority of pediatric hernias, can be considered an impedance of normal development, rather than an acquired weakness. During the normal course of development, the testes descend from the intra-abdominal space into the scrotum in the third trimester. Their descent is preceded by the gubernaculum and a diverticulum of peritoneum, which protrudes through the inguinal canal and becomes the processus vaginalis. Between 36 and 40 weeks of gestation, the processus vaginalis closes and eliminates the peritoneal opening at the internal inguinal ring.[9] Failure of the peritoneum to close results in a patent processus vaginalis (PPV), hence the high incidence of indirect inguinal hernias in preterm babies. Children with congenital indirect inguinal hernias will present with a PPV; however, a patent processus does not necessarily indicate an inguinal hernia (Fig. 37-10). In a study of nearly 600 adults undergoing general laparoscopy, bilateral inspection revealed that 12% had PPV. None of these patients had clinically significant symptoms of a groin hernia.[10] In a group of 300 patients undergoing unilateral laparoscopic inguinal hernia repair, 12% were found to have a contralateral PPV, which was associated with a fourfold 5-year incidence of inguinal hernia.[11]

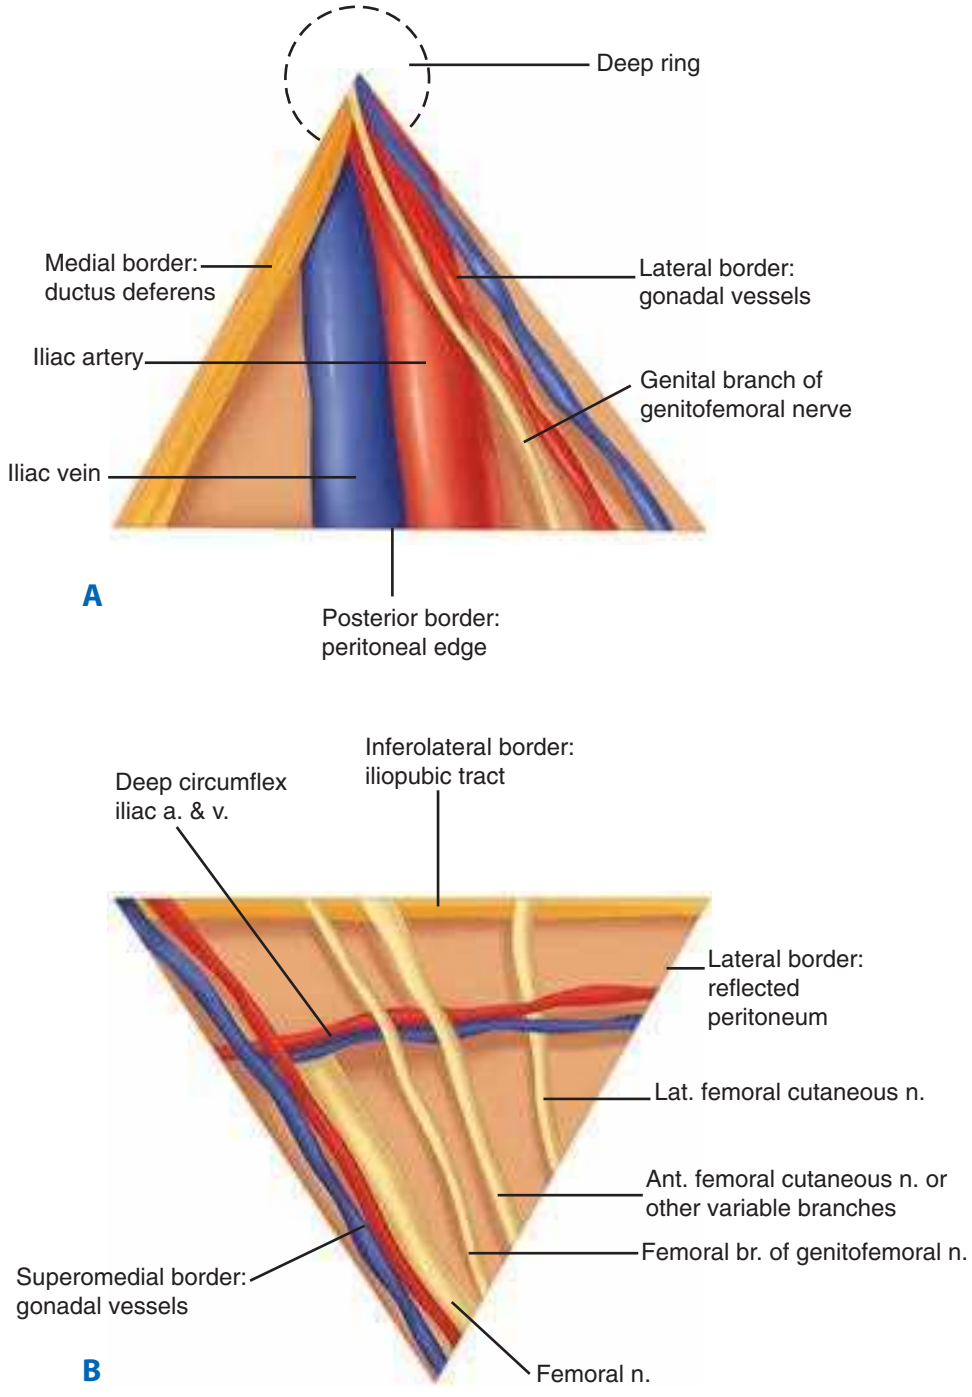

Figure 37-9. Borders and contents of the (**A**) triangle of doom and (**B**) triangle of pain. a. = artery; Ant. = anterior; br. = branch; Lat. = lateral; n. = nerve; v. = vein. (*Modified with permission from Colborn GL, Skandalakis JE. Laparoscopic cadaveric anatomy of the inguinal area.* Probl Gen Surg. *1995;12:13.*)

The presence of a PPV likely predisposes a patient to the development of an inguinal hernia. This likelihood depends on the presence of other risk factors such as inherent tissue weakness, family history, and strenuous activity. Overall, there are limited data regarding the etiology of inguinal hernia development. Several studies have documented strenuous physical activity as a risk factor for acquired inguinal hernia.[12,13] Repeated physical exertion may increase intra-abdominal pressure; however, whether this process occurs in combination with a PPV or through age-related weakness of abdominal wall musculature is unknown. A case-controlled study of over 1400 male patients with inguinal hernia revealed that a positive family history was associated with an eightfold lifetime incidence of inguinal hernia. Chronic obstructive pulmonary disease also significantly increases the risk of direct inguinal hernias, as it is accompanied by repeated episodes of high intra-abdominal pressure.[14] Several studies have suggested a protective effect of obesity. In a large, population-based prospective study of American individuals (First National Health and Nutrition Examination Survey), the risk of inguinal hernia development in obese men was only 50% that of normal weight males, whereas the risk in overweight males was 80% that of nonobese men. A possible explanation is the increased difficulty in detecting inguinal hernias in obese individuals.[15]

Epidemiologic studies have identified risk factors that may predispose to a hernia. Microscopic examination of skin of inguinal hernia patients demonstrated significantly decreased ratios of type I to type III collagen. Type III collagen does not contribute to wound tensile strength as significantly as type I collagen. Additional analyses revealed disaggregated collagen tracts with decreased collagen fiber density in hernia patients' skin.[16] Collagen disorders such as Ehlers-Danlos syndrome are also associated with an increased incidence of hernia formation (Table 37-4). Recent studies have found an association between concentrations of extracellular matrix elements and hernia formation.[17] Although a significant amount of work remains to elucidate the biologic nature of hernias, current evidence suggests they have a multifactorial etiology with both environmental and hereditary influences.

DIAGNOSIS

History

Inguinal hernias present along a spectrum of scenarios. These range from incidental discovery to surgical emergencies such as incarceration and strangulation of the hernia sac contents. Patients who present with a symptomatic groin hernia will

frequently report groin pain. Extrainguinal symptoms such as a change in bowel habits or urinary symptoms are less common. Inguinal hernias may compress adjacent nerves, leading to generalized pressure, localized sharp pain, and referred pain. Pressure or heaviness in the groin is a common complaint, especially at the conclusion of the day or following prolonged activity. Sharp pain tends to indicate an impinged nerve and may not be related to the extent of physical activity performed by the patient. Neurogenic pain may be referred to the scrotum, testicle, or inner thigh. Questions should be directed to elicit and characterize extrainguinal symptoms. A change in bowel habits or urinary symptoms may indicate a sliding hernia consisting of intestinal contents or involvement of the bladder within the hernia sac.

Important considerations of the patient's history include the duration and timing of symptoms. Hernias will often increase in size and content over a protracted time. Much less commonly, a patient will present with a history of acute inguinal herniation following a strenuous activity. It is more likely that an asymptomatic inguinal hernia became evident once the patient experienced symptoms after an acute event. Questions should also be directed to characterize whether the hernia is reducible. Patients will often reduce the hernia by pushing the contents back into the abdomen, thereby providing temporary relief. As the defect size increases and more intra-abdominal contents fill the hernia sac, the hernia may become harder to reduce.

Physical Examination

Physical examination is essential to the diagnosis of inguinal hernia. Asymptomatic hernias are frequently diagnosed incidentally on physical examination or may be brought to the patient's attention as an abnormal bulge. Ideally, the patient should be examined in a standing position to increase intra-abdominal pressure, with the groin and scrotum fully exposed. Inspection is performed first, with the goal of identifying an abnormal bulge along the groin or within the scrotum. If an obvious bulge is not detected, palpation is performed to confirm the presence of the hernia.

Palpation is performed by advancing the index finger through the scrotum toward the external inguinal ring (Fig. 37-11). This allows the inguinal canal to be explored. The patient is then asked to perform Valsalva's maneuver to protrude the hernia contents. These maneuvers will reveal an abnormal bulge and allow the clinician to determine whether the hernia is reducible or not. Examination of the contralateral side affords the clinician the opportunity to compare the presence and extent of herniation between sides. This is especially useful in the case of a small hernia. In addition to inguinal hernia, a number of other diagnoses may be considered in the differential of a groin bulge (Table 37-5).

Certain techniques of the physical examination have classically been used to differentiate between direct and indirect hernias. The inguinal occlusion test entails the examiner blocking the internal inguinal ring with a finger as the patient is instructed to cough. A controlled impulse suggests an indirect hernia, while persistent herniation suggests a direct hernia. Transmission of the cough impulse to the tip of the finger implies an indirect hernia, while an impulse palpated on the dorsum of the finger implies a direct hernia. When results of physical examination are compared against operative findings, there is a probability somewhat higher than chance (i.e., 50%) of correctly diagnosing the type of hernia.[18,19] Accordingly,

these tests should be used to detect hernias, but not to diagnose hernia types.

External groin anatomy is difficult to assess in obese patients, making the physical diagnosis of inguinal hernia challenging. A further challenge to the physical examination is the identification of a femoral hernia. Femoral hernias should be palpable below the inguinal ligament, lateral to the pubic tubercle. In obese patients, a femoral hernia may be missed or misdiagnosed as a hernia of the inguinal canal. In contrast, a prominent inguinal fat pad in a thin patient, otherwise known as a *femoral pseudohernia*, may prompt an erroneous diagnosis of femoral hernia.

Imaging

In the case of an ambiguous diagnosis, radiologic investigations may be used as an adjunct to history and physical examination. Imaging in obvious cases is unnecessary and costly. The most common radiologic modalities include ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI). Each technique has certain advantages over physical examination alone; however, each modality is associated with potential limitations.

US is the least invasive technique and does not impart any radiation to the patient. Anatomic structures can be more easily identified by the presence of bony landmarks; however, because there are few bones in the inguinal canal, other structures such as the inferior epigastric vessels are used to define groin anatomy. Positive intra-abdominal pressure is used to elicit the herniation of abdominal contents. Movement of these contents through the canal is essential to making the diagnosis with US, and lack of this movement may lead to a false-negative result. A recent meta-analysis demonstrated that US detects inguinal hernia with a sensitivity of 86% and specificity of 77%.[20] In thin patients, normal movement of the spermatic cord and posterior abdominal wall against the anterior abdominal wall may lead to false-positive diagnoses of hernia.[21]

CT and MRI provide static images that are able to delineate groin anatomy, to detect groin hernias, and to exclude potentially confounding diagnoses (Fig. 37-12). A meta-analysis determined that standard CT detects inguinal hernia with a sensitivity of 80% and specificity of 65%. Although direct herniography has a higher sensitivity and specificity than CT, its invasiveness and limited availability restrict its routine use.[20] As CT imaging increases in resolution, its sensitivity in detecting inguinal hernia is expected to expand; however, this has yet to be clinically confirmed by surgical correlation.[22]

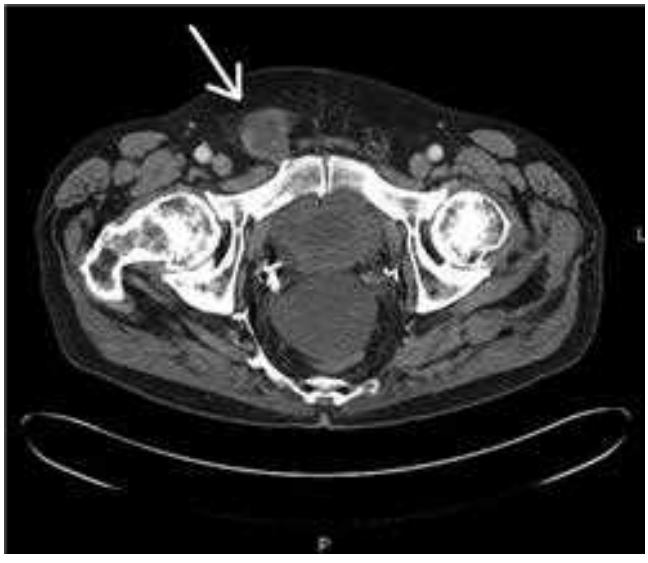

Figure 37-12. Computed tomography scan depicting a large right inguinal hernia (*arrow*). A smaller left inguinal hernia is also visualized.

When used to diagnose inguinal hernia, MRI is frequently reserved for cases where physical examination detects a groin bulge, but where US is inconclusive. In a 1999 study of 41 patients with clinical findings of inguinal hernia, laparoscopy revealed that MRI was an effective diagnostic test, with a sensitivity of 95% and specificity of 96%.[23] MRI has become more sophisticated since 1999; however, its high cost and limited access remain obstacles to more routine use.

TREATMENT

Surgical repair is the definitive treatment of inguinal hernias; however, operation is not necessary in a subset of patients. When the patient's medical condition confers an unacceptable level of operative risk, elective surgery should be deferred until the condition resolves, and operations reserved for life-threatening emergencies. Although the natural history of untreated inguinal hernias is poorly defined, the rates of incarceration and strangulation are low in the asymptomatic population. As a result, nonoperative management is an appropriate consideration in minimally symptomatic patients. Prospective studies and meta-analyses have demonstrated no difference in intent-to-treat outcomes, quality of life, or cost-effectiveness between nonoperative management and elective repair among healthy inguinal hernia patients.[24,25] A 2012 systematic review found that 72% of asymptomatic inguinal hernia patients developed symptoms (mostly pain) and had surgical repair within 7.5 years of diagnosis.[26] Nevertheless, the complication rates of immediate and delayed elective tension-free repair are equivalent.[25,27] A nonoperative strategy is safe for minimally symptomatic inguinal hernia patients, and it does not increase the risk of developing hernia complications.

Nonoperative inguinal hernia treatment targets pain, pressure, and protrusion of abdominal contents in the symptomatic patient population. The recumbent position aids in hernia reduction via the effects of gravity and a relaxed abdominal wall. Trusses externally confine hernias to a reduced state and intermittently relieve symptoms in up to 65% of patients; however, they do not prevent complications, and they may be associated with an increased rate of incarceration.[28] The risks of incarceration and strangulation appear to decrease over the first year, likely because gradual enlargement of the abdominal wall defect facilitates spontaneous reduction of hernia contents. The sheer volume of protruding tissue in an inguinal hernia does not necessarily signify severe morbidity.

Femoral and symptomatic inguinal hernias carry higher complication risks, and so surgical repair is performed earlier for these patients. Irrespective of symptoms, one study found the 3-month and 2-year cumulative incidences of strangulation were 2.8% and 4.5%, respectively, for inguinal hernias and 22% and 45%, respectively, for femoral hernias.[29] Data from the Swedish Hernia Registry demonstrate that emergent operation is associated with a sevenfold increase in all-cause mortality over that of elective surgery among 107,838 groin hernia repairs.[30] For this reason, it is recommended that femoral hernias and symptomatic inguinal hernias be electively repaired, when possible.

The administration of preoperative prophylactic antibiotics in elective inguinal hernia repair remains controversial. A systematic review of 7843 elective open hernia repairs from the Cochrane Database in 2012 revealed an overall decrease in infection rates (odds ratio [OR] 0.64, confidence interval [CI] 0.50–0.82) when prophylactic antibiotics are administered; however, the absolute risk reduction was not sufficient to justify universal recommendations for or against the practice. Overall wound infection rates are higher than those expected for clean operations, and there was a significant reduction in the rate of wound infection among patients undergoing repair with a prosthetic mesh.[31,32] Although there is no universal guideline regarding the administration of prophylactic antibiotics for open elective hernia repair, it is our experience that meticulous perioperative protocol and surgical technique are more reliable countermeasures to prevent wound infection than antibiotics. Nevertheless, data trends and quality improvement measures have resulted in routine administration of prophylactic perioperative antibiotics in inguinal hernia repairs.

Incarceration occurs when hernia contents fail to reduce; however, a minimally symptomatic, chronically incarcerated hernia may also be treated nonoperatively. Taxis should be attempted for incarcerated hernias without sequelae of strangulation, and the option of surgical repair should be discussed prior to the maneuver. To perform taxis, analgesics and light sedatives are administered, and the patient is placed in the Trendelenburg position. The hernia sac is elongated with both hands, and the contents are compressed in a milking fashion to ease their reduction into the abdomen.

The indication for emergent inguinal hernia repair is impending compromise of intestinal contents. As such, strangulation of hernia contents is a surgical emergency. Clinical signs that indicate strangulation include fever, leukocytosis, and hemodynamic instability. The hernia bulge is usually warm and tender, and the overlying skin may be erythematous or discolored. Symptoms of bowel obstruction in patients with sliding or incarcerated inguinal hernias may also indicate strangulation. Taxis should not be performed when strangulation is suspected, as reduction of potentially gangrenous tissue into the abdomen may result in an intra-abdominal catastrophe. Preoperatively, the patient should receive fluid resuscitation, nasogastric decompression, and prophylactic intravenous antibiotics.

Open Approach

Open inguinal hernia repairs are subdivided into techniques that employ prostheses to create a tension-free repair and those that reconstruct the inguinal floor using native tissue. Tissue repairs are indicated when the use of prosthetic material is contraindicated, (contamination or strangulation).

The option to administer locoregional anesthesia is an advantage of the open approach. Common anesthetic agents include lidocaine or the longer-acting bupivacaine, both with the option of adding epinephrine. In advance of the initial incision, a field block or ilioinguinal nerve block may be employed. A regional block is an option for patients who cannot tolerate general anesthesia, and it exerts a broader effect than local anesthesia alone.

Exposure of the anterior inguinal region is common to the open approaches. An oblique or horizontal incision is performed over the groin (Fig. 37-13). The incision begins two fingerbreadths inferior and medial to the anterior superior iliac spine. It is then extended medially for approximately 6 to 8 cm. The subcutaneous tissue is dissected using electrocautery. Scarpa's fascia is divided to expose the external oblique aponeurosis. A small incision is made in the external oblique aponeurosis parallel to the direction of the muscle fibers. Metzenbaum scissors are introduced and spread beneath the fibers to separate adhesions to the underlying ilioinguinal nerve. The scissors are then used to incise the aponeurosis superior to the inguinal ligament, splitting the external inguinal ring.

The flaps of the external oblique aponeurosis are elevated with Hemostat clamps. The interior oblique fibers are dissected bluntly from the overlying external oblique flaps. Dissection of the inferior flap reveals the shelving edge of the inguinal ligament. The iliohypogastric and ilioinguinal nerves are identified and preserved. Effort should be made to avoid removing nerves from their natural bed and disrupting the protective investing fascia. The pubic tubercle is identified and the cord structures are atraumatically dissected off of the pubis, encircled, and elevated with a Penrose drain. The cord is elevated 2 cm over the pubic symphysis in an avascular plane, and cremasteric fibers are preserved to avoid injuring cord structures (Fig. 37-14).

An indirect hernia sac will generally be found on the anterolateral surface of the spermatic cord after division of the cremasteric muscle in the direction of its fibers. The genital nerve is visualized along the inferolateral surface of the cord adjacent to the external spermatic vein. The floor of the inguinal canal is fully assessed for direct hernias. If a hernia is not visualized upon entry into the inguinal canal, the preperitoneal space should be explored for a femoral hernia. In addition to sac identification, the vas deferens and vessels of the spermatic cord must be identified to allow dissection of the sac from the cord. At the leading edge of the sac, the two layers of peritoneum will fold upon themselves and reveal a white edge, which may help in the identification of the sac. The sac can then be grasped with a tissue forceps and bluntly dissected from the cord. The dissection is carried proximally toward the deep inguinal ring.

In cases where the viability of sac contents is in question, the sac should be incised, and hernia contents should be evaluated for signs of ischemia. The defect should be enlarged to augment blood flow to the sac contents. Viable contents may be reduced into the peritoneal cavity, while nonviable contents should be resected, and synthetic prostheses should be avoided in the repair. In elective cases, the sac may be amputated at the internal inguinal ring or inverted into the preperitoneum. Both methods are effective; however, patients undergoing sac excision had significantly increased postoperative pain in a prospective trial.[33] Dissection of a densely adherent sac may result in injury to cord structures and should be avoided; however, sac ligation at the internal inguinal ring is necessary in these cases. A hernia sac that extends into the scrotum may require division within the inguinal canal, as extensive dissection and reduction risks injury to the pampiniform plexus, resulting in testicular atrophy and orchitis.

At this point, the inguinal canal is reconstructed, either with native tissue or with prostheses. The following sections describe the most commonly performed types of tissue-based and prosthetic-based reconstructions.

Tissue Repairs. Tissue-based herniorrhaphy is a suitable alternative when prosthetic materials cannot be used safely. Indications for tissue repairs include operative field contamination, emergency surgery, and when the viability of hernia contents

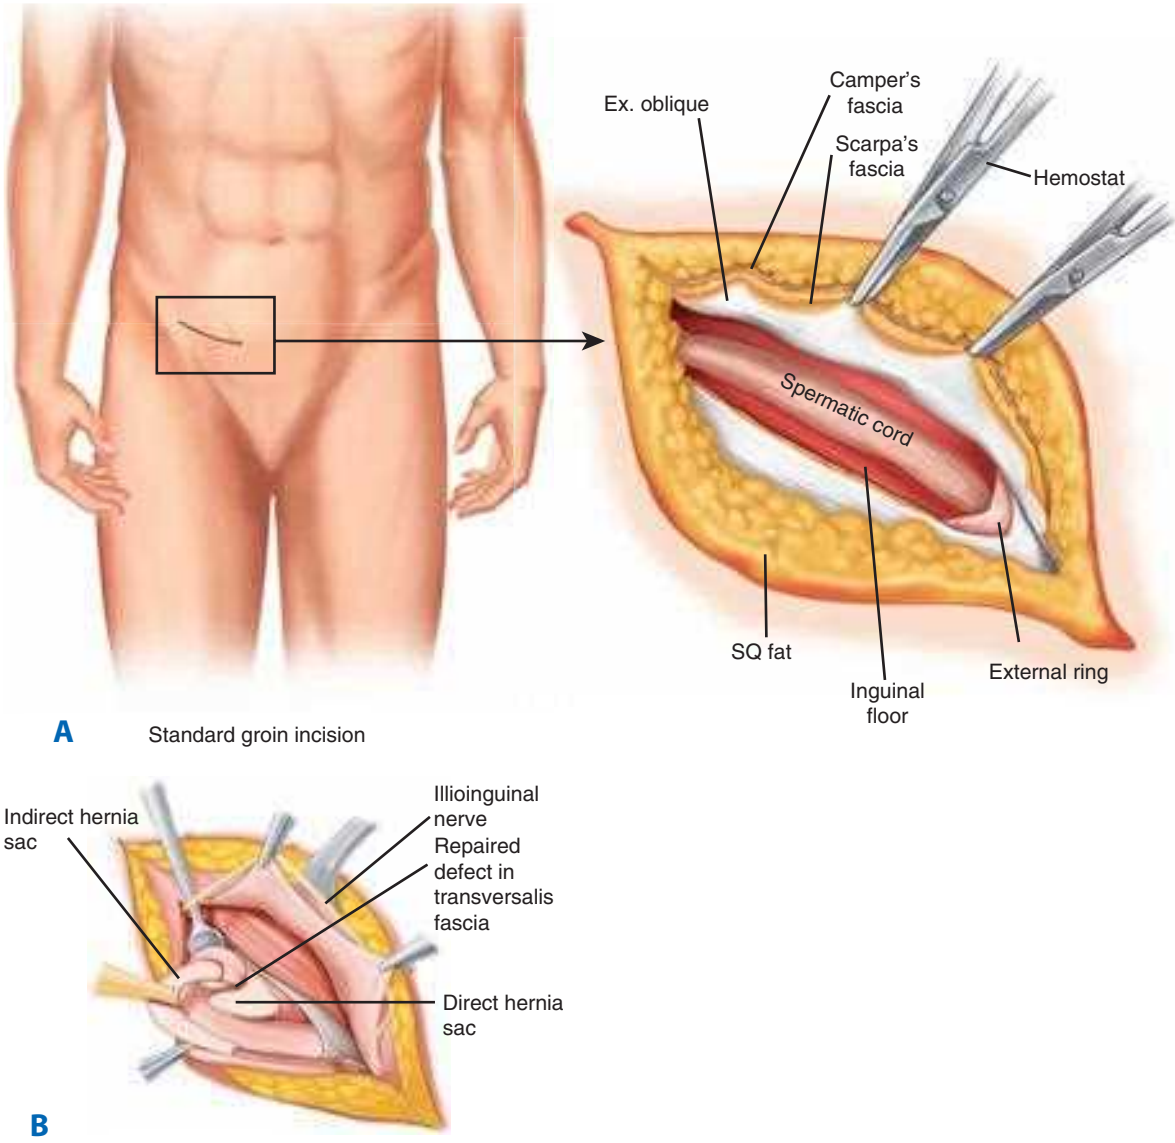

Figure 37-13. **A.** Layers of the abdominal wall in the anterior open approach to hernia repair. **B.** Identification of indirect and direct hernia sacs with retraction of the spermatic cord and ilioinguinal nerve. Ex. = external; SQ = subcutaneous.

is uncertain. General surgeons should understand inguinal anatomy and possess the expertise and ability to perform an effective tissue-based repair.

Bassini Repair The Bassini repair was an historic advancement in operative technique. Its current use is limited, as modern techniques reduce recurrence. The original repair includes dissection of the spermatic cord, dissection of the hernia sac with high ligation, and extensive reconstruction of the floor of the inguinal canal (Fig. 37-15). After exposing the inguinal floor, the transversalis fascia is incised from the pubic tubercle to the internal inguinal ring. Preperitoneal fat is bluntly dissected from the upper margin of the posterior side of the transversalis fascia to permit adequate tissue mobilization. A triple-layer repair is then performed. The internal oblique, transversus abdominis, and transversalis fascia are fixed to the shelving edge of the inguinal ligament and pubic periosteum with interrupted sutures. The lateral aspect of the repair reinforces the medial border of the internal inguinal ring.

Shouldice Repair The Shouldice repair recapitulates principles of the Bassini repair, and its distribution of tension over several

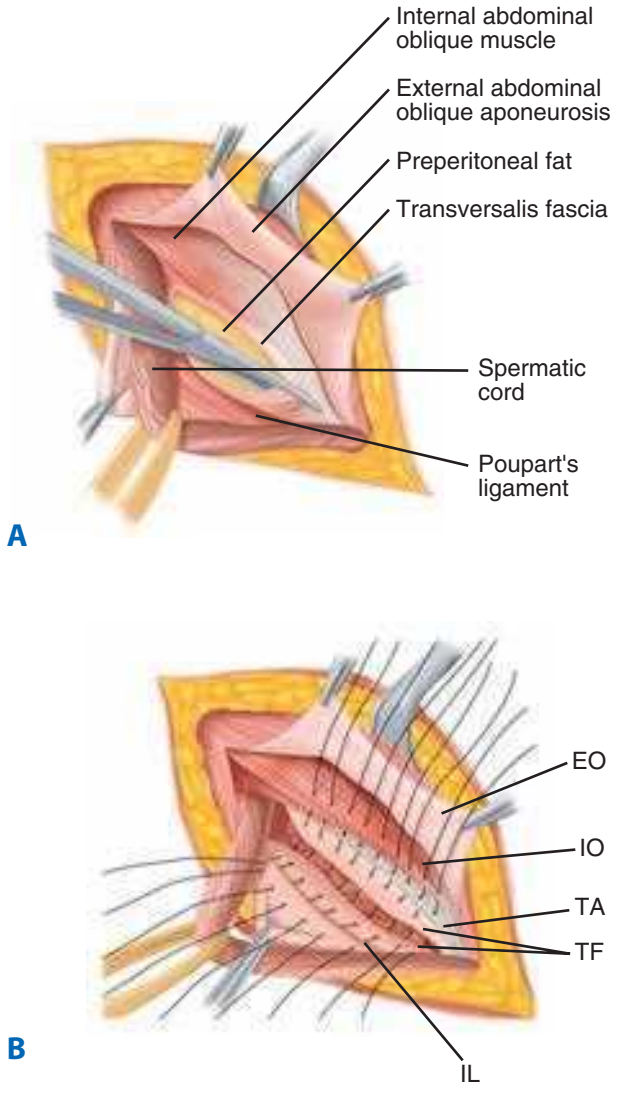

Figure 37-15. Bassini repair. **A.** The transversalis fascia is opened **B.** Reconstruction of the posterior wall by suturing the transversalis fascia (TF), the transversus abdominis muscle (TA), and the internal oblique muscle (IO) medially to the inguinal ligament (IL) laterally. EO = external oblique aponeurosis.

tissue layers results in lower recurrence rates (Fig. 37-16). During dissection of the cord, the genital branch of the genitofemoral nerve is routinely divided, resulting in ipsilateral loss of sensation to the scrotum in men or the mons pubis and labium majus in women. With the posterior inguinal floor exposed, an incision in the transversalis fascia is made between the pubic tubercle and internal ring. Care is taken to avoid injury to preperitoneal structures, which are bluntly dissected to mobilize the upper and lower fascial flaps. At the pubic tubercle, the iliopubic tract is sutured to the lateral edge of the rectus sheath using a synthetic, nonabsorbable, monofilament suture. This continuous suture progresses laterally, approximating the edge of the inferior transversalis flap to the posterior aspect of the superior flap. At the internal inguinal ring, the suture continues back in the medial direction, approximating the edge of the superior transversalis fascia flap to the shelving edge of the inguinal ligament. At the pubic tubercle, this suture is tied to the tail of the original stitch. The next suture begins at the internal inguinal ring, and it continues medially, apposing the aponeuroses of the internal oblique and transversus abdominis to the external oblique aponeurotic fibers. At the pubic

Shouldice repair. **A.** The iliopubic tract is sutured to the medial flap of the transversalis fascia and the internal oblique and transverse abdominis muscles. **B.** The second of the four suture lines, reversing toward the pubic tubercle approximating the internal oblique and transversus muscles to the inguinal ligament. Two more suture lines affix the internal oblique and transversus muscles medially.

tubercle, the suture doubles back through the same structures laterally toward the tightened internal ring.

McVay Repair The McVay repair addresses both inguinal and femoral ring defects. This technique is indicated for femoral hernias and in cases where the use of prosthetic material is contraindicated (Fig. 37-17). Once the spermatic cord has been

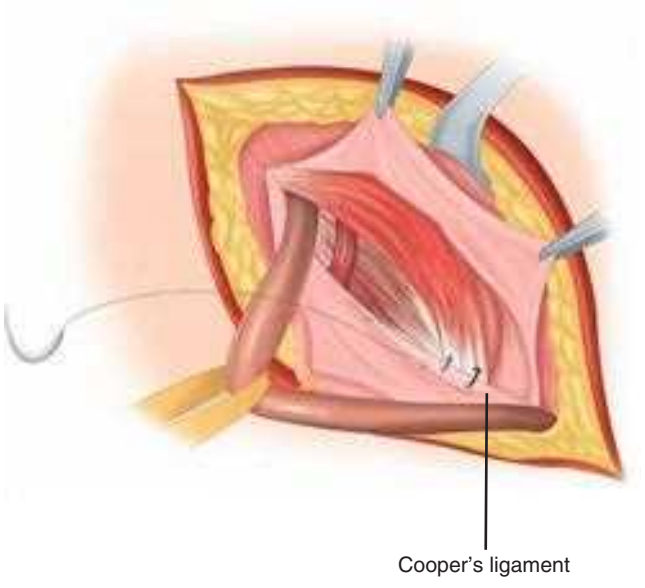

Figure 37-17. McVay Cooper's ligament repair.

isolated, an incision in the transversalis fascia permits entry into the preperitoneal space. The upper flap is mobilized by gentle blunt dissection of underlying tissue. Cooper's ligament is bluntly dissected to expose its surface. A 2- to 4-cm relaxing incision is made in the anterior rectus sheath vertically from the pubic tubercle. This incision is essential to reduce tension on the repair; however, it may result in increased postoperative pain and higher risk of ventral abdominal herniation. Using either interrupted or continuous suture, the superior transversalis flap is then fastened to Cooper's ligament, and the repair is continued laterally along Cooper's ligament to occlude the femoral ring. Lateral to the femoral ring, a transition stitch is placed, affixing the transversalis fascia to the inguinal ligament. The transversalis is then sutured to the inguinal ligament laterally to the internal ring.

Prosthetic Repairs. The popularization of tension-free prosthetic mesh repairs signified a paradigm shift in the surgical concept of inguinal hernia pathophysiology. Mesh-based hernioplasty is the most commonly performed general surgical procedure, owing to the technique's efficacy and improved outcomes. The techniques of the most commonly performed prosthetic repairs are presented in this section.

Lichtenstein Tension-Free Repair The Lichtenstein technique expands the domain of the inguinal canal by reinforcing the inguinal floor with a prosthetic mesh, thereby minimizing tension in the repair (Fig. 37-18). Initial exposure and mobilization of cord structures is identical to other open approaches. The inguinal canal is dissected to expose the shelving edge of the inguinal ligament, the pubic tubercle, and sufficient area for mesh. The mesh is a 7 × 15 cm rectangle with a rounded medial edge, and it must be large enough to extend 2 to 3 cm superior to Hesselbach's triangle. The lateral portion of the mesh is split such that the superior tail comprises two thirds of its width, and the inferior tail comprises the remaining one third. The medial edge of the mesh is affixed to the anterior rectus sheath such that it overlaps the pubic tubercle by 1.5 to 2 cm. This refinement to the original Lichtenstein technique minimizes medial recurrence.[34]

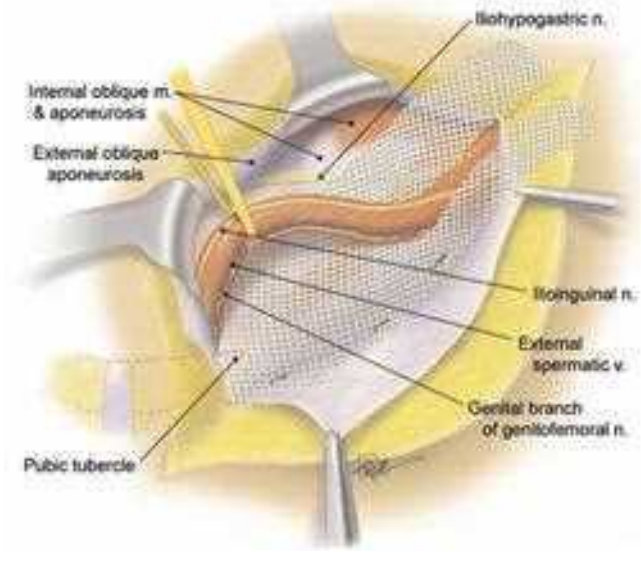

Figure 37-18. Lichtenstein tension-free hernioplasty. m. = muscle; n. = nerve; v. = vein.

For fixation of the inferior margin of the mesh, a permanent, synthetic, monofilament suture is used, taking care to avoid placing sutures directly into the periosteum of the pubic tubercle. Fixation is continued along the shelving edge of the inguinal ligament from medial to lateral, ending at the internal ring. The upper tail of the mesh is then fixed to the internal oblique aponeurosis and the medial edge to the rectus sheath using a synthetic, absorbable suture.

In the case of a femoral hernia, a triangular extension of the inferior aspect of the mesh is sutured to Cooper's ligament medially and to the inguinal ligament laterally. The lateral tails of the mesh are tailored to fit snugly around the cord at the internal ring, but not too tight to strangulate it. The tails are then sutured to the inguinal ligament with an interrupted stitch and placed beneath the external oblique aponeurosis.

Plug and Patch Technique A modification of the Lichtenstein repair, the plug and patch technique was developed by Gilbert and later popularized by Rutkow and Robbins.[35] Prior to placing the prosthetic mesh patch over the inguinal floor, a three-dimensional prosthetic plug is placed in the space previously occupied by the hernia sac (Fig. 37-19). In the case of an indirect

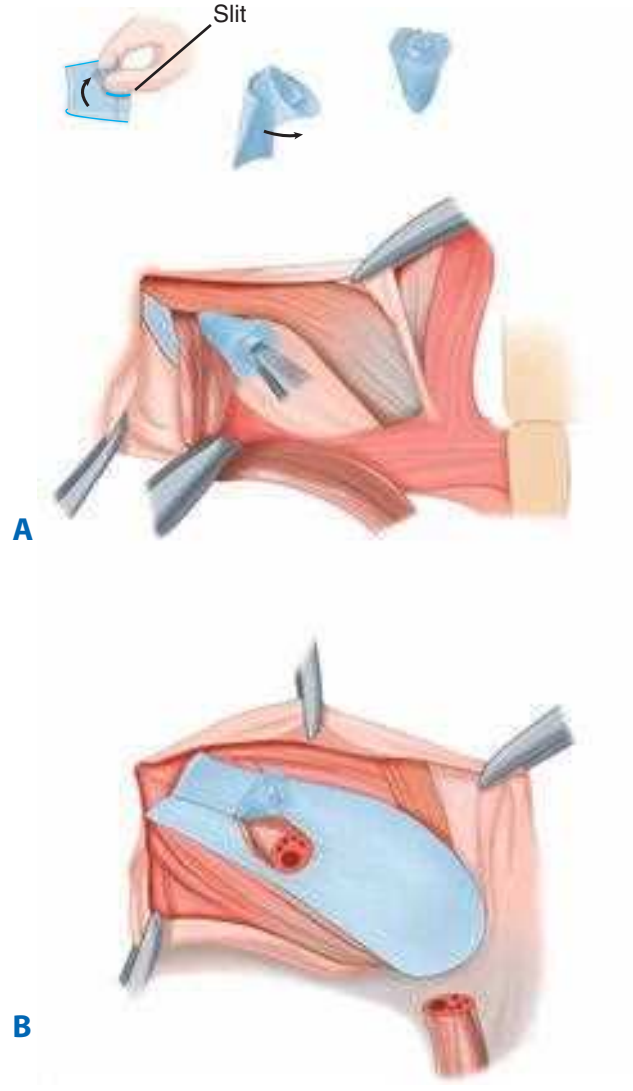

Figure 37-19. Plug and patch repair. **A.** A plug may be created from a flat piece of mesh, or a preformed, commercially available plug is placed in the internal ring. **B.** Final view of the repair following placement of the plug and patch.

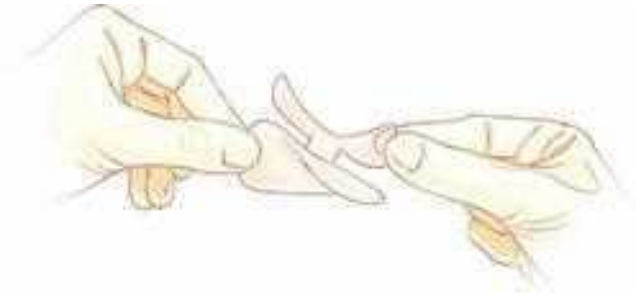

Figure 37-20. The Prolene Hernia System prosthesis.

hernia, the plug is placed alongside the spermatic cord through the internal ring. Prosthetic plugs of various sizes are available, and one of appropriate size is fixed to the margins of the internal ring with interrupted sutures.[36] For direct hernias, the sac is reduced, and the plug is sutured to Cooper's ligament, the inguinal ligament, and the internal oblique aponeurosis.

Prolene Hernia System The Prolene Hernia System (PHS) repair provides reinforcement to the anterior and posterior aspects of the abdominal wall. Exposure of the inguinal canal is identical to that of other open approaches. With an indirect hernia, the sac is dissected from the spermatic cord, and the preperitoneal space is bluntly dissected through the internal ring. With a direct hernia, the transversalis fascia is opened at the defect, and the preperitoneal space is bluntly dissected to create space for the mesh. The mesh has an underlay flap and an onlay flap, joined by a short cylindrical connector (Fig. 37-20). The underlay portion of the mesh is then placed through the hernia defect into the preperitoneal space. The advantage of the preperitoneal mesh position is that increased intra-abdominal pressure pushes the mesh into closer apposition to the abdominal wall. The overlay flap reinforces the inguinal floor similar to a tension-free repair. The spermatic cord is placed through a slit in the onlay portion of the mesh. Three to four circumferential interrupted sutures anchor the anterior layer of the mesh to the inguinal canal floor.

Wound Closure. Once the reconstruction of the inguinal canal is complete, the cord contents are returned to their anatomic position. The external oblique aponeurosis is then reapproximated continuously from medial to lateral using an absorbable suture. The external ring should be reconstructed in close apposition to the spermatic cord to avoid the appearance of recurrence on future examination. Scarpa's fascia and skin are appropriately closed.

Giant Prosthetic Reinforcement of the Visceral Sac. In giant prosthetic reinforcement of the visceral sac, also known as the Stoppa repair, a broad prosthetic mesh is placed in the preperitoneal space from an anterior approach. In unilateral repair, an 8- to 10-cm Pfannenstiel or low transverse incision is made above the internal inguinal ring. The lateral aspect of the rectus sheath and the oblique muscles are divided along the length of the incision. The transversalis is incised, and the preperitoneal space is dissected widely (Fig. 37-21). The preperitoneal dissection is carried medially to expose Cooper's ligament and laterally over the iliopubic tract to the anterior superior iliac spine. If bilateral hernias are present, a lower midline incision allows for access and the preperitoneal dissection spans the entire area between both anterior superior iliac spines and both inguinal canals. For direct defects, the transversalis fascia may be sutured

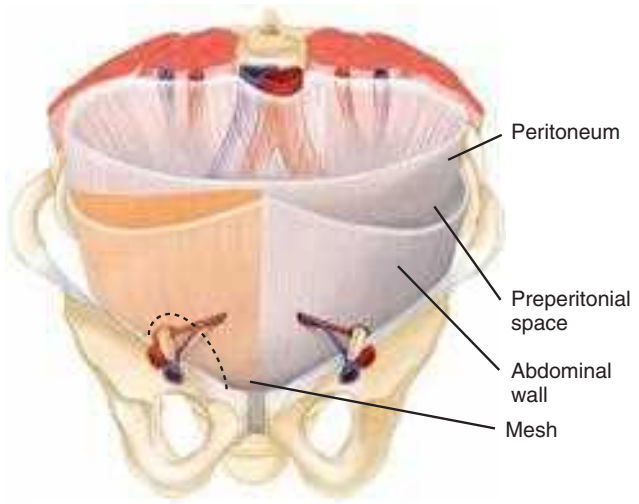

Figure 37-21. Extensive dissection of the preperitoneal space on both sides will accommodate a large prosthesis.

to Cooper's ligament to obliterate the sac's laxity. Indirect hernias require directed dissection from the internal ring. Large or densely adherent indirect hernia sacs are dissected from the cord at the internal ring and ligated, and the peritoneum is closed.

The mesh should be large enough to cover the area from the midline to 1 cm medial to the anterior superior iliac spine and from the umbilicus to the pubic symphysis. The middle portion and lower corners of the mesh are clamped. The mesh is placed flat along the inferior margin of the preperitoneal space (Fig. 37-22). The medial clamp is directed into the space of Retzius, the middle clamp is placed over the pubic ramus and iliac vessels, and the lateral clamp is placed into the iliac fossa cover the spermatic cord. Splitting the mesh to accommodate the cord may predispose to hernia recurrence. Alternatively, the mesh may be fixed with interrupted sutures to the anterior abdominal wall; however, care must be taken to avoid injuring the lateral femoral cutaneous nerve and the inferior epigastric vessels. For bilateral hernias, a single large mesh is placed into the preperitoneal space using up to eight clamps along its inferior edge. The transversalis is reapproximated and the wound is closed.

Laparoscopic Approach

Laparoscopic inguinal hernia repairs reinforce the abdominal wall via a posterior approach. Principal laparoscopic methods include the transabdominal preperitoneal (TAPP) repair, the totally extraperitoneal (TEP) repair, and the less commonly performed intraperitoneal onlay mesh (IPOM) repair.

Although laparoscopic repairs in experienced hands are relatively expedient, they necessitate the administration of general anesthesia and its inherent risks. Any patient with a contraindication to the use of general anesthesia should not undergo laparoscopic hernia repair. Occasionally, general anesthesia induction may result in reduction of an incarcerated or strangulated inguinal hernia. If the surgeon suspects this might have occurred, the abdomen should be explored for nonviable tissue either via laparoscopy or upon conversion to an open laparotomy.

The indications for laparoscopic inguinal hernia repair are similar to those for open repair. Most surgeons would agree that the laparoscopic approach to bilateral or recurrent inguinal hernias is superior to the open approach.[37] Concurrent inguinal hernia repair should be considered if a hernia patient

3▶

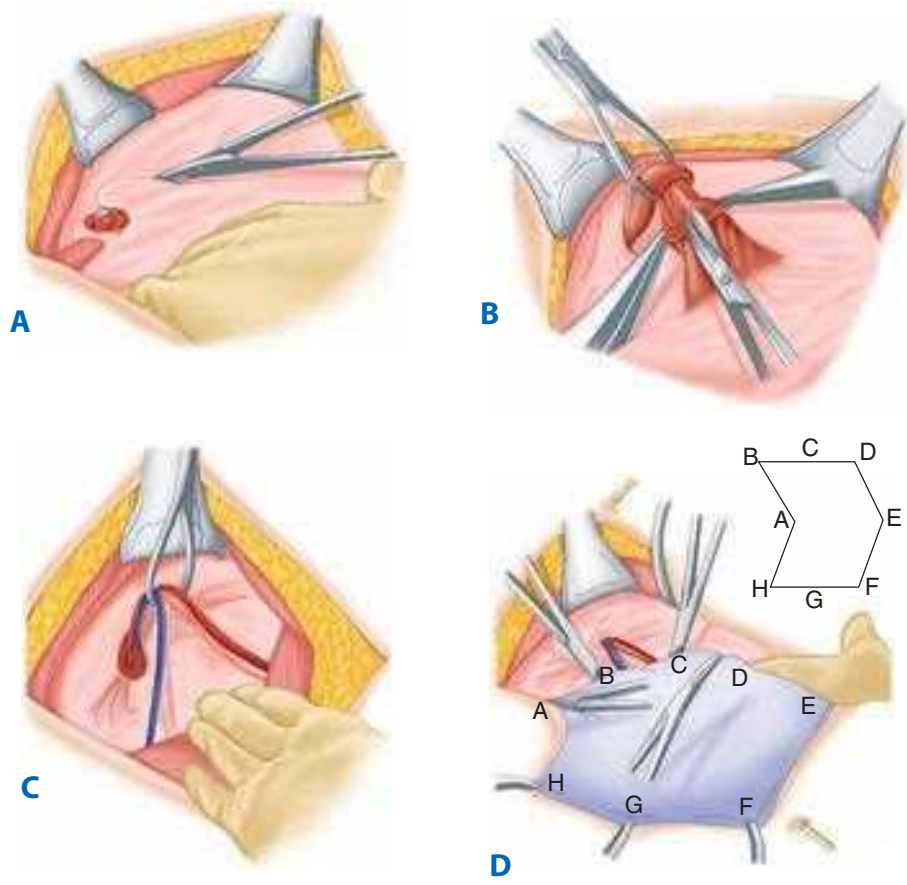

Figure 37-22. Giant prosthetic reinforcement of the visceral sac. **A.** Exposure of the preperitoneal space. **B.** Dissection of the hernia sac from the spermatic cord. **C.** Reduction of the sac and elevation of the cord. **D.** Orientation and placement of the giant mesh.

is scheduled to undergo another clean laparoscopic procedure, such as prostatectomy.[38,39] International Endohernia Society (IEHS) guidelines offer a Grade A recommendation that TEP and TAPP are preferred alternatives to Lichtenstein repair for recurrent hernias after open anterior repair.[40] The possibility of bilateral repair should be discussed with all patients undergoing laparoscopic inguinal hernia surgery.

The operating room configuration is identical for TAPP, TEP, and IPOM procedures. The patient is placed in the Trendelenburg position, and video screens are placed at the foot of the bed. The surgeon stands contralateral to the hernia, and the assistant stands opposite the surgeon. The patient's arms are tucked to the sides. Fig. 37-23 demonstrates a typical operating room setup for laparoscopic inguinal hernia repair. The following sections outline the most commonly performed laparoscopic inguinal hernia repair techniques.

Transabdominal Preperitoneal Procedure. The transabdominal approach confers the advantage of an intraperitoneal perspective, which is useful for bilateral hernias, large hernia defects, and scarring from previous lower abdominal surgery. The abdominal cavity is accessed using a dissecting trocar or open Hasson technique. Pneumoperitoneum is instilled to a level of 15 mmHg. Two 5-mm trocars are placed lateral and slightly inferior to the umbilical trocar, avoiding injury to the inferior epigastric vessels (Fig. 37-24). The patient is then placed in the Trendelenburg position, and the pelvis is inspected.

The bladder, median and medial umbilical ligaments, external iliac, and inferior epigastric vessels are visualized. An incision is made in the peritoneum at the medial umbilical ligament 3 to 4 cm superior to the hernia defect, and it is carried laterally to the anterior superior iliac spine. For bilateral inguinal hernia repair, bilateral peritoneal incisions are advisable, leaving a midline bridge of tissue to avoid injuring a potential patent urachus. The inferior edge of incised peritoneum is retracted, and the preperitoneum is dissected to expose the spermatic cord. If a direct hernia is encountered, the sac is inverted and fixed to Cooper's ligament to prevent development of hematoma or seroma. An indirect hernia sac will usually protrude anterior to the spermatic cord. In this case, the sac is grasped and elevated superiorly from the cord and the space below is developed bluntly to allow for mesh placement. The sac is dissected from its adhesions, and the cord is skeletonized.

The mesh usually measures 10 × 15 cm to completely cover the myopectineal orifice (Fig. 37-25). It is rolled lengthwise and placed through the 12-mm trocar. It is unrolled in the preperitoneal space and secured medially to Cooper's ligament using a spiral tacker. During this fixation, the surgeon palpates the end of the tacker from the abdominal surface to ensure its proper angle and to stabilize the pelvis. The mesh is then pulled taut and fixed lateral to the anterior superior iliac spine. Tacks are placed above the iliopubic tract to avoid injury to the lateral cutaneous nerve of the thigh and the femoral branch of the genitofemoral nerve. The peritoneal edges are reapproximated using tacks or intracorporeal sutures as the mesh is stabilized. The peritoneum should be closed completely to avoid contact between the mesh and the intestine. The abdomen is desufflated and the trocars are removed. The fascial defect of the 12-mm port and the skin incisions are appropriately closed.

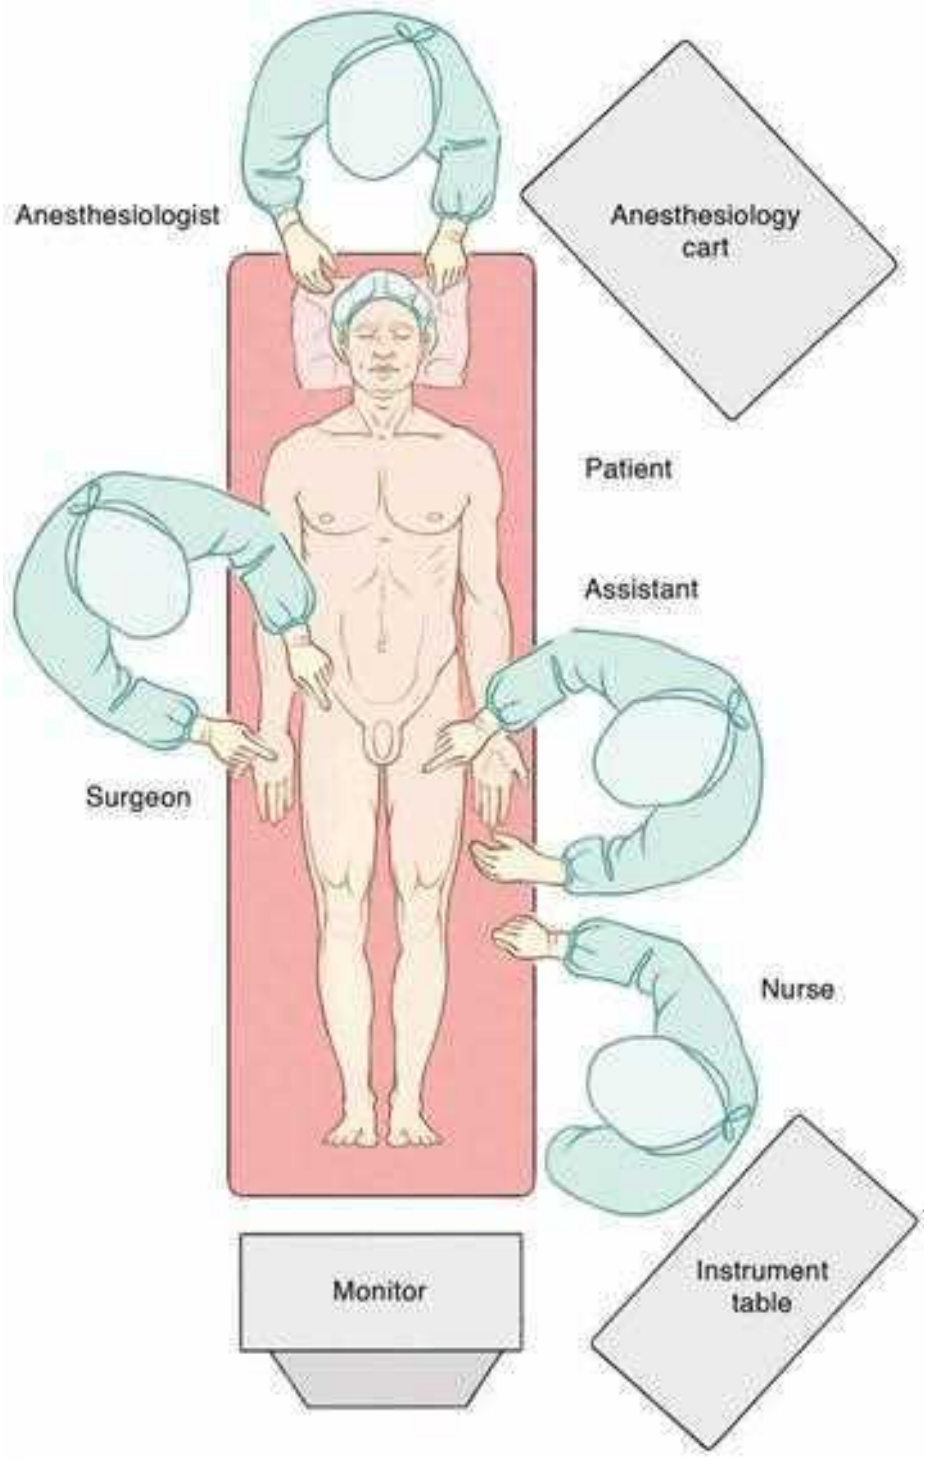

Figure 37-23. Operating room setup for laparoscopic inguinal hernia repair.

Totally Extraperitoneal Procedure. The advantage of the TEP repair is the access to the preperitoneal space without intraperitoneal infiltration. Consequently, this approach minimizes the risk of injury to intra-abdominal organs and port site herniation through an iatrogenic defect in the abdominal wall. As with TAPP, TEP is indicated for repair of bilateral inguinal hernias or for unilateral hernias when scarring makes the anterior approach challenging.

A small horizontal incision is made inferior to the umbilicus. Subcutaneous tissue is dissected to the level of the anterior rectus sheath, which is then incised lateral to the linea alba. The rectus muscle is retracted superolaterally, and a dissecting balloon is advanced through the incision toward the pubic symphysis. Under direct visualization with a 30° laparoscope, the balloon is inflated slowly to bluntly dissect the preperitoneal space (Fig. 37-26). The dissecting balloon is replaced with a 12-mm balloon trocar, and pneumopreperitoneum is achieved by insufflation to 15 mmHg. A 5-mm trocar is placed suprapubically in the midline, and another is placed inferior to the insufflation port (see Fig. 37-24). The patient is placed in the Trendelenburg position, and the operation proceeds in an identical fashion to TAPP. No modifications are necessary to repair bilateral inguinal hernias with the TEP approach.

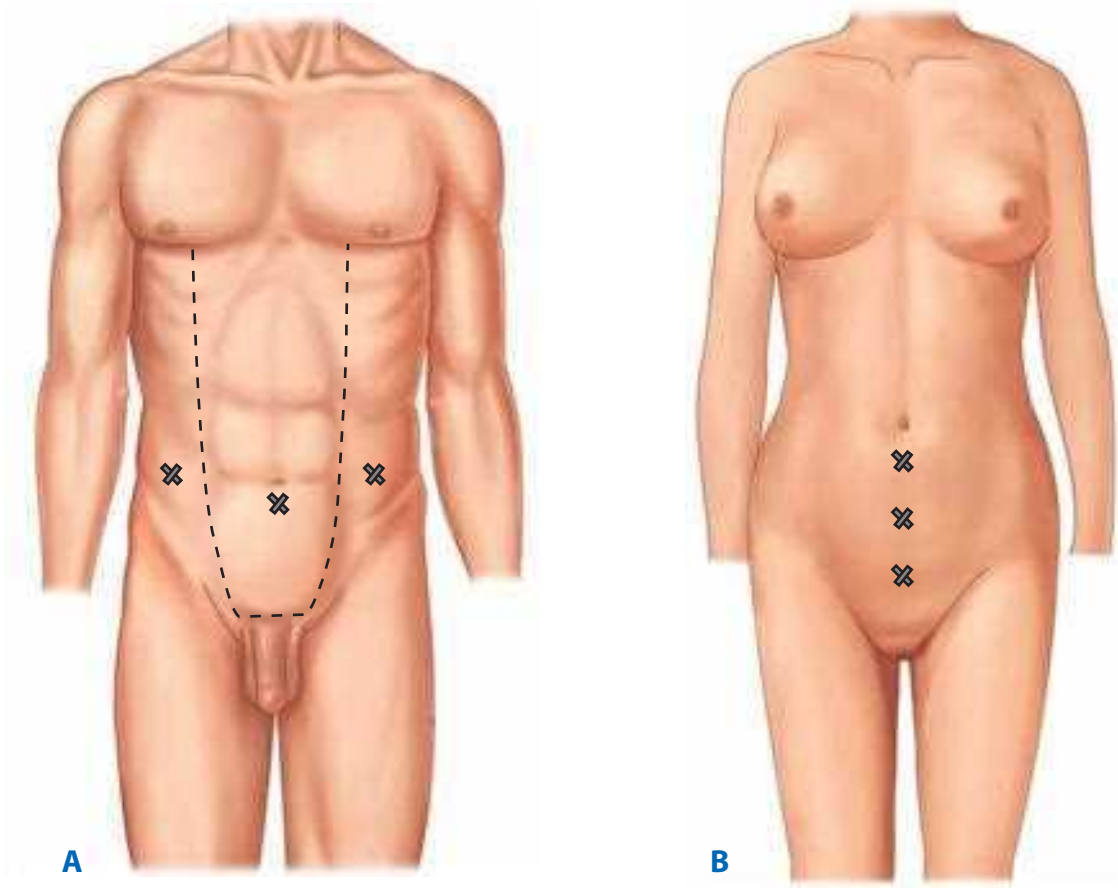

Figure 37-24. Trocar placement for (**A**) transabdominal preperitoneal repair and (**B**) totally extraperitoneal repair.

Figure 37-25. View of mesh placement in posterior repairs. A large mesh overlaps the myopectineal orifice.

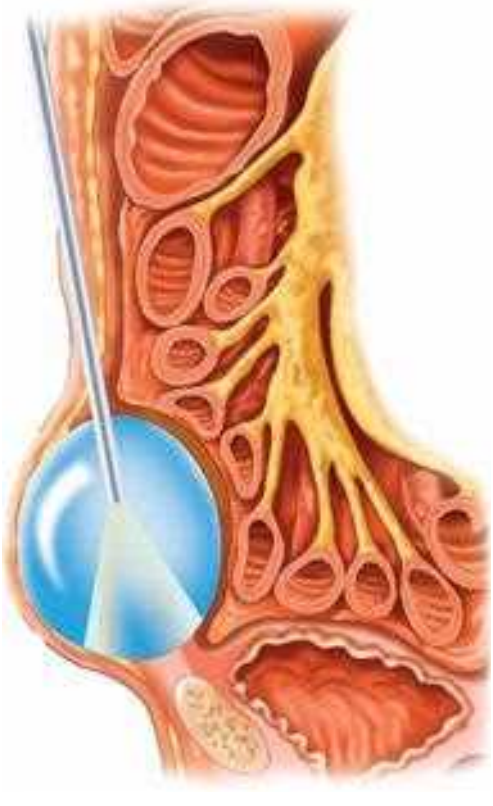

Figure 37-26. Balloon dissection of the preperitoneal space in a totally extraperitoneal inguinal hernia repair.

Any peritoneal rents should be repaired prior to desufflation to prevent mesh from contacting intraperitoneal structures. Following mesh placement, the preperitoneal space is desufflated slowly under direct vision to ensure proper mesh positioning. Trocars are removed, and the anterior rectus sheath is closed with an interrupted suture.

Intraperitoneal Onlay Mesh Procedure. In contrast to TAPP and TEP, the IPOM procedure permits the posterior approach without preperitoneal dissection. It is an attractive procedure in cases where the anterior approach is unfeasible, in recurrent hernias that are refractory to other approaches, or where extensive preperitoneal scarring would make TEP or TAPP challenging. Port placement and inguinal hernia identification are identical to TAPP. Hernia sac contents are reduced; however, the sac itself is not inverted from the preperitoneal space. Instead, mesh is placed directly over the defect and fixed in place with sutures or spiral tacks. Because these anchors are placed through the peritoneum without preperitoneal inspection, the lateral cutaneous nerve of the thigh and the genitofemoral nerve are especially prone to injury. Furthermore, intraperitoneal mesh migration is a documented phenomenon that can lead to postoperative morbidity, recurrence, and reoperation.

Prosthesis Considerations

The success of prosthetic repairs has generated considerable debate about the desirable physical attributes of mesh and their fixation. An ideal mesh should be easy to handle, flexible, strong, immunologically inert, contraction-resistant, infection-resistant, and inexpensive to manufacture.[41] The following section reviews the most common types of mesh and fixatives currently available.

Synthetic Mesh Material. Polypropylene and polyester are the most common synthetic prosthetic materials used in hernia repair. These materials are permanent and hydrophobic, and they promote a local inflammatory response that results in cellular infiltration and scarring with slight contraction in size. Other synthetic mesh materials are under investigation with the goals of minimizing postoperative pain and preventing infection or recurrence. In selecting mesh material, considerations include mesh absorbability, thickness, weight, porosity, and strength.

Variations in the fiber diameter and fiber count of mesh materials categorize them as heavyweight or lightweight in density. Commonly used lightweight mesh materials include β-D-glucan, titanium-coated polypropylene, and polypropylene-poliglecaprone. These materials have greater elasticity and less theoretical surface area contact with surrounding tissues than their heavyweight counterparts.[42] Accordingly, they are hypothesized to reduce scarring and chronic pain with equivalent recurrence rates. The use of lightweight mesh in TEP and TAPP repairs is associated with fewer 3-month cumulative mesh-related complications.[40] A 2012 meta-analysis of 2310 patients undergoing open or laparoscopic hernia repairs found a lower incidence of chronic pain (relative risk [RR] 0.61, CI 0.50–0.74) following use of lightweight mesh versus heavyweight mesh, and no significant difference in rates of recurrence.[43] When available, lightweight mesh should be considered for all prosthetic repairs to minimize postoperative chronic pain.

4▶

A disadvantage of currently available commercial prostheses is their high cost. In settings where resources are limited, prosthetic repairs are performed using alternative materials. Polypropylene and polyethylene mosquito nets are inexpensive and ubiquitous in sub-Saharan Africa and India, and they have similar mechanical properties to commercially available hernioplasty meshes. Meta-analysis of 577 hernioplasties performed using sterilized mosquito nets demonstrated similar rates of short-term mesh-related complications (6.1%) and recurrence (0.17%) to those using commercial meshes.[44] Furthermore, the disability-adjusted life-years (DALYs) prevented by inguinal hernia repair signify a comparable impact to that of vaccination in sub-Saharan Africa.[45,46] Expensive prostheses are not necessarily needed for hernia surgery, either in resource-limited or in resource-abundant settings, and the anticipated benefits should be evaluated with consideration of increased costs.

Biologic Mesh. Although indications for the use of biologic prostheses have not been absolutely defined, they are commonly reserved for contaminated cases or when domain expansion is necessary in the face of high infection risk. There are numerous biologic materials available with differing properties, but in general, they have lower tensile strength and subsequent higher rates of rupture than synthetic prostheses.[47] They also have varying degrees of tensile strength and tissue biocompatibility between them. In ventral hernia repairs, xenograft material was associated with a lower rate of recurrence than allograft material.[48] A review of biologic materials concluded that cross-linked graft materials are more durable and less prone to failure than non–cross-linked grafts.[49] Nevertheless, their diminished ability to remodel adversely affects rates of infection and incorporation. While new prosthetic materials continue to be developed, no single biologic warrants routine use. These materials will continue to evolve, and they remain an important tool for challenging cases when used judiciously.

Fixation Technique. Independent of prosthesis material, the method of its fixation remains disputed. Suturing, stapling, and tacking prostheses entail tissue perforation, which may cause inflammation, neurovascular injury, and chronic pain development. Conversely, improper prosthesis fixation may result in mesh migration, repair failure, meshoma pain, and hernia recurrence. Mesh may be fixed with fibrin-derived glue, and self-gripping mesh has been developed to minimize trauma to surrounding tissues and to reduce the risk for entrapment neuropathy. For hernias repaired via a strictly preperitoneal approach, prosthesis fixation may not be necessary at all.

Fibrin glue fixation is a successful alternative to tack fixation in hernia repair with a synthetic prosthesis. Recent studies comparing fibrin glue fixation and suture fixation in open hernia repair show superior rates of chronic pain with both Lichtenstein and plug and patch techniques.[50,51] Meta-analyses of laparoscopic hernia repair determined the incidence of chronic postoperative pain after tacker fixation was significantly higher than after fibrin glue fixation, with one showing an RR of 4.64 (CI 1.9–11.7). Rates of other postoperative complications and recurrence were similar between both fixation methods.[52,53] Glue fixation is a promising technical refinement; however, its questionable efficacy in larger hernias, long-term outcomes, and cost remain considerations.

In TEP repairs, fixation of mesh may not be compulsory. A prospective randomized trial comparing fixation and no fixation in TEP repairs found a significant increase in new pain and equivalent recurrence rates in the fixation group several months after repair.[54] A 2012 meta-analysis comparing laparoscopic tacker mesh fixation to no mesh fixation found no statistically significant differences in operative duration, pain, mesh-related

complications, recurrence, or length of stay between the two methods.[55] Studies of three-dimensional, ergonomically contoured mesh without fixation, as well as self-gripping meshes, have yielded similar results.[56] In the preperitoneal approach, the re-approximation of surrounding tissues and physiologic intra-abdominal pressure hypothetically prevent mesh migration. Due to higher theoretical risk of mesh migration, repair without fixation is not recommended for anterior or transperitoneal approaches.

COMPLICATIONS

As with other clean operations, the most common complications of inguinal hernia repair include bleeding, seroma, wound infection, urinary retention, ileus, and injury to adjacent structures (Table 37-6). Complications specific to herniorrhaphy and hernioplasty include hernia recurrence, chronic inguinal and pubic pain, and injury to the spermatic cord or testis. The incidence, prevention, and treatment of these complications are discussed in the ensuing section.

Hernia Recurrence

When a patient develops pain, bulging, or a mass at the site of an inguinal hernia repair, clinical entities such as seroma, persistent cord lipoma, and hernia recurrence should be considered. Common medical issues associated with recurrence include malnutrition, immunosuppression, diabetes, steroid use, and smoking. Technical causes of recurrence include improper mesh size, tissue ischemia, infection, and tension in the reconstruction. A focused physical examination should be performed. As with primary hernias, US, CT, or MRI can elucidate ambiguous physical findings. When a recurrent hernia is discovered and warrants re-operation, an approach through a virgin plane facilitates its dissection and exposure. Extensive dissection of the scarred field and mesh may result in injury to cord structures, viscera, large blood vessels, and nerves. After an initial anterior approach, the posterior laparoscopic approach will usually be easier and more effective than another anterior dissection. Conversely, failed preperitoneal repairs should be approached using an open anterior repair.

Pain

Pain after inguinal hernia repair is classified into acute or chronic manifestations of three mechanisms: nociceptive (somatic), neuropathic, and visceral pain. Nociceptive pain is the most common of the three. Because it is usually a result of ligamentous or muscular trauma and inflammation, nociceptive pain is reproduced with abdominal muscle contraction. Treatment consists of rest, nonsteroidal anti-inflammatory drugs (NSAIDs), and reassurance, as it resolves spontaneously in most cases. Neuropathic pain occurs as a result of direct nerve damage or entrapment. It may present early or late, and it manifests as a localized, sharp, burning or tearing sensation. It may respond to pharmacologic therapy and to local steroid or anesthetic injections when indicated. Visceral pain refers to pain conveyed through afferent autonomic pain fibers. It is usually poorly localized and may occur during ejaculation as a result of sympathetic plexus injury.

Chronic postoperative pain remains an important measure of clinical outcome that has been reported in as many as 63% of inguinal hernia repair cases.[57–59] Despite the significant anatomic variation in the three inguinal nerves, literature reviews suggest

identification of all three nerves is possible in 70% to 90% of cases.[60] Meticulous nerve identification may prevent injury that results in debilitating chronic postoperative pain syndromes. Notwithstanding, moderate-to-severe pain adversely affects physical activity, social interactions, healthcare utilization, employment, and productivity in 6% to 8% of patients.[58,59,61–64] Pain in this subset of patients comprises a tremendous individual and societal burden.

Post-herniorrhaphy inguinodynia is a debilitating chronic complication caused by a combination of nociceptive, neuropathic, and visceral elements. Its incidence is independent of the method of hernia repair; however, the original operative technique determines options for intervention and remedial surgery.[62] Treatment is based on repair technique, subsequent re-operations, pain character, and the presence of recurrence, meshoma, and fixation material. Selective ilioinguinal, iliohypogastric, and genitofemoral neurolysis or neurectomy, removal of mesh and fixation material, and revision of the repair are common options for treatment. Nevertheless, anatomic variation and cross-innervation of the inguinal nerves in the retroperitoneum and inguinal canal make selective neurectomy less reliable.[65–69] When inguinodynia is refractory to pharmacologic and interventional measures, triple neurectomy with removal of meshoma is arguably the most effective option for the majority of patients.[64, 67–74] Refractory inguinodynia with concurrent orchialgia also requires resection of the paravasal nerves.[74]

Other chronic pain syndromes include local nerve entrapment, meralgia paresthetica, and osteitis pubis. At greatest risk of entrapment are the ilioinguinal and iliohypogastric nerves in anterior repairs and the genitofemoral and lateral femoral cutaneous nerves in laparoscopic repairs. Clinical manifestations of nerve entrapment mimic acute neuropathic pain, and they occur with a dermatomal distribution. Injury to the lateral femoral cutaneous nerve results in meralgia paresthetica, a condition characterized by persistent paresthesias of the lateral thigh. Initial treatment of nerve entrapment consists of rest, ice, NSAIDs, physical therapy, and possible local corticosteroid and anesthetic injection. Osteitis pubis is characterized by inflammation of the pubic symphysis and usually presents as medial groin or symphyseal pain that is reproduced by thigh adduction. Avoiding the pubic periosteum when placing sutures and tacks reduces the risk of developing osteitis pubis. CT scan or MRI excludes hernia recurrence, and bone scan is confirmatory for the diagnosis. Initial treatment is identical to that of nerve entrapment; however, if pain remains intractable, orthopedic surgery consultation should be sought for possible bone resection and curettage. Irrespective of treatment, the condition often takes 6 months to resolve.[75]

Cord and Testes Injury

Injury to spermatic cord structures may result in ischemic orchitis or testicular atrophy. Ischemic orchitis is likely caused by injury to the pampiniform plexus and not to the testicular artery. It usually manifests within 1 week of inguinal hernia repair as an enlarged, indurated, and painful testis, and it is almost certainly self-limited. It occurs in <1% of primary hernia repairs; however, this figure is larger for recurrent inguinal hernia repairs.[76] US will demonstrate testicular blood flow to differentiate between ischemia and necrosis. Emergent orchiectomy is only necessary in the case of necrosis. Injury to the testicular artery also may lead to testicular atrophy, which is manifest over a protracted period. Treatment for ischemic orchitis most frequently consists of reassurance, NSAIDs, and comfort measures. Intraoperatively, proximal ligation of large hernia sacs to avoid cord manipulation minimizes the risk of injury.

Injury to the vas deferens within the cord may lead to infertility. In open inguinal hernia repairs, isolating the vas deferens along with the cord structures using digital manipulation may cause injury or disruption. In laparoscopic approach, grasping the vas may result in a crush injury. Transections of the vas deferens should be addressed with a urologic consult and early anastomosis, if possible. Historically, surgeons and their patients speculated that synthetic material would increase the risks of mesh rejection, carcinogenesis, and inflammation; however, as mesh became used more frequently, these concerns did not manifest. Nevertheless, one study found prosthetic mesh may exert long-term deleterious effects upon the vas deferens, causing azoospermia.[77] Similar studies report varied results, though. A recent prospective study from the Swedish Hernia Registry discovered no difference in rates of patient-reported infertility between the general population and patients who underwent either mesh or tissue-based inguinal hernia repair.[78] Chronic scarring may lead to vas deferens obstruction, resulting in decreased fertility rates and a dysejaculation syndrome. Pain and burning during ejaculation are usually self-limited, and more common causes, such as sexually transmitted diseases, should be excluded.

In females, the round ligament is the analog to the spermatic cord, and it maintains uterine anteversion. Injury to the artery of the round ligament does not result in clinically significant morbidity.

Laparoscopic Complications

In general, the risks of the TEP technique mirror those of open anterior repairs, as the peritoneal space is not violated. Complications of transabdominal laparoscopy include urinary retention, paralytic ileus, visceral injuries, vascular injuries, and less commonly, bowel obstruction, hypercapnia, gas embolism, and pneumothorax. The most common complications of laparoscopic inguinal hernia repair are presented in this section.

Urinary Retention. The most common cause of urinary retention after hernia repair is general anesthesia, which is routine in laparoscopic hernia repairs. Among 880 patients undergoing inguinal hernia repair with local anesthesia only, 0.2% developed urinary retention, whereas the rate of urinary retention was 13% among 200 patients undergoing repair with general or spinal anesthesia.[79] Other risk factors for postoperative urinary retention include pain, narcotic analgesia, and perioperative bladder distention. Initial treatment of urinary retention requires decompression of the bladder with short-term catheterization. Patients will generally require an overnight admission and trial of normal voiding before discharge. Failure to void normally requires reinsertion of the catheter for up to a week. Chronic requirement of a urinary catheter is rare, although older patients may require prolonged catheterization.

Ileus and Bowel Obstruction. The laparoscopic transabdominal approach is associated with a higher incidence of ileus than other modes of repair. This complication is self-limited; however, it necessitates sustained inpatient observation, intravenous fluid maintenance, and possibly nasogastric decompression. Abdominal imaging may be helpful to confirm the diagnosis and to exclude bowel obstruction. Prolonged absence of bowel function, in conjunction with a suspicious abdominal

series, should raise concern for obstruction. In this case, CT of the abdomen is helpful to distinguish anatomic sites of obstruction, inflammation, and ischemia. In TAPP repairs, obstruction occurs most commonly secondary to herniation of bowel loops through peritoneal defects or large trocar insertion sites; however, the use of smaller trocars and the preponderance of TEP repairs have reduced the frequency of this complication. True obstruction warrants reoperation.

Visceral Injury. Small bowel, colon, and bladder are at risk for injury in laparoscopic hernia repair. The presence of intra-abdominal adhesions from previous surgeries may predispose to visceral injuries. Direct bowel injuries may also result from trocar placement. In reoperative abdominal surgery, open Hasson technique and direct visualization of trocars are recommended to reduce the likelihood of visceral injury. Bowel injury may also occur secondary to electrocautery and instrument trauma outside of the camera field. Missed bowel injuries are associated with increased mortality. If injury to the bowel is suspected, its entire length should be examined, and conversion to open repair may be necessary.

Bladder injuries are less common than visceral injuries, and they are usually associated with perioperative bladder distention or extensive dissection of perivesical adhesions. As with bladder injuries encountered in open surgery, cystotomies must be repaired in several layers with 1 to 2 weeks of Foley catheter decompression. A confirmatory cystogram may be performed before catheter removal to confirm healing of the injury.

Vascular Injury. The most severe vascular injuries usually occur in iliac or femoral vessels, either by misplaced sutures in anterior repairs, or by trocar injury or direct dissection in laparoscopic repairs. In these cases, exsanguination may be swift. Conversion to an open approach may be necessary, and bleeding should be temporarily controlled with mechanical compression until vascular control is obtained.

The most commonly injured vessels in laparoscopic hernia repair include the inferior epigastrics and external iliacs. Although apparent upon initial approach, these vessels may be obscured during mesh positioning, and tacks or staples may injure them. Often, due to tamponade effect, injury to the inferior epigastric vessels is not apparent until the adjacent trocar is removed. If injured, the inferior epigastrics may be ligated with a percutaneous suture passer or endoscopic hemoclips.

If the tissue pressure exerted by pneumoperitoneum is greater than an injured vessel's hydrostatic intraluminal pressure, bleeding will not manifest until pneumoperitoneum is released. The presentation of an inferior epigastric vein injury is often delayed because of this effect, and it may result in a significant rectus sheath hematoma. Accordingly, the surgeon should be aware of this intraoperative consideration.

Hematomas and Seromas

Hematomas may present as localized collections or as diffuse bruising over the operative site. Injury to spermatic cord vessels may result in a scrotal hematoma. Although they are self-limited, characteristic dark blue discoloration of the entire scrotum may alarm patients. Intermittent warm and cold compression aids in resolution. Hematomas may also develop in the incision, retroperitoneum, rectus sheath, and peritoneal cavity. The latter three sites are more frequently associated with laparoscopic repair. Bleeding within the peritoneum or preperitoneal space may not be readily apparent on physical examination. For this reason, close monitoring of subjective complaints, vital signs, urine output, and physical parameters is necessary.

Seromas are loculated fluid collections that most commonly develop within 1 week of synthetic mesh repairs. Large hernia sac remnants may fill with physiologic fluid and mimic seromas. Patients often mistake seromas for early recurrence. Treatment consists of reassurance and warm compression to accelerate resolution. To avoid secondary infection, seromas should not be aspirated unless they cause discomfort or they restrict activity for a prolonged time.

OUTCOMES

The incidence of recurrence is the most-cited measure of postoperative outcome following inguinal hernia repair. In evaluating the various available techniques, other salient signifiers of outcome include complication rates, operative duration, hospital stay, and quality of life. The following section summarizes the evidence-based outcomes of the various approaches to inguinal hernia repair.

Among tissue repairs, the Shouldice operation is the most commonly performed technique, and it is most frequently executed at specialized centers. A 2012 meta-analysis from the Cochrane Database demonstrated significantly lower rates of hernia recurrence (OR 0.62, CI 0.45–0.85) in patients undergoing Shouldice operations when compared with other open tissue-based methods.[80] In experienced hands, the overall recurrence rate for the Shouldice repair is about 1%.[81] Although it is an elegant procedure, its meticulous nature requires significant technical expertise to achieve favorable outcomes, and it is associated with longer operative duration and longer hospital stay. One study found the recurrence rate for Shouldice repairs decreased from 9.4% to 2.5% after surgeons performed the repair six times.[82] Compared with mesh repairs, the Shouldice technique resulted in significantly higher rates of recurrence (OR 3.65, CI 1.79–7.47); however, it is the most effective tissue-based repair when mesh is unavailable or contraindicated.[80]

Hernia recurrence is drastically reduced as a result of the Lichtenstein tension-free repair.[83] Compared with open elective tissue-based repairs, mesh repair is associated with fewer recurrences (OR 0.37, CI 0.26–0.51) and with shorter hospital stay and faster return to usual activities.[84,85] In a multiinstitutional series, 3019 inguinal hernias were repaired using the Lichtenstein technique, with an overall recurrence rate of 0.2%.[86] Among other tension-free repairs, the Lichtenstein technique remains the most commonly performed procedure worldwide. Meta-analysis demonstrates no significant differences in outcomes between the Lichtenstein and the plug and patch techniques; however, intra-abdominal plug migration and erosion into contiguous structures occurs in approximately 6% of cases.[84,87,88] The Stoppa technique results in longer operative duration than the Lichtenstein technique. Nevertheless, postoperative acute pain, chronic pain, and recurrence rates are similar between the two methods.[89] Perhaps the most compelling advantage of the Lichtenstein technique is that nonexpert surgeons rapidly achieve similar outcomes to their expert counterparts. Guidelines issued by the European Hernia Society recommend the Lichtenstein repair for adults with either unilateral or bilateral inguinal hernias as the preferred open technique.[85]

Compared to open approaches, laparoscopic primary inguinal hernia repair produces equivalent recurrence rates and improved recovery time, pain prevention, and return to normal

activities.[90] In a study of 168 patients randomized to either TEP or Lichtenstein repair, the 5-year recurrence rates were extremely low in both groups.[91,92] Similarly, a study of 200 male patients randomized to either ambulatory TEP or Lichtenstein repair demonstrated no recurrences in either group after 1 year.[93] Because laparoscopic surgery requires specialized instruments and longer operative times, its cost is higher than conventional open repair; however, the potential financial benefit of shorter recovery and decreased pain may offset these costs in the long term.

6▶

Perhaps the most salient difference between open and laparoscopic techniques is the number of cases needed to develop technical proficiency. In a randomized controlled trial performed by the Veterans Affairs Cooperative Study, 2-year recurrence rates were 10.1% in patients undergoing laparoscopic repair and 4.9% in those undergoing open repair, and the outcomes of laparoscopic repairs improved after each surgeon performed at least 250 cases.[94] More recently, Lal and colleagues found that surgeons sustained a decrease from 9% to 2.9% in postoperative recurrences after performing 100 TEP operations.[95] Other studies also suggest surgeons develop proficiency in these laparoscopic techniques after performing 30 to 100 cases; however, this estimate has decreased precipitously since laparoscopic technique was first introduced.[94,96,97]

Although controversy persists regarding the utility of TEP vs. TAPP, reviews to date find no significant differences in operative duration, length of stay, time to recovery, or short-term recurrence rate between the two approaches. In TAPP repair, the risk of intra-abdominal injury is higher than in TEP repair. This finding prompted the IEHS to recommend that TAPP should only be attempted by surgeons with sufficient experience.[40] A Cochrane systematic review found that rates of port-site hernias and visceral injuries were higher for the TAPP technique, whereas TEP may be associated with a higher rate of conversion to an alternative approach; however, neither finding was sufficiently compelling to recommend one technique over the other.[97]

The frequency with which the above inguinal hernia repair techniques are performed reinforces the importance of broad experience. The authors recommend that surgeons become proficient in several techniques to address different manifestations of inguinal hernias. Surgeons should tailor this experience to optimize outcomes for each patient.

chapter 38

Thyroid, Parathyroid, and Adrenal

Geeta Lal and Orlo H. Clark

THYROID

Historical Background

Goiters (from the Latin *guttur*, throat), defined as an enlargement of the thyroid, have been recognized since 2700 B.C. even though the thyroid gland was not documented as such until the Renaissance period. In 1619, Hieronymus Fabricius ab Aquapendente recognized that goiters arose from the thyroid gland. The term *thyroid gland* (Greek *thyreoeides*, shield-shaped) is, however, attributed to Thomas Wharton in his *Adenographia* (1656). In 1776, the thyroid was classified as a ductless gland by Albrecht von Haller and was thought to have numerous functions ranging from lubrication of the larynx to acting as a reservoir for blood to provide continuous flow to the brain, and to beautifying women's necks. Burnt seaweed was considered to be the most effective treatment for goiters.

The first accounts of thyroid surgery for the treatment of goiters were given by Roger Frugardi in 1170. In response to failure of medical treatment, two setons were inserted at right angles into the goiter and tightened twice daily until the goiter separated. The open wound was treated with caustic powder and left to heal. However, thyroid surgery continued to be hazardous with prohibitive mortality rates (>40%) until the latter half of the nineteenth century, when advances in general anesthesia, antisepsis, and hemostasis enabled surgeons to perform thyroid surgery with significantly reduced mortality and morbidity rates. The most notable thyroid surgeons were Emil Theodor Kocher (1841–1917) and C.A. Theodor Billroth (1829–1894), who performed thousands of operations with increasingly successful results. However, as more patients survived thyroid operations, new problems and issues became apparent. After total thyroidectomy, patients (particularly children) became myxedematous with cretinous features. Myxedema was first effectively treated in 1891 by George Murray using a subcutaneous injection of an extract of sheep's thyroid, and later, Edward Fox demonstrated that oral therapy was equally effective. In 1909, Kocher was awarded the Nobel Prize for medicine in recognition "for his works on the physiology, pathology, and surgery of the thyroid gland."

Embryology

The thyroid gland arises as an outpouching of the primitive foregut around the third week of gestation. It originates at the base of the tongue at the foramen cecum. Endoderm cells in the floor of the pharyngeal anlage thicken to form the medial thyroid anlage (Fig. 38-1) that descends in the neck anterior to structures that form the hyoid bone and larynx. During its descent, the anlage remains connected to the foramen cecum via an epithelial-lined tube known as the *thyroglossal duct*. The epithelial cells making up the anlage give rise to the thyroid follicular cells. The paired lateral anlages originate from the fourth branchial pouch and fuse with the median anlage at approximately the fifth week of gestation. The lateral anlages are neuroectodermal in origin (ultimobranchial bodies) and provide the calcitonin producing parafollicular or C cells, which thus come to lie in the superoposterior region of the gland. Thyroid follicles are initially apparent by 8 weeks, and colloid formation begins by the eleventh week of gestation.

Developmental Abnormalities

Thyroglossal Duct Cyst and Sinus. Thyroglossal duct cysts are the most commonly encountered congenital cervical anomalies. During the fifth week of gestation, the thyroglossal duct lumen starts to obliterate, and the duct disappears by the eighth week of gestation. Rarely, the thyroglossal duct may persist in whole or in part. Thyroglossal duct cysts may occur anywhere along the migratory path of the thyroid, although 80% are found in juxtaposition to the hyoid bone. They are usually asymptomatic but occasionally become infected by oral bacteria, prompting the patient to seek medical advice. Thyroglossal duct sinuses result from infection of the cyst secondary to spontaneous or

Key Points

1. There has been a paradigm shift in the surgical management of Graves' disease with increased use of total or near-total thyroidectomy, rather than subtotal thyroidectomy.
2. Familial nonmedullary thyroid cancer is increasingly being recognized as a separate entity. Surgeons must be aware of the potential for false-negative fine-needle aspiration biopsy in this setting.
3. Fine-needle aspiration biopsies are now classified into six groups based on the risk of malignancy associated with each group (Bethesda criteria).
4. Total thyroidectomy is the surgical treatment of choice for most thyroid cancers, provided complication rates are low.
5. Due to the limitations of fine-needle aspiration biopsy in the setting of indeterminate thyroid nodules, a number of molecular markers are being evaluated as adjuncts to refine the diagnosis and management of these patients.
6. Focused mini-incision parathyroidectomy, after appropriate localization, has become the procedure of choice for the treatment of sporadic primary hyperparathyroidism.
7. Parathyroidectomy has been shown to improve the classic and the so-called *nonspecific symptoms* and metabolic complications of primary hyperparathyroidism.
8. Normocalcemic hyperparathyroidism is being increasingly recognized; however, there are no definitive guidelines for management.
9. Very high calcium and parathyroid hormone levels in a patient with primary hyperparathyroidism should alert the surgeon to the presence of a possible parathyroid carcinoma.
10. Subclinical Cushing's syndrome is characterized by subtle abnormalities in corticosteroid synthesis, and many of its manifestations appear to be treated by adrenalectomy.
11. Fine-needle aspiration biopsy has a very limited role in the evaluation of adrenal incidentalomas unless the patient has previously had a cancer and should only be performed after appropriate biochemical studies have been performed to rule out pheochromocytoma.
12. Laparoscopic adrenalectomy has become the procedure of choice for excision of most adrenal lesions, except known or suspected cancers.

surgical drainage of the cyst and are accompanied by minor inflammation of the surrounding skin. Histologically, thyroglossal duct cysts are lined by pseudostratified ciliated columnar epithelium and squamous epithelium, with heterotopic thyroid tissue present in 20% of cases.

The diagnosis usually is established by observing a 1- to 2-cm, smooth, well-defined midline neck mass that moves upward with protrusion of the tongue. Routine thyroid imaging is not necessary, although thyroid scintigraphy and ultrasound have been performed to document the presence of normal thyroid tissue in the neck. Treatment involves the "Sistrunk operation," which consists of en bloc cystectomy and excision of the central hyoid bone to minimize recurrence. Approximately 1% of thyroglossal duct cysts are found to contain cancer, which is usually papillary (85%). The role of total thyroidectomy in this setting is debated, but is advised in patients with large tumors, particularly if there are additional thyroid nodules and evidence of cyst wall invasion or lymph node metastases.[1] Squamous, Hürthle cell, and anaplastic cancers also have been reported but are rare. Medullary thyroid cancers (MTCs) are, however, not found in thyroglossal duct cysts.

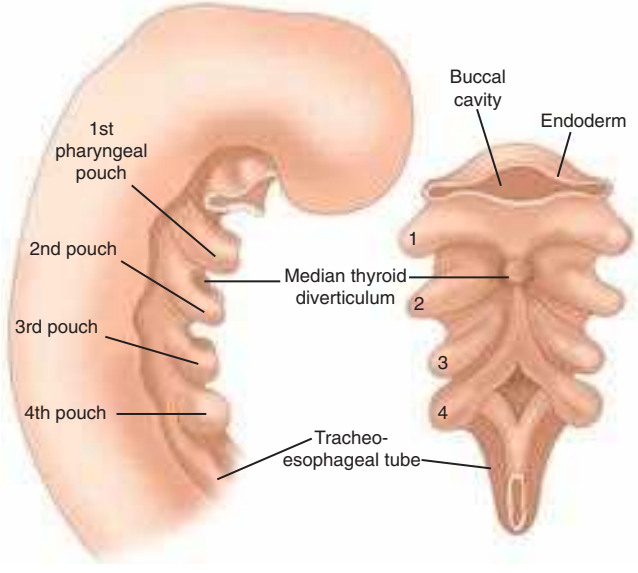

Figure 38-1. Thyroid embryology—early development of the median thyroid anlage as a pharyngeal pouch. *(Reproduced with permission from Embryology and developmental abnormalities. In: Cady B, Rossi R, eds.* Surgery of the Thyroid and Parathyroid Glands. *Philadelphia: WB Saunders; 1991:6.)*

Lingual Thyroid. A lingual thyroid represents a failure of the median thyroid anlage to descend normally and may be the only thyroid tissue present. Intervention becomes necessary for obstructive symptoms such as choking, dysphagia, airway obstruction, or hemorrhage. Many of these patients develop hypothyroidism. Medical treatment options include administration of exogenous thyroid hormone to suppress thyroid-stimulating hormone (TSH) and radioactive iodine (RAI) ablation followed by hormone replacement. Surgical excision is rarely needed but, if required, should be preceded by an evaluation of normal thyroid tissue in the neck to avoid inadvertently rendering the patient hypothyroid.

Ectopic Thyroid. Normal thyroid tissue may be found anywhere in the central neck compartment, including the esophagus, trachea, and anterior mediastinum. Thyroid tissue has been observed adjacent to the aortic arch, in the aortopulmonary window, within the upper pericardium, or in the interventricular septum. Often, "tongues" of thyroid tissue are seen to extend off the inferior poles of the gland and are particularly apparent in large goiters. Thyroid tissue situated lateral to the carotid sheath and jugular vein, previously termed *lateral aberrant*

thyroid, almost always represents metastatic thyroid cancer in lymph nodes, and not remnants of the lateral anlage that had failed to fuse with the main thyroid, as previously suggested by Crile. Even if not readily apparent on physical examination or ultrasound imaging, the ipsilateral thyroid lobe contains a focus of papillary thyroid cancer (PTC), which may be microscopic.

Pyramidal Lobe. Normally the thyroglossal duct atrophies, although it may remain as a fibrous band. In about 50% of individuals, the distal end that connects to the thyroid persists as a pyramidal lobe projecting up from the isthmus, lying just to the left or right of the midline. In the normal individual, the pyramidal lobe is not palpable, but in disorders resulting in thyroid hypertrophy (e.g., Graves' disease, diffuse nodular goiter, or lymphocytic thyroiditis), the pyramidal lobe usually is enlarged and palpable.

Thyroid Anatomy

The anatomic relations of the thyroid gland and surrounding structures are depicted in Fig. 38-2. The adult thyroid gland is brown in color and firm in consistency and is located posterior to the strap muscles. The normal thyroid gland weighs approximately 20 g, but gland weight varies with body weight and iodine intake. The thyroid lobes are located adjacent to the thyroid cartilage and connected in the midline by an isthmus that is located just inferior to the cricoid cartilage. A pyramidal lobe is present in about 50% of patients. The thyroid lobes extend to the midthyroid cartilage superiorly and lie adjacent to the carotid sheaths and sternocleidomastoid muscles laterally. The strap muscles (sternohyoid, sternothyroid, and superior belly of the omohyoid) are located anteriorly and are innervated by the ansa cervicalis (ansa hypoglossi). The thyroid gland is enveloped by a loosely connecting fascia that is formed from the partition of the deep cervical fascia into anterior and posterior divisions. The true capsule of the thyroid is a thin, densely adherent fibrous layer that sends out septa that invaginate into the gland, forming pseudolobules. The thyroid capsule is condensed into the posterior suspensory or Berry's ligament near the cricoid cartilage and upper tracheal rings.

Blood Supply. The superior thyroid arteries arise from the ipsilateral external carotid arteries and divide into anterior and posterior branches at the apices of the thyroid lobes. The inferior

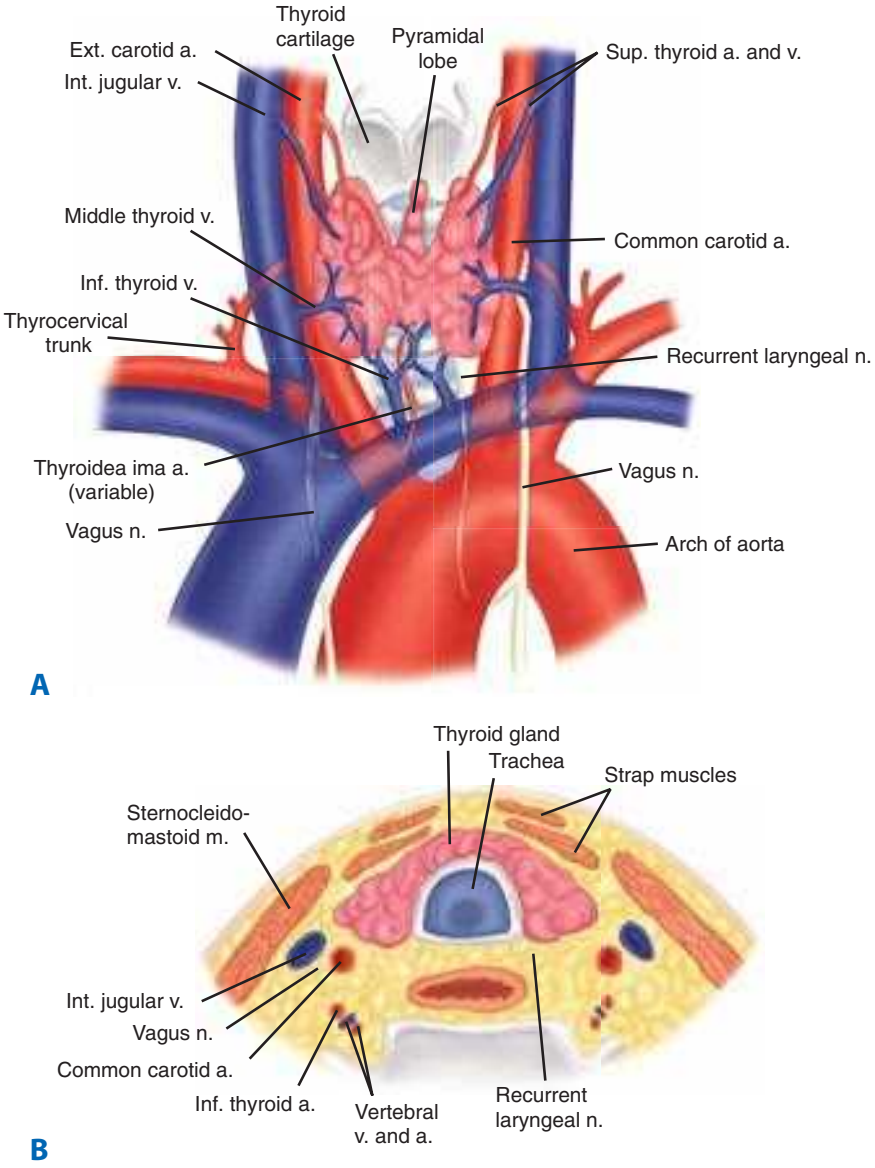

Figure 38-2. Anatomy of the thyroid gland and surrounding structures, viewed anteriorly (**A**) and in cross-section (**B**). a. = artery; m. = muscle; n. = nerve; v. = vein.

thyroid arteries arise from the thyrocervical trunk shortly after their origin from the subclavian arteries. The inferior thyroid arteries travel upward in the neck posterior to the carotid sheath to enter the thyroid lobes at their midpoint. A thyroidea ima artery arises directly from the aorta or innominate in 1% to 4% of individuals to enter the isthmus or replace a missing inferior thyroid artery. The inferior thyroid artery crosses the recurrent laryngeal nerve (RLN), necessitating identification of the RLN before the arterial branches can be ligated. The venous drainage of the thyroid gland occurs via multiple small surface veins, which coalesce to form three sets of veins—the superior, middle, and inferior thyroid veins. The superior thyroid veins run with the superior thyroid arteries bilaterally. The middle vein or veins are the least consistent. The superior and middle veins drain directly into the internal jugular veins. The inferior veins often form a plexus, which drains into the brachiocephalic veins.

Nerves. The left RLN arises from the vagus nerve where it crosses the aortic arch, loops around the ligamentum arteriosum, and ascends medially in the neck within the tracheoesophageal groove. The right RLN arises from the vagus at its crossing with the right subclavian artery. The nerve usually passes posterior to the artery before ascending in the neck, its course being more oblique than the left RLN. Along their course in the neck, the RLNs may branch, and pass anterior, posterior, or interdigitate with branches of the inferior thyroid artery (Fig. 38-3). The right RLN may be nonrecurrent in 0.5% to 1% of individuals and often is associated with a vascular anomaly. Nonrecurrent left RLNs are rare but have been reported in patients with situs inversus and a right-sided aortic arch. The RLN may branch in its course in the neck, and identification of a small nerve should alert the surgeon to this possibility. Identification of the nerves or their branches often necessitates mobilization of the most lateral and posterior extent of the thyroid gland, the tubercle of Zuckerkandl, at the level of the cricoid cartilage. The last segments of the nerves often course below the tubercle and are closely approximated to the ligament of Berry. Branches of the nerve may traverse the ligament in 25% of individuals and are particularly vulnerable to injury at this junction. The RLNs terminate by entering the larynx posterior to the cricothyroid muscle.

The RLNs innervate all the intrinsic muscles of the larynx, except the cricothyroid muscles, which are innervated by the external laryngeal nerves. Injury to one RLN leads to paralysis of the ipsilateral vocal cord, which comes to lie in the paramedian or the abducted position. The paramedian position results in a normal but weak voice, whereas the abducted position leads to a hoarse voice and an ineffective cough. Bilateral RLN injury may lead to airway obstruction, necessitating emergency tracheostomy, or loss of voice. If both cords come to lie in an abducted position, air movement can occur, but the patient has an ineffective cough and is at increased risk of repeated respiratory tract infections from aspiration.

The superior laryngeal nerves also arise from the vagus nerves. After their origin at the base of the skull, these nerves travel along the internal carotid artery and divide into two branches at the level of the hyoid bone. The internal branch of the superior laryngeal nerve is sensory to the supraglottic larynx. Injury to this nerve is rare in thyroid surgery, but its occurrence may result in aspiration. The external branch of the superior laryngeal nerve lies on the inferior pharyngeal constrictor muscle

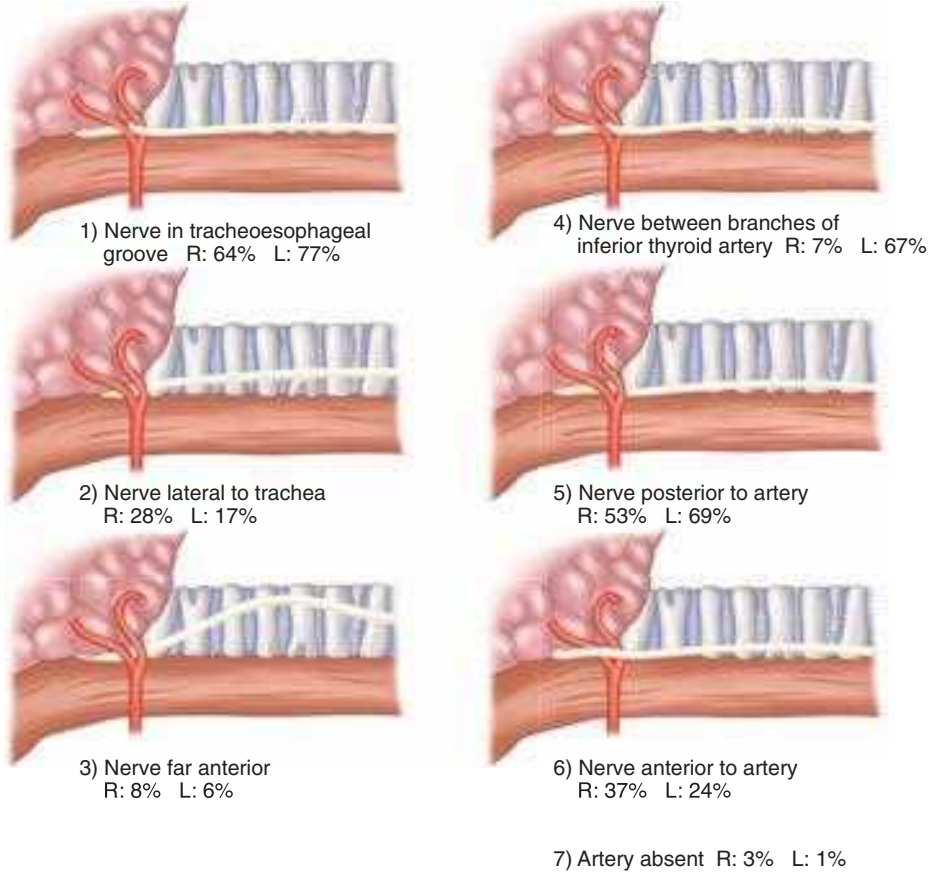

Figure 38-3. Relationship of recurrent laryngeal nerve to the inferior thyroid artery—the superior parathyroid is characteristically dorsal to the plane of the nerve, whereas the inferior gland is ventral to the nerve.

and descends alongside the superior thyroid vessels before innervating the cricothyroid muscle. Cernea and colleagues[2] proposed a classification system to describe the relationship of this nerve to the superior thyroid vessels (Fig. 38-4). The type 2a variant, in which the nerve crosses below the tip of the thyroid superior pole, occurs in up to 20% of individuals and places the nerve at a greater risk of injury. Therefore, the superior pole vessels should not be ligated en masse, but should be individually divided, low on the thyroid gland and dissected lateral to the cricothyroid muscle. Injury to this nerve leads to inability to tense the ipsilateral vocal cord and hence difficulty "hitting high notes," difficulty projecting the voice, and voice fatigue during prolonged speech.

Sympathetic innervation of the thyroid gland is provided by fibers from the superior and middle cervical sympathetic ganglia. The fibers enter the gland with the blood vessels and are vasomotor in action. Parasympathetic fibers are derived from the vagus nerve and reach the gland via branches of the laryngeal nerves.

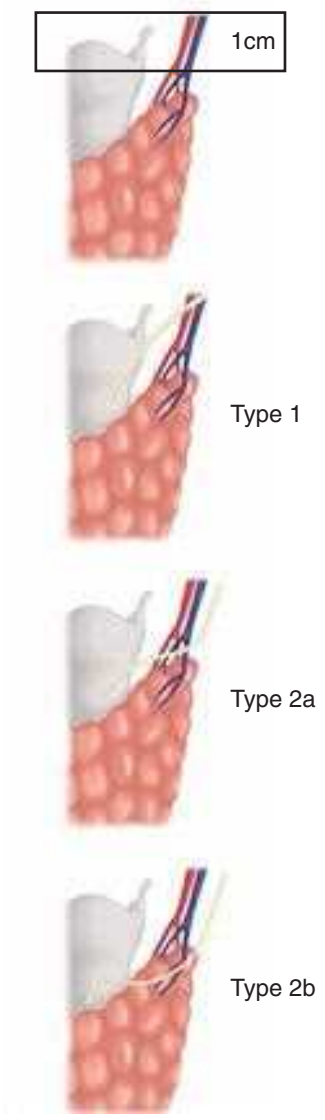

Figure 38-4. Relationship of the external branch of the superior laryngeal nerve and superior thyroid artery originally described by Cernea and colleagues.[2] In type 1 anatomy, the nerve crosses the artery ≥1 cm above the superior aspect of the thyroid lobe. In type 2 anatomy, the nerve crosses the artery <1 cm above the thyroid pole (2a) or below (2b) it. *(Reproduced with permission from Bliss RD et al. Surgeon's approach to the thyroid gland: Surgical anatomy and the importance of technique.* World J Surg. *2000;24:893. With kind permission of Springer Science + Business Media.)*

Parathyroid Glands. The embryology and anatomy of the parathyroid glands are discussed in detail in the Parathyroid Gland section of this chapter. About 85% of individuals have four parathyroid glands that can be found within 1 cm of the junction of the inferior thyroid artery and the RLN. The superior glands are usually located dorsal to the RLN, whereas the inferior glands are usually found ventral to the RLN (Fig. 38-5).

Lymphatic System. The thyroid gland is endowed with an extensive network of lymphatics. Intraglandular lymphatic vessels connect both thyroid lobes through the isthmus and also drain to perithyroidal structures and lymph nodes. Regional lymph nodes include pretracheal, paratracheal, perithyroidal, RLN, superior mediastinal, retropharyngeal, esophageal, and upper, middle, and lower jugular chain nodes. These lymph nodes can be classified into seven levels as depicted in Fig. 38-6. The central compartment includes nodes located in the area between the two carotid sheaths, whereas nodes lateral to the vessels are present in the lateral compartment. Thyroid cancers may metastasize to any of these regions, although metastases to submaxillary nodes (level I) are rare (<1%). There also can be "skip" metastases to nodes in the lateral ipsilateral neck without central neck nodes.

Thyroid Histology

Microscopically, the thyroid is divided into lobules that contain 20 to 40 follicles (Fig. 38-7). There are about 3×10^6 follicles in the adult male thyroid gland. The follicles are spherical and average 30 μm in diameter. Each follicle is lined by cuboidal epithelial cells and contains a central store of colloid secreted from the epithelial cells under the influence of the pituitary hormone TSH. The second group of thyroid secretory cells is the C cells or parafollicular cells, which contain and secrete the hormone calcitonin. They are found as individual cells or clumped in small groups in the interfollicular stroma and located in the upper poles of the thyroid lobes.

Thyroid Physiology

Iodine Metabolism. The average daily iodine requirement is 0.1 mg, which can be derived from foods such as fish, milk, and eggs or as additives in bread or salt. In the stomach and jejunum, iodine is rapidly converted to iodide and absorbed into the bloodstream, and from there it is distributed uniformly throughout the extracellular space. Iodide is actively transported into the thyroid follicular cells by an adenosine triphosphate (ATP)–dependent process. The thyroid is the storage site of >90% of the body's iodine content and accounts for one third of the plasma iodine loss. The remaining plasma iodine is cleared via renal excretion.

Thyroid Hormone Synthesis, Secretion, and Transport. The synthesis of thyroid hormone consists of several steps (Fig. 38-8). The first, iodide trapping, involves active (ATP-dependent) transport of iodide across the basement membrane of the thyrocyte via an intrinsic membrane protein, the sodium/iodine (Na^+/I^-) symporter. Thyroglobulin (Tg) is a large (660 kDa) glycoprotein, which is present in thyroid follicles and has four tyrosyl residues. The second step in thyroid hormone synthesis involves oxidation of iodide to iodine and iodination of tyrosine residues on Tg, to form monoiodotyrosines (MIT)

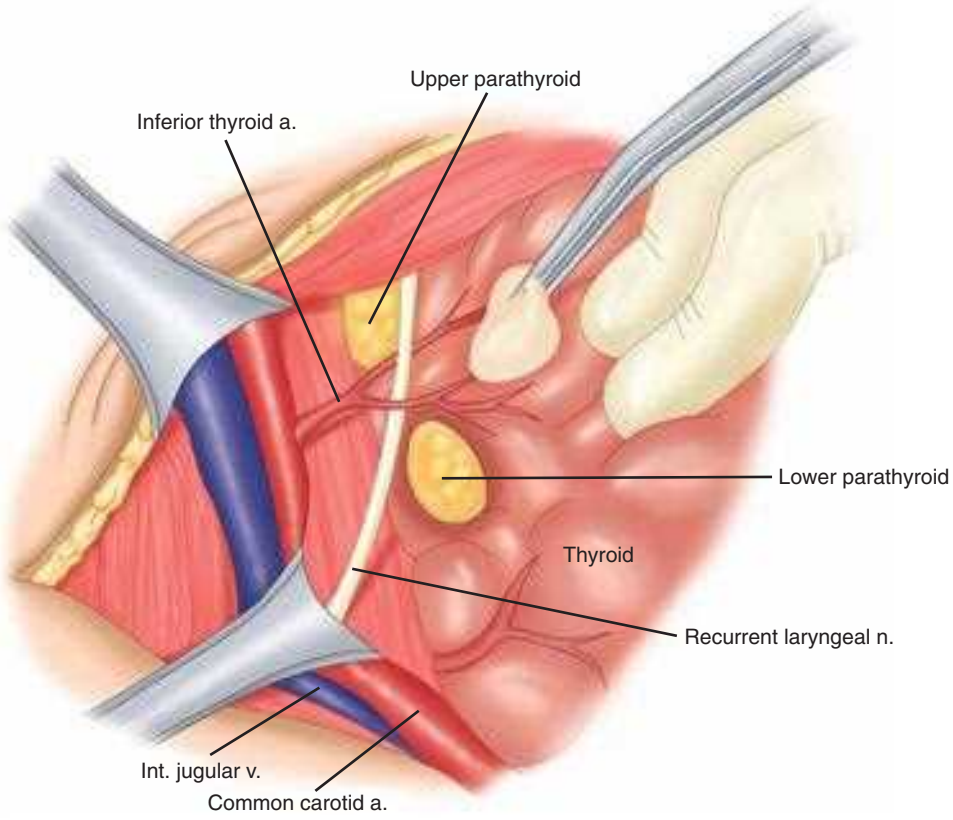

Figure 38-5. Relationship of the parathyroids to the recurrent laryngeal nerve. a. = artery; v. = vein.

and diiodotyrosines (DIT). Both processes are catalyzed by thyroid peroxidase (TPO). A recently identified protein, pendrin, is thought to mediate iodine efflux at the apical membrane. The third step leads to coupling of two DIT molecules to form tetra-iodothyronine or thyroxine (T_4), and one DIT molecule with one MIT molecule to form 3,5,3′-triiodothyronine (T_3) or 3,3′,5′-triiodothyronine reverse (rT_3). When stimulated by TSH, thyrocytes form pseudopodia, which encircle portions of cell membrane containing Tg, which in turn, fuse with enzyme-containing lysosomes. In the fourth step, Tg is hydrolyzed to release free iodothyronines (T_3 and T_4) and mono- and diiodotyrosines. The latter are deiodinated in the fifth step to yield iodide, which is reused in the thyrocyte. In the euthyroid state, T_4 is produced and released entirely by the thyroid gland, whereas only 20% of the total T_3 is produced by the thyroid. Most of the T_3 is produced by peripheral deiodination (removal of 5′-iodine from the outer ring) of T_4 in the liver, muscles, kidney, and anterior pituitary, a reaction that is catalyzed by 5′-mono-deiodinase. Some T_4 is converted to rT_3, the metabolically inactive compound, by deiodination of the inner ring of T_4. In conditions such as Graves' disease, toxic multinodular goiter, or a stimulated thyroid gland, the proportion of T_3 released from the thyroid may be dramatically elevated. Thyroid hormones are transported in serum bound to carrier proteins such as T_4-binding globulin, T_4-binding prealbumin, and albumin. Only a small fraction (0.02%) of thyroid hormone (T_3 and T_4) is free (unbound) and is the physiologically active component. T_3 is the more potent of the two thyroid hormones, although its circulating plasma level is much lower than that of T_4. T_3 is less tightly bound to protein in the plasma than T_4, and so it enters tissues more readily. T_3 is three to four times more active than T_4 per unit weight, with a half-life of about 1 day, compared to approximately 7 days for T_4.

The secretion of thyroid hormone is controlled by the hypothalamic-pituitary-thyroid axis (Fig. 38-9). The hypothalamus produces a peptide, the thyrotropin-releasing hormone (TRH), which stimulates the pituitary to release TSH or thyrotropin. TRH reaches the pituitary via the portovenous circulation. TSH, a 28-kDa glycopeptide, mediates iodide trapping, secretion, and release of thyroid hormones, in addition to increasing the cellularity and vascularity of the thyroid gland. The TSH receptor (TSH-R) belongs to a family of G-protein–coupled receptors that have seven transmembrane-spanning domains and use cyclic adenosine monophosphate in the signal-transduction pathway. TSH secretion by the anterior pituitary is also regulated via a negative feedback loop by T_4 and T_3. Because the pituitary has the ability to convert T_4 to T_3, the latter is thought to be more important in this feedback control. T_3 also inhibits the release of TRH.

The thyroid gland also is capable of autoregulation, which allows it to modify its function independent of TSH. As an adaptation to low iodide intake, the gland preferentially synthesizes T_3 rather than T_4, thereby increasing the efficiency of secreted hormone. In situations of iodine excess, iodide transport, peroxide generation, and synthesis and secretion of thyroid hormones are inhibited. Excessively large doses of iodide may lead to initial increased organification, followed by suppression, a phenomenon called the *Wolff-Chaikoff effect*. Epinephrine and human chorionic gonadotropin hormones stimulate thyroid hormone production. Thus, elevated thyroid hormone levels are found in pregnancy and gynecologic malignancies such as hydatidiform mole. In contrast, glucocorticoids inhibit thyroid

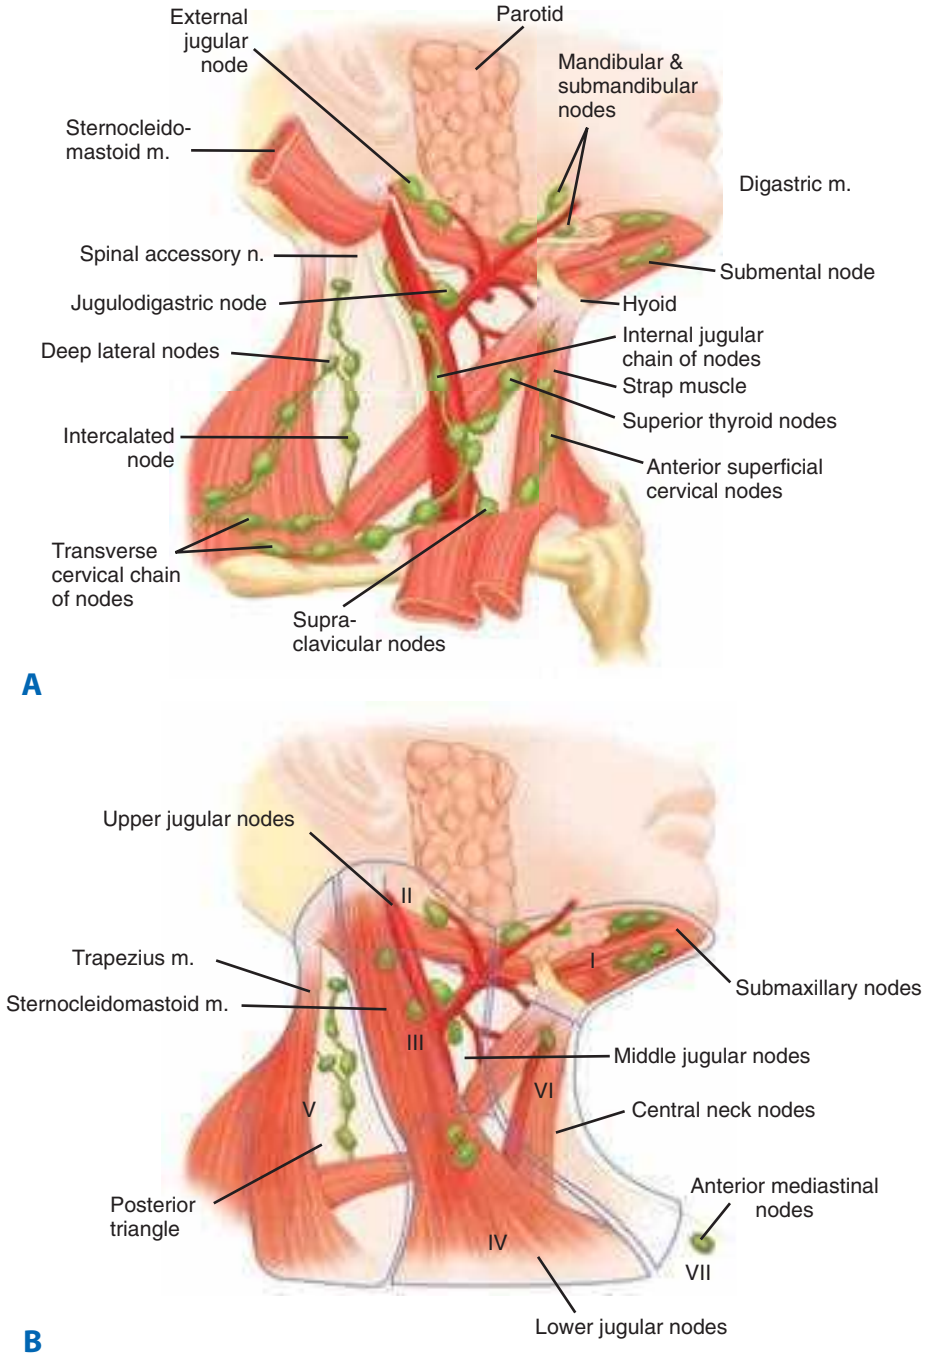

Figure 38-6. **A** and **B.** Lymph nodes in the neck can be divided into six regions. Upper mediastinal nodes constitute level VII. m. = muscle; n. = nerve.

hormone production. In severely ill patients, peripheral thyroid hormones may be reduced, without a compensatory increase in TSH levels, giving rise to the euthyroid sick syndrome.

Thyroid Hormone Function. Free thyroid hormone enters the cell membrane by diffusion or by specific carriers and is carried to the nuclear membrane by binding to specific proteins. T_4 is deiodinated to T_3 and enters the nucleus via active transport, where it binds to the thyroid hormone receptor. The T_3 receptor is similar to the nuclear receptors for glucocorticoids, mineralocorticoids, estrogens, vitamin D, and retinoic acid. In humans, two types of T_3 receptor genes (α and β) are located on chromosomes 3 and 17. Thyroid receptor expression depends on peripheral concentrations of thyroid hormones and is tissue specific—the α form is abundant in the central nervous system, whereas the β form predominates in the liver. Each gene product has a ligand-independent, amino-terminal domain; a ligand-binding, carboxy-terminal domain; and centrally located DNA-binding regions. Binding of thyroid hormone leads to the transcription and translation of specific hormone-responsive genes.

Thyroid hormones affect almost every system in the body. They are important for fetal brain development and skeletal maturation. T_3 increases oxygen consumption, basal metabolic rate, and heat production by stimulation of Na^+/K^+ ATPase in various tissues. It also has positive inotropic and chronotropic effects on the heart by increasing transcription of the Ca^{2+} ATPase in the

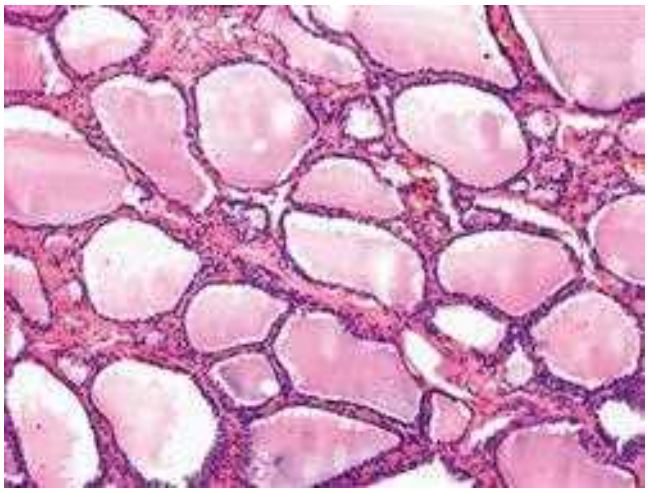

Figure 38-7. Normal thyroid histology—follicular cells surround colloid.

sarcoplasmic reticulum and increasing levels of β-adrenergic receptors and concentration of G proteins. Myocardial α receptors are decreased, and actions of catecholamines are amplified. Thyroid hormones are responsible for maintaining the normal hypoxic and hypercapnic drive in the respiratory center of the brain. They also increase gastrointestinal (GI) motility, leading to diarrhea in hyperthyroidism and constipation in hypothyroidism. Thyroid hormones also increase bone and protein turnover and the speed of muscle contraction and relaxation. They also increase glycogenolysis, hepatic gluconeogenesis, intestinal glucose absorption, and cholesterol synthesis and degradation.

Evaluation of Patients with Thyroid Disease

Tests of Thyroid Function. A multitude of different tests are available to evaluate thyroid function. No single test is sufficient to assess thyroid function in all situations, and the results must be interpreted in the context of the patient's clinical condition.

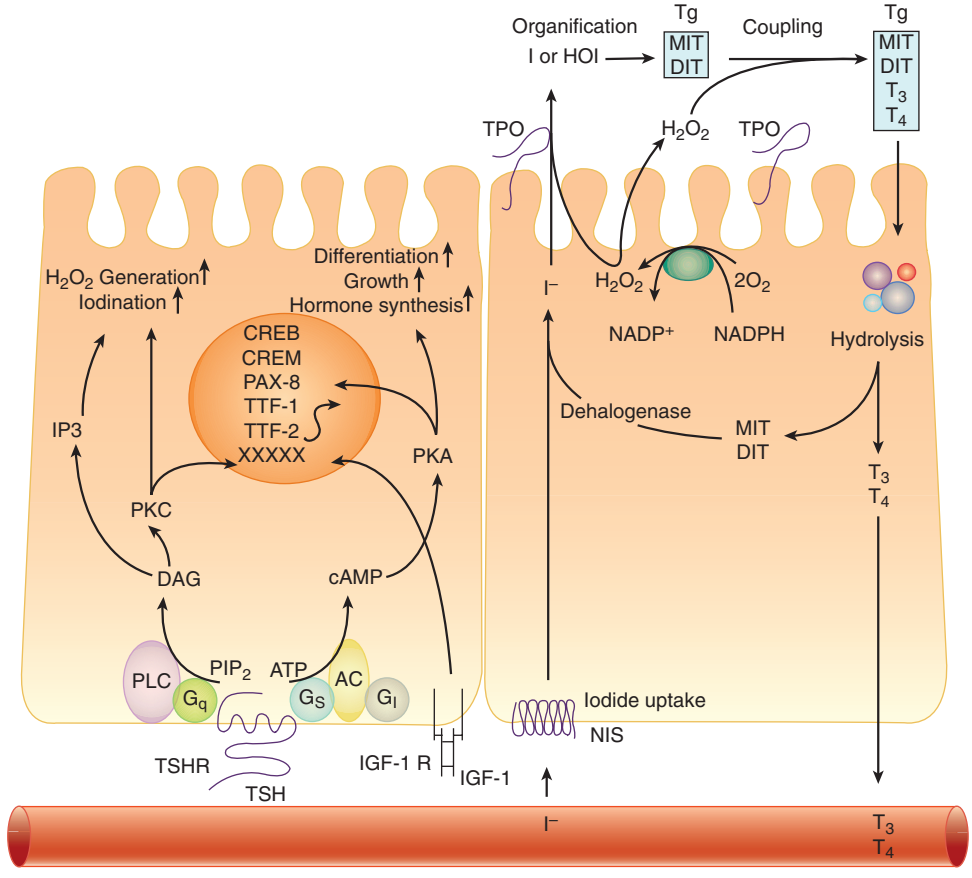

Figure 38-8. Thyroid follicular cell showing the major signaling pathways involved in thyroid cell growth and function and key steps in thyroid hormone synthesis. The basal membrane of the cell in contact with the circulation and its apical surface contact the thyroid follicle. Thyroid hormone synthesis is initiated by the binding of thyroid-stimulating hormone (TSH) to the TSH receptor (TSHR), a G-protein–coupled transmembrane receptor, on the basal membrane. Activation leads to an increase in cyclic adenosine monophosphate (cAMP), phosphorylation of protein kinase A (PKA), and activation of target cytosolic and nuclear proteins. The protein kinase C (PKC) pathway is stimulated at higher doses of TSH. Iodide is actively transported into the cell via the Na/I symporter (NIS) and flows down an electrical gradient to the apical membrane. There, thyroid peroxidase (TPO) oxidizes iodide and iodinated tyrosyl residues on thyroglobulin (Tg) in the presence of peroxide (H_2O_2). Mono- and diiodotyrosyl (MIT, DIT) residues are also coupled to form T_4 and T_3 by TPO. Thyroglobulin carrying T_4 and T_3 is then internalized by pinocytosis and digested in lysosomes. Thyroid hormone is released into the circulation, while MIT and DIT are deiodinated and recycled. ATP = adenosine triphosphate; CREB = cAMP response element binding protein; CREM = cAMP response element modulator; DAG = diacylglycerol; IGF-1 = insulin-like growth factor 1; IP3 = inositol-3-phosphate; NADP+ = nicotinamide adenine dinucleotide phosphate, oxidized form; NADPH = nicotinamide adenine dinucleotide phosphate; PIP_2 = phosphatidylinositol; PLC = phospholipase C; T_3 = 3,5′,3-triiodothyronine; T_4 = thyroxine. *(Reproduced with permission from Kopp P. Pendred's syndrome and genetic defects in thyroid hormone synthesis.* Rev Endocr Metab Disord. *2000;1:114. Kluwer Academic Publishers.)*

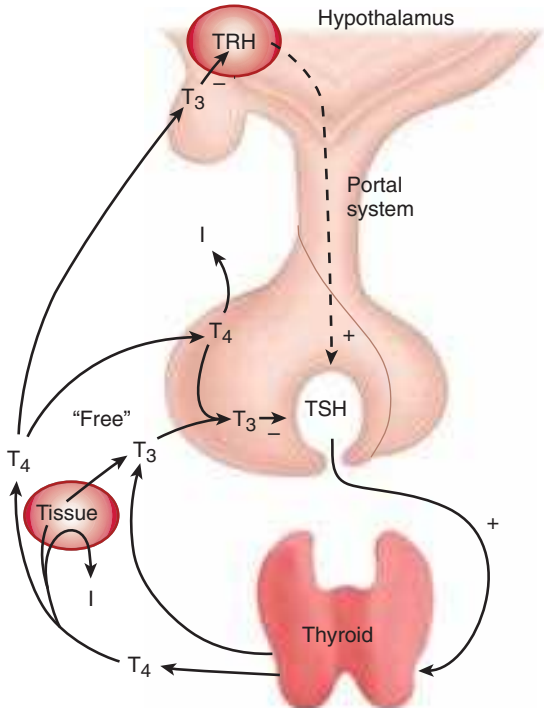

Figure 38-9. Hypothalamic-pituitary-thyroid hormone axis. In both the hypothalamus and pituitary, 3,5′,3-triiodothyronine (T_3) is primarily responsible for inhibition of thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH) secretion. T_4 = thyroxine. *(Reproduced with permission from Greenspan FS. The thyroid gland. In: Greenspan FS, Gardner D, eds.* Basic and Clinical Endocrinology. *6th ed. New York: McGraw-Hill; 2001:217. TSH is the only test necessary in most patients with thyroid nodules that clinically appear to be euthyroid.

Serum Thyroid-Stimulating Hormone (Normal 0.5–5 μU/mL) The tests for serum TSH are based on the following principle: monoclonal TSH antibodies are bound to a solid matrix and bind serum TSH. A second monoclonal antibody binds to a separate epitope on TSH and is labeled with radioisotope, enzyme, or fluorescent tag. Therefore, the amount of serum TSH is proportional to the amount of bound secondary antibody (immunometric assay). Serum TSH levels reflect the ability of the anterior pituitary to detect free T_4 levels. There is an inverse relationship between the free T_4 level and the logarithm of the TSH concentration—small changes in free T_4 lead to a large shift in TSH levels. The ultrasensitive TSH assay has become the most sensitive and specific test for the diagnosis of hyper- and hypothyroidism and for optimizing T_4 therapy.
