• Asymptomatic patients with moderate or severe MS, favorable valve morphology, and pulmonary hypertension (PASP >50 mm Hg at rest, >60 mm Hg with exercise), without left atrial thrombus or moderate to severe MR	I	C
• Symptomatic patients (NYHA III, IV) with moderate or severe MS and favorable valve morphology, who are high risk or not candidates for surgery	IIa	C
• Asymptomatic patients with moderate or severe MS, favorable valve morphology, and new onset atrial fibrillation, without left atrial thrombus or moderate to severe MR	IIb	C
• Symptomatic patients (NYHA II, III, IV) with MV area >1.5 cm^2 if there is evidence of hemodynamically significant MS (PASP >60 mm Hg, PAWP ≥25 mm Hg, mean MV gradient >15 mm Hg during exercise)	IIb	C
• Symptomatic patients (NYHA III, IV) with moderate or severe MS and favorable valve morphology, as an alternative to surgery	IIb	C
• Patients with mild MS	III – Harm	C
• Patients with moderate to severe MR or left atrial thrombus	III – Harm	C
Surgery for Mitral Stenosis*		
• Symptomatic patients (NYHA III, IV) with moderate or severe MS when: Balloon valvotomy is unavailable Balloon valvotomy is contraindicated due to thrombus or MR Valve morphology is not favorable for balloon valvotomy	I	B
• Symptomatic patients with moderate to severe MS who also have moderate to severe MR	I	C
• Mildly symptomatic patients (NYHA I, II) with severe MS and severe pulmonary hypertension (PASP >60 mm Hg)	IIa	C
• Asymptomatic patients with moderate or severe MS and recurrent embolic events while receiving adequate anticoagulation, when the likelihood of successful MVr is high	IIb	C
• MVr in the setting of mild MS	III – Harm	C
• Closured commissurotomy in the setting of MVr; open commissurotomy should be performed	III – Harm	C
Surgery for Mitral Regurgitation*		
• Symptomatic patients with acute severe MR	I	B
• Symptomatic patients (NYHA II, III, IV) with chronic severe MR without LV dysfunction (LVEF <0.30) and/or end-systolic dimension >55 mm	I	B
• Asymptomatic patients with chronic severe MR and mild to moderate LV dysfunction (LVEF 0.30–0.60) and/or end-systolic dimension ≥40 mm	I	B
• Asymptomatic patients with chronic severe MR and preserved LV function (LVEF >0.60, end-systolic dimension <40 mm), when the likelihood of successful MVr is >90%	IIa	B
• Asymptomatic patients with chronic severe MR, preserved LV function, and 1) New onset atrial fibrillation, 2) Pulmonary hypertension (PASP >50 mm Hg at rest, >60 mm Hg with exercise)	IIa	C
• Symptomatic patients (NYHA III, IV) with chronic severe MR due to a primary abnormality of the mitral apparatus and severe LV dysfunction (LVEF <0.30, end-systolic dimension >55 mm), when the likelihood of successful MVr is high	IIa	C
• Symptomatic patients (NYHA III, IV) with chronic severe MR secondary to severe LV dysfunction (LVEF <0.30) who remain symptomatic despite optimal medical management for heart failure, including biventricular pacing	IIb	C
• Asymptomatic patients with MR and preserved LV function (LVEF >0.60, end-systolic dimension <40 mm), when the likelihood of successful repair is low	III – Harm	C
• Isolated MV surgery in the setting of mild or moderate MR	III – Harm	C

LV = left ventricular; LVEF = left ventricular ejection fraction; MR = mitral regurgitation; MS = mitral stenosis; MV = mitral valve; MVr = mitral valve repair; MVR = mitral valve replacement; NYHA = New York Heart Association; PASP = pulmonary artery systolic pressure; PAWP = pulmonary artery wedge pressure; * = mitral valve repair should be performed when possible in this population.

determine the severity and anatomic basis of MR, and to evaluate LV systolic function.[70] Preoperative TEE is also indicated in cases when discrepancy exists between a patient's functional status and the severity of MR on TTE, and is helpful for preoperative planning when assessing the feasibility of repair in the individual patient. Exercise stress-echocardiography may also be useful to detect LV systolic dysfunction in well-compensated patients, who may not demonstrate a rise in the end-systolic dimension of the heart or a drop in ejection fraction on routine TTE.[97] Coronary angiography should be performed prior to valve surgery in patients with evidence of ischemia, decreased LV systolic function, a history of coronary artery disease or coronary risk factors, including postmenopausal status and age ≥35 in men and premenopausal women.[70]

Indications for Operation. Based on the morphology and severity of MR (Table 21-10), MV repair, MV replacement with preservation of part or all of the mitral apparatus, or MV replacement with removal of the mitral apparatus may be variably performed for the treatment of MR. As the intraoperative findings may dictate MV replacement whenever a MV repair is planned, current recommendations are for MV surgery in general (Table 21-11).[70]

5▶

Mitral Valve Operative Techniques and Results

Mitral valve surgery is performed on the arrested heart with the assistance of cardiopulmonary bypass. Traditionally, a median sternotomy incision is used; however, the left atrium can also be approached via minimally-invasive incisions, such as a minithoracotomy or a partial sternotomy. The MV is commonly exposed through a left atrial incision placed posterior and parallel to the intra-atrial groove, or though a right atriotomy with transseptal incision.

Commissurotomy. Upon opening the left atrium, the MV is visualized and the left atrium is examined for thrombus. A nerve hook or right-angle clamp is subsequently introduced beneath the commissures and used to evaluate the MV apparatus for leaflet mobility, commissural fusion, and subvalvular chordal abnormalities. The commissure is then carefully incised in a slightly anterior direction 2 to 3mm at a time, making sure with each extension of the incision that the chordae tendineae remain attached to the commissural leaflets. The commissurotomy is generally stopped 1 to 2mm from the annulus where the leaflet tissue thins, indicating the transition to normal commissural tissue. The papillary muscles are subsequently examined and incised as necessary in order to maximize the mobility of the leaflets.

After the commissurotomy is complete, and the associated chordae tendineae and papillary muscles are mobilized, leaflet mobility is assessed. The anterior leaflet is grasped with forceps and brought through its complete range of motion. If subvalvular restriction or leaflet rigidity is identified, further division or excision of fused chordae and debridement of calcium may be necessary. Occasionally, the leaflets can be debrided carefully to increase mobility. Valve replacement may be more appropriate if extensive secondary mobilization is required. At the end of the procedure, competence of the valve is assessed with injection of cold saline into the ventricle.

Open surgical commissurotomy has an operative risk of <1%, and has been shown to have good long term results, with freedom from reoperation as high as 88.5%, 80.3%, and 78.7% at 10, 20, and 30 years, respectively.[98] The incidence of postoperative thromboembolic complications is generally <1% per patient-year, and the lack of required systemic anticoagulation precludes the development of hemorrhagic complications long-term.[99]

Mitral Valve Replacement. After exposing the valve, an incision is made in the anterior mitral leaflet at approximately the 12 o'clock position, and leaflet tissue is excised as needed. The papillary muscles are reattached to the annulus and, if possible, the posterior leaflet along with its associated subvalvular structures are preserved. The annulus is subsequently sized, and an appropriate mitral prosthesis is implanted using pledgeted horizontal mattress sutures. The annular sutures may be placed from the atrial to the ventricular side, seating the valve intra-annularly, or from the ventricular to the atrial side, seating the valve in a supra-annular position. When placing the mattress sutures, care must be taken to stay within the annular tissue, as excessively deep bites may cause injury to critical structures such as the circumflex coronary artery posterolaterally, the atrioventricular node anteromedially, or the aortic valve anterolaterally. The sutures are subsequently placed through the sewing ring, and the valve prosthesis is lowered onto the annulus, where it is secured (Fig. 21-7).

The factors associated with increased operative risk for MV replacement include age, left ventricular function, emergent procedure status, NYHA functional status, previous cardiac surgery, associated coronary artery disease, and concomitant disease in another valve. However, for most patients, MV replacement is associated with an operative mortality between 2% to 6%, and 65% to 70% five-year survival.[100,101] Although preservation of the mitral apparatus during MV replacement is important for subsequent left ventricular function, there appears to be no difference between complete and partial preservation with respect to 30-day and 5-year mortality.[100] Mechanical valves are associated with increased durability compared to bioprosthetic valves, and have demonstrated a freedom from reoperation of 98% vs. 79% at 15 years, respectively.[102] Despite these findings, the choice of prosthetic valve depends on many factors, and should be decided on a patient-by-patient basis.

Mitral Valve Repair. There are many techniques available for MV repair that are variably used depending on the

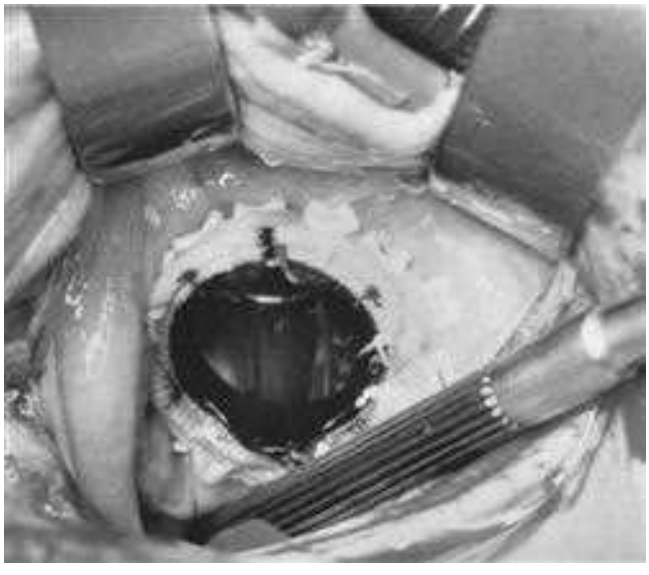

Figure 21-7. Mitral valve replacement. A St. Jude bileaflet mechanical valve is viewed through a left atriotomy.

intraoperative assessment of valvular pathology. On opening the atrium, the endocardium is examined for a *jet lesion*, a roughened area caused by a regurgitant jet striking the wall, in order to better localize the area of valvular insufficiency. The commissures are examined for evidence of prolapse, fusion, and malformation. The subvalvular apparatus and individual leaflets are subsequently examined, and areas of prolapse, restriction, fibrosis, and calcification are identified. Leaflet perforations are generally repaired primarily, or with a pericardial patch. The degree of annular dilation is also noted. The basic components of MV repair based on this assessment may include resection of the posterior leaflet, chordal shortening, chordal transposition, artificial chordal replacement, triangular resection of the anterior leaflet, and annuloplasty. Recent trends have been toward leaflet preservation.

One of the mainstays of MV repair is triangular resection of the posterior leaflet. Excision of the diseased leaflet tissue extends down towards but generally not to the mitral annulus. After repair has been completed, valvular competency is evaluated by injecting saline into the ventricle with a bulb syringe and assessing leaflet mobility and apposition. If focal insufficiency is identified in other areas, additional procedures are performed.

The anterior leaflet may be repaired via chordal shortening, chordal transposition, artificial chordal replacement, and triangular resection of the anterior leaflet. Chordal shortening has generally been abandoned in favor of chordal replacement. During chordal transposition, a resected portion of the posterior leaflet with attached chordae is transposed onto the prolapsed portion of the anterior leaflet to provide structural support, and followed with posterior leaflet repair as described above. The procedure of artificial chordal replacement uses polytetrafluoroethylene sutures to attach the papillary muscle to the free edge of the prolapsing anterior leaflet. Triangular resection with primary repair of the anterior leaflet removes the prolapsing segment of the anterior MV leaflet, while preserving adjacent chordal tissue, and may be especially helpful in patients with a ruptured chord or large amount of redundant anterior leaflet tissue.

Annular dilation is generally corrected using a MV annuloplasty device, such as a ring or partial band, and is known to improve the durability of MV repair (Fig. 21-8).[103] Several devices are available, and include rigid or semirigid rings that geometrically remodel the annulus, flexible rings or bands that restrict annular dilation while maintaining the physiologic sphincter motion of the annulus, and semirigid bands that provide a combination of annular remodeling and support of physiologic motion.

Another technique known as the "*double-orifice*" or "*edge-to-edge*" repair was introduced in 1995, and involves tacking the free edge of the anterior leaflet to the opposing free edge of the posterior leaflet.[104] This procedure effectively gives the valve a double-orifice "bow tie" configuration, and has been used as both a primary repair technique and an adjunct to other repair techniques, usually in cases of anterior leaflet pathology, or Barlow's disease. While some groups report excellent late results, its use remains controversial.

Due to the variety in operations and etiologies of MV disease, there is heterogeneity in outcomes following MV repair. In general, the operative risk for patients undergoing MV repair is generally <1%, and late results across a broad range of patients have demonstrated benefits in survival and valve-related complications, such as thromboembolic events, infective endocarditis, and anticoagulation-related hemorrhage, compared to

Figure 21-8. Mitral valve repair. The narrow arrow indicates the posterior leaflet repair, and the wide arrow indicates the ring annuloplasty as viewed through a left atriotomy.

MV replacement.[69,84] Patients with MR due to degenerative disease have especially encouraging outcomes, demonstrating rates of survival and freedom from reoperation of >50% and >94% at 20 years, respectively.[84] Historically, isolated anterior leaflet prolapse increased the risk of reoperation five-fold in this population. However, increasing experience and the expanded use of chordal replacement has greatly improved these results in recent series.[105] Independent predictors of mortality have included higher NYHA class, lower left ventricular ejection fraction, and age. Older patients have demonstrated slightly worse outcomes overall, with an operative mortality of approximately 4%, and a 10-year survival of 54% in patients ≥65 years of age. However, the superiority of repair over replacement persists even for patients >80 years of age.[101]

Patients with rheumatic disease have also demonstrated slightly worse outcomes, with one study showing significantly better freedom from operation at 10 years in patients with nonrheumatic MV disease (88% vs. 73%, $p<.005$).[106] Despite these differences in outcomes, MV repair remains the procedure of choice for the majority of patients with amenable MV disease.

AORTIC VALVE DISEASE

Aortic Stenosis

Etiology. The most common cause of adult aortic stenosis (AS) is calcification of a normal trileaflet or congenital bicuspid aortic valve, particularly in patients >70 years of age. Another important cause of AS is rheumatic heart disease, which is particularly common in developing countries (Fig. 21-9).

Pathology. Calcific aortic valve disease, also known as *senile* or *degenerative disease*, is an age-related disorder characterized by lipid accumulation, proliferative and inflammatory changes, upregulation of angiotensin-converting enzyme activity, oxidative stress, and infiltration of macrophages and

Figure 21-9. Aortic stenosis. The aorta has been removed to demonstrate the thickened, fused aortic valve leaflets associated with rheumatic heart disease. (Image courtesy of the Centers for Disease Control and Prevention, Edwin P. Ewing, Jr.)

T lymphocytes.[107] This process, which closely resembles atherosclerotic vascular calcification, initially results in bone formation within the base of the cusps, reducing leaflet motion. Calcification progresses to involve the leaflets, and eventually results in obstructive disease, with a reduced effective valve area without signs of leaflet fusion.

Pathophysiology. In general, once moderate AS is present, the average rate of progression includes an increase in jet velocity of 0.3 m/s/year, an increase in mean pressure gradient of 7 mm Hg/year, and a decrease in valve area of 0.1 cm^2/year (Table 21-12).[70]

In most adult patients with AS, obstruction develops gradually and includes a long latent period free from symptoms. During this time, the left ventricle typically hypertrophies in response to systolic pressure overload, and normal intracavitary volume is maintained.[108] Afterload, which is defined as left ventricular systolic wall stress, and thus ejection fraction remain normal early in this process, as the increase in myocardial thickness is usually enough to counter increased intracavitary systolic pressures. Patients without a typical hypertrophic response to systolic pressure overload, or with a depressed contractile state of the myocardium, do not follow the common clinical course, but experience an early decrease in ejection fraction due to excessively increased afterload, without a compensatory response.[109]

Concentric left ventricular hypertrophy without chamber dilatation eventually leads to increased end-diastolic pressures and early diastolic dysfunction. Forceful atrial contraction in the face of elevated end-diastolic pressures becomes an important component of ventricular filling, even as mean left atrial and pulmonary venous pressures remain in the normal range. Disorders such as atrial fibrillation that disrupt atrial contraction typically lead to clinical deterioration. Although systolic function is generally preserved long into the natural history of the disease, left ventricular decompensation eventually occurs in the setting of longstanding increased afterload and is an indication for surgery even in the absence of other symptoms.

Although concentric hypertrophy is a compensatory mechanism to maintain ejection fraction in the face of high intracavitary pressures, the hypertrophied heart becomes increasingly vulnerable to ischemic injury. Coronary blood flow may become inadequate, despite the absence of epicardial coronary artery disease.[110] Coronary vasodilation is mitigated

Table 21-12

Data from ACC/AHA guidelines for the classification of the severity of aortic valve disease in adults

AORTIC STENOSIS			
INDICATOR	MILD	MODERATE	SEVERE
Jet velocity (m per s)	<30	3.0–4.0	>40
Mean gradient (mm Hg)*	<25	25–40	>4.0
Valve area (cm^2)	>1.5	1.0–1.5	<1.0
Valve area index (cm^2 per m^2)			<0.6
AORTIC REGURGITATION			
QUALITATIVE	MILD	MODERATE	SEVERE
Angiographic grade	1+	2+	3–4+
Color Doppler jet width	Central jet, width <25% of left ventricular outflow tract	Greater than mild, but no signs of severe regurgitation	Central jet, width >65% of left ventricular outflow tract
Doppler vena contracta width (cm)	<0.3	0.3–0.6	>0.6
QUANTITATIVE (CATH OR ECHO)			
Regurgitant volume (ml per beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Regurgitant orifice area (cm^2)	<0.1	0.1–0.29	≥0.3
ADDITIONAL ESSENTIAL CRITERIA			
Left ventricular size			Enlarged

*Valve gradients are flow dependent and when used as estimates of severity of valve stenosis should be assessed with knowledge of cardiac output or forward flow across the valve.

by the hypertrophied myocardium, and the hemodynamic stress of exercise or tachyarrhythmias can lead to subendocardial ischemia and further systolic or diastolic dysfunction. When ischemic injuries occur, patients with ventricular hypertrophy experience larger infarcts and higher mortality rates than those without hypertrophy.[111] In some patients, ventricular hypertrophy occurs in excess of what is needed to compensate for increased intracavitary pressures, creating a high-output state that is also associated with increased perioperative morbidity and mortality.[112]

Clinical Manifestations. The characteristic auscultatory findings of AS include a harsh, crescendo-decrescendo systolic murmur at the right second intercostal space, often with radiation to the carotid arteries.[1] As the disease progresses, aortic valve closure may follow pulmonic valve closure, causing paradoxical splitting of the second heart sound. Other physical findings associated with AS include an apical impulse commonly described as a "prolonged heave," and the presence of a narrow and sustained peripheral pulse, known as *pulsus parvus et tardus*.

The classic symptoms of AS are exertional dyspnea, angina, and syncope.[1] Although many patients are diagnosed prior to the onset of symptoms, the most common clinical presentation in patients with a known diagnosis of AS followed prospectively is worsening exertional dyspnea due to a limited capacity to increase cardiac output with exercise, and a progressive rise in end-diastolic pressures leading to pulmonary congestion. Angina occurs in over half of patients with AS, and is due to the increased oxygen demand of the hypertrophied myocardium in the setting of reduced oxygen supply secondary to coronary compression. Although some patients may have concomitant ischemic disease, angina occurs *without* significant epicardial coronary artery disease in half of all patients with AS. Syncope is most common during exertion, as systemic vasodilation in the setting of a fixed cardiac output causes decreased cerebral perfusion. However, at times, it may occur at rest secondary to paroxysmal atrial fibrillation and subsequent loss of atrial booster pump function. Late findings of AS include atrial fibrillation, pulmonary hypertension, systemic venous hypertension, and rarely sudden death.

Diagnostic Studies. Evidence of left ventricular hypertrophy is found in approximately 85% of patients with AS on routine EKG, though the correlation between the absolute electrocardiographic voltages in precordial leads and the severity of AS is poor.[1] EKG also may demonstrate signs of left atrial enlargement, and various forms and degrees of atrioventricular or intraventricular block due to calcific infiltration of the conduction system. Routine chest X-ray usually demonstrates a normal heart size, with rounding of the left ventricular border and apex. Cardiac enlargement on chest X-ray is a sign of left ventricular failure and cardiomegaly, and is a late finding.

Transthoracic echocardiography is indicated in all patients with a systolic murmur graded ≥2/6, a single second heart sound, or symptoms characteristic of AS.[70] Initial TTE examinations are often diagnostic, and provide an assessment of left ventricular size and function, the degree of left ventricular hypertrophy, the degree of valvular calcification, and the presence of other associated valvular disease. Doppler evaluation should be performed to define the maximum jet velocity, which is the most useful measure for following disease severity and predicting clinical outcome.[1]Additionally, color flow Doppler assesses the severity of the stenotic lesion by allowing calculations of the mean transvalvular pressure gradient, and effective valve orifice area (Table 21-12).[70] Follow-up TTE is variably indicated depending on the severity of AS in order to assess changes from baseline parameters and direct the timing of surgery: yearly for severe AS; every 1 to 2 years for moderate AS; and every 3 to 5 years for mild AS. Any abrupt change in signs or symptoms in a patient with AS is an indication for TTE examination.

Additional preoperative studies may be necessary in some patients. Rarely, when TTE images are suboptimal, TEE or fluoroscopy may be indicated to assess the degree of valve calcification and effective valve orifice area. As in other patients with valvular heart disease, coronary angiography should be performed prior to aortic valve surgery in most patients.[70] Since the symptoms of AS oftentimes mimic those of ischemic disease, cardiac catheterization and coronary angiography may be necessary at the initial evaluation in patients with AS. Stress-echocardiography may also be useful in the asymptomatic patient with AS in order to elicit exercise-induced symptoms, or abnormal blood pressure responses during exertion. It is also useful in the evaluation of low-gradient AS in patients with depressed LV function.[70] However, exercise stress-echocardiography is contraindicated in patients with ischemic heart disease.[70] In patients with evidence of aortic root disease by TTE, chest computed tomography is useful in evaluating aortic dilatation at several anatomic levels, and is necessary for clinical decision making and surgical planning.[1]

Indications for Operation. Based on the severity of AS and the overall physical condition of the patient (Table 21-12), AVR may be recommended for the treatment of AS (Table 21-13).[70] In patients with severe calcific AS, AVR is the only effective treatment, though controversy exists as to the timing of intervention in asymptomatic patients. Balloon valvotomy creates a modest hemodynamic effect and temporary symptom improvement in patients with calcific AS. However, the procedure has not been shown to affect long-term outcomes, and is often used in high-risk patients in which the contribution of the AS to the patients' symptoms is a matter of debate.[113]

Aortic Insufficiency

Etiology. The most common cause of isolated aortic insufficiency (AI) in patients undergoing AVR is aortic root disease, and represents over 50% of such patients in some studies.[1] Other common causes of AI include congenital abnormalities of the aortic valve such as bicuspid aortic valve, calcific degeneration, rheumatic disease, infective endocarditis, systemic hypertension, myxomatous degeneration, dissection of the ascending aorta, and Marfan syndrome. Less common causes of AI include traumatic injuries to the aortic valve, ankylosing spondylitis, syphilitic aortitis, rheumatoid arthritis, osteogenesis imperfecta, giant cell aortitis, Ehlers-Danlos syndrome, Reiter's syndrome, discrete subaortic stenosis, and ventricular septal defects with prolapse of an aortic cusp.[70] Although most of these lesions produce chronic aortic insufficiency, rarely acute severe aortic regurgitation can result, often with devastating consequences.

Pathology. Regardless of its cause, AI produces volume overload with dilation and hypertrophy of the left ventricle, and subsequent dilation of the MV annulus. Depending on the severity of AI, the left atrium may undergo dilation and hypertrophy as well. Frequently, the regurgitant jet causes endocardial lesions at the site of impact on the left ventricular wall.

Table 21-13

Data from ACC/AHA guidelines for AV surgery in specific clinical contexts.

CLINICAL SETTING	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
Balloon Valvotomy for Aortic Stenosis		
• Bridge to surgery in hemodynamically unstable patients with AS at high risk for AVR	IIb	C
• Palliation in adult patients with AS, who are not candidates for AVR	IIb	C
• Alternative to AVR in adult patients with AS	III – Harm	B
Surgery for Aortic Stenosis		
• Symptomatic patients with severe AS	I	B
• Severe AS in the setting of 1) Concomitant CABG 2) Concomitant valvular or aortic surgery 3) LV systolic dysfunction (LVEF <0.50)	I	C
• Moderate AS in the setting of 1) Concomitant CABG 2) Concomitant valvular or aortic surgery	IIa	B
• Asymptomatic patients with severe AS and • Abnormal response to exercise • High likelihood of rapid progression • High likelihood of delay if surgery is withheld until time of symptom onset • Expected operative mortality ≤1.0%	IIb	C
• Mild AS in patients undergoing CABG, when there is high likelihood of rapid progression	IIb	C
• AVR for prevention of sudden death in asymptomatic patients with AS without any of the findings above	III – Harm	B
Surgery for Aortic Insufficiency		
• Symptomatic patients with severe AI	I	B
• Asymptomatic patients with chronic severe AI in the setting of 1) Concomitant CABG 2) Concomitant valvular or aortic surgery 3) LV systolic dysfunction (LVEF ≤0.50)	I	C C B
• Asymptomatic patients with severe AI, normal LV systolic function (LVEF >0.50), but severe LV dilatation (end-diastolic dimension >75 mm, end-systolic dimension >55 mm)	IIa	B
• Moderate AI in the setting of 1) Concomitant CABG 2) Concomitant surgery on the ascending aorta	IIb	C
• Asymptomatic patients with severe AI, normal LV systolic function at rest (LVEF >0.50), and LV dilatation (end-diastolic dimension ≥70 mm, end-systolic dimension ≥50 mm) in the setting of 1) Progressive LV dilatation 2) Declining exercise tolerance 3) Abnormal hemodynamic responses to exercise	IIb	C
• Asymptomatic patients with mild, moderate, or severe AI and normal LV systolic function (LVEF >0.50), when the degree of LV dilatation is not moderate or severe (end-diastolic dimension <70 mm, end-systolic dimension <50 mm)	III – Harm	B

AS = aortic stenosis; AVR = aortic valve replacement; CABG = coronary artery bypass grafting; LV = left ventricular; LVEF = left ventricular ejection fraction; NYHA = New York Heart Association.

Diseases causing AI can be classified as primary disorders of the aortic valve leaflets, and/or disorders involving the wall of the aortic root. Diseases causing dilation of the ascending aorta are a more common indication for AVR due to isolated AI, and include disorders such as age-related (degenerative) aortic dilation, cystic medial necrosis of the aorta as is seen in Marfan syndrome, aortic dilation secondary to bicuspid valves, and aortic dissection, to name a few.[114] In these disorders, the aortic annulus becomes dilated, causing separation of the valve leaflets and subsequent AI. The diseased aortic wall may dissect secondarily and further escalate regurgitation across the valve, and secondary thickening and shortening of the valve

cusps may occur due to undue tension placed on the valvular apparatus by the dilated aortic root. As the disease progresses, the valves become too small to close the aortic orifice, causing further aortic insufficiency and exacerbating dilation of the ascending aorta.

There are also many primary valvular diseases that cause AI, generally in association with AS. One such disorder is age-related calcific AS, which causes some degree of AI in up to 75% of patients.[1] Infective endocarditis may involve the aortic valve apparatus and cause AI through direct destruction of the valve leaflets, perforation of a leaflet, or formation of vegetations that interfere with proper coaptation of the valve cusps. Rheumatic disease causes fibrous infiltration of the valve cusps and subsequent retraction of the valve leaflets, inhibiting apposition of the cusps during diastole and producing a central regurgitant jet. Patients with large ventricular septal defects or membranous subaortic stenosis may develop progressive AI, owing to a Venturi effect that results in prolapse of the aortic valve leaflets.

Pathophysiology. The basic pathophysiologic abnormality of AI is the retrograde flow of a portion of the LV stroke volume into the left ventricle during diastole, producing left ventricular volume overload.

Acute severe AI results most commonly from infective endocarditis, acute aortic dissection, or trauma, and causes a sudden volume overload on the left ventricle.[31] Although an acute increase in preload provides a small increase in overall stroke volume due to the Starling mechanism, the left ventricle is unable to accommodate the large regurgitant volume and maintain forward stroke volume in the acute setting due to a lack of remodeling. Left ventricular end-diastolic and left atrial pressures increase dramatically, as the left ventricle is unable to develop compensatory chamber dilation. Although tachycardia develops as a compensatory mechanism to maintain forward flow, this attempt is often inadequate, and patients frequently present in heart failure and even cardiogenic shock. Moreover, subendocardial myocardial ischemia frequently develops as a result of decreased coronary diastolic perfusion pressures and increased left ventricular end-diastolic pressure, as well as increased myocardial oxygen demand due to acute dilation. In the setting of a chronic ventricular hypertrophy and preexisting diastolic dysfunction, the pressure-volume relationship is even more extreme, exacerbating the hemodynamic derangements seen in acute AI.

Chronic AI generally has a more indolent course, with volume overload of the left ventricle causing compensatory increases in left ventricular end-diastolic volume and chamber compliance, and a combination of eccentric and concentric hypertrophy.[115] Compensatory remodeling of the left ventricle allows for accommodation of the regurgitant volume without a significant increase in filling pressures, and maintains the preload reserve of the chamber. Eccentric left ventricular hypertrophy develops, permitting normal contractile performance across the enlarged chamber circumference and subsequent ejection of a larger total stroke volume in order to maintain forward flow, despite the regurgitant fraction.[115,116] However, the enlarged chamber size results in an increase in systolic myocardial wall stress, and causes further ventricular hypertrophy. As the disease progresses, recruitment of preload reserve and compensatory hypertrophy maintains ejection fraction within the normal range despite elevated afterload, causing many patients to remain asymptomatic throughout the compensatory phase. [115,117]

Eventually, left ventricular compensatory mechanisms fail and systolic dysfunction ensues. As the disease progresses, preload reserve may become exhausted, the hypertrophic response may become inadequate, and/or impaired myocardial contractility may develop so that ejection fraction begins to decline. [118]Although left ventricular systolic dysfunction related to excessive afterload is reversible early in the course, irreversible damage occurs once chamber enlargement predominates as the primary cause of diminished myocardial contractility.

Clinical Manifestations. In cases of acute severe AI, patients are symptomatic and invariably present with compensatory tachycardia, often associated with acute pulmonary congestion and cardiogenic shock.[1] Because the left ventricular and aortic pressures often equalize before the end of diastole, the diastolic murmur of AI may be short and/or soft. The reduced systolic pressure may attenuate the increase in peripheral pulse pressure seen in chronic AI, and early closing of the mitral valve due to elevated left ventricular end-diastolic pressures may diminish the intensity of the first heart sound in the acute setting.

In patients with chronic AI, symptoms of heart failure and myocardial ischemia develop after the compensatory phase.[1] Patients gradually begin to complain of exertional dyspnea, fatigue, orthopnea, and paroxysmal nocturnal dyspnea, often after significant myocardial dysfunction has developed. Angina is a common complaint late in the course, especially during sleep when heart rate slows and arterial diastolic pressure falls. Patients may also experience exertional angina secondary to diminished coronary perfusion in the setting of myocardial hypertrophy. Occasionally, the compensatory tachycardia that develops with chronic AI will cause palpitations, and the increased pulse pressure will cause a sensation of pounding in the patient's head. Peripherally, the widened pulse pressure causes a forceful, bounding, and quickly collapsing pulse known as Corrigan's or water-hammer pulses. Premature ventricular contractions have been reported to cause particularly troubling symptoms, owing to the heave of the volume-loaded left ventricle during the postextrasystolic beat. The classic auscultatory finding associated with AI is a high-pitched decrescendo diastolic murmur heard best in the left third intercostal space; an associated S_3 gallop is often indicative of late disease. The Austin Flint murmur has also been described, and is heard as a middiastolic rumble at the apex that simulates mitral stenosis, and occurs in severe AI when the regurgitant jet impedes mitral opening.

Diagnostic Studies. In the acute setting, TTE should be performed to confirm the presence and severity of aortic regurgitation, the degree of pulmonary hypertension, and the cause of valvular dysfunction.[70] When aortic dissection is suspected as the cause of acute AI, TEE should be performed for diagnosis, though chest computed tomography may be substituted if more readily available.[119,120] Cardiac catheterization, aortography, and coronary angiography are rarely indicated, and often delay necessary urgent surgical intervention.

In cases of chronic AI, the EKG frequently demonstrates signs consistent with left axis deviation and, late in the course, intraventricular conduction defects associated with left ventricular dysfunction. On chest X-ray, the left ventricle enlarges predominantly in an inferior and leftward direction, causing marked increase in the long axis diameter of the heart, frequently with little or no change in the transverse diameter. The chest X-ray should be examined for aneurysmal dilation of the aorta.[1] An initial

TTE should be performed to confirm the diagnosis and severity of AI, assess the cause of AI (including valve morphology, and aortic root size and morphology), and assess the degree of left ventricular hypertrophy, volume, and systolic function.[70] Follow-up TTE is indicated on an annual or semiannual basis in patients with asymptomatic moderate to severe AI in order to assess changes from baseline parameters and direct the timing of surgery. Any abrupt change in signs or symptoms in a patient with chronic AI is also an indication for TTE examination.

Additional preoperative studies are variably indicated in certain patient populations.[70] In patients with poor windows on TTE, TEE, or magnetic resonance imaging is indicated for initial and serial assessment of AI severity, and left ventricular volume and function at rest. In symptomatic patients with chronic AI, it is reasonable to proceed directly to TEE or cardiac catheterization if TTE examinations are inadequate. Exercise stress testing may be helpful for an assessment of functional capacity and symptomatic responses in patients with a history of equivocal symptoms. Coronary angiography should be performed prior to valve surgery in most patients.[70]

Indications for Operation. Based on the morphology and severity of valve dysfunction (Table 21-12), AV repair or replacement may be performed for the treatment of AI (Table 21-13).[70] Although the indications for AV repair and AV replacement do not differ, it is recommended that AV repair be performed only in those surgical centers that have developed the appropriate technical expertise, gained experience in patient selection, and demonstrated outcomes equivalent to those of valve replacement.

Aortic Valve Operative Techniques and Results

Aortic valve surgery has traditionally been performed through a median sternotomy incision with the assistance of cardiopulmonary bypass and moderate systemic hypothermia. However, minimally invasive incisions for aortic valve surgery have been introduced, including mini-sternotomy and mini-thoracotomy approaches. After the aorta is cross-clamped, cold blood cardioplegia is delivered antegrade through the aortic root, and/or retrograde through the coronary sinus. A left ventricular vent may be inserted through the right superior pulmonary vein to help maintain a bloodless field during the procedure, and to aid in de-airing at the conclusion of the operation.

Aortic Valve Replacement. During aortic valve replacement, an aortotomy is performed, extending medially from approximately 1to 2cm above the right coronary artery and inferiorly into the noncoronary sinus, and the valve is completely excised. The annulus is thoroughly debrided of calcium deposits. After the calcium has been removed, the ventricle is copiously irrigated with saline. At this point, the annulus is sized and an appropriate prosthesis is selected. Pledgeted horizontal mattress sutures are then placed into the aortic valve annulus and subsequently through the sewing ring of the prosthetic valve, taking care to avoid damage to the coronary ostia, the conduction system, and the MV apparatus. The annular sutures may be placed from below the annulus, seating the valve supra-annularly, or from above the annulus for intra-annular placement (Fig. 21-10).

The major components to increased operative risk associated with surgical AVR include age, body surface area, diabetes, renal failure, hypertension, chronic lung disease, peripheral vascular disease, neurologic events, infectious endocarditis, previous cardiac surgery, myocardial infarction, cardiogenic shock, NYHA functional status, and pulmonary hypertension. For most patients, the risk associated with AVR is 1% to 5%, and 5-year survival has been reported to be >80%, even in patients >70 years of age.[69,121] The choice of valve is dependent on many patient-related factors, and is accompanied by the attendant postoperative risks of decreased durability, and thromboembolic vs. hemorrhagic complications for biological and mechanical valves, respectively.

Figure 21-10. Aortic valve replacement. The stented porcine bioprosthesis as viewed through an aortotomy.

Aortic Valve Repair. Although aortic valve replacement is performed more commonly, AV repair may be recommended at surgical centers with extensive experience, technical expertise, and outcomes equivalent to valve replacement. [70]

For patients with aortoannular ectasia, AI is due to annular dilatation and distortion of the sinotubular junction. For these patients, competence of the aortic valve can be achieved by functionally repairing the annulus in a method analogous to homograft implantation. The aneurysmal portion of the aortic root is excised, and the aortic valve is reimplanted inside a tubular Dacron graft, with concomitant reimplantation of the coronary arteries. Alternatively, the aneurysmal tissue and supravalvular tissue can be excised in their entirety, with subsequent implantation of the Dacron graft onto the superior aspect of the annulus and reimplantation of the coronary arteries.

Valve-sparing root replacement for root and annular stabilization in patients with AI due to aortoannular ectasia has led to a more durable outcome than is seen with subcommissural annuloplasty or leaflet-related procedures alone. One study demonstrated equivalent overall survival between patients undergoing subcommissural annuloplasty or aortic valve repair without annuloplasty, and patients undergoing valve-sparing root replacement at 6 years. [122] However, patients that underwent valve-sparing root replacement had higher freedoms from reoperation and aortic insufficiency >2+ (100% vs. 90%, P=0.03; and 100% vs. 77%, P=0.002, respectively) at midterm follow-up.

For patients with AI associated with redundant leaflet tissue, aortic valve repair may be accomplished with free margin plication or resuspension of the valve cusps, with or without triangular resection of the redundant segment. Excision of the

diseased portion of the involved valve cusp improves symmetry of the valve leaflets, and annular plication of one or both commissures helps to ensure adequate coaptation. Generally, the free margins of the excised leaflets are reapproximated primarily, but in the absence of adequate cusp tissue, a triangular autologous or bovine pericardial patch may be used for cusp restoration.

AV cusp repair with a free margin plication or resuspension technique has demonstrated encouraging results, both in patients with tricuspid and bicuspid aortic valves. Freedom from AV reoperation in patients with a tricuspid AV has been reported to be 89% to 92% at 10 years, with a freedom from recurrent AI >2+ of 80% to 86% at the same time point. In patients with bicuspid aortic valves, who generally represent a younger cohort of patients, 10-year survival has been reported at 94% following AV repair, with a freedom from AV reoperation of 81% at the same time point. [123]

Ross Procedure. As mentioned previously, the Ross procedure involves replacing the diseased AV with the patient's native pulmonary valve as an autograft, which is in turn replaced with a homograft in the pulmonic position.[80] The autograft may be implanted in the aortic position directly with resuspension of the valve commissures, or in association with a root replacement, which requires reimplantation of the coronary ostia.

The cylinder root replacement technique is most reproducible, and involves transecting the native aorta approximately 5mm above the sinotubular ridge, with subsequent excision of the aortic valve leaflets and supra-annular tissue. The main pulmonary artery is transected at the bifurcation and the right ventricular outflow tract is incised, allowing the pulmonary valve and artery to be removed en bloc from the outflow tract. The annulus of the pulmonary autograft is sewn to the native aortic annulus with continuous or interrupted sutures, and the coronary ostia are reimplanted into the pulmonary artery graft. The pulmonary valve and right ventricular outflow tract are subsequently reconstructed using homograft tissue.

The primary benefit of the Ross procedure compared to traditional AV surgery is a low risk of thromboembolism without the need for systemic anticoagulation. Although patients undergoing the Ross procedure are generally younger, perioperative mortality has been reported to be as low as 2.5% in this group, with an overall survival of 90% at 18-year follow-up.[124] However, the long-term durability of the procedure is somewhat questionable. Although Ross reported a freedom from autograft replacement of 75% at 20 years, other groups have reported freedom from autograft reoperation and allograft reintervention of 51% and 82%, respectively, at 18-year follow-up.[124,125] Progressive aortic insufficiency has been described as a cause of late failure in these patients, as well as calcification of the pulmonary homograft and pulmonary stenosis.

Transcatheter Aortic Valve Replacement. Transcatheter aortic valve replacement (TAVR) is relatively new technology that has proven beneficial for the treatment of AS in seriously ill patients who are not candidates for conventional surgery. The procedure remains the focus of ongoing clinical trials, and thus there are no published indications for operation endorsed by the American College of Cardiology or the American Heart Association. However, the Edwards SAPIEN heart-valve system that has been used thus far in the TAVR experience has been recently approved by the Food and Drug Administration for labeled-indications associated with published early results.

The Edwards SAPIEN heart-valve system consists of a trileaflet bovine pericardial valve with a balloon-expandable stainless steel support frame, and can be inserted by either the transfemoral, transaortic, or transapical route. The transfemoral route involves performing a standard balloon aortic valvuloplasty, followed by transfemoral insertion of either a 22- or 24-French sheath, depending on the size of the valve selected for implantation. The balloon catheter and overlying collapsed bioprosthetic heart valve is then advanced across the native aortic valve under fluoroscopy, and deployed during rapid right ventricular pacing. If the patient's peripheral vascular system is not amenable to femoral arterial cannulation, the transapical or transaortic route is chosen. In the transapical approach, a small intercostal incision is performed over the left ventricular apex, and a dedicated delivery catheter is inserted through the left ventricular apex and across the native aortic valve as described above. The transaortic approach is usually done through a ministernotomy. Other approaches that have been described include transaxillary, transsubclavian, and transcarotid. The particular role of each approach in a specific patient still remains to be defined, and continues to change as the technology improves.

A large multicenter clinical trial has been performed on patients that were judged to be too high risk or inoperable for traditional AVR, based on assumed risks of ≥10% to 15% and ≥50% 30-day mortality, respectively. In patients that had previously been deemed inoperable, TAVR markedly reduced the rate of death from any cause (49.7% vs. 30.7%, $P = <0.001$), the rate of death from cardiovascular causes (41.9% vs. 19.6%, $p = <.001$), and the rate of repeat hospitalization (44.1% vs. 22.3%, $p = <.001$) at one year compared with standard medical therapy.[126] Although the rates of neurological events (10.6% vs. 4.5%, $P = 0.04$), major vascular complications (16.8% vs. 2.2%, $P = <.001$), and major bleeding events (22.3% vs. 11.2%, $P = 0.007$) were higher in the TAVR group, these patients also experienced a significant reduction in symptoms and increased functional capacity compared with patients receiving standard medical therapy. In patients at high risk for traditional AVR, the rate of death from any cause, and from cardiovascular causes, was found to be noninferior in the TAVR group, compared with the surgical group.[127] The rate of major bleeding events was higher in the surgical group (19.5% vs. 9.3%, $P= <0.001$) at 30 days, and patients in the TAVR group had a significantly shorter length of stay in the intensive care unit (3 vs. 5 days, $P = <0.001$), and a shorter index hospitalization (8 vs. 12 days, $P = <.001$). Although more patients in the TAVR group experienced a reduction in symptoms to NYHA class II or lower ($P = <0.001$), they also experienced more neurological events (8.3% vs. 4.3%, $P = 0.04$), and major vascular complications (11.3% vs. 3.5%, $P = <.001$) at one year.

Although it is clear that TAVR represents a distinct set of periprocedural risks, it has demonstrated benefits in morbidity and mortality, especially in patients deemed inoperable for surgical AVR. Ongoing trials are examining the potential role of TAVR in patients with AS at moderate risk for traditional AVR.

TRICUSPID VALVE DISEASE

Tricuspid Stenosis and Insufficiency

Etiology. Acquired tricuspid valve (TV) disease can be classified as either organic or functional, and affects approximately 0.8% of the general population.[128] Tricuspid stenosis is almost

always a result of organic disease, namely rheumatic heart disease and endocarditis. In the case of rheumatic disease, tricuspid stenosis with or without associated insufficiency is invariably associated with mitral valve disease. Other less common causes of obstruction to right atrial emptying include congenital tricuspid atresia, right atrial tumors, and endomyocardial fibrosis.

Tricuspid insufficiency, on the other hand, is most often a functional disease caused by secondary dilation of the tricuspid annulus due to pulmonary hypertension and/or right heart failure. This is most commonly caused by MV disease. Conditions such as right ventricular infarction and pulmonic stenosis can also lead to increased right ventricular pressures and functional tricuspid insufficiency (TI). The less common causes of organic TI, with or without associated stenosis, include carcinoid syndrome, radiation therapy, trauma such as repeated endomyocardial biopsy specimens, and Marfan syndrome.

Pathology. The changes associated with tricuspid stenosis (TS) closely resemble those associated with MS, including fusion of the commissures.[128] In the case of rheumatic disease, mixed TS and TI may result from fusion and shortening of the chordae tendineae, and fusion of the commissures, causing retraction of the valve leaflets. The right atrium is frequently dilated and thickened in chronic TS, and chronic obstruction to right ventricular filling often produces signs of systemic venous congestion such as hepatomegaly and splenomegaly.[1]

In most cases of TI, dilation and deformation of the tricuspid annulus is the most prominent feature; the valve leaflets oftentimes appear stretched, but are otherwise pliable and normal in appearance.[1] When TI is caused by carcinoid syndrome, white fibrous carcinoid plaques are found on the ventricular surfaces of the TV, causing the cusps to adhere to the underlying right ventricular wall and stenting the valve open.[1]

Pathophysiology. The basic pathophysiologic abnormality of both TS and severe TI is elevated right atrial pressures, producing signs of systemic congestion and right heart failure. Severe TS is marked by a valve area <1.0 cm^2, and severe TI is defined as a vena contracta width of >0.7 cm in combination with systolic flow reversal in the hepatic veins.[70] However, in patients with TS, a diastolic pressure gradient of only 5 mm Hg, or a TV orifice <1.5 cm^2, is frequently enough to cause jugular venous distention, organomegaly, and peripheral edema. In severe cases, cardiac output is compromised, especially during exercise when the fixed obstruction prevents an increase in forward flow. Patients with severe insufficiency and pulmonary hypertension experience similar hemodynamic derangements.

Clinical Manifestations. Patients with TS and severe TI develop symptoms of right heart failure associated with chronically elevated right atrial pressures.[1] The classic clinical signs and symptoms of TS and severe TI are jugular venous distention, hepatomegaly, splenomegaly, ascites, and lower extremity edema. Uncomfortable fluttering in the neck has been reported in patients with TV disease, and sensations of throbbing in the eyeballs and pulsatile varicose veins have been reported to occur, especially in patients with severe TI.

The low cardiac output occasionally associated with TS and severe TI can cause fatigue, weakness, and exercise intolerance in these patients. In the absence of pulmonary hypertension, dyspnea is not a prominent feature of tricuspid disease. The auscultatory findings associated with TS include a presystolic and middiastolic murmur characterized by a tricuspid opening snap that increases on inspiration. The lower left parasternal murmur of TI may be holosystolic or less than holosystolic, depending on the degree of regurgitation, may be associated with a middiastolic murmur in severe cases, and may increase on inspiration.

Diagnostic Studies. In patients with TV disease, chest X-ray frequently demonstrates enlargement of the right atrium and ventricle. Patients with TS demonstrate an exaggerated *a* wave and a diminished rate of *y* descent in the jugular venous pulse, while patients with TR have abnormal systolic *c* and *v* waves.[1] TTE examination should be performed in patients with TV disease in order to characterize the structure and motion of the TV, the size of the tricuspid annulus, and other cardiac abnormalities that may affect TV function.[70] In patients with a pulmonary artery systolic pressure >55mm Hg, TI commonly occurs in the setting of structurally normal valves; however, structural derangement of the TV apparatus is frequently present if TI is documented with a pulmonary artery systolic pressure <40mm Hg. Doppler TTE allows estimations of the severity of TI, the right ventricular systolic pressure, and the TV diastolic gradient.

Indications for Operation. As an isolated lesion, mild or moderate TV disease does not require surgical correction. However, patients with severe TV disease should be considered for surgical intervention, especially in the setting of right ventricular enlargement and impaired systolic function, as this improves life expectancy and the development of sequelae such as heart failure and atrial fibrillation.[128] Depending on the patient's clinical status and the cause of TV dysfunction, TV repair and TV replacement be variably recommended for the treatment of TV dysfunction (Table 21-14).[70] In patients with TI, the valve can usually be repaired with modern techniques.

Operative Techniques and Results. The TV can be approached through a median sternotomy, a right thoracotomy, or minimally invasive port-based techniques. Surgery is performed with the assistance of cardiopulmonary bypass and, though TV surgery is usually performed on the beating heart, a brief period of cardioplegic arrest is rarely needed to allow for complete inspection of the interatrial septum, and close any defects that may be present.

TV repair may include a suture or ring annuloplasty as well as valvuloplasty, and multiple methods have been described.[128] Historically, bicuspidization of the TV was accomplished by a figure-of-eight suture plication of the annulus of the posterior leaflet; however, this technique has been essentially replaced by suture or ring annuloplasty. Suture annuloplasty is generally performed by placing 0 polypropylene pledgeted sutures along the base of the anterior and posterior leaflets, partially encircling the annulus. Ring annuloplasty can be accomplished by suturing the TV annulus to a variety of rigid or semirigid annuloplasty rings, which generally have an opening at the level of the anteroseptal commissure to avoid passing the anchoring sutures too close to the conduction system. Most surgeons favor ring over suture annuloplasty. In severe annular dilatation, augmentation of the anterior leaflet with autologous pericardium has been used with some success. Tricuspid valvuloplasty is infrequently performed and may include commissurotomy, triangular leaflet resection, primary perforation repair, and traditional leaflet repair techniques such as chordal transfer, shortening, and replacement, papillary muscle plication, tricuspid leaflet augmentation, and the edge-to-edge repair technique used in MV prolapse.

For patients with functional TV disease, TV repair is generally preferred to replacement due to favorable results without the associated risks of thrombosis and anticoagulation. In the

Table 21-14

Data from ACC/AHA guidelines for TV surgery in specific clinical contexts.

CLINICAL SETTING	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
Surgery for Tricuspid Valve Disease		
• TVr for severe TI in patients with MV disease requiring MV surgery	I	B
• TVR or annuloplasty for severe symptomatic primary TI	IIa	C
• TVR for severe TI secondary to diseased/abnormal TV leaflets not amenable to annuloplasty or TVr	IIa	C
• Annuloplasty for less than severe TI in patients undergoing MV surgery in the setting of 1) Pulmonary hypertension 2) Tricuspid annular dilatation	IIb	C
• TVR or annuloplasty is not indicated in asymptomatic patients with TI, a normal MV, and a PASP <60 mm Hg	III – Harm	C
• TVR or annuloplasty is not indicated in patients with mild primary TI	III – Harm	C

MV = mitral valve; PASP = pulmonary artery systolic pressure; TI = tricuspid insufficiency; TV = tricuspid valve; TVr = tricuspid valve repair; TVR = tricuspid valve replacement.

setting of concomitant mitral valve surgery, TV repair has not been associated with additional perioperative complications, and 5-year freedom from reoperation has been impressive at 98%.[85] However, a subgroup of patients report late failure following TV repair, and this may be worse following suture annuloplasty compared with ring annuloplasty.

Prosthetic valve replacement may be necessary due to extensive leaflet destruction or marked annular dilatation not amenable to repair. In some cases, the valve prosthesis may be anchored directly to the leaflet tissue instead of the valve annulus, reducing the risk of injury to the conduction system.[128] If this technique is used, it should be confirmed that the residual tissue does not interfere with the movement of the prosthetic leaflets after implantation. Pledgeted sutures should be used, and may be placed on the ventricular or atrial side of the annulus.

Outcomes data following TV replacement are difficult to interpret, as most reports are in patients with previous TV surgery and/or signs of severe right heart failure. Operative mortality has been over 20% in some studies.[128] One study of 87 patients undergoing TV replacement between 1194 and 2007 showed an in-hospital mortality of only 1.4%. The choice of prosthetic valve is also somewhat controversial. Though bioprosthetic valves are more durable in the tricuspid than mitral or aortic positions, valve degeneration is an important cause of bioprosthetic valve dysfunction at reoperation. The increased risk of valve thrombosis seen with mechanical valves, however, underlines the need for rigorous systemic anticoagulation. Even with these precautions, mechanical tricuspid valves are associated with an increased risk of hemorrhagic and thrombotic complications. The choice of valve is usually decided on a case-by-case basis and late outcomes have been similar with biological and mechanical valves in this position. In general, TV replacement may be a reasonable choice in select patients, though more data are needed regarding long-term outcomes in the modern era.

Multivalve Disease

Pathology involving multiple valves is relatively common, and may result from diseases such as rheumatic fever, calcific disease, Marfan syndrome, and other connective tissue disorders.[1] However, multivalve disease may also be caused by secondary valvular dysfunction due to a distal valvular lesion, as in the case of myxomatous degeneration of the mitral valve, resulting in pulmonary hypertension, dilation of the tricuspid annulus, and functional TI. If the primary pathology is corrected early in the disease course, these secondary functional changes may resolve without further intervention.

In patients with multivalve disease, the clinical manifestations may be dependent on the severity of each individual valve lesion, but this is not always the case.[1] In patients with concomitant mitral and tricuspid dysfunction, the prominent symptoms of dyspnea, paroxysmal nocturnal dyspnea, and orthopnea commonly associated with MV dysfunction are frequently diminished by associated TV dysfunction. Symptoms of multivalve disease are most commonly masked when valvular abnormalities are of approximately equal severity, highlighting the importance of careful examination of each valve both preoperatively and in the operating room.

Surgery for multivalve disease is associated with a higher perioperative mortality than single-valve procedures, and this risk is exacerbated by factors such as pulmonary artery hypertension, age, triple-valve procedures, concomitant coronary artery bypass grafting, previous heart surgery, and diabetes.[129] Failing to recognize significant concomitant valvular dysfunction at the time of surgery is also associated with higher perioperative mortality. For this reason, patients suspected of having multivalve involvement should undergo full preoperative Doppler TTE or TEE evaluation, and heart catheterization.[70] In selected patients, procedures correcting multivalve disease demonstrate significant clinical improvement in symptoms and quality of life, as well as acceptable mortality and survival rates.[129]

SURGICAL THERAPY FOR THE FAILING HEART

Epidemiology of Heart Failure

Heart failure affects approximately 5 million patients in the United States, with >550,000 new cases diagnosed annually.[130]

The disorder is the primary reason for 12 to 15 million office visits and >1 million hospitalizations each year. Overall 1-year mortality is estimated to be around 25%, but this can increase to as high as 75% for patients with more advanced heart failure (NYHA class IV).[131] While heart transplantation remains the gold standard for the treatment of end stage disease, an increasing number of patients deteriorate while on the waiting list and up to 30% die before transplantation.[132] The total direct and indirect costs associated with the treatment of heart failure are estimated to be $32 billion, and this is projected to increase to $70 billion by 2030.[133] Advances in the surgical management of heart failure over the last decade have pushed surgery for CHF into the mainstream. As a result, there is an increasing number of patients with late- or end-stage disease who are being considered for surgical therapies.

Etiology and Pathophysiology

Heart failure can be classified as acute vs. chronic, genetic vs. acquired, left-sided vs. right-sided and systolic vs. diastolic dysfunction. The underlying causes and treatments for each of these vary considerably. In the Framingham Heart Study, coronary artery disease accounted for 67% of heart failure cases, valvular heart disease accounted for 10%, and 20% of cases were attributable to primary myocardial diseases, of which dilated cardiomyopathy predominated.[134] In all cases, heart failure is a progressive disorder that through complex mechanisms of ventricular remodeling, altered hemodynamics, neurohumoral activation, cytokine overexpression, and vascular and endothelial dysfunction either disrupts the ability of the myocardium to generate force or results in a loss of functioning cardiac myocytes, thereby preventing normal myocardial contraction.

CABG for Ischemic Cardiomyopathy

Surgical coronary revascularization is among the most commonly performed procedures for CHF. CABG is beneficial as it protects from further myocardial infarction and/or malignant ventricular arrhythmias. It is most successful when treating hibernating as opposed to infarcted myocardium.

While the majority of evidence supporting CABG for patients with ischemic cardiomyopathy comes from nonrandomized, retrospective studies, the prospective, randomized, multicenter international Surgical Treatment of Ischemic Heart Failure (STICH) trial compared CABG with medical therapy to medical therapy alone. Entry criteria included an EF ≤35% with CAD and anatomy suitable for CABG. No significant difference was seen in overall mortality by study completion, but patients who underwent CABG did have fewer deaths or hospitalizations from cardiovascular causes (58% vs. 68%, $P<0.001$).[135,136] This difference is despite the facts that only 50% of patients had myocardial viability testing, that 17% of patients in the medical therapy group underwent CABG and that 9% of patients randomized to CABG did not have surgery.

Myocardial viability testing has been shown by multiple studies to be pivotal in identifying patients that will have improved outcomes following CABG for ischemic cardiomyopathy.[137,138] A meta-analysis performed by Allman et al demonstrated an 80% reduction in mortality in patients who underwent revascularization with viable myocardium compared to patients who received medical therapy alone (3.2% vs. 16%, $p<0.0001$). Most important, in this analysis CABG had no benefit over medical therapy for patients without viable myocardium. A more recent study by Gerber et al prospectively compared CABG and medical therapy to medical therapy alone in 114 patients with CAD and low EF (24 ± 8) who underwent viability testing using delayed-enhancement cardiac MRI.[139] That study demonstrated worse 3-year survival in medically treated patients with dysfunctional but viable myocardium than in medically treated patients with nonviable myocardium (48% vs. 77%, $P = 0.02$). This corresponded with a 4.56 hazard of death of viable myocardium when medical treatment was selected over full revascularization. In contrast, survival after CABG was not significantly different whether myocardium was viable or not (88% vs. 71%, P = NS). These studies underscore both the importance of viable myocardium as well as the adverse consequences of not offering a patient with viability surgical intervention.

Patients with ischemic cardiomyopathy are a heterogeneous group, and, as with any surgery, appropriate patient selection is central to success. In one retrospective study of 96 patients with ischemic cardiomyopathy (EF ≤25%), age, and poor distal vessel quality were predictors of poor outcomes.[140] Mortality in patients with poor vessel quality was 100%, compared with 90% when vessel quality was fair and 10% when it was good. Therefore, poor vessel quality should be considered a contraindication to surgical revascularization even in the presence of angina.

LV size and LV dyssynchrony are also risk factors for adverse short and intermediate term outcomes. A LV end diastolic dimension of >100 mL/m^2 is associated with a significantly reduced 5-year survival following CABG (85% vs. 53%, $p<0.05$), as well as worse 5-year freedom from recurrent CHF (85% vs. 31%).[141] Moreover, LV dyssynchrony has been shown to have a significant impact on mortality in patients undergoing moderate to high risk revascularization and may compound risk in patients with nonviable myocardium.[142] In patients with severe preoperative LV dyssynchrony the 30-day mortality was 27% vs. 3% in patients without significant dyssynchrony ($p<0.001$). Similar differences were seen with the presence of postoperative LV dyssynchrony, and outcomes were worse when patients also had fewer segments of viable myocardium.

Secondary Mitral Regurgitation

Secondary mitral regurgitation describes MR that results from damage to the left ventricle as a result of either ischemia or dilated cardiomyopathy rather than from a problem with the valve itself.[143] Ischemic MR (IMR) typically results from systolic restriction of the mitral leaflets due to tethering of the subvalvular apparatus. This occurs mainly from regional wall motion abnormalities in areas of the LV adjacent to papillary muscle attachments. Alterations in the size and shape of the mitral annulus and posterior displacement of the posteromedial papillary muscle, which occurs primarily after an inferoposterior MI, may also contribute. Additionally, functional MR (FMR) is caused by LV dilatation and increased sphericity, which displace the papillary muscles apically and radially, creating lateral forces on the valve that lead to increased retraction of the mitral leaflets by the chordae tendineae. LV dyssynchrony may also contribute to FMR through poor coordination of the contraction of the septum and lateral walls, producing MR that may vary in intensity during the cardiac cycle. Functional MR is usually referred to as a Carpentier class I/IIIb lesion due to the presence of both annular dilatation (Carpentier type I) and systolic restriction of the mitral leaflets due to LV dysfunction (Carpentier type IIIb). Ultimately, increased regurgitation leads

to increased preload, LV wall tension, and LV work load, all of which contribute to progressive dysfunction of the LV and worsening heart failure.

Several observational and population based studies have demonstrated a significant impact of secondary MR on long-term survival. Following MI, the 5-year survival rate dropped significantly from 61% in patients who did not have MR to 47% and 29% in patients with mild and moderate to severe MR, respectively.[144] Similarly, in a series of 2,057 patients with symptomatic heart failure and a LVEF <40%, the 5-year survival rate for patients without MR was 54%, and it decreased to 40% in patients with moderate to severe secondary MR.[145] In a cox proportional hazards analysis, increasing severity of MR was an independent predictor of decreased survival (HR = 1.23, [1.13–1.34], $p = 0.0001$), and this observation held for patients with both ischemic and nonischemic disease etiologies. Moreover, medical therapy and PCI have not reduced the impact of IMR on late mortality.[146]

Although specific recommendations to intervene for secondary MR are controversial and have not been rigorously defined, guidelines are available (Table 21-15).[70,147] Some surgeons initially advocated performing only revascularization in cases of moderate ischemic MR with the idea that revascularizing viable myocardium would lead to improvements in LV function and effect reverse remodeling, ultimately contributing to a decrease in MR. While several studies have shown that MR often persists following revascularization alone, the addition of a mitral valve annuloplasty in those studies did not improve long-term functional status or survival in patients with ischemic MR.[148-150] Nevertheless, other studies have shown that the persistence of MR after CABG is associated with a decreased survival rate and that CABG alone only has modest effects on reducing MR at 1 month follow-up.[143] As a result, a growing number of centers have elected to repair moderate MR in this patient population. Indications for surgery in ischemic MR patients in the absence of revascularization options are even less well-defined.

For patients with functional MR, the goal of mitral valve surgery is to avoid or postpone transplantation in eligible patients, but it should generally not be performed in patients with end-stage heart failure who present with low EF and limited myocardial viability. Those patients are often best suited by transplantation and/or ventricular assist device implantation.

Mitral valve repair is the procedure of choice when surgery is indicated for secondary MR. Currently, recommendations are to use a semirigid or rigid annuloplasty ring to downsize the mitral annulus.[143] There have also been various techniques proposed to correct the papillary muscle displacement, but most reports are single center, retrospective and small. Mitral valve replacement with preservation of the subvalvular apparatus is indicated when repair is not feasible due to severe tethering of the leaflets or massive LV dilation.

Outcomes from surgery vary between centers and amongst patients in this heterogeneous group. Operative mortality ranges between 0% to 9% in most modern series.[143] Generally speaking, mortality and recurrence rates are higher and long term prognosis is worse compared to outcomes for primary MR. Recurrent MR is as high as 15% to 30% in some series and 5-year mortality is between 44% to 48%.[143,151,152] Some reductions in left atrial dimension and LV reverse remodeling may be achieved.[153]

Left Ventricular Aneurysmorrhaphy and Surgical Ventricular Restoration

Pathophysiology of Ventricular Aneurysms. A transmural infarction of approximately 5% to 10% of the myocardium may result in formation of an LV aneurysm as necrotic myocardium is replaced by fibrous tissue. This usually occurs 4 to 8 weeks following the infarct. In the last decade, prompt revascularization of the culprit artery by either surgical or interventional techniques generally results in sparing of the subepicardial muscle while the subendocardial muscle remains necrotic.[154] Therefore, it is not uncommon for the LV wall to show both living myocardium during thallium testing and an akinetic zone on echocardiogram or angiogram. It has been demonstrated that once more than 20% of the myocardium is necrosed there is irreversible progression to ventricular dilation and failure.[155] The classic aneurysm is a 4 to 6 mm thick scar, which bulges outward in paradoxical motion as the LV contracts during systole. More than 80% develop in the anteroseptal and apical portions of the

Table 21-15

Data guidelines for surgical intervention for secondary mitral regurgitation.

CLINICAL SETTING	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
Chronic Ischemic MR (ESC Guidelines)		
• Severe MR, LVEF >30%, undergoing CABG	I	C
• Moderate MR, undergoing CABG, if mitral repair is feasible	IIa	C
• Severe MR, symptomatic patients, LVEF <30%, candidate for revascularization	IIa	C
• Severe MR, LVEF >30%, no option for revascularization, refractory to optimal medical therapy, low comorbidity	IIb	C
Chronic Functional MR (ESC and ACC/AHA Guidelines)		
• Chronic severe MR due to LV dysfunction, EF <30%, persistent NYHA class III-IV, symptoms despite optimal medical therapy	IIb	C

MR = mitral regurgitation, ESC = European Society of Cardiology, CABG = coronary artery bypass grafting, LVEF = left ventricular ejection fraction, LV = left ventricle, ACC = American College of Cardiology, AHA = American Heart Association, NYHA = New York Heart Association.

left ventricle as a result of left anterior descending artery occlusion. The rest are inferior in location and the result of circumflex or right coronary occlusion.

This patient population typically suffers from associated ventricular arrhythmias for several reasons. First, electrical dyssynchrony results from postinfarction remodeling, and triggers for ventricular arrhythmias typically occur in the scar border zone in patients with ischemic cardiomyopathy.[156,157] Second, increased ventricular volume causes high wall stress and stretch, and stretch has been shown to be arrhythmogenic.[158] Third, LV aneurysms represent an independent risk factor for SCD after MI.[159] Surgical ventricular restoration (SVR) addresses each of these issues by removing the anatomic substrate during resection of the postinfarct scar and/or aneurysm, accomplishing volume reduction and mechanical resynchronization and relieving ischemia through complete revascularization and reduction in myocardial wall tension and oxygen demand.

Clinical Presentation and Diagnosis. Symptoms of LV aneurysms include angina, CHF, ventricular arrhythmias and rarely embolic phenomenon. Rupture is extremely uncommon. Patients generally present for coronary artery bypass or during evaluation of CHF or arrhythmias. While transthoracic echocardiography gives pertinent information regarding LV function, size, mitral valve function and the presence of thrombus, it is generally accepted that cardiac MRI is the best diagnostic modality to accurately identify areas of scar and viable tissue and to best define ventricular geometry.[155]

Surgical Treatment and Results. In 1985, Vincent Dor described a surgical technique called the endoventricular circular patch plasty that was intended to improve geometric reconstruction compared with the standard linear repair in LV aneurysm surgery. SVR is a somewhat broader term that arose from surgical repair of ventricular aneurysms and has now come to be applied to a group of surgical procedures designed to correct the effects of postinfarction ventricular remodeling. It is also sometimes referred to as surgical ventricular remodeling or reconstruction, surgical anterior ventricular endocardial reconstruction (SAVER), or the Dor procedure. SVR is specifically intended to reduce the size and sphericity of the LV by excluding akinetic and dyskinetic areas, most often by using a circular patch inserted inside the ventricle on contractile myocardium (Fig. 21-11A & B).

Candidates for SVR are typically patients who have had a remote anterior or anteroseptal myocardial infarction, significant ventricular enlargement with a significant area of akinetic or dyskinetic myocardium, a discrete aneurysm, a clinical picture consistent with heart failure (LVEF <40%), retained function of the basilar and lateral portions of the heart and good right ventricular function. These patients should also be candidates for repair of any other concomitant cardiac disease. Dor currently emphasizes the importance of complete revascularization and repair of any mitral pathology at the time of operative SVR. In patients with spontaneous (13%) or inducible (25%) ventricular tachycardia (VT), it is additionally necessary to perform nonguided endocardial resection and cryoablation encircling the resected area.[155]

Results with this approach have been good in treating both heart failure and its sequelae, such as VT. In Dor's series of 1150 patients, the operative mortality was dependent on the EF and ranged from 1% for patients with EF >40% to 13% for patients with EF <30%, and the 5-year survival approached 85%.[155] Overall, more than 80% of survivors are either stabilized or improved, and quality of life has been shown to improve significantly by 6 months after the Dor procedure.[160] This is likely due in part to the fact that the Dor procedure restores LV geometry, resulting in a mean ejection fraction increase between 10% to 15%, with significant alleviation of symptoms.[155,161-163] These data are reinforced by the international RESTORE group, which examined SVR in a registry of 1198 postinfarction patients between 1998 and 2003.[164] They found that 5-year overall freedom from hospital readmission for CHF was 78%. Moreover, 67% of patients had preoperative NYHA class III or IV symptoms, whereas 85% of patients were NYHA functional class I or II postoperatively.

With respect to VT, Dor et al. reported on 106 patients with ischemic ventricular arrhythmias that underwent reconstruction for postinfarction LV aneurysm and visually-directed endocardiectomy plus or minus cryoablation and coronary revascularization [165]. At a mean follow-up of 21.3 months, only 10.8% of patients had inducible VT and no spontaneous VT was documented. Results from similar series have also been excellent,[148,163,166] but the efficacy of left ventricular restoration alone has been controversial.[167,168] Inferior results seen in some series have been attributed to failure to perform endocardial resection and/or cryoablation at the border of the transitional zone, as well

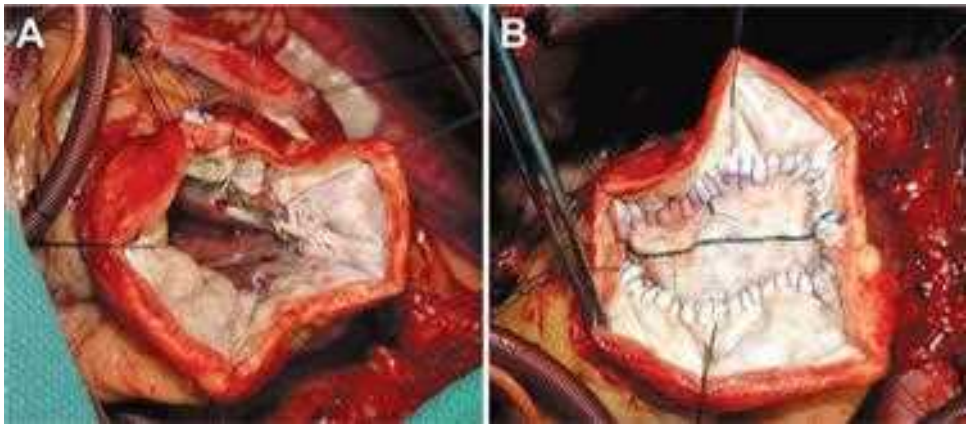

Figure 21-11. Surgical ventricular restoration of a ventricular aneurysm using the Dor Procedure. **A.** The size and sphericity of the left ventricle are reduced by excluding akinetic and dyskinetic areas. **B.** Most often this is completed using a circular patch inserted inside the ventricle on contractile myocardium.

as differences in stimulation protocols and possible inadequate volume reduction of the ventricle.

Recently, a large, randomized, multicenter study, the STICH trial, has reported the conclusion that adding SVR to reduce ventricular volume to CABG does not improve symptoms or exercise tolerance and fails to lower death rate or cardiac rehospitalization compared to CABG alone[135]. While this trial has some shortcomings, it has resulted in a marked decrease in referrals for this procedure The main problem is that the LV volume was reduced by only 19% in the STICH trial, reflecting an inadequate repair as determined by the Surgery Therapy Committee, whose "acceptable STICH procedure" guideline required a 30% reduction at the 4-month postoperative cardiac MRI.[169] Previous studies have reported an average reduction of end-systolic volume index (ESVI) of 40% with a range between 30% and 58%, suggesting that the STICH SVR procedure may have involved an inadequately small LV plication or limited intracavitary reconstruction.[169] Moreover, this trial enrolled 13% of patients who had never had an MI and changed criteria such that enrollment required documented LV anterior wall dysfunction rather than demonstration of scar. This could have captured patients with hibernating myocardium that would recover following CABG alone. Dor subsequently published the results of 117 patients who would have been eligible for the STICH trial and demonstrated durable improvement in left ventricular function.[170] However, this was a single-center, restrospective experience. Caution should be exercised so as not to broadly extrapolate the results of the STICH trial and inappropriately deny appropriate patients effective treatment.

Mechanical Circulatory Support

Intra-aortic Balloon Pump. The intra-aortic balloon pump (IABP) is the most commonly used device for mechanical circulatory support, and it may be easily deployed in the catheterization laboratory, in the operating room or at the bedside. The device is inserted percutaneously through the femoral artery into the thoracic aorta. It is synchronized so that the balloon is inflated during diastole and deflated during systole, resulting in augmentation of diastolic perfusion of the coronary arteries and decreased afterload. Typically, this improves cardiac index and decreases both preload and myocardial oxygen consumption.

The indication for use of an IABP is most often cardiogenic shock during or after cardiac catheterization or cardiac surgery. It also is indicated for preoperative stabilization of high-risk patients with either severe coronary artery disease, LV dysfunction, or refractory, unstable angina. Kang et al have reported that risk-adjusted mortality was significantly lower for selected high-risk patients undergoing open heart surgery when a preoperative IABP was used.[171]

Generally, an IABP is used for a few days and weaned as the patient's condition improves. Morbidity associated with device use is typically minimal; however, in one series of 911 patients undergoing CABG who received an IABP, there was a 12% incidence of minor or major vascular complications, including an approximately 3% incidence of limb ischemia requiring thromboembolectomy. This is the most serious complication of IABP placement. To prevent this problem, frequent lower extremity neurovascular checks are necessary while an IABP is in place [172].

Ventricular Assist Device Indications and Cannulation. Patients in need of ventricular assist devices (VADs) may have preexisting chronic heart failure, refractory ventricular arrhythmias, or acute heart failure following an MI, cardiopulmonary arrest, viral illness, pregnancy, or cardiotomy. Device therapy is intended to preserve end-organ perfusion and function and may be categorized as short- or long-term support for the left heart, the right heart, or both. In general, VADs may be used for support while the heart recovers (bridge to recovery, BTR), while the patient waits for a heart transplant (bridge to transplant, BTT) or as a final option to treat a chronic heart failure patient who is not a transplant candidate (destination therapy, DT). The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database, a joint effort by the NHLBI, FDA, CMS, academia, and industry to prospectively track patient outcomes, reported that between January 2009 and June 2010 indications for device implantation were BTR (1%), BTT (41%), bridge to decision (43%), DT (14%), and rescue therapy (0.5%).[173] However, the percentage of patients receiving a VAD as destination therapy is increasing as results and devices improve. In 2011, 38% of patients had a primary device strategy of DT, whereas only 23% were considered BTT.

Left ventricular assist devices (LVADs) provide support for the failing heart by unloading blood from the left ventricle and pumping it into the aorta. Cannulas may be inserted into the LV apex or the left atrium for inflow into the pump, and return is through an arterial cannula or graft sewn to either the ascending or descending aorta. For right sided devices, inflow drainage is most often from a cannula in the right atrium, and blood is returned through a graft sewn to the pulmonary artery or right ventricular outflow tract.

Left Ventricular Assist Devices. The first generation LVADs were pulsatile devices. They provided adequate support for the heart but were limited by their large size and durability.[174] More recently, continuous-flow LVADs based on rotary pump technology have been introduced. These devices are smaller, quieter, and durable enough for long term support. The two most commonly used devices today are the HeartMate II (Thoratec, Pleasanton, CA) and the HeartWare HVAD (HeartWare, Inc., Framingham, MA) (Fig. 21-12A & B, 21-13A & B). These devices differ in that the HeartMate II is implanted subdiaphragmatically, whereas the smaller HeartWare HVAD is implanted within the pericardium. Frequently used short-term support devices include the Abiomed BVS 5000 (Abiomed, Inc., Danvers, MA) and the CentriMag (Thoratec), which are both extracorporeal pumps, as well as the Impella (Abiomed), which may be inserted percutaneously. These devices are commonly used in either post-MI or postcardiotomy heart failure. They have the benefit of faster and easier insertion, making them ideal rescue devices and allowing time for patient transfer to a tertiary referral center, device weaning, transplantation, or transition to a permanent VAD as DT or BTT.

Bridge to Recovery. The ideal clinical situation would be for all LVADs to be temporary with the goal of myocardial recovery. However, as noted above, this is rare with only 1% of devices in the most recent INTERMACS data placed with intent for bridge to recovery.[175] The LVAD Working Group Recovery Study, a prospective multicenter trial investigating myocardial recovery in BTT patients, has shown significant improvements in left ventricular ejection fraction and significant reductions in left ventricular end-diastolic diameter following support with continuous flow pumps, but myocardial recovery resulting in device explantation was still only seen in six patients (9%).[176] Current data suggest that significant reverse remodeling is more likely to occur in the young and those with myocarditis.[177]

Figure 21-12. The HeartMate II LVAD viewed from the (**A**) outside and (**B**) inside. The device is an axial flow, rotary pump that produces no pulsatile action. The pump contains a magnet, and the rotor assembly functions by the electromotive force generated by the motor. The result is that blood is propelled from the inflow cannula to systemic circulation at flows up to 10 L/min. (Images reprinted with the permission of Thoratec Corporation.)

Nevertheless, some encouraging results have been reported using a combination of treatment modalities. In a few small studies of patients with LVADs inserted for nonischemic cardiomyopathy, deliberate and aggressive medical therapy, including the β2-agonist clenbuterol resulted in successful LVAD explantation in 69% to 73% of patients,[178,179] but these results have been difficult to replicate. Moreover, early results from clinical trials using stem cell therapy to treat patients with ischemic cardiomyopathy suggest that stem cells may be another adjuvant treatment with potential to aid in myocardial recovery.[180,181]

Bridge to Transplant. LVADs are used as a bridge to transplant in patients who are candidates for heart transplantation but are not predicted to survive the waiting list period due to sequelae of cardiac failure, including end-organ dysfunction, rising pulmonary artery pressures, escalating inotrope requirements, malignant ventricular arrhythmias, and risk for sudden death. Due to the scarcity of donor organs, the improved survival seen with LVAD usage has resulted in more patients remaining alive while on the transplantation waiting list. It is currently estimated that 35% of patients who go on to receive a heart transplant have had a previous LVAD implantation, although at more aggressive tertiary care facilities this number may be as high as 75% to 90%.[131]

The HeartMate II pump was evaluated as a BTT in an observational, prospective multicenter trial of 133 patients with persistent NYHA class IV heart failure despite optimal medical management who were status 1A or 1B on the transplant list.[182] At 6 months, 100 patients (75%) had undergone transplantation, had cardiac recovery, or continued on mechanical support while remaining eligible for transplantation. There were significant improvements in both quality of life and functional status with

Figure 21-13. The HeartWare HVAD system. **A.** Both the device controller and batteries are held in a wearable carrying case and connected to the ventricular assist device through the driveline. **B.** The main component is a centrifugal blood pump, called the HVAD, which is implanted within the pericardium. The only moving part in the device, the impeller, is suspended within the pump using magnets and thrust bearings. Similar to the HeartMate II, it can deliver a flow rate of up to 10 L/min. (Images reproduced with permission from HeartWare.)

device therapy. At 3 months, 81% of patients were in class I or II heart failure. Moreover, complications, including bleeding requiring reoperation, stroke, drive-line infection, and need for right ventricular assist device support, were significantly less frequent than with the previous generation HeartMate XVE.[183] These data led to FDA approval of the HeartMate II as a BTT LVAD in 2008, and clinical use of the device increased dramatically. More recently, a multicenter, prospective trial compared the HeartWare HVAD to contemporaneously inserted devices for use as a BTT.[184] This trial demonstrated noninferiority of the HeartWare HVAD, but in contrast to the 2007 trial, approximately 90% of patients in both groups were transplanted, explanted for recovery, or remained alive and eligible for transplant with LVAD support at 6 months. Most important, data suggest that patients bridged to transplant with an LVAD in the current era experience similar short- and long-term post-transplant survival and complications and do not have a higher incidence of allosensitization compared to standard cardiac transplant patients [185,186].

Destination Therapy. The Randomized Evaluation of Mechanical Assistance for Treatment of Congestive Heart Failure (REMATCH) trial was conducted to compare the efficacy of LVAD insertion against optimal medical management in patients with NYHA class IV heart failure. While the pulsatile devices used in this trial had high failure rates, poor durability, and high associated mortality, there was still a clear survival benefit in patients treated with LVADs. This led to the FDA approval of the first LVADs for destination therapy in 2002.[174]

7▶

Subsequent trials have proven the increased efficacy of second generation devices for DT. In one such landmark trial, patients with advanced heart failure who were ineligible for transplantation were randomized in a 2:1 ratio to either a HeartMate II or HeartMate XVE.[187] While both groups showed significant improvements in functional capacity and quality of life, actuarial survival at 2 years was superior for HeartMate II patients (58% vs. 24%, P=0.008) and adverse event rates were significantly lower. These data established the benefit of continuous flow LVADs over optimal medical management for end-stage heart failure, and led to FDA approval of the HeartMate II for DT in 2010. In certain populations, 2-year survival with the HeartMate II is now 80%.[175] Several smaller third generation devices are in various stages of development or clinical trials. Some of these devices eliminate the drive line by using alternative energy sources, thereby removing a significant nidus for device infections. Long-term outcomes with these devices are expected to continue to improve, approaching that of cardiac transplantation and providing a viable solution to organ shortage for many patients.[175]

Current eligibility criteria for mechanical support as destination therapy include: (a) medically refractory NYHA class III or IV heart failure for at least 60 days, (b) peak oxygen consumption <12 ml/kg/min or failure to wean from continuous IV inotropes, (c) left ventricular ejection fraction <25%, and (d) presence of a contraindication for heart transplantation (i.e., age >65 years, irreversible pulmonary hypertension, chronic renal failure, insulin-dependent diabetes with end organ damage, or other clinically significant comorbidities).[131] Once a patient has an LVAD inserted as DT, close and intensive follow-up by a multidisciplinary heart failure team is required in order to optimize medical therapy, reduce device-related morbidity and improve survival.

It is also important to keep in mind that while some contraindications to transplantation are irreversible, others can be modified. As such, approximately 10% of patients implanted with an initial strategy of destination therapy become BTT patients,[131] and in some patients, the LVAD itself facilitates this transition. For example, an improvement in mean pulmonary vascular resistance was reported following implantation of the HeartMate II in patients with end-stage heart failure (2.1 vs. 3.6 Woods units, P<0.001).[188] These data are also relevant to the 43% of patients that receive LVADs as a bridge to decision.

Right Ventricular Assist Devices and Biventricular Assist Devices

Most patients who present with advanced heat failure and a failing left ventricle also have some degree of right-ventricular dysfunction, but the majority of these patients do well with only an LVAD. However, implantation of an LVAD may cause acute worsening of tricuspid regurgitation and exacerbations of right-heart failure through leftward deviation of the intraventricular septum and as a result of the significant volume-loading and transfusion requirement that is often necessary to achieve adequate flows postoperatively. Overall, approximately 20% of HeartMate II BTT patients had persistent right ventricular failure (RVF) requiring either a subsequent RVAD (6%) or intravenous inotropic support for >14 days (14%), and these patients had significantly worsened 6 month survival compared to those without RVF (71% vs. 89%, P<0.001).[189] Typically, mechanical right-ventricular support is temporary with intent to wean the device, and isolated right-ventricular assist devices are unusual.

Biventricular support is most commonly indicated for acute cardiogenic shock after an MI or postcardiotomy heart failure. Biventricular support is temporary, although some patients may be successfully bridged to transplant or permanent left-sided assist devices. There is currently no destination therapy device for biventricular failure.

Total Artificial Heart

The total artificial heart (TAH, SynCardia Systems, Tucson, AZ) is currently indicated as a bridge to transplant for patients in biventricular failure, particularly for those who are critically ill and too large for extracorporeal BiVAD support. Unlike ventricular assist devices, the TAH replaces the entire heart. The ventricles of the TAH are implanted orthotopically to the atrial cuffs on the ventricular side of the AV groove, and the outflow conduits are attached to the great vessels. This approach has the benefit of obviating the hemodynamic influence of pulmonary hypertension, right heart failure, myocardial or valvular problems, cardiac arrhythmias, and inotropic agents.[190] While this device has failed to reach its potential as a replacement for cardiac transplantation, the TAH has achieved favorable results as a BTT with a >70% survival in selected centers.[191-193] However, at most centers results with the TAH have been suboptimal, and it is not frequently used.

SURGERY FOR ARRYHTMIAS

The success of catheter-based ablation and implantable cardioverter defibrillators (ICDs) has significantly diminished referrals for the surgical treatment of arrhythmias such as ventricular tachycardia, Wolff-Parkinson-White syndrome, atrial flutter, and atrioventricular nodal reentry. On the other hand, the introduction of surgical ablation modalities such as radiofrequency and cryothermal energy, has simplified the surgical treatment of atrial fibrillation (AF) and has led to a dramatic increase the in the number of surgical procedures performed annually for AF.[194]

Atrial Fibrillation

Epidemiology of Atrial Fibrillation. Atrial fibrillation remains the most common arrhythmia in the world with an overall incidence of 0.4% to 1% that increases to 8% in those older than 80 years old.[195] The most serious complication of AF is thromboembolism with resultant stroke,[196] but serious morbidity and mortality may also result from hemodynamic compromise due to loss of atrial contraction, exacerbations of congestive heart failure from atrioventricular asynchrony and tachycardia-induced cardiomyopathy.

Medical Management. Most patients are treated medically, but the shortcomings of pharmacological management have left an important role for interventional therapies. Antiarrhythmic medications have been limited by modest efficacies and significant proarrhythmic and systemic toxicities.[197] Conversely, rate control strategies leave the patient in AF, do not address the impaired hemodynamics or symptoms associated with this arrhythmia, and may render subsequent attempts at rhythm control therapies less effective for younger patients that may suffer irreversible cardiac remodeling due to the prolonged period of time in AF.

Restoration of normal sinus rhythm has several potential benefits over other strategies [198-200]. These include improvements in atrial systolic function, which improves cardiac output and often improves symptoms in patients with congestive heart failure; a lower risk of stroke; possible discontinuation of anticoagulation; and the benefit of potentially reversing atrial structural and/or electrical remodeling.

Indications for Surgical Management. Recent consensus guidelines published by the Heart Rhythm Society state that surgical ablation for atrial fibrillation is indicated for: (a) all symptomatic AF patients undergoing other cardiac surgery; (b) selected asymptomatic AF patients undergoing cardiac surgery in which the ablation can be performed with minimal additional risk; and (c) symptomatic patients with lone AF who have failed medical therapy and prefer a surgical approach, have failed one or more attempts at catheter ablation, or are poor candidates for catheter ablation.[195] At our institution, relative indications for surgical ablation in patients with permanent AF that were not included in the consensus statement are: (a) a contraindication to long term anticoagulation for patients at high risk for stroke (CHADS2 score ≥ 2) and (b) a history of stroke while on therapeutic anticoagulation.

The Cox-Maze IV Procedure. The first successful operation for atrial fibrillation, the Cox-Maze procedure, was introduced clinically in 1987 by James Cox. The procedure involved the completion of a maze-like pattern of surgical incisions across both the right and left atrial that were designed to interrupt the multiple macroreentrant circuits that were thought to be responsible for AF, while still allowing propagation of the sinus impulse, restoring atrioventricular synchrony, and preserving atrial transport function. While effective at eliminating AF and reducing the risk of thromboembolism, it was not widely performed due to the fact that it was technically difficult and significantly prolonged time on cardiopulmonary bypass. In 2002, the Cox-Maze IV, was introduced. The Cox-Maze IV uses a combination of bipolar radiofrequency (RF) ablation and cryoablation to effectively replace the majority of incisions that comprise the Cox-Maze III while significantly shortening cross-clamp time and reducing operative complexity.

The Cox-Maze IV is performed on cardiopulmonary bypass through either a median sternotomy, often in combination with other cardiac surgery, or a right minithoracotomy.[201] In most cases, the right atrial lesion set is performed on the beating heart, whereas the left atrial lesions are performed during cardioplegic arrest (Fig. 21-14).

8▶ Results from the Cox-Maze IV procedure have been excellent. A recent, prospective analysis of 100 consecutive lone Cox-Maze IV patients demonstrated postoperative freedom from AF of 93%, 90%, and 90% at 6, 12, and 24 months, respectively, and freedom from AF off antiarrhythmic drugs was 82%, 82%, and 84% at the same intervals.[201] Outcomes are comparable when patients undergo concomitant cardiac surgery,[202] and a propensity analysis has shown that results are similar between the traditional "cut-and-sew" maze and the Cox-Maze IV.[203] This procedure is often successful in patients who are poor candidates for catheter-based ablation, such as those with large left atria and patients with long-standing persistent AF.

The combination of surgical excision of the LAA and restoration of normal sinus rhythm after the Cox-Maze procedure significantly reduces stroke risk. It is our practice to stop warfarin at 3 months postoperatively in patients who are in

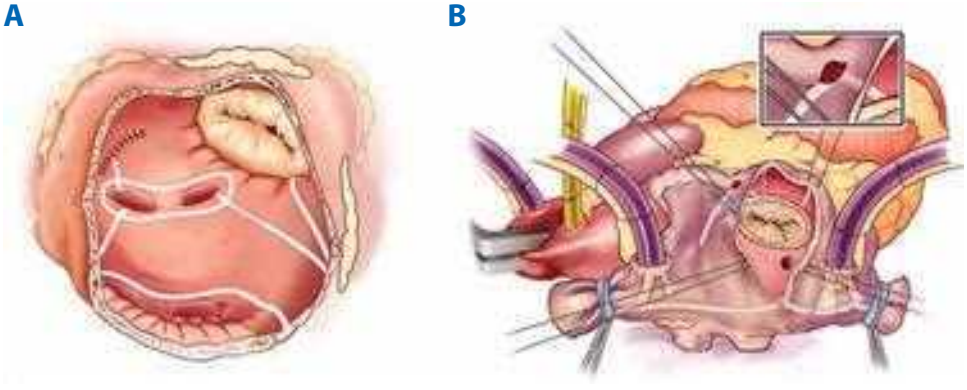

Figure 21-14. The Cox-Maze IV Lesion Set. **A.** The left atrial lesion set is comprised of right and left pulmonary vein isolation, connecting lesions between the left and right superior and inferior pulmonary veins, a lesion from the left atrial appendage excision site to the pulmonary vein and a lesion to the mitral valve annulus. **B.** The right atrial lesion set consists of lines of ablation along the superior and inferior vena cavae, the free wall of the right atrium and down to the tricuspid valve annulus. (From Weimar T, Bailey MS, Watanabe Y, et al. The Cox-Maze IV procedure for lone atrial fibrillation: a single center experience in 100 consecutive patients. *J Interv Card Electrophysiol*. 2011;31: 47-54. With kind permission from Springer Science & Business Media.)

normal sinus rhythm and without another indication for anticoagulation, regardless of CHADS2 score. With this approach, the stroke rate following the Cox-Maze procedure off anticoagulation has been remarkably low (annual risk = 0.2%).[204] In contrast, in one report the annual rate of intracranial hemorrhage in anticoagulated patients with AF was 0.9% per year, and the overall rate of major bleeding complications was 2.3% per year.[205]

Left Atrial Lesion Sets. Some surgeons perform more limited ablation procedures, such as isolated pulmonary vein isolation or lesion sets that are limited to the left side of the heart. This is done in order to further reduce the complexity of the procedure and takes advantage of the fact that in most patients AF originates from the pulmonary veins and posterior left atrium. Although, there is seldom justification for limited lesion sets in experienced hands.

While there is a high degree of variability in both the techniques and energy sources that have been attempted for left-sided atrial lesion sets, these procedures have all incorporated some subset of the left atrial lesion set of the Cox-Maze procedure. Pulmonary vein isolation is ubiquitously performed, and the LAA is often excised. Results differ greatly between series, but a meta-analysis of the published literature by Ad and colleagues revealed that a biatrial lesion set resulted in a significantly higher late freedom from AF compared with a left atrial lesion set alone (87% vs. 73%, $P = 0.05$).[206] These results are not surprising, as our intraoperative mapping experience with such patients showed a distinct region of stable dominant frequency in the left atrium only 30% of the time.[207] The dominant frequency was located in the right atrium 12% of the time and moved during the recording period in almost half of all patients. It must also be kept in mind that recurrent right atrial flutter is a known complication of performing only the left atrial lesions. When it does occur, atrial flutter can be treated with catheter-based ablation; however, recurrent left atrial flutter can be very difficult to ablate.

Pulmonary Vein Isolation. Pulmonary vein isolation (PVI) is an attractive therapeutic option due to the fact that it can be performed off of cardiopulmonary bypass (CPB) through small or thoracoscopic incisions. The results of PVI have been variable and highly dependent on patient selection since outcomes are consistently worse in patients with longstanding persistent AF. In a study from Edgerton et al, only 56% of patients were free from AF at 6 months (35% off antiarrhythmic drugs), and with concomitant procedures, the success rate of PVI has been even lower.[208] Several devices are available to close the LAA at the time of PVI. These include staplers and epicardial clips that can be placed without the need for CPB.

While surgical PVI has had poorer results than a Cox-Maze procedure, it has had superior results to catheter-based PVI. The Atrial Fibrillation Catheter Ablation Versus Surgical Ablation Treatment (FAST) Trial, which was a two center, randomized clinical trial, compared catheter-based ablation to thoracoscopic PVI in patients with antiarrhythmic drug-refractory AF and either left atrial dilatation and hypertension or failed prior catheter-ablation.[209] This study demonstrated that the 12-month freedom from AF and antiarrhythmic drugs was 37% for the catheter ablation group and 66% for the PVI group ($P = 0.0022$).

SURGERY FOR PERICARDIAL DISEASE

Acute Pericarditis

Pericarditis is characterized by infiltration of the cellular and fibrous pericardium by inflammatory cells. The exact incidence and prevalence of pericarditis is unknown, but it is estimated that pericarditis is found in approximately 1% of autopsies and accounts for up to 5% of presentations of nonischemic chest pain.[210,211] The etiologies of acute pericarditis are diverse and may result from primary pericardial disorders or occur secondary to a systemic illness.[212] In developed countries, 80% to 90% of cases are now considered idiopathic or related to a viral pathogen, but nonviral infection, autoimmune diseases, myocardial infarction, radiation, malignancy, endocrinopathy, myocarditis, aortic dissection, uremia, trauma, pharmacological side effects, and previous cardiothoracic surgery must be included in the differential diagnosis. The relative incidences of peri-infarction pericarditis, which was once common, and post-cardiac injury syndrome have been dramatically reduced with the advent of thrombolytics and coronary angioplasty.[212]

Clinical Presentation and Diagnosis. Diagnosis of acute pericarditis typically requires the identification of at least two of four cardinal features (Table 21-16). The presentation may be confused with several more common cardiopulmonary conditions, particularly myocardial infarction, making a careful history and physical critical. Patients with pericarditis classically complain of sudden onset, retrosternal pain that may be pleuritic in nature. The pain may also be positional, with alleviation of pain when the patient is upright and leaning forward. Pain from pericarditis is typically sharp or stabbing, as opposed to the dull pain or pressure that is common with angina, and it typically does not crescendo. While both conditions cause pain that often radiates to the neck, arms, and shoulders, pericarditis pain may uniquely radiate to the trapezius ridge due to innervation from the phrenic nerve.[213,214]

The presence of a pericardial friction rub is pathognomonic for pericarditis, but it tends to vary in intensity over time and may be absent in 15% to 65% of patients.[213,215] As such, the sensitivity of this physical finding is dependent on the frequency and quality of auscultation. A pericardial friction rub is best heard at the left lower sternal border and is typically described as a high-pitched scratchy or squeaky sound with a triphasic cadence corresponding to the movement of the heart during atrial systole, ventricular systole, and early ventricular diastole. However, it may be monophasic or biphasic in up to 50% of patients.

Electrocardiogram (EKG) changes typically progress through four stages representing global subepicardial myocarditis and subsequent recovery. Pericarditis patients may have concave ST deflections with diffuse changes, spanning the leads of multiple coronary artery distributions, but ST segment abnormalities are absent in 20% to 40% of patients.[216,217] Acute pericarditis should not result in the development of infarct patterns, such as Q-waves or loss of R-waves, and T-wave inversions from pericarditis tend to result later in the disease process after the ST segment has returned to baseline.

Table 21-16

Features of acute pericarditis.

- Pleuritic and positional, retrosternal chest pain
- Pericardial friction rub
- EKG changes: diffuse ST elevation and PR depression
- Pericardial effusion

EKG = Electrocardiogram.

Echocardiography is routinely performed in the evaluation of acute pericarditis. Its role is primarily to assess for a pericardial effusion.Although, in a patient who can be demonstrated to have previously had normal cardiac function, it may be used to exclude segmental wall motion abnormalities that may suggest ischemia.

The remaining work-up should attempt to determine the underlying cause of the pericarditis and should be directed by the history and physical. Most inflammatory markers and laboratory tests are nonspecific, but C-reactive protein (CRP) may be useful in predicting recurrence risks and in guiding the duration of anti-inflammatory medications.[218] Rarely, other imaging modalities, such as CT scanning, pericardial biopsies, or pericardiocentesis may aid in diagnosis.

Treatment. The preferred treatment depends on the underlying cause of the pericarditis. The disease usually follows a self-limited and benign course and can be successfully treated with a short course of nonsteroidal anti-inflammatory agents (NSAIDs). Some patients may require judicious use of steroids or IV antibiotics. In cases of purulent pyogenic pericarditis, surgical exploration and drainage are occasionally necessary. Rarely, accumulation of fluid in the pericardium may lead to tamponade, requiring prompt evacuation of the pericardial space. While pericardiocentesis will typically suffice, surgical drainage may be required for thick, viscous, or clotted fluid or in patients with significant scarring from previous surgeries. More commonly, surgical intervention is required to manage recurrent disease.

9▶

Relapsing Pericarditis

As many as one-third of patients with acute pericarditis will develop at least one episode of relapse.[212] While many of these patients can be treated medically during their initial relapse and do not experience further episodes, a subset of patients experience chronic relapsing pericarditis that can significantly impact their quality of life. Recurrence may develop either from the original etiology or from an autoimmune process that occurs as a consequence of damage from the initial episode. Relapsing pericarditis normally responds to a longer course of NSAIDS ± colchicine. While steroids may induce rapid symptomatic response, their use should be limited to patients who have multiple relapses and are unresponsive to first-line agents, as several studies have suggested that steroid administration may favor relapse.[219]

Pericardiectomy may be considered a last resort treatment in patients with relapsing pericarditis who are severely symptomatic despite optimal medical management, are unable to tolerate steroids or have recurrence with tamponade. Evidence for this approach is lacking, as few studies have described pericardiectomy in this population.[220-222] The largest study and the only one to compare surgical treatment with medical management for patients with persistent relapsing pericarditis was a report of 184 patients from the Mayo Clinic.[221] About 58 patients were identified as having undergone a pericardiectomy after failed medical treatment, whereas the remainder were treated with medical management only. Compared to medical treatment only, pericardiectomy resulted in significantly fewer relapses (8.6% vs. 28.6%, $P = 0.009$) at long term follow-up, as well as a nonsignificant trend towards less medication and corticosteroid usage. Of note, 80% of patients in the pericardiectomy group who had relapses reported significant improvements in their symptoms and had fewer relapses than before pericardiectomy. No perioperative deaths were observed, and only 2 patients (3%) had major complications. Hence, at experienced centers pericardiectomy may be a safe and viable option in select patients with relapsing pericarditis.

Chronic Constrictive Pericarditis

Etiology, Pathology, and Pathophysiology. Constrictive pericarditis can occur after any pericardial disease process but remains a rare outcome of recurrent pericarditis. It results when chronic pericardial scarring and fibrosis cause adhesion of the visceral and parietal layers and resultant obliteration of the pericardial space. While the pericardium is often grossly thickened with either focal or diffuse calcification in chronic disease, constriction may occur with normal pericardial thickness in approximately 20% of cases.[212,223] In developed nations, idiopathic causes and cardiac surgery (accounting for almost 40% of cases in some series) are the predominant underlying etiologies, followed by mediastinal radiation, pyogenic infections (i.e., Staphylococcus), and other miscellaneous causes. Tuberculosis is an additional common cause in immunosuppressed patients and in developing or underdeveloped countries.

Clinically, pericardial constriction limits diastolic filling of the ventricles and mimics right heart failure since the right-sided chambers are more affected by a rise in filling pressures. Subsequent increases in central venous pressure result in the progressive development of hepatomegaly, ascites, peripheral edema, abdominal pain, dyspnea on exertion, anorexia, and nausea (in part due to hepatic and bowel congestion). In many patients, these symptoms develop insidiously over a course of years. Since many of these symptoms are similar to those seen in patients with restrictive cardiomyopathy, the distinction between the two entities is difficult, but it remains critical because the treatment is completely different for restriction. The primary difference is that restrictive cardiomyopathy is defined by a nondilated ventricle with a rigid myocardium that causes a significant decrease in myocardial compliance, which is not seen in constrictive pericarditis.

Clinical and Diagnostic Findings. Classic physical exam findings include jugular venous distention with Kussmaul's sign, diminished cardiac apical impulses, peripheral edema, ascites, pulsatile liver, a pericardial knock, and, in advanced disease, signs of liver dysfunction, such as jaundice or cachexia. The "pericardial knock" is an early diastolic sound that reflects a sudden impediment to ventricular filling, similar to an S3 but of higher pitch.

Several findings are characteristic on noninvasive and invasive testing. CVP is often elevated 15 to 20 mm Hg or higher. EKG commonly demonstrates nonspecific low voltage QRS complexes and isolated repolarization abnormalities. Chest X-ray may demonstrate calcification of the pericardium, which is highly suggestive of constrictive pericarditis in patients with heart failure, but this is present in only 25% of cases.[219] Cardiac CT or MRI (cMRI) typically demonstrate increased pericardial thickness (>4 mm) and calcification, dilation of the inferior vena cava, deformed ventricular contours, and flattening or leftward shift of the ventricular septum. Pericardial adhesions may also be seen on tagged cine MRI studies.

As discussed, it is most important to distinguish pericardial constriction from restrictive cardiomyopathy, which is best done with either echocardiography or right heart catheterization. Findings favoring constriction on echocardiography include respiratory variation of ventricular septal motion and

mitral inflow velocity, preserved or increased mitral annulus early diastolic filling velocity, and increased hepatic vein flow reversal with expiration.[212,219] Cardiac catheterization will show increased atrial pressures, equalization of end-diastolic pressure and early ventricular diastolic filling with a subsequent plateau, called the "*square-root sign*." Additional findings upon catheterization that would favor constriction include respiratory variation in ventricular filling and increased ventricular interdependence, manifest as a discordant change in the total area of the LV and RV systolic pressure curve with respiration.

Surgical Treatment. Transient constrictive pericarditis may occur weeks to months after an initial injury and follows a self-limiting course of weeks to a few months. These patients are best treated with medical therapy alone. They often lack calcification of their pericardium, and the degree of late gadolinium enhancement of the pericardium on cardiac MRI has shown promise in predicting which patients may have resolution of the process.[224] Still, there is no ideal way to distinguish these patients from those who will develop chronic constrictive pericarditis, which is permanent. Therefore, if a newly diagnosed patient is hemodynamically stable, it is recommended that conservative management is attempted for two to three months prior to performing a pericardiectomy.[223] Surgical therapy should not be delayed indefinitely, however, as results are improved when the operation is performed earlier in the course of the disease. Additional factors that predict adverse long-term outcomes include older age and prior ionizing radiation, as well as cardiopulmonary and renal dysfunction.[219] Surgery should therefore be approached cautiously in patients with very advanced, "end-stage" constrictive pericarditis, patients with mixed constrictive-restrictive disease (often from radiation), and those with significant myocardial or renal dysfunction, as those patients are at increased risk from surgery and may not experience improvement of symptoms.

In order to minimize recurrence following pericardiectomy, complete pericardial resection is desirable. This is typically performed through either a median sternotomy or left anterolateral thoracotomy while on cardiopulmonary bypass. Radical pericardiectomy involves wide resection of the constricting pericardium from the anterior surface of the heart between the phrenic nerves and the diaphragmatic surface. Decortication of the right atrium and vena cavae is not universally performed, but doing so improves the risk of persistent disease or relapse.[225,226]

The extent of myocardial involvement may also affect long-term outcomes, and, thus, the depth of decortication is an important consideration.[225] Even when an adequate pericardiectomy is performed, epicardial sclerosis can cause persistent hemodynamic instability or a delayed response to surgery. Sclerotic epicardium is often thin and nearly transparent, but in cases of severe chronic constrictive pericarditis it can be difficult to remove it without injury to the heart.

Surgical Results. While most patients experience significant improvement in their symptoms following pericardiectomy, symptomatic relief may take several months. Since there is a significant perioperative morbidity and mortality, pericardiectomy is best performed by experienced surgeons at high-volume centers. Between 1970 and 1985, the operative mortality was reported to be 12%, but a lower mortality of approximately 4% to 8% was noted between 1977 and 2006 at several experienced centers.[223,226-230]

Long-term survival is in part determined by etiology of the disease. In a report from the Cleveland Clinic, seven-year survival rates following pericardiectomy for idiopathic, postsurgical, and radiation-induced constrictive pericarditis were 88%, 66%, and 27%, respectively.[227] Results are worst for radiation-induced disease because ionizing radiation is often associated with myocardial injury as well as pericardial disease.

Despite the risks, many patients experience significant benefits from surgical treatment. In one large series, 83% of patients were reported to be free of symptoms at last follow-up.[230] This is in agreement with other studies that have shown a significant improvement in NYHA functional status from class III/IV preoperatively to class I/II following pericardiectomy in >95% of patients.[226,228-230]

CARDIAC NEOPLASMS

Overview and General Clinical Features

Cardiac neoplasms are rare, with an incidence ranging from 0.001% to 0.3% in autopsy studies and a 0.15% incidence in major echocardiographic series.[231,232] Benign cardiac tumors are most common and account for 75% of primary neoplasms. Approximately 50% of benign cardiac tumors are myxomas, with the remainder being papillary fibroelastomas, lipomas, rhabdomyomas, fibromas, hemangiomas, teratomas, lymphangiomas, and others, in order of decreasing frequency. Most malignant primary cardiac tumors are sarcomas (angiosarcoma, rhabdomyosarcoma, fibrosarcoma, leiomyosarcoma, and liposarcoma), with a small incidence of malignant lymphomas. Metastatic cardiac tumors, while still infrequent, have been reported to occur 100-fold more often than primary lesions.

Clinical Presentation. The clinical presentation of cardiac neoplasms varies greatly depending on the location of the tumor, as well as its size, rate of growth, invasiveness, and friability. While as many as 10% of patients are asymptomatic, most manifest some combination of symptoms from the classic triad resulting from blood flow obstruction, tumor embolization, and constitutional symptoms.[233,234] Systemic manifestations of disease include fever, myalgias, chills, night sweats, weight loss, and fatigue and occur in up to one-third of patients.

Obstruction of cardiac blood flow accounts for the majority of presenting symptoms.[234] When the tumor is located in the left atrium, symptoms tend to mimic mitral valve disease with dyspnea and pulmonary edema; although more severe presentations with syncopal episodes, hypotension, and sudden cardiac death have been reported from temporary valve orifice occlusion. When the tumor is located in the right atrium, symptoms may mimic right heart failure and include hepatomegaly, ascites, and peripheral edema. Outflow tract obstruction is rare but may be caused by large ventricular tumors.[235]

Tumor lysis and embolization may also lead to neurologic presentations such as stroke, retinal artery occlusion, or cerebral aneurysms, particularly in the case of pedunculated tumors and those with frond-like projections.[236] Embolic tumor cells are able to lodge and penetrate distant vessel walls via subintimal growth, which leads to weakening of the arterial wall and subsequent aneurysm formation. This has been documented as late as five years out from successful primary myxoma resection.[237] Alternatively, embolic implants may metastasize and create space occupying lesions. While rare, myxomatous tumor emboli have also been identified in the coronary arteries, common iliac and femoral arteries, kidney, spleen, pancreas, and liver.[236]

Certain clinical features may be helpful in distinguishing benign from malignant primary cardiac tumors[234] Malignant tumors, primarily sarcomas, do not demonstrate a gender preference and tend to present after the fourth decade of life. They are often multifocal within the right atrium, and intramyocardial invasion can lead to refractory congestive heart failure, arrhythmias, hemopericardium, and ischemia. Conversely, benign tumors, primarily myxomas, are typically unifocal in the left atrium, have a 3:1 female preference, and occur in younger patients. Arrhythmias and pericardial effusions are very rare in this population.

Diagnosis and Characterization of Cardiac Masses. Transthoracic echocardiography is the mainstay imaging technique for the detection of cardiac tumors.[234] However, echocardiography is limited by dependence on an acoustic window, suboptimal visualization of extracardiac extension, and poor soft-tissue visualization. Transesophageal echocardiography is generally only beneficial for small localized tumors due to its limited field of view. Cardiac MRI is therefore the current standard for delineating the anatomical extent of the tumor and assessing the paracardiac space and great vessels. Advantages of cMRI over CT scans include better soft-tissue evaluation without the need for iodinated contrast and no exposure to ionizing radiation.

It is important in the initial workup to distinguish a cardiac tumor from an intracardiac thrombus, which may be common in the atria of patients with AF and can mimic echocardiographic features of atrial myxomas. This determination is critical, as an atrial thrombus may be expected to resolve with anticoagulation, whereas a tumor requires surgical intervention. Moreover, anticoagulation can potentially increase the risk of peripheral embolization in patients with cardiac tumors. Delayed enhancement cMRI is the best modality to separate these two entities. cMRI may show vascularization, areas of necrosis, hemorrhage, or calcification in cardiac tumors that are not present in thrombi.

Myxoma

Pathology and Genetics. Cardiac myxomas are the most common cardiac tumor and are characterized by several distinguishing features. About 75% of the time, they arise from the interatrial septum near the fossa ovalis in the left atrium.[238] Most others will develop in the right atrium, but, less commonly, they can arise from valvular surfaces and the walls of other cardiac chambers. Macroscopically, these tumors are pedunculated with a gelatinous consistency, and the surface may be smooth (65%), villous, or friable.[233] Size varies greatly with these tumors and ranges from 1 to 15 cm in diameter. Internally, myxomas are heterogeneous and often contain hemorrhage, cysts, necrosis, or calcification. Histologically, these tumors contain cells that arise from a multipotent mesenchyme and are contained within a mucopolysaccharide stroma.[239]

10▸

While the majority of myxomas occur spontaneously with the highest incidence in women aged 40 to 60 years old, approximately 7% of cases are familial as part of Carney complex.[233] Carney complex is an autosomal dominant disorder characterized by two or more of the following conditions: atrial and extracardiac myxomas, schwannomas, cutaneous lentiginosis, spotty pigmentation, myxoid fibroadenomas of the breast, endocrine overactivity (pituitary adenomas or primary adrenal hyperplasia with Cushing's syndrome), and testicular tumors. Compared to sporadic myxomas, those that occur as part of Carney complex are more commonly found in the right atrium (37% vs. 18%) or one of the ventricles (25% vs. 0%), more often multicentric (33% vs. 6%) and more likely to recur (20% vs. 3%).[238] They also present earlier at an average age of 24 years old (range 4–48 years).

Pathophysiology. Larger tumors are more likely to be associated with cardiovascular symptoms from obstruction, and embolic symptoms tend to occur from organized thrombi present on friable or villous tumors (Fig. 21-15). The relative frequencies of symptoms was illustrated by a series of 112 patients who reported cardiovascular symptoms (67%), most commonly resembling mitral valve obstruction; systemic embolization (29%); neurologic deficits (20%); and constitutional symptoms (34%).[233] Similar incidences of symptoms have been reported in other large studies.

Treatment. Cardiac myxomas should be promptly excised after diagnosis due to the significant risk of embolization and cardiovascular complications, including sudden death. Resection may be performed through either a median sternotomy or a minimally invasive right thoracotomy while on cardiopulmonary bypass. Care is taken not to manipulate the tumor before cross clamping of the aorta in order to avoid embolization. Left atrial tumors may be approached through a standard left atriotomy.[240] Exposure of large tumors attached to the interatrial septum may be facilitated by an additional parallel incision in the right atrium, but this is rarely necessary. An ideal resection encompasses both the tumor and a portion of the cardiac wall or interatrial septum to which it is attached. In order to prevent recurrence, a full thickness excision of the attachment site is

Figure 21-15. Massive left atrial myxoma. **A.** Intraoperative echocardiogram of a large left atrial mass, diagnosed preoperatively as a left atrial myxoma. The mass can be seen prolapsing through the mitral valve orifice causing intermittent symptoms of mitral stenosis. **B.** The resected specimen. The neck of the mass that was obstructing the mitral orifice is clearly delineated.

preferred, but partial thickness excisions and cryoablation of the base have been performed with good late results.[240] The defect created in the atrial septum can either be repaired primarily or with a small patch. Finally, patients with valvular involvement may require additional valvular reconstruction or replacement, and rare cases of cardiac autotransplantation (with atrial reconstruction) or transplantation have been reported as strategies for complex cases of recurrent atrial myxoma.[241,242]

Short- and long-term results following excision are excellent for benign cardiac myxomas. Operative mortality is low, and the probability of disease-free survival at 20 years has been reported to be as high as 92% for benign, sporadic myxomas.[233,240] Risk of recurrence is significantly higher for familial cases.

Other Benign Cardiac Tumors

There are several benign cardiac tumors apart from myxomas that are infrequent but have distinct pathophysiologic features.[234] Papillary fibroelastomas are the second most common primary cardiac tumor, representing approximately 8% of all cases. These tumors typically occur in more elderly patients; are small (<1 cm in diameter) sessile, pedunculated masses that arise from the mitral or aortic valves; and frequently result in embolization. Fibroelastomas can almost always be resected with preservation of the native valve leaflets, and cryoablation of the valve leaflet after resection can help prevent recurrence. Lipomas are encapsulated tumors that usually arise from the epicardium and remain asymptomatic in most patients. Hemangiomas, which may arise from any cardiac structure, including the pericardium, account for 2% of benign cardiac tumors, and atrioventricular node tumors, which often lead to sudden cardiac death from heart block and ventricular fibrillation, are exceedingly rare.

In children, rhabdomyomas are the most common primary cardiac tumor, whereas fibromas are the most commonly resected cardiac tumor. Rhabdomyomas are myocardial hamartomas that are often multicentric in the ventricles. About 50% of cases are associated with tuberous sclerosis, and while resection is occasionally necessary, most disappear spontaneously. Fibromas are congenital lesions that one-third of the time are found in children younger than one-year old. These tumors, conversely, are ordinarily solitary lesions found in the inner interventricular septum, and they may present with heart failure, cyanosis, arrhythmias, syncopal episodes, chest pain, or sudden cardiac death.

Malignant Cardiac Tumors

Primary cardiac malignancies are very rare, but when they occur they tend to have a right-sided predominance and frequently demonstrate extracardiac extension and involvement.[234,243] Malignant cardiac tumors include angiosarcoma, osteosarcoma, leiomyosarcoma, rhabdomyosarcoma, liposarcoma, and primary cardiac lymphomas. Angiosarcomas are aggressive, rapidly invading adjacent structures, and 47% to 89% of patients present with lung, liver, or brain metastases by the time of diagnosis. Leiomyosarcomas are sessile masses with a mucous appearance that are typically found in the posterior wall of the left atrium. Rhabdomyosarcomas are bulky (>10 cm in diameter) tumors that usually occur in children and do not have a predilection for any particular chamber. They frequently invade nearby cardiac structures and are multicentric in 60% of cases. Finally, while not as frequent as secondary cardiac lymphomas, primary cardiac lymphomas are increasing in frequency due to lymphoproliferative disorders caused by Epstein-Barr virus in immunosuppressed patients. The absence of necrotic foci in lymphomas can be used to differentiate these tumors from cardiac sarcomas.

Metastatic Cardiac Tumors

Cardiac metastases have been found in approximately 10% of autopsies performed for malignant disease.[234] Secondary cardiac tumors, unlike primary tumors, are therefore relatively common. They may arise from direct extension of mediastinal tumors, hematological spread, intracavitary extension from the inferior vena cava or lymphatic extension, although the latter is the most common mechanism.

While they can occur with most any primary tumor, they are generally observed late in the course of disease. Malignant melanomas have a high potential for cardiac involvement, but other soft tissue tumors such as lung cancer, breast cancer, sarcomas, renal carcinoma, esophageal cancer, hepatocellular carcinoma, and thyroid cancer may all progress to cardiac involvement. Cardiac metastases may also develop from leukemia and lymphoma in 25% to 40% of cases.[244]

Metastatic cardiac tumors are typically found in random locations, excluding the valvular tissue where lymphatics are absent, and they may be multifocal or diffusely extend along the epicardial surface. Signs of malignant cardiac involvement in cancer patients include pericardial effusion or tamponade, tachyarrhythmias, and heart failure symptoms. Workup is similar to other cardiac tumors. Treatment is generally with combined chemotherapy and radiation and is rarely effective.

chapter 22

Thoracic Aneurysms and Aortic Dissection

Scott A. LeMaire, Raja R. Gopaldas, and Joseph S. Coselli

ANATOMY OF THE AORTA

The aorta consists of two major segments—the proximal aorta and the distal aorta—whose anatomic characteristics affect both the clinical manifestations of disease in these segments and the selection of treatment strategies for such disease (Fig. 22-1). The proximal aortic segment includes the ascending aorta and the transverse aortic arch. The ascending aorta begins at the aortic valve and ends at the origin of the innominate artery. The first portion of the ascending aorta is the aortic root, which includes the aortic valve annulus and the three sinuses of Valsalva; the coronary arteries originate from two of these sinuses. The aortic root joins the tubular portion of the ascending aorta at the sinotubular ridge. The transverse aortic arch is the area from which the brachiocephalic branches arise. The distal aortic segment includes the descending thoracic aorta and the abdominal aorta. The descending thoracic aorta begins distal to the origin of the left subclavian artery and extends to the diaphragmatic hiatus, where it joins the abdominal aorta. The descending thoracic aorta gives rise to multiple bronchial and esophageal branches, as well as to the segmental intercostal arteries, which provide circulation to the spinal cord.

The volume of blood that flows through the thoracic aorta at high pressure is far greater than that found in any other vascular structure. For this reason, any condition that disrupts the integrity of the thoracic aorta, such as aortic dissection, aneurysm rupture, or traumatic injury, can have catastrophic consequences.

Historically, open surgical repair of such conditions has been an intimidating undertaking associated with significant morbidity and mortality. Strategies for protecting the brain and spinal cord during such repairs have become critical in preventing devastating complications. In recent years, endovascular therapy for thoracic aortic disease in selected patients has become accepted practice, producing fewer adverse outcomes than traditional approaches do.

THORACIC AORTIC ANEURYSMS

Aortic aneurysm is defined as a permanent, localized dilatation of the aorta to a diameter that is at least 50% greater than is normal at that anatomic level.[1] The annual incidence of thoracic aortic aneurysms is estimated to be 5.9 per 100,000 persons.[2] The clinical manifestations, methods of treatment, and treatment results in patients with aortic aneurysms vary according to the cause and the aortic segment involved. Causes of thoracic aortic aneurysms include degenerative disease of the aortic wall, aortic dissection, aortitis, infection, and trauma. Aneurysms can be localized to a single aortic segment, or they can involve multiple segments. Thoracoabdominal aortic aneurysms, for example, involve both the descending thoracic aorta and the abdominal aorta. In the most extreme cases, the entire aorta is aneurysmal; this condition is often called *mega-aorta*.

Aortic aneurysms can be either "true" or "false." True aneurysms can take two forms: fusiform and saccular. Fusiform aneurysms are more common and can be described as symmetrical dilatations of the aorta. Saccular aneurysms are localized outpouchings of the aorta. False aneurysms, also called *pseudoaneurysms*, are leaks in the aortic wall that are contained by the outer layer of the aorta and/or the periaortic tissue; they are caused by disruption of the aortic wall and lead blood to collect in pouches of fibrotic tissue.

Aneurysms of the thoracic aorta consistently increase in size and eventually progress to cause serious complications. These include rupture, which is usually a fatal event. Therefore, aggressive treatment is indicated in all but the poorest surgical candidates. Small, asymptomatic thoracic aortic aneurysms can be followed, especially in high-surgical-risk patients, and can be treated surgically later if symptoms or complications develop, or if progressive enlargement occurs. Meticulous control of hypertension is the primary medical treatment for patients with small, asymptomatic aneurysms.

Key Points

1. Assessing urgency of repair is essential to developing the appropriate management plan. Although emergent repair carries greater operative risk than does elective repair, any inappropriate delay of repair risks death.
2. The clinical progression of an aortic aneurysm is continued expansion and eventual rupture. Hence, regular noninvasive imaging studies, as part of a lifelong surveillance plan, are necessary to ensure long-term patient health. Even small asymptomatic aneurysms should be routinely imaged to assess overall growth and yearly rate of expansion.
3. Endovascular repair devices are approved for the treatment of descending thoracic aortic aneurysms, and some of the newer devices are also approved for the treatment of aortic trauma and penetrating aortic ulcer.
4. Practice guidelines were recently published that have helped to standardize the decision-making process and select an appropriate surgical intervention, as well as to standardize the use of imaging studies for patients with thoracic aortic disease.
5. Ascending aortic aneurysms that are symptomatic or >5.5 cm should be repaired. This threshold is lowered for patients with connective tissue disorders.
6. Surgical repair involves the development of a patient-tailored plan based on careful preoperative medical evaluation. When appropriate, optimizing a patient's health status—to mitigate existing comorbidities—is important before surgical intervention.
7. The development and use of surgical adjuncts like antegrade selective cerebral perfusion and cerebrospinal fluid drainage have significantly reduced the morbidity rates traditionally associated with complex aortic repair.
8. Proximal aortic dissection is a life-threatening condition, and immediate operative repair is generally indicated, although definitive aortic repair may be delayed until after severe malperfusion has been treated.

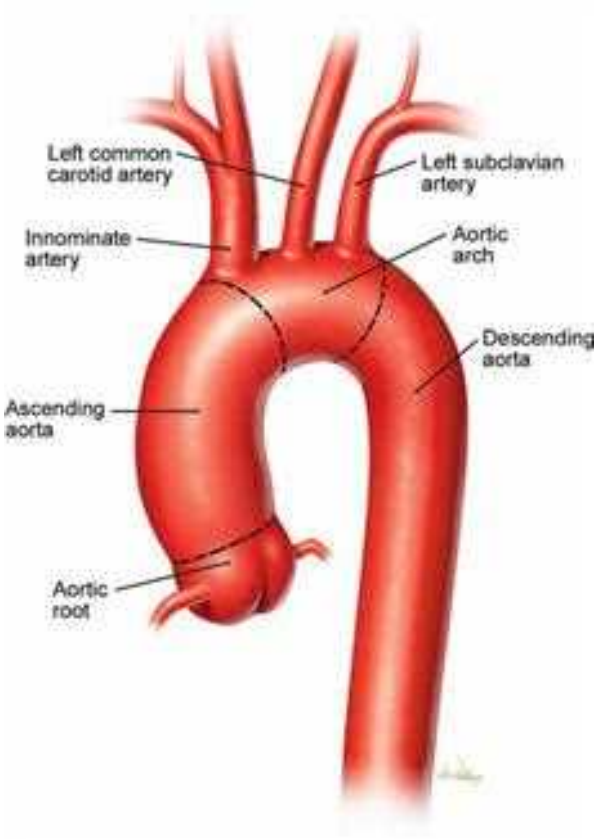

Figure 22-1. Illustration of normal thoracic aortic anatomy. The brachiocephalic vessels arise from the transverse aortic arch and are used as anatomic landmarks to define the aortic regions. The ascending aorta is proximal to the innominate artery, whereas the descending aorta is distal to the left subclavian artery.

Elective resection with graft replacement is indicated in asymptomatic patients with an aortic diameter of at least twice normal in the involved segment (5–6 cm in most thoracic segments). Elective repair is contraindicated by extreme operative risk due to severe coexisting cardiac or pulmonary disease and by other conditions that limit life expectancy, such as malignancy. An emergency operation is performed for any patient in whom a ruptured aneurysm is suspected.

Patients with thoracic aortic aneurysm often have coexisting aneurysms of other aortic segments. A common cause of death after repair of a thoracic aortic aneurysm is rupture of a different aortic aneurysm. Therefore, staged repair of multiple aortic segments often is necessary. As with any major operation, careful preoperative evaluation for coexisting disease and subsequent medical optimization are important for successful surgical treatment.

An alternative to traditional open repair of a descending thoracic aortic aneurysm is endovascular stent grafting. Certain anatomic criteria need to be satisfied for this treatment option to be considered, including the presence of at least a 2-cm landing zone of healthy aortic tissue proximally and distally to the aneurysm to be excluded. Although data on long-term outcomes are still lacking, endovascular repair of a descending thoracic aortic aneurysm has become an accepted practice that produces excellent midterm results.

Causes and Pathogenesis

General Considerations. The normal aorta derives its elasticity and tensile strength from the medial layer, which contains approximately 45 to 55 lamellae of elastin, collagen, smooth muscle cells, and ground substance. Elastin content is highest within the ascending aorta, as would be expected because of its compliant nature, and decreases distally into the descending and abdominal aorta. Maintenance of the aortic matrix involves complex interactions among smooth muscle cells, macrophages, proteases, and protease inhibitors. Any alteration in this delicate balance can lead to aortic disease.

Thoracic aortic aneurysms have a variety of causes (Table 22-1). Although these disparate pathologic processes differ in biochemical and histologic terms, they share the final common pathway of progressive aortic expansion and eventual rupture.

Hemodynamic factors clearly contribute to the process of aortic dilatation. The vicious cycle of increasing diameter and increasing wall tension, as characterized by Laplace's law

Table 22-1

Causes of thoracic aortic aneurysms

Nonspecific medial degeneration
Aortic dissection
Genetic disorders
Marfan syndrome
Loeys-Dietz syndrome
Ehlers-Danlos syndrome
Familial aortic aneurysms
Aneurysms-Osteoarthritis syndrome
Congenital bicuspid aortic valve
Bovine aortic arch
Poststenotic dilatation
Infection
Aortitis
Takayasu arteritis
Giant cell arteritis
Rheumatoid aortitis
Trauma

(tension = pressure × radius), is well established. Turbulent blood flow is also recognized as a factor. Poststenotic aortic dilatation, for example, occurs in some patients with aortic valve stenosis or coarctation of the descending thoracic aorta. Hemodynamic derangements, however, are only one piece of a complex puzzle.

Atherosclerosis is commonly cited as a cause of thoracic aortic aneurysms. However, although atherosclerotic disease often is found in conjunction with aortic aneurysms, the notion that atherosclerosis is a distinct cause of aneurysm formation has been challenged. In most thoracic aortic aneurysms, atherosclerosis appears to be a coexisting process, rather than the underlying cause.

Research into the pathogenesis of abdominal aortic aneurysms has focused on the molecular mechanisms of aortic wall degeneration and dilatation. For example, imbalances between proteolytic enzymes (e.g., matrix metalloproteinases) and their inhibitors contribute to abdominal aortic aneurysm formation. Building on these advances, current investigations are attempting to determine whether similar inflammatory and proteolytic mechanisms are involved in thoracic aortic disease, in hope of identifying potential molecular targets for pharmacologic therapy.

Nonspecific Medial Degeneration. Nonspecific medial degeneration is the most common cause of thoracic aortic disease. Histologic findings of mild medial degeneration, including fragmentation of elastic fibers and loss of smooth muscle cells, are expected in the aging aorta. However, an advanced, accelerated form of medial degeneration leads to progressive weakening of the aortic wall, aneurysm formation, and eventual dissection, rupture, or both. The underlying causes of medial degenerative disease remain unknown.

Aortic Dissection. An aortic dissection usually begins as a tear in the inner aortic wall, which initiates a progressive separation of the medial layers and creates two channels within the aorta. This event profoundly weakens the outer wall. As the most common catastrophe involving the aorta, dissection represents a major, distinct cause of thoracic aortic aneurysms and is discussed in detail in the second half of this chapter.

Genetic Disorders.

Marfan Syndrome Marfan syndrome is an autosomal dominant genetic disorder characterized by a specific connective tissue defect that leads to aneurysm formation. The phenotype of patients with Marfan syndrome typically includes a tall stature, high palate, joint hypermobility, eye lens disorders, mitral valve prolapse, and aortic aneurysms. The aortic wall is weakened by fragmentation of elastic fibers and deposition of extensive amounts of mucopolysaccharides (a process previously called *cystic medial degeneration* or *cystic medial necrosis*). Patients with Marfan syndrome have a mutation in the fibrillin gene located on the long arm of chromosome 15. The traditionally held view is that abnormal fibrillin in the extracellular matrix decreases connective tissue strength in the aortic wall and produces abnormal elasticity, which predisposes the aorta to dilatation from wall tension caused by left ventricular ejection impulses.[3] More recent evidence, however, shows that the abnormal fibrillin causes degeneration of the aortic wall matrix by increasing the activity of transforming growth factor beta (TGF-β).[4] Between 75% and 85% of patients with Marfan syndrome have dilatation of the ascending aorta and annuloaortic ectasia (dilatation of the aortic sinuses and annulus).[5] Such aortic abnormalities are the most common cause of death among patients with Marfan syndrome.[6] Marfan syndrome also is frequently associated with aortic dissection.

Loeys-Dietz Syndrome Loeys-Dietz syndrome is phenotypically distinct from Marfan syndrome. It is characterized as an aneurysmal syndrome with widespread systemic involvement. Loeys-Dietz syndrome is an aggressive, autosomal dominant condition that is distinguished by the triad of arterial tortuosity and aneurysms, hypertelorism (widely spaced eyes), and bifid uvula or cleft palate. It is caused by heterozygous mutations in the genes encoding TGF-β receptors.[7,8] Patients with Loeys-Dietz syndrome—including young children—are at increased risk of aortic rupture and aortic dissection; diameter-based thresholds of repair tend to be lower for patients with this syndrome than for patients with other connective tissue disorders.

Ehlers-Danlos Syndrome Ehlers-Danlos syndrome includes a spectrum of inherited connective tissue disorders of collagen synthesis. The subtypes represent differing defective steps of collagen production. Vascular type Ehlers-Danlos syndrome is characterized by an autosomal dominant defect in type III collagen synthesis, which can have life-threatening cardiovascular manifestations. Spontaneous arterial rupture, usually involving the mesenteric vessels, is the most common cause of death in these patients. Thoracic aortic aneurysms and dissections are less commonly associated with Ehlers-Danlos syndrome, but when they do occur, they pose a particularly challenging surgical problem because of the reduced integrity of the aortic tissue.[9] An Ehlers-Danlos variant of periventricular heterotopia associated with joint and skin hyperextensibility and aortic dilation has been described as being caused by mutations in the gene encoding filamin A (*FLNA*), an actin-binding protein that links the smooth muscle cell contractile unit to the cell surface.[10]

Familial Aortic Aneurysms Families without the heritable connective tissue disorders described earlier also can be affected by genetic conditions that cause thoracic aortic aneurysms. In fact, it is estimated that at least 20% of patients with thoracic aortic aneurysms and dissections have a genetic predisposition to them. The involved mutations are characterized by autosomal dominant inheritance with decreased penetrance and variable expression. Thus far, mutations involving the genes for TGF-β receptors (*TGFβR1* and *TGFβR2*), TGF-β2, β-myosin (*MYH11* and *MYLK*), and α-smooth muscle cell actin (*ACTA2*)

have been identified as causes of familial thoracic aortic aneurysms and dissection.[11-13] *ACTA2* mutations are present in approximately 14% of families with familial thoracic aortic aneurysms and dissections.

Aneurysms-Osteoarthritis Syndrome Aneurysms-osteoarthritis syndrome is a recently identified autosomal dominant disorder. Patients with this syndrome suffer from aortic and arterial aneurysms, arterial tortuosity, aortic dissection, mild craniofacial abnormalities, and early onset osteoarthritis. Aneurysms-osteoarthritis syndrome is caused by mutations in the gene encoding SMAD3, a transcription factor for TGF-β. Affected patients have a high incidence of aortic dissection, which often occurs in a mildly dilated aorta (4–4.5 cm) and causes sudden death.[14]

Congenital Bicuspid Aortic Valve Bicuspid aortic valve is the most common congenital malformation of the heart or great vessels, affecting up to 2% of Americans.[15] Compared to patients with a normal, trileaflet aortic valve, patients with bicuspid aortic valve have an increased incidence of ascending aortic aneurysm formation and, often, a faster rate of aortic enlargement.[16] The location of the fused leaflet, or raphe, may be predictive of aortic dilation and other abnormalities.[17] About 50% to 70% of adults with bicuspid aortic valve, but without significant valve dysfunction, have echocardiographically detectable aortic dilatation.[18,19] This dilatation usually is limited to the ascending aorta and root.[20] Dilation occasionally is found in the arch and only rarely in the descending or abdominal aorta. In addition, aortic dissection occurs 10 times more often in patients with bicuspid valves than in the general population.[21] Recent findings suggest that aneurysms associated with bicuspid aortic valve have a fundamentally different pathobiologic cause than aneurysms that occur in patients with trileaflet valves.[22]

Although the exact mechanism responsible for aneurysm formation in patients with bicuspid aortic valve remains unclear, evidence suggests that these patients have a congenital connective tissue abnormality that predisposes the aorta to medial degeneration.[22-28] For example, fibrillin 1 content is significantly lower and matrix metalloproteinase activity is significantly higher in the aortic media in patients with bicuspid aortic valve than in persons with a normal, tricuspid aortic valve.[22-24] Further, the process of medial degeneration in patients with bicuspid aortic valve may be exacerbated by the presence of chronic turbulent flow through the deformed valve.

Bovine aortic arch Bovine aortic arch—a common origin of the innominate and left common carotid arteries—has been considered a normal anatomic variant. Recent studies from Yale University have identified a higher prevalence of bovine aortic arch in patients with thoracic aortic disease; an association was found between this anomaly and a generalized increase in aortic aneurysmal disease (without any predisposition to a particular aortic region). However, bovine aortic arch was not associated distinctly with bicuspid aortic valve or aortic dissection, but with a higher mean aortic growth rate: 0.29 cm/year in patients with bovine aortic arch, compared with 0.09 cm/year in controls. Therefore, bovine aortic arch may be better characterized as a precursor of aortic aneurysm than as a simple normal anatomic variant.[29] Further studies are needed to delineate the underlying mechanism for this association.

Infection. Primary infection of the aortic wall resulting in aneurysm formation is rare. Although these lesions are termed *mycotic aneurysms*, the responsible pathogens usually are bacteria rather than fungi. Bacterial invasion of the aortic wall may result from bacterial endocarditis, endothelial trauma caused by an aortic jet lesion, or extension from an infected laminar clot within a preexisting aneurysm. The most common causative organisms are *Staphylococcus aureus, Staphylococcus epidermidis, Salmonella*, and *Streptococcus*.[30,31] Unlike most other causes of thoracic aortic aneurysms, which generally produce fusiform aneurysms, infection often produces saccular aneurysms located in areas of aortic tissue destroyed by the infectious process.

Although syphilis was once the most common cause of ascending aortic aneurysms, the advent of effective antibiotic therapy has made syphilitic aneurysms a rarity in developed nations. In other parts of the world, however, syphilitic aneurysms remain a major cause of morbidity and mortality. The spirochete *Treponema pallidum* causes an obliterative endarteritis of the vasa vasorum that results in medial ischemia and loss of the elastic and muscular elements of the aortic wall. The ascending aorta and arch are the most commonly involved areas. The emergence of HIV infection in the 1980s was associated with a substantial increase in the incidence of syphilis in both HIV-positive and HIV-negative patients. Because syphilitic aortitis often presents 10 to 30 years after the primary infection, the incidence of associated aneurysms may increase in the near future.

Aortitis. In patients with preexisting degenerative thoracic aortic aneurysms, localized transmural inflammation and subsequent fibrosis can develop. The dense aortic infiltrate responsible for the fibrosis consists of lymphocytes, plasma cells, and giant cells. The cause of the intense inflammatory reaction is unknown. Although the severe inflammation is a superimposed problem rather than a primary cause, its onset within an aneurysm can further weaken the aortic wall and precipitate expansion.

Systemic autoimmune disorders also cause thoracic aortitis. Aortic Takayasu arteritis generally produces obstructive lesions related to severe intimal thickening, but associated medial necrosis can lead to aneurysm formation. In patients with giant cell arteritis (temporal arteritis), granulomatous inflammation may develop that involves the entire thickness of the aortic wall, causing intimal thickening and medial destruction. Rheumatoid aortitis is an uncommon systemic disease that is associated with rheumatoid arthritis and ankylosing spondylitis. The resulting medial inflammation and fibrosis can affect the aortic root, causing annular dilatation, aortic valve regurgitation, and ascending aortic aneurysm formation.

Pseudoaneurysms. Pseudoaneurysms of the thoracic aorta usually represent chronic leaks that are contained by surrounding tissue and fibrosis. By definition, the wall of a pseudoaneurysm is not formed by intact aortic tissue; rather, the wall develops from organized thrombus and associated fibrosis. Pseudoaneurysms can arise from primary defects in the aortic wall (e.g., after trauma or contained aneurysm rupture) or from anastomotic or cannulation site leaks that occur after cardiovascular surgery. Anastomotic pseudoaneurysms can be caused by technical problems or by deterioration of the native aortic tissue, graft material, or suture. Commonly, they occur in patients with Marfan syndrome.[32] Tissue deterioration usually is related to either progressive degenerative disease or infection. Improvements in sutures, graft materials, and surgical techniques have decreased the incidence of thoracic aortic pseudoaneurysms. Should thoracic aortic pseudoaneurysms occur, they typically require expeditious surgical or other intervention because they are associated with a high incidence of morbidity and rupture.

Clinical History

Treatment decisions in cases of thoracic aortic aneurysm are guided by our current understanding of the clinical history of these aneurysms, which classically is characterized as progressive aortic dilatation and eventual dissection, rupture, or both.

1▶ An analysis by Elefteriades of data from 1600 patients with thoracic aortic disease has helped quantify these well-recognized risks.[33] Average expansion rates were 0.07 cm/y in ascending aortic aneurysms and 0.19 cm/y in descending thoracic aortic aneurysms. As expected, aortic diameter was a strong predictor of rupture, dissection, and mortality. For thoracic aortic aneurysms >6 cm in diameter, annual rates of catastrophic complications were 3.6% for rupture, 3.7% for dissection, and 10.8% for death. Critical diameters, at which the incidence of expected complications significantly increased, were 6.0 cm for aneurysms of the ascending aorta and 7.0 cm for aneurysms of the descending thoracic aorta; the corresponding risks of rupture after reaching these diameters were 31% and 43%, respectively.[34]

Certain types of aneurysms have an increased propensity for expansion and rupture. For example, aneurysms in patients with Marfan or Loeys-Dietz syndrome dilate at an accelerated rate and rupture or dissect at smaller diameters than non–connective tissue disorder-related aneurysms. Before the era of surgical treatment for aortic aneurysms, this aggressive form of aortic disease resulted in an average life expectancy of 32 years for Marfan patients; aortic root complications caused the majority of deaths.[35] Saccular aneurysms, which commonly are associated with aortic infection and typically affect only a discrete small section of the aorta, tend to grow more rapidly than fusiform aneurysms, which are associated with more widespread degenerative changes and generally affect a larger section of the aorta.

One common clinical scenario deserves special attention. A moderately dilated ascending aorta (i.e., 4–5 cm) often is encountered during aortic valve replacement or coronary artery bypass operations. The clinical history of these ectatic ascending aortas has been defined by several studies. Michel and colleagues[36] studied patients whose ascending aortic diameters were >4 cm at the time of aortic valve replacement; 25% of these patients required reoperation for ascending aortic replacement. Prenger and colleagues[37] reported that aortic dissection occurred in 27% of patients who had aortic diameters of >5 cm at the time of aortic valve replacement. Recently, attention has been directed toward whether or not a mildly dilated aortic root should be replaced in patients with bicuspid aortic valve who are undergoing isolated valve replacement, and at what threshold to intervene. Although this is a controversial issue, many surgeons believe that the tendency toward late aortic dilatation in these patients warrants aggressive treatment.[38,39] Current practice guidelines indicate that such early replacement should be considered in these patients when the ascending aorta is 4.0 to 4.5 cm.[40]

Clinical Manifestations

In many patients with thoracic aortic aneurysms, the aneurysm is discovered incidentally when imaging studies are performed for unrelated reasons. Therefore, patients often are asymptomatic at the time of diagnosis. However, thoracic aortic aneurysms that initially go undetected eventually create symptoms and signs that correspond with the segment of aorta that is involved. These aneurysms have a wide variety of manifestations, including compression or erosion of adjacent structures, aortic valve regurgitation, distal embolism, and rupture.

Local Compression and Erosion. Initially, aneurysmal expansion and impingement on adjacent structures causes mild, chronic pain. The most common symptom in patients with ascending aortic aneurysms is anterior chest discomfort; the pain is frequently precordial in location but may radiate to the neck and jaw, mimicking angina. Aneurysms of the ascending aorta and transverse aortic arch can cause symptoms related to compression of the superior vena cava, the pulmonary artery, the airway, or the sternum. Rarely, these aneurysms erode into the superior vena cava or right atrium, causing acute high-output failure. Expansion of the distal aortic arch can stretch the recurrent laryngeal nerve, which results in left vocal cord paralysis and hoarseness. Descending thoracic and thoracoabdominal aneurysms frequently cause back pain localized between the scapulae. When the aneurysm is largest in the region of the aortic hiatus, it may cause middle back and epigastric pain. Thoracic or lumbar vertebral body erosion typically causes severe, chronic back pain; extreme cases can present with spinal instability and neurologic deficits from spinal cord compression. Although mycotic aneurysms have a peculiar propensity to destroy vertebral bodies, spinal erosion also occurs with degenerative aneurysms. Descending thoracic aortic aneurysms may cause various degrees of airway obstruction, manifesting as cough, wheezing, stridor, or pneumonitis. Pulmonary or airway erosion presents as hemoptysis. Compression and erosion of the esophagus cause dysphagia and hematemesis, respectively. Thoracoabdominal aortic aneurysms can cause duodenal obstruction or, if they erode through the bowel wall, gastrointestinal bleeding. Jaundice due to compression of the liver or porta hepatis is uncommon. Erosion into the inferior vena cava or iliac vein presents with an abdominal bruit, widened pulse pressure, edema, and heart failure.

Aortic Valve Regurgitation. Ascending aortic aneurysms can cause displacement of the aortic valve commissures and annular dilatation. The resulting deformation of the aortic valve leads to progressively worsening aortic valve regurgitation. In response to the volume overload, the heart remodels and becomes increasingly dilated. Patients with this condition may present with progressive heart failure, a widened pulse pressure, and a diastolic murmur.

Distal Embolization. Thoracic aortic aneurysms—particularly those involving the descending and thoracoabdominal aorta—are commonly lined with friable, atheromatous plaque and mural thrombus. This debris may embolize distally, causing occlusion and thrombosis of the visceral, renal, or lower-extremity branches.

Rupture. Patients with ruptured thoracic aortic aneurysms often experience sudden, severe pain in the anterior chest (ascending aorta), upper back or left chest (descending thoracic aorta), or left flank or abdomen (thoracoabdominal aorta). When ascending aortic aneurysms rupture, they usually bleed into the pericardial space, producing acute cardiac tamponade and death. Descending thoracic aortic aneurysms rupture into the pleural cavity, producing a combination of severe hemorrhagic shock and respiratory compromise. External rupture is extremely rare; saccular syphilitic aneurysms have been observed to rupture externally after eroding through the sternum.

Diagnostic Evaluation

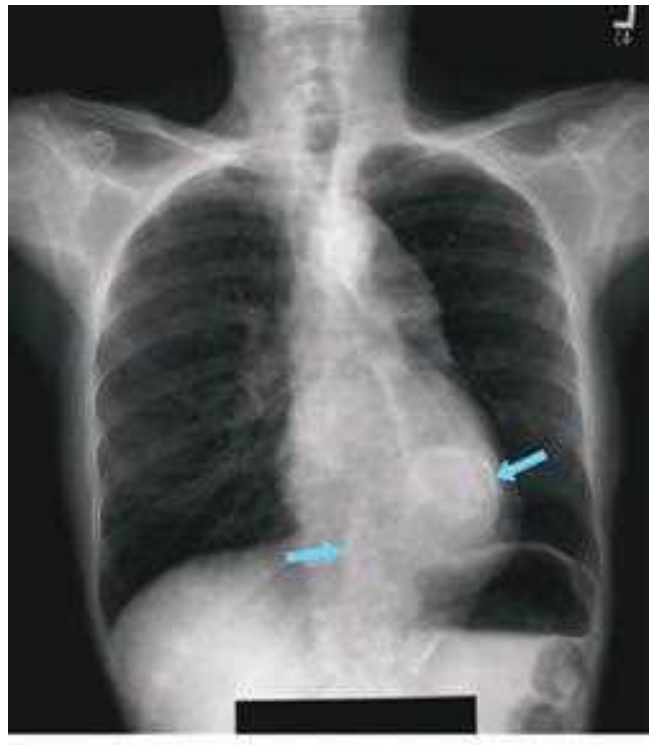
Diagnosis and characterization of thoracic aneurysms require imaging studies, which also provide critical information that

guides the selection of treatment options. Although the best choice of imaging technique for the thoracic and thoracoabdominal aorta is somewhat institution-specific, varying with the availability of imaging equipment and expertise, efforts have been made to standardize key elements of image acquisition and reporting. Recent practice guidelines[40] recommend that aortic imaging reports plainly state the location of aortic abnormalities (including calcification and the extent to which abnormalities extend into branch vessels), the maximum external aortic diameters (rather than internal, lumen-based diameters), internal filling defects, and any evidence of rupture. Whenever possible, all results should be compared to those of prior imaging studies.

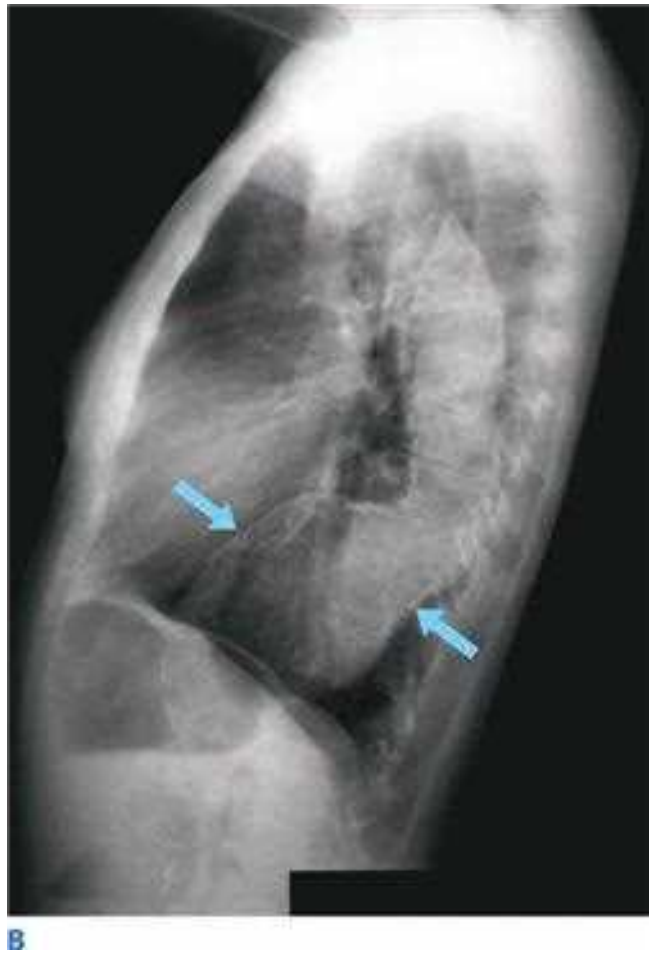
Plain Radiography. Plain radiographs of the chest, abdomen, or spine often provide enough information to support the initial diagnosis of thoracic aortic aneurysm. Ascending aortic aneurysms produce a convex shadow to the right of the cardiac silhouette. The anterior projection of an ascending aneurysm results in the loss of the retrosternal space in the lateral view. An aneurysm may be indistinguishable from elongation and tortuosity.[41] Above all, chest radiographs (CXRs) may appear normal in patients with thoracic aortic disease and, thus, cannot exclude the diagnosis of aortic aneurysm. Aortic root aneurysms, for example, often are hidden within the cardiac silhouette. Plain CXRs may reveal convexity in the right superior mediastinum, loss of the retrosternal space, or widening of the descending thoracic aortic shadow, which may be highlighted by a rim of calcification outlining the dilated aneurysmal aortic wall. Aortic calcification also may be seen in the upper abdomen on a standard radiograph made in the anteroposterior or lateral projection (Fig. 22-2). Once a thoracic aortic aneurysm is detected on plain radiographs, additional studies are required to define the extent of aortic involvement.

Echocardiography and Abdominal Ultrasonography. Ascending aortic aneurysms are commonly discovered during echocardiography in patients presenting with symptoms or signs of aortic valve regurgitation. Both transthoracic and transesophageal echocardiography provide excellent visualization of the ascending aorta, including the aortic root.[42] Transesophageal echocardiography also allows visualization of the descending thoracic aorta but is not ideal for evaluating the transverse aortic arch (which is obscured by air in the tracheobronchial tree) or the upper abdominal aorta. Effective echocardiography requires considerable technical skill, both in obtaining adequate images and in interpreting them. This imaging modality has the added benefit of assessing cardiac function and revealing any other abnormalities that may be present. During ultrasound evaluation of a suspected infrarenal abdominal aortic aneurysm, if a definitive neck cannot be identified at the level of the renal arteries, the possibility of thoracoabdominal aortic involvement should be suspected and investigated by using other imaging modalities. Caution should be exercised while interpreting aneurysm dimensions from ultrasound imaging because intraluminal measurements are often reported, whereas external measurements are usually used in other imaging modalities.

Computed Tomography. Computed tomographic (CT) scanning is widely available, provides visualization of the entire thoracic and abdominal aorta, and permits multiplanar and 3-dimensional aortic reconstructions. Consequently, CT is the most common—and arguably the most useful—imaging modality for evaluating thoracic aortic aneurysms.[43] In addition to establishing the diagnosis, CT provides information about



A



B

Figure 22-2. Chest radiographs showing a calcified rim (*arrows*) in the aortic wall of a thoracoabdominal aortic aneurysm. **A.** Anteroposterior view. **B.** Lateral view.

an aneurysm's location, extent, anatomic anomalies, and relationship to major branch vessels. CT is particularly useful in determining the absolute diameter of the aorta, especially in the presence of a laminated clot, and also detects aortic calcification. Contrast-enhanced CT provides information about the aortic lumen and can detect mural thrombus, aortic dissection, inflammatory periaortic fibrosis, and mediastinal or retroperitoneal hematoma due to contained aortic rupture. To increase consistency and ensure uniform reporting, current practice guidelines suggest that measurements be taken perpendicular to blood flow and at standard anatomic locations[40] (Fig. 22-3); this should reduce the likelihood of erroneous measurements, especially during serial imaging surveillance.

2▶

The major disadvantage of contrast-enhanced CT scanning is the possibility of contrast-induced acute renal failure in patients who are at risk (e.g., patients with preexisting renal disease or diabetes).[44] If possible, surgery is performed ≥1 day after contrast administration to allow time to observe renal function and to permit diuresis of the contrast agent. If renal insufficiency occurs or is worsened, elective surgery is postponed until renal function returns to normal or stabilizes.

Figure 22-3. Current practice guidelines[40] seek to standardize the reporting of aortic diameters by indicating key locations of measurement. These include (1) the sinuses of Valsalva, (2) the sinotubular junction, (3) the mid-ascending aorta, (4) the proximal aortic arch at the origins of the innominate artery, (5) the mid-aortic arch, which is between the left common carotid and left subclavian arteries, (6) the proximal descending thoracic aorta, which begins at the isthmus (approximately 2 cm distal to the origins of the left subclavian artery), (7) the mid-descending thoracic artery, (8) the aorta at the diaphragm, and (9) the abdominal aorta at the origins of the celiac axis. *(Used with permission of Baylor College of Medicine.)*

Magnetic Resonance Angiography. Magnetic resonance angiography (MRA) is becoming widely available and can facilitate visualization of the entire aorta. This modality produces aortic images comparable to those produced by contrast-enhanced CT but does not necessitate exposure to ionizing radiation. In addition, MRA offers excellent visualization of branch vessel details, and it is useful in detecting branch vessel stenosis.[45] However, MRA is limited by high expense and a susceptibility to artifacts created by ferromagnetic materials, and gadolinium—the contrast agent for MRA—may be linked to nephrogenic systemic fibrosis and acute renal failure in patients with advanced renal insufficiency.[46] Furthermore, the MRA environment is not appropriate for many critically ill patients, and unlike CT imaging, MRA imaging is suboptimal in patients with extensive aortic calcification.

Invasive Aortography and Cardiac Catheterization. Although catheter-based contrast aortography was previously considered the gold standard for evaluating thoracic aortic disease, cross-sectional imaging (i.e., CT and MRA) has largely replaced this modality. Technologic improvements have enabled CT and MRA to provide excellent aortic imaging while causing less morbidity than catheter-based studies do, so CT and MRA are now the primary modes for evaluating thoracic aortic disease. Today, the use of invasive aortography in patients with thoracic aortic disease is generally limited to those undergoing endovascular therapies or when other types of studies are contraindicated or have not provided satisfactory results.

Unlike standard aortography, cardiac catheterization continues to play an important role in diagnosis and preoperative planning, especially in patients with ascending aortic involvement. Proximal aortography can reveal not only the status of the coronary arteries and left ventricular function but also the degree of aortic valve regurgitation, the extent of aortic root involvement, coronary ostial displacement, and the relationship of the aneurysm to the arch vessels.

The value of the information one can obtain from catheter-based diagnostic studies should be weighed against the established limitations and potential complications of such studies. A key limitation of aortography is that it images only the lumen and may therefore underrepresent the size of large aneurysms that contain laminated thrombus. Manipulation of intraluminal catheters can result in embolization of laminated thrombus or atheromatous debris. Proximal aortography carries a 0.6% to 1.2% risk of stroke. Other risks include allergic reaction to contrast agent, iatrogenic aortic dissection, and bleeding at the arterial access site. In addition, the volumes of contrast agent required to adequately fill large aneurysms can cause significant renal toxicity. To minimize the risk of contrast nephropathy, patients receive periprocedural intravenous (IV) fluids for hydration, mannitol for diuresis, and acetylcysteine.[47,48] As with contrast-enhanced CT, surgery is performed ≥1 day after angiography whenever possible to ensure that renal function has stabilized or returned to baseline.

Treatment

Selecting the Appropriate Treatment. Once a thoracic aortic aneurysm is detected, management begins with patient

education, particularly if the patient is asymptomatic, because aortic disease may progress rapidly and unexpectedly in some patients. A detailed medical history is collected, a physical examination is performed, and a systematic review of medical records is carried out to clearly assess the presence or absence of pertinent symptoms and signs, despite any initial denial of symptoms by the patient. Signs of genetic diseases such as Marfan syndrome or Loeys-Dietz syndrome are thoroughly reviewed. If clinical criteria are met for such a genetic condition, confirmatory laboratory tests are conducted. Patients with such genetic diseases are best treated in a dedicated aortic clinic where they can be appropriately followed up. Surveillance imaging and aggressive blood pressure control are the mainstays of initial management for asymptomatic patients. When patients become symptomatic or their aneurysms grow to meet certain size criteria, the patients become surgical candidates.

Although long-term data are still lacking, endovascular therapy has become an accepted treatment for thoracic aortic aneurysms.[49] Its role in treating proximal aortic disease and thoracoabdominal aortic aneurysms remains experimental. Nonetheless, endoluminal stenting is approved by the U.S. Food and Drug Administration for the treatment of isolated descending thoracic aortic aneurysms, and some newer devices are approved for the treatment of blunt aortic injury and penetrating aortic ulcer. In practice, however, the off-label application of aortic stent grafts is widespread and accounts for well over half their use.[50] Endovascular approaches may be helpful in emergent aneurysm repair, such as for patients with aortic rupture.[51] Recently, endovascular therapy has evolved to include hybrid repairs, which combine open "debranching" techniques (to reroute branching vessels) with endovascular aortic repair. Despite these advances, for the repair of aneurysms with proximal aortic involvement and of thoracoabdominal aortic aneurysms, open procedures remain the gold standard and preferred approach.

Determination of the Extent and Severity of Disease. Cross-sectional imaging with reconstruction is critical when one is evaluating a thoracic aneurysm, determining treatment strategy, and planning necessary procedures. Note that, commonly, patients with a thoracic aortic aneurysm also have a remote aneurysm.[2] In such cases, the more threatening lesion usually is addressed first. In many patients, staged operative procedures are necessary for complete repair of extensive aneurysms involving the ascending aorta, transverse arch, and descending thoracic or thoracoabdominal aorta.[52] When the descending segment is not disproportionately large (compared with the proximal aorta) and is not causing symptoms, the proximal aortic repair is carried out first. An important benefit of this approach is that it allows treatment of valvular and coronary artery occlusive disease at the first operation.

Proximal aneurysms (proximal to the left subclavian artery) usually are addressed via a sternotomy approach. Aneurysms involving the descending thoracic aorta are evaluated in terms of criteria (described later) for potential endovascular repair; those unsuitable for an endovascular approach are repaired with open techniques through a left thoracotomy. A CT scan can reveal detailed information about aortic calcification and luminal thrombus. These details are important in preventing embolization during surgical manipulation.

Indications for Operation Thoracic aortic aneurysms are repaired to prevent fatal rupture. Therefore, on the basis of the natural history studies and other data, practice guidelines for thoracic aortic disease[40] recommend elective operation in asymptomatic patients when the diameter of an ascending aortic aneurysm is >5.5 cm, when the diameter of a descending thoracic aortic aneurysm is >6.0 cm, or when the rate of dilatation is >0.5 cm/y. In patients with connective tissue disorders such as Marfan and Loeys-Dietz syndromes, the threshold for operation is based on a smaller aortic diameter (4.0–5.0 cm for the ascending aorta and 5.5 to 6.0 cm for the descending thoracic aorta). For women with connective tissue disorders who are considering pregnancy, prophylactic aortic root replacement is considered because the risk of aortic dissection or rupture increases at an aortic diameter of 4.0 cm or greater. For low-risk patients with chronic aortic dissection, descending thoracic repair is recommended at an aortic diameter of 5.5 cm or greater. For patients undergoing aortic valve replacement or repair, smaller ascending aortic aneurysms (>4.5 cm) are considered for concomitant repair.

The acuity of presentation is a major factor in decisions about the timing of surgical intervention. Many patients are asymptomatic at the time of presentation, so there is time for thorough preoperative evaluation and improvement of their current health status, such as through smoking cessation and other optimization programs. In contrast, patients who present with symptoms may need urgent operation. Symptomatic patients are at increased risk of rupture and warrant expeditious evaluation. The onset of new pain in patients with known aneurysms is especially concerning, because it may herald significant expansion, leakage, or impending rupture. Emergent intervention is reserved for patients who present with aneurysm rupture or superimposed acute dissection.[53]

Open Repair vs. Endovascular Repair As noted earlier, endovascular repair of thoracic aortic aneurysms has become an accepted treatment option in selected patients, particularly patients with isolated degenerative descending thoracic aortic aneurysms; in fact, practice guidelines recommend that endovascular repair be strongly considered for patients with descending thoracic aneurysm at an aortic diameter of 5.5 cm (which is slightly below the 6.0-cm threshold for open repair).[40] For endovascular repairs to produce optimal outcomes, several anatomic criteria must be met. For one, the proximal and distal neck diameters should fall within a range that will allow proper sealing. Also, the proximal and distal landing zones should ideally be at least 20 mm long so that an appropriate seal can be made. Note that the limiting structures proximally and distally are the brachiocephalic vessels and celiac axis, respectively. Another anatomic limitation for this therapy relates to vascular access: The femoral and iliac arteries have to be wide enough to accommodate the large sheaths necessary to deploy the stent grafts, although newer devices use a smaller sheath (or are "sheathless" self-deployed stent grafts) to accommodate smaller arteries. Tortuosity of the iliac vessels and abdominal aorta can make these procedures technically challenging. Occasionally, a "side graft" anastomosed to the iliac artery through a retroperitoneal incision is used because of poor distal access. When any of these anatomic criteria are not met, an open approach is preferable to an endovascular approach.

Of note, attempts have been made to extend the use of endovascular therapy to aortic arch aneurysms and thoracoabdominal aortic aneurysms. Although reports of purely endovascular repair of the aortic arch remain limited, Greenberg and colleagues[54] have reported their experience with a large series of

purely endovascular thoracoabdominal aortic repairs. Additionally, there have been numerous reports of small series of off-label, experimental hybrid procedures that involve debranching the aortic arch or the visceral vessels of the abdominal aorta, followed by endovascular exclusion of the aneurysm. The majority of hybrid approaches involve repairing the aortic arch. In its simplest form, hybrid arch repair involves an open bypass from the left subclavian to the left common carotid artery, which is followed by deliberate coverage of the origins of the left subclavian artery by the stent graft. In its most complex form, hybrid arch repair involves rerouting all of the brachiocephalic vessels, followed by proximal placement of the stent graft in the ascending aorta and extending repair distally into the aortic arch and descending thoracic aorta.

The patients who theoretically may benefit more from an endovascular approach than from traditional open techniques are those who are of advanced age or have significant comorbidities. For example, the open repair of a descending thoracic aortic aneurysm can result in significant pulmonary morbidity. Therefore, patients with borderline pulmonary reserve may better tolerate an endovascular procedure than standard open repair. In contrast, patients with significant intraluminal atheroma may be better served by an open approach because of the risk of embolization and stroke posed by catheter manipulation. Similarly, patients with connective tissue disorders generally are not considered candidates for elective endovascular repair. Endovascular repair in patients with connective tissue disorders has produced poor results, which are mainly due to progressive dilatation, stent graft migration, and endoleak.[55]

Preoperative Assessment and Preparation. Given the impact of comorbid conditions on perioperative complications, a careful preoperative assessment of physiologic reserve is critical in assessing operative risk. Therefore, most patients undergo a thorough evaluation—with emphasis on cardiac, pulmonary, and renal function—before undergoing elective surgery.[56,57]

Cardiac Evaluation Coronary artery disease is common in patients with thoracic aortic aneurysm and is responsible for a substantial proportion of early and late postoperative deaths in such patients. Similarly, valvular disease and myocardial dysfunction have important implications when one is planning anesthetic management and surgical approaches for aortic repair. Transthoracic echocardiography is a satisfactory noninvasive method for evaluating both valvular and biventricular function. Dipyridamole-thallium myocardial scanning identifies regions of myocardium that have reversible ischemia, and this test is more practical than exercise testing in older patients with concomitant lower-extremity peripheral vascular disease. Cardiac catheterization and coronary arteriography are performed in patients who have evidence of coronary disease—as indicated by either the patient's history or the results of noninvasive studies—or who have a left ventricular ejection fraction of ≤30%. If significant valvular or coronary artery disease is identified before a proximal aortic operation, the disease can be addressed directly during the procedure. Patients who have asymptomatic distal aortic aneurysms and severe coronary occlusive disease undergo percutaneous transluminal angioplasty or surgical revascularization before the aneurysmal aortic segment is replaced.

Pulmonary Evaluation Pulmonary function screening with arterial blood gas measurement and spirometry is routinely performed before thoracic aortic operations. Patients with a forced expiratory volume in 1 second of >1.0 L and a partial pressure of carbon dioxide of <45 mmHg are considered surgical candidates. In suitable patients, borderline pulmonary function can be improved by implementing a regimen that includes smoking cessation, weight loss, exercise, and treatment of bronchitis for a period of 1 to 3 months before surgery. Although surgery is not withheld from patients with symptomatic aortic aneurysms and poor pulmonary function, adjustments in operative technique should be made to maximize these patients' chances of recovery. In such patients, preserving the left recurrent laryngeal nerve, the phrenic nerves, and diaphragmatic function is particularly important.

Renal Evaluation Renal function is assessed preoperatively by measuring serum electrolyte, blood urea nitrogen, and creatinine levels. Information about kidney size and perfusion can be obtained from the imaging studies used to evaluate the aorta.

Obtaining accurate information about baseline renal function has important therapeutic and prognostic implications. For example, perfusion strategies and perioperative medications are adjusted according to renal function. Patients with severely impaired renal function frequently require at least temporary hemodialysis after surgery. These patients also have a mortality rate that is significantly higher than normal. Patients with thoracoabdominal aortic aneurysms and poor renal function secondary to severe proximal renal occlusive disease undergo renal artery endarterectomy, stenting, or bypass grafting during the aortic repair.

Operative Repair.

Proximal Thoracic Aortic Aneurysms

Open Repair Traditional open operations to repair proximal aortic aneurysms—which involve the ascending aorta, transverse aortic arch, or both—are performed through a midsternal incision and require cardiopulmonary bypass. The best choice of aortic replacement technique depends on the extent of the aneurysm and the condition of the aortic valve. The spectrum of operations (Fig. 22-4) ranges from simple graft replacement of the tubular portion of the ascending aorta (Fig. 22-4A) to graft replacement of the entire proximal aorta, including the aortic root, and reattachment of the coronary arteries and brachiocephalic branches. The options for treating aortic valve disease, repairing aortic aneurysms, and maintaining perfusion during repair procedures each deserve detailed consideration (Table 22-2).

Aortic Valve Disease and Root Aneurysms Many patients undergoing proximal aortic operations have aortic valve disease that requires concomitant surgical correction. When such disease is present and the sinus segment is normal, separate repair or replacement of the aortic valve and graft replacement of the tubular segment of the ascending aorta are carried out. In such cases, mild to moderate valve regurgitation with annular dilatation can be addressed by plicating the annulus with mattress sutures placed below each commissure, thereby preserving the native valve. In patients with more severe valvular regurgitation or with valvular stenosis, the valve is replaced with a stented biologic or mechanical prosthesis. Mechanical prostheses necessitate following a lifelong anticoagulation regimen. Separate replacement of the aortic valve and ascending aorta is not performed in patients with Marfan syndrome, because progressive dilatation of the remaining sinus segment eventually leads to complications that necessitate reoperation. Therefore, patients with Marfan syndrome or those with annuloaortic ectasia require some form of aortic root replacement.[58]

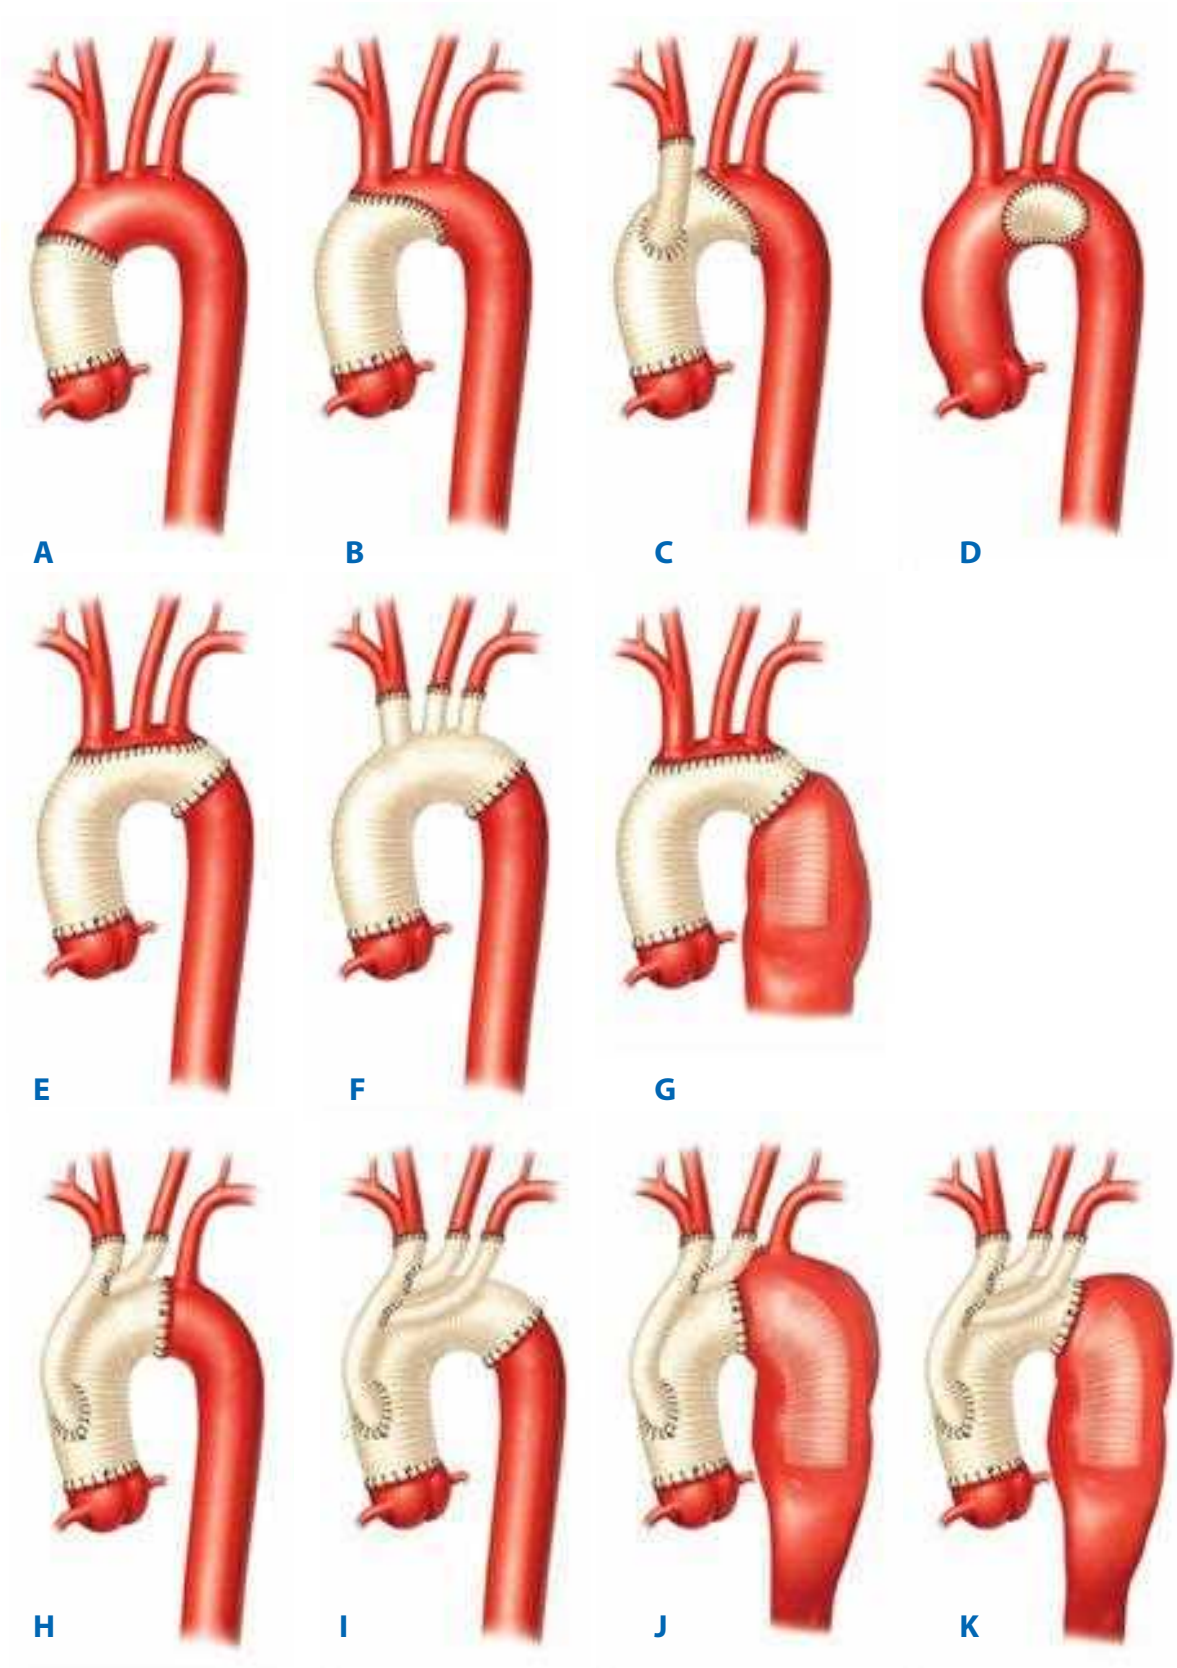


Figure 22-4. Illustrations of proximal aortic repairs in which the native aortic root is left intact. **A.** Graft replacement of the tubular portion of the ascending aorta with the aortic arch left intact. **B.** Hemiarch beveled graft replacement, in which the ascending aorta and a portion of the lesser curvature of the aortic arch are replaced. **C.** A modified hemiarch with additional graft replacement of the innominate artery. **D.** Patch repair of the aortic arch. **E.** Traditional total arch replacement using an island approach to reattach the brachiocephalic vessels. **F.** The branched graft approach, which replaces the brachiocephalic vessels by following their original anatomic location. **G.** The elephant trunk approach with a concomitant island brachiocephalic artery reattachment. Contemporary Y-graft arch repairs include **H.** the single Y-graft approach, **I.** the double Y-graft approach, **J.** the elephant trunk approach with a single Y-graft, and **K.** the elephant trunk approach with a double Y-graft. *(Used with permission of Baylor College of Medicine.)*

Table 22-2

Options for open surgical repair of proximal aortic aneurysms

Options for treating aortic valve disease
- Aortic valve annuloplasty (annular plication)
- Aortic valve replacement with mechanical or biologic prosthesis
- Aortic root replacement
  - Composite valve graft
  - Aortic homograft
  - Stentless porcine root
  - Pulmonary autograft (Ross procedure)
  - Valve-sparing techniques

Options for graft repair of the aortic aneurysm
- Patch aortoplasty
- Ascending replacement only
- Beveled hemiarch replacement
- Total arch replacement with reattachment of brachiocephalic branches
- Total arch replacement with bypass grafts to the brachiocephalic branches (Y-graft approaches)
- Elephant trunk technique with island reattachment
- Elephant trunk technique with Y-graft approach

Perfusion options
- Standard cardiopulmonary bypass
- Profound hypothermic circulatory arrest without adjuncts
- Hypothermic circulatory arrest with adjuncts
  - Retrograde cerebral perfusion
  - Antegrade cerebral perfusion
    - Balloon perfusion catheters
    - Right axillary artery cannulation
    - Innominate artery cannulation
  - Combined antegrade and retrograde cerebral perfusion

In many cases, the aortic root is replaced with a mechanical or biologic graft that has both a valve and an aortic conduit. Currently, three graft options are commercially available: composite valve grafts, which consist of a bileaflet mechanical valve attached to a polyester tube graft; aortic root homografts, which are harvested from cadavers and cryopreserved; and stentless porcine aortic root grafts.[59,60] Another option for surgeons is to construct a bioprosthetic composite valve graft during the operation by suturing a stented tissue valve to a polyester graft tube.

Although select patients may be offered the Ross procedure, in which the patient's pulmonary artery root is excised and placed in the aortic position and then the right ventricular outflow tract is reconstructed by using a cryopreserved pulmonary homograft, this option is rarely used. This is largely because it is a technically demanding procedure, and there are concerns about the potential for autograft dilatation in patients with connective tissue disorders.[61]

An additional option is valve-sparing aortic root replacement, which has evolved substantially during the past decade.[62] The valve-sparing technique that is currently favored is called *aortic root reimplantation* and involves excising the aortic sinuses, attaching a prosthetic graft to the patient's annulus (Fig. 22-5), and resuspending the native aortic valve inside the graft. The superior hemodynamics of the native valve and the avoidance of anticoagulation are major advantages of the valve-sparing approach. Long-term results in carefully selected patients have been excellent.[63] Although the durability of this procedure in patients with either Marfan syndrome or bicuspid aortic valve has been questioned, reports suggest that long-term durability is possible for patients with Marfan syndrome who undergo the procedure at experienced centers.[64,65] Further, acceptable midterm outcomes have been reported for patients with bicuspid aortic valve.[66] Patients who have structural leaflet deterioration or excessive annular dilatation are typically deemed unsuitable for valve-sparing repair.

Regardless of the type of conduit used, aortic root replacement requires reattaching the coronary arteries to openings in the graft. In the original procedure described by Bentall and De Bono,[67] this was accomplished by suturing the intact aortic wall surrounding each coronary artery to the openings in the graft. The aortic wall was then wrapped around the graft to establish hemostasis. However, this technique frequently produced leaks at the coronary reattachment sites that eventually led to pseudoaneurysm formation. The Cabrol modification, in which a separate, small tube graft is sutured to the coronary ostia and the main aortic graft, achieves tension-free coronary anastomoses and reduces the risk of pseudoaneurysm formation.[68] Kouchoukos's button modification of the Bentall procedure is currently the most widely used technique.[69] The aneurysmal aorta is excised, and buttons of aortic wall are left surrounding both coronary arteries, which are then mobilized and sutured to the aortic graft (Fig. 22-6). The coronary suture lines may be reinforced with polytetrafluoroethylene felt or pericardium to enhance hemostasis. When the coronary arteries cannot be mobilized adequately because of extremely large aneurysms or scarring from previous surgery, the Cabrol technique or a related modification can be used. Another option, originally described by Zubiate and Kay,[70] is the construction of bypass grafts by using interposition saphenous vein or synthetic grafts.

Aortic Arch Aneurysms Several options are also available for handling aneurysms that extend into the transverse aortic arch (Fig. 22-4). The surgical approach depends on the extent of involvement and the need for cardiac and cerebral protection. Saccular aneurysms that arise from the lesser curvature of the distal transverse arch and that encompass <50% of the aortic circumference can be treated by patch graft aortoplasty. For fusiform aneurysms, when the distal portion of the arch is a reasonable size, a single, beveled replacement of the lower curvature (hemiarch) is performed. More extensive arch aneurysms require total replacement involving a distal anastomosis to the proximal descending thoracic aorta and separate reattachment of the brachiocephalic branches. The brachiocephalic vessels are reattached to one or more openings made in the graft, or if these vessels are aneurysmal, they are replaced with separate, smaller grafts. Recently, Y-graft approaches to aortic arch repair have been introduced[71] that essentially debranch the brachiocephalic vessels and move them forward. This permits the distal anastomosis to be brought forward and aids in hemostasis. When the aneurysm involves the entire arch and extends into the descending thoracic aorta, it is approached by using Borst's elephant trunk technique of staged total arch replacement.[72] The distal anastomosis may be constructed by using a collared graft to accommodate any discrepancy in aortic diameter[73] and is performed such that a portion of the graft is

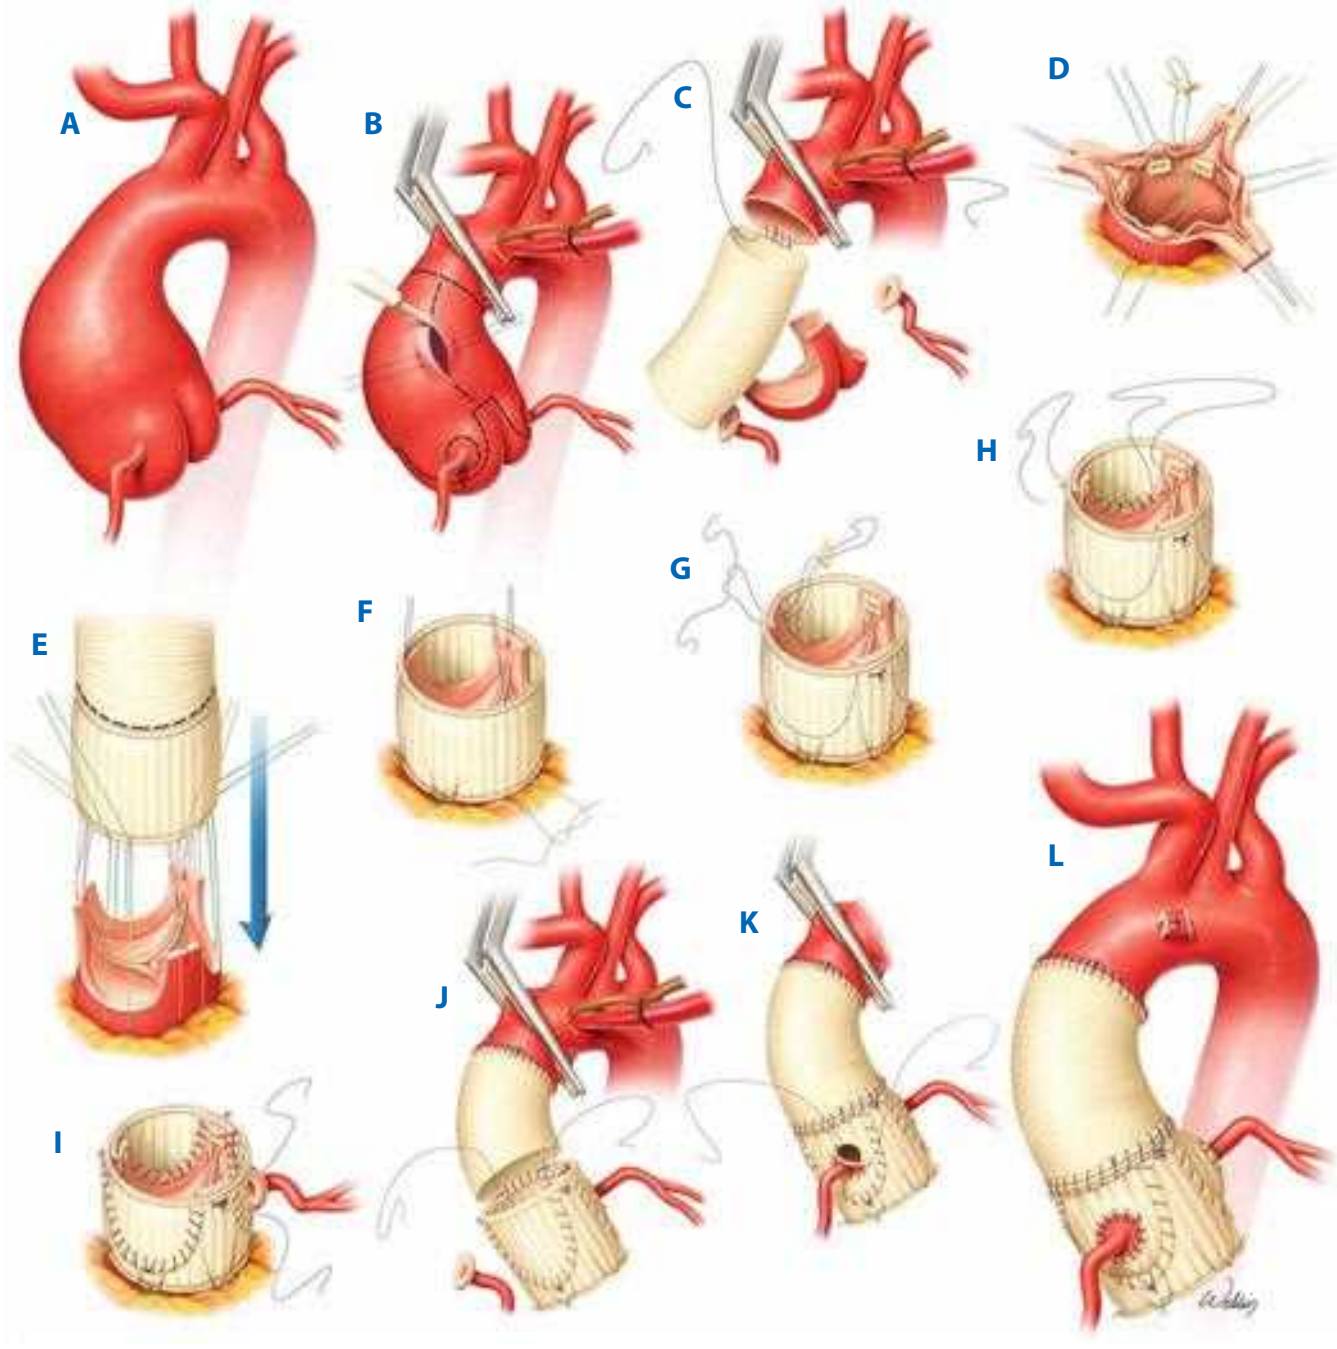

Figure 22-5. Illustration of our current valve-sparing procedure for replacing the aortic root and ascending aorta for treatment of **A.** aortic root aneurysm. **B.** The ascending aorta is opened after cardiopulmonary bypass and cardioplegic arrest are established and the distal ascending aorta is clamped. The diseased aortic tissue (including the sinuses of Valsalva) is excised. Buttons of surrounding tissue are used to mobilize the origins of the coronary arteries. **C.** A synthetic graft is sewn to the distal ascending aorta with continuous suture. **D.** After the distal anastomosis is completed, six sutures reinforced with Teflon pledgets are placed in the plane immediately below the aortic valve annulus. **E.** The subannular sutures are placed through the base of a synthetic aortic root graft, which is then is parachuted down around the valve. **F.** After the root graft is cut to an appropriate length, the valve commissures and leaflets are positioned within the graft. The annular sutures are then tied. **G**. Each of the three commissures is then secured near the top of the graft. **H.** The supra-annular aortic tissue is sewn to the graft in continuous fashion. **I.** The button surrounding the origin of the left main coronary artery is sewn to an opening cut in the root graft. **J.** The two aortic grafts are sewn together with continuous suture. **K.** The button surrounding the origin of the right coronary artery is sewn to an opening cut in the root graft. **L.** The completed valve-sparing aortic root replacement and graft repair of the ascending aorta is shown. *(Used with permission of Baylor College of Medicine.)*

left suspended within the proximal descending thoracic aorta (Fig. 22-7). During a subsequent operation, this "trunk" is used to facilitate repair of the descending thoracic aorta through a thoracotomy incision. This technique permits access to the distal portion of the graft during the second operation without the need for dissection around the distal transverse aortic arch; this reduces the risk of injuring the left recurrent laryngeal nerve, esophagus, and pulmonary artery if an open approach is used at the second stage. As described in the section on hybrid repair of arch aneurysms (see later), the elephant trunk can be completed

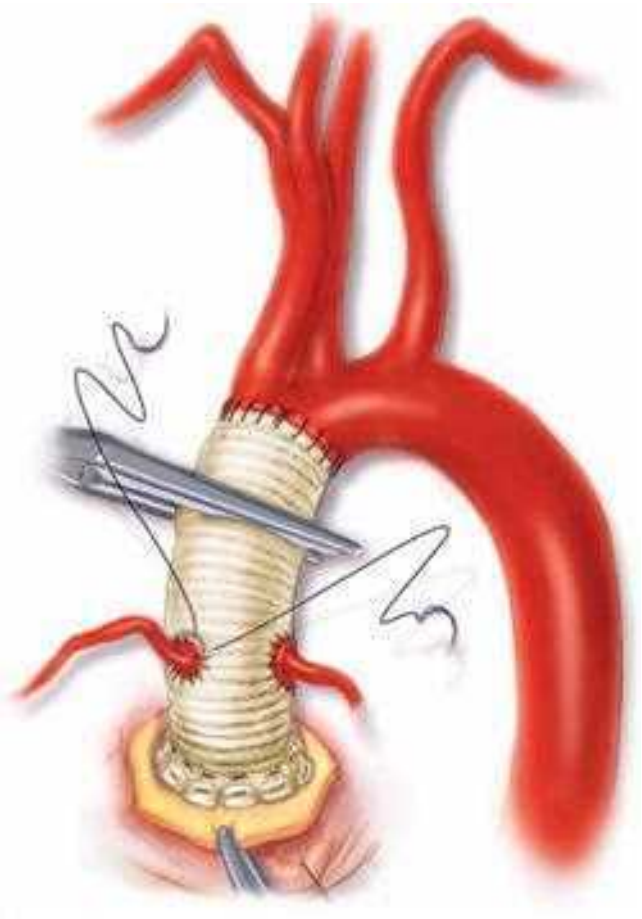

Figure 22-6. Illustration of a modified Bentall procedure for replacing the aortic root and ascending aorta. The aortic valve and entire ascending aorta, including the sinuses of Valsalva, have been replaced by a mechanical composite valve graft. The coronary arteries with buttons of surrounding aortic tissue have been mobilized and are being reattached to openings in the aortic graft.

by using a hybrid endovascular approach (Fig. 22-8) in certain settings.

Cardiopulmonary Bypass Perfusion Strategies Like the operations themselves, perfusion strategies used during proximal aortic surgery depend on the extent of the repair. Aneurysms that are isolated to the ascending segment can be replaced by using standard cardiopulmonary bypass and distal ascending aortic clamping. This provides constant perfusion of the brain and other vital organs during the repair. Aneurysms involving the transverse aortic arch, however, cannot be clamped during the repair, which necessitates the temporary withdrawal of cardiopulmonary bypass support; this is called *circulatory arrest.* To protect the brain and other vital organs during the circulatory arrest period, hypothermia must be initiated before pump flow is stopped. However, hypothermia is not without risk, and coagulopathy is associated with deep levels of hypothermia (below 20°C), which have been traditionally used in open arch repair. Recently, more moderate levels of hypothermia (often between 22°C and 24°C) have been introduced that appear to decrease risks associated with deep hypothermia while still providing sufficient brain protection. Nonetheless, although brief periods of circulatory arrest generally are well tolerated, even this recently modified technique continues to have substantial limitations; as the duration of circulatory arrest increases, the well-recognized risks of brain injury and death increase dramatically. Additionally, some authors have raised the concern that reducing the degree of hypothermia narrows the safety margin that deep hypothermia provides, because it increases the risk of ischemic complications involving the spinal cord, kidneys, and other organs that now receive less hypothermic protection.[74]

Because of the inherent complexity of aortic arch repairs and their general tendency to require longer periods of hypothermic circulatory arrest, two cerebral perfusion strategies—retrograde cerebral perfusion (RCP) and antegrade cerebral perfusion (ACP)—were developed to supplement this process by delivering cold, oxygenated blood to the brain and further reduce the risks associated with repair. Retrograde cerebral perfusion involves directing blood from the cardiopulmonary bypass circuit into the brain through the superior vena cava.[75] However, RCP is thought to be less beneficial than ACP,[76] and although it may be helpful in the retrograde flushing of air and debris from the arch, most centers have stopped using RCP.

In contrast, ACP delivers blood directly into the brachiocephalic arteries to maintain cerebral flow. Although its use was cumbersome in the past, contemporary ACP techniques (Fig. 22-9) have been simplified and commonly involve cannulating either the right axillary artery or the innominate artery and subsequent connection to the cardiopulmonary bypass circuit.[77,78] Often, a small section of graft is used as a conduit to ease cannulation, but there remains a small procedure-related risk of brachial plexus or vascular injury. Upon initiation, cold blood is delivered into the brain via the right common carotid artery. Note that, with this technique, blood flow to the left side of the brain requires an intact circle of Willis.

Methods to help determine the adequacy of unilateral ACP to deliver cerebral cross-circulation include preoperative imaging and intraoperative monitoring. Our preferred method of intraoperative monitoring is brain near-infrared spectroscopy (NIRS), which measures cerebral oxygenation. If NIRS monitoring indicates inadequate perfusion, an additional perfusion catheter can be inserted into the left common carotid artery to provide blood flow to the left side of the brain. Because of the use of more moderate levels of hypothermia, some groups supplement ACP with additional perfusion strategies that provide flow to the descending aorta during arch repair.[79,80]

Endovascular Repair Experience with purely endovascular treatment of proximal aortic disease remains limited and only investigational. The unique anatomy of the aortic arch and the need for uninterrupted cerebral perfusion pose difficult challenges. There are reports of the use of "homemade" grafts to exclude arch aneurysms; however, these grafts are highly experimental at this time. For example, in 1999, Inoue and colleagues[81] reported placing a triple-branched stent graft in a patient with an aneurysm of the aortic arch. The three brachiocephalic branches were positioned by placing percutaneous wires in the right brachial, left carotid, and left brachial arteries. The patient underwent two subsequent procedures: surgical repair of a right brachial pseudoaneurysm and placement of a distal stent graft extension to control a major perigraft leak. Since then, efforts to employ endovascular techniques in the treatment of the proximal aorta have been essentially limited to the use of approved devices for off-label indications, such as the exclusion of pseudoaneurysms in the ascending aorta.

Hybrid Repair Unlike purely endovascular approaches, hybrid repairs of the aortic arch have entered the mainstream clinical

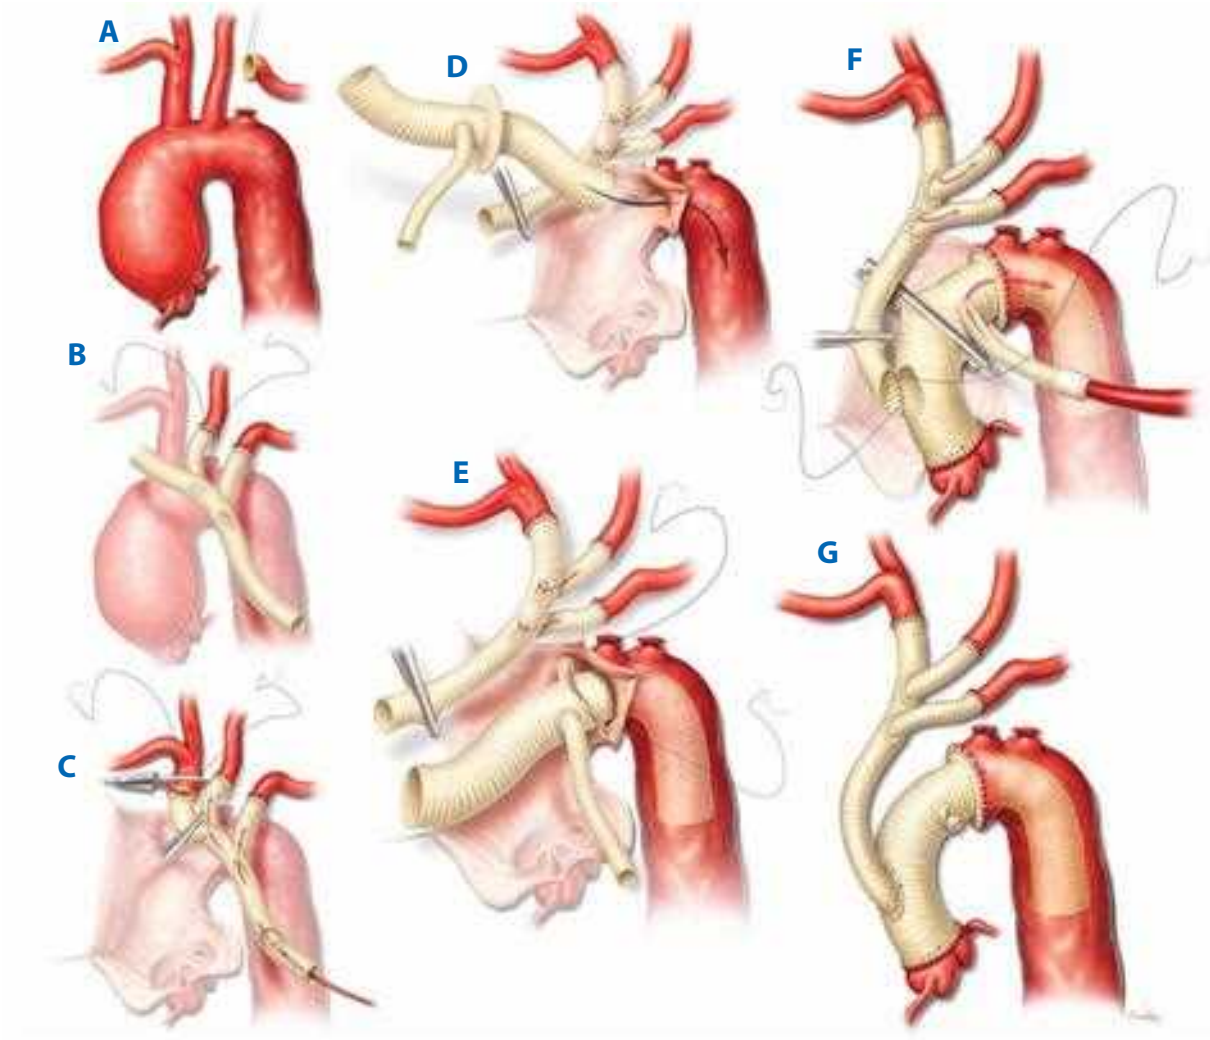

Figure 22-7. Illustration of a contemporary Y-graft approach to total arch replacement for aortic arch aneurysm. **A.** The proximal portions of the brachiocephalic arteries are exposed. **B.** The first two branches of the graft are sewn end-to-end to the transected left subclavian and left common carotid arteries. The proximal ends of the transected brachiocephalic arteries are ligated. **C.** A balloon-tipped perfusion cannula is placed inside the double Y-graft and used to deliver antegrade cerebral perfusion. After systemic circulatory arrest is initiated, the innominate artery is clamped, transected, and sewn to the distal end of the main graft. **D.** The proximal aspect of the Y-graft is clamped. This directs flow from the axillary artery to all three brachiocephalic arteries. The arch is then replaced with a collared elephant trunk graft. **E.** The distal anastomosis between the elephant trunk graft and the aorta is created between the innominate and left common carotid arteries. The collared graft accommodates any discrepancy in aortic diameter. **F.** The aortic graft is clamped, and a second limb from the arterial inflow tubing of the cardiopulmonary bypass circuit is used to deliver systemic perfusion through a side-branch of the arch graft while the proximal portion of the ascending aorta is replaced. Once the proximal aortic anastomosis is completed, the main trunk of the double Y-graft is cut to an appropriate length, and the beveled end is then sewn to an oval opening created in the right anterolateral aspect of the ascending aortic graft, which completes the repair **G.** *(Adapted from LeMaire et al,[73] Fig. 2. Used with permission. Copyright The Society of Thoracic Surgeons.)*

arena, although they remain controversial. Hybrid arch repairs involve some form of "debranching" of the brachiocephalic vessels (which are not unlike Y-graft approaches), followed by endovascular exclusion of some or all of the aortic arch (Fig. 22-10). Although this technique has many variants, they often involve sewing a branched graft to the proximal ascending aorta with the use of a partial aortic clamp. The branches of the graft are then sewn to the arch vessels. Once the arch is "debranched," the arch aneurysm can be excluded with an endograft. Commonly, a zone 0 approach (Fig. 22-11) is undertaken, in which the proximal end of the endograft lies between the ascending aorta and the origins of the innominate artery. Other hybrid approaches aim to extend repair into the distal arch and descending thoracic aorta (see later). The arguments for using a hybrid approach to treat aortic arch aneurysms include the elimination of cardiopulmonary bypass, circulatory arrest, and cardiac ischemia, although in practice, these adjuncts are frequently used during hybrid proximal aortic repairs.[82]

It is not yet clear whether hybrid repairs are as durable as traditional ones because little mid- or long-term data have been published, and no large-scale studies have compared hybrid and traditional repairs. Procedure-related risks include the risk of embolization and stroke due to wire and device manipulation within the aortic arch (this risk appears to be greatest in zone 0 repairs[83]), retrograde acute aortic dissection,[84] type I endoleak,[85]

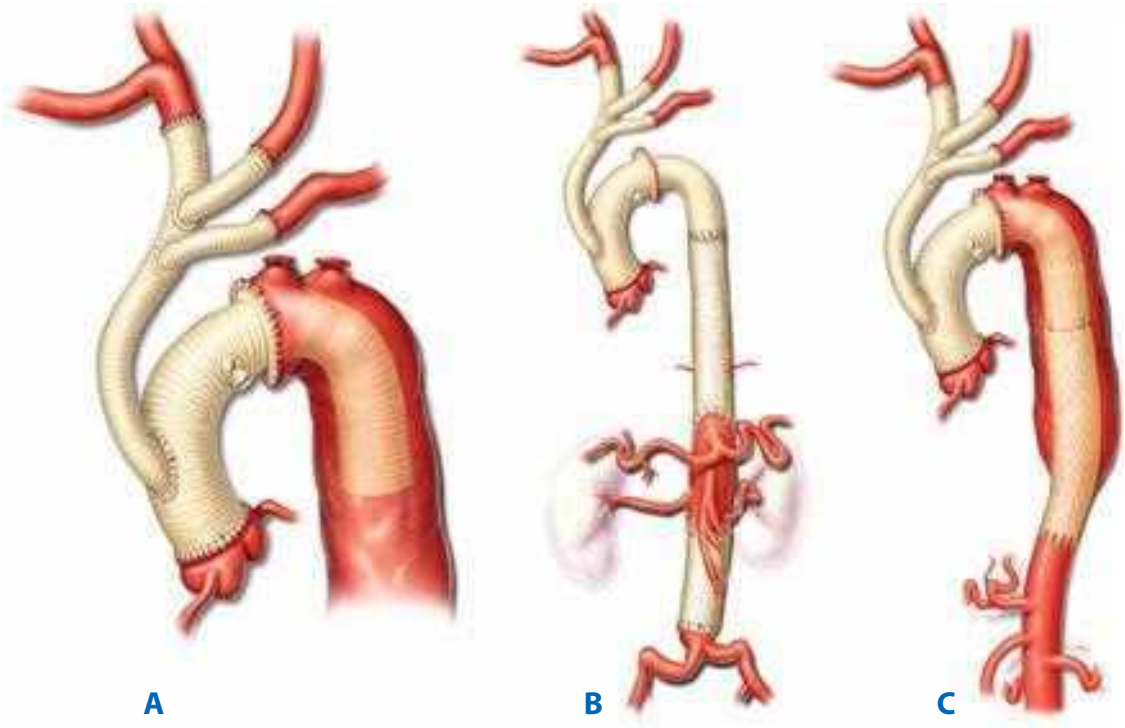

Figure 22-8. Illustration of Borst's elephant trunk technique using a contemporary Y-graft approach. **A.** Stage 1: The proximal repair includes replacing the ascending aorta and entire arch, with Y-graft reattachment of the brachiocephalic vessels. The distal anastomosis is facilitated by using a collared elephant trunk graft to accommodate the larger diameter of the distal aorta. A section of the graft is left suspended within the proximal descending thoracic aorta. **B.** Stage 2: The distal repair uses the floating "trunk" for the proximal anastomosis. **C.** An alternate "hybrid" approach may be used in patients with less extensive distal aortic disease. Endovascular stent grafts are placed within the elephant trunk to complete the repair. *(Used with permission of Baylor College of Medicine.)*

and paraplegia.[24] Some centers have begun to replace a small section of the ascending aorta such that the endograft does not land in native aortic tissue, because this may reduce the risk of iatrogenic dissection.[84] In a recent expert consensus document, the recommendation was to limit direct stenting of the aortic arch to patients who fall into the high surgical risk category. These are patients with significant comorbidities such as chronic pulmonary disease.[86]

Distal Thoracic Aortic Aneurysms

Open Repair In patients with descending thoracic or thoracoabdominal aortic aneurysms, several aspects of treatment—including

Figure 22-9. Landing Zone Classifications

Figure 22-11. Illustration of the Criado landing zones, which are used to describe aortic anatomy during thoracic endovascular repair. The arch is the short segment that includes the origins of the three brachiocephalic arteries—the innominate artery, the left common carotid artery, and the left subclavian artery. Zone 0 includes the ascending aorta and the origin of the innominate artery. Zone 1 includes the origin of the left common carotid artery. Zone 2 includes the left subclavian artery origin. Zone 3 is a short section of the aorta that comprises the 2 cm immediately distal to the origin of the left subclavian artery, and Zone 4 begins where Zone 3 ends. *(Used with permission from Baylor College of Medicine.)*

preoperative risk assessment, anesthetic management, choice of incision, and use of protective adjuncts—are dictated by the overall extent of aortic involvement. By definition, descending thoracic aortic aneurysms involve the portion of the aorta between the left subclavian artery and the diaphragm. Thoracoabdominal aneurysms can involve the entire thoracoabdominal aorta, from the origin of the left subclavian artery to the aortic bifurcation. Surgical repair of thoracoabdominal aortic aneurysms is categorized by the extent of aortic replacement according to the Crawford classification scheme (Fig. 22-12). Extent I thoracoabdominal aortic aneurysm repairs involve most of the descending thoracic aorta, usually beginning near the left subclavian artery, and extend down into the suprarenal abdominal aorta. Extent II repairs also begin near the left subclavian artery but extend distally into the infrarenal abdominal aorta, and they often reach the aortic bifurcation. Extent III repairs extend from the lower descending thoracic aorta (below the sixth rib) and into the abdomen. Extent IV repairs begin at the diaphragmatic hiatus and often involve the entire abdominal aorta.

Descending thoracic aortic aneurysms are repaired through a left thoracotomy. In patients with thoracoabdominal aortic aneurysms, the thoracotomy is extended across the costal margin and into the abdomen. Use of a double-lumen endobronchial tube allows selective ventilation of the right lung and deflation of the left lung. Transperitoneal exposure of the thoracoabdominal aorta is achieved by performing medial visceral rotation and circumferential division of the diaphragm. During a period of aortic clamping, the diseased segment is replaced with a polyester tube graft. Important branch arteries—including intercostal arteries and the celiac, superior mesenteric, and renal arteries—are reattached to openings made in the side of the graft. Visceral and renal artery occlusive disease is commonly encountered during aneurysm repair; options for correcting branch vessel stenosis include endarterectomy, direct arterial stenting, and bypass grafting.

Clamping the descending thoracic aorta causes ischemia of the spinal cord and abdominal viscera. Clinically significant manifestations of hepatic, pancreatic, and bowel ischemia are relatively uncommon. However, both acute renal failure and spinal cord injury resulting in paraplegia or paraparesis remain major causes of morbidity and mortality after these

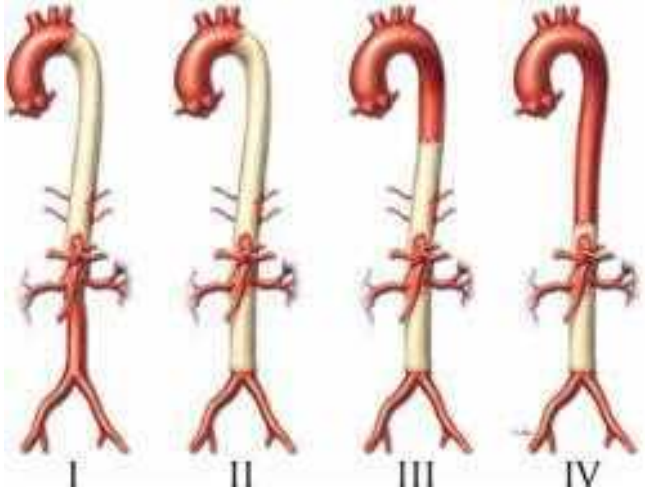

Figure 22-12. Illustration of the Crawford classification of thoracoabdominal aortic aneurysm repair based on the extent of aortic replacement. *(Reproduced with permission from Coselli et al,[232] Fig. 1. Copyright The Society of Thoracic Surgeons.)*

Table 22-3

Current strategy for spinal cord and visceral protection during repair of distal thoracic aortic aneurysms

All extents
- Permissive mild hypothermia (32°C–34°C, nasopharyngeal)
- Moderate heparinization (1 mg/kg)
- Aggressive reattachment of segmental arteries, especially between T8 and L1
- Sequential aortic clamping when possible
- Perfusion of renal arteries with 4°C crystalloid solution when possible

Crawford extent I and II thoracoabdominal repairs
- Cerebrospinal fluid drainage
- Left heart bypass during proximal anastomosis
- Selective perfusion of celiac axis and superior mesenteric artery during intercostal and visceral anastomoses

operations. Therefore, several aspects of the operation are devoted to minimizing spinal and renal ischemia (Table 22-3). Our multimodal approach to spinal cord protection includes expeditious repair to minimize aortic clamping time, moderate systemic heparinization (1.0 mg/kg) to prevent small-vessel thrombosis, mild permissive hypothermia (32°C–34°C [89.6°–93.2°F] nasopharyngeal temperature), and reattachment of segmental intercostal and lumbar arteries. As the aorta is replaced from proximal to distal, the aortic clamp is moved sequentially to lower positions along the graft to restore perfusion to newly reattached branch vessels. During extensive thoracoabdominal aortic repairs (i.e., Crawford extent I and II repairs), cerebrospinal fluid drainage is used. The benefits of this adjunct, which improves spinal perfusion by reducing cerebrospinal fluid pressure, have been confirmed in a prospective, randomized trial performed by our group.[87] Motor evoked potentials are used by some groups to monitor the spinal cord throughout the operation.[88,89] Left heart bypass, which provides perfusion of the distal aorta and its branches during the clamping period, is also used during extensive thoracoabdominal aortic repairs.[90-92] Because left heart bypass unloads the heart, it is also useful in patients with poor cardiac reserve. Balloon perfusion cannulas connected to the left heart bypass circuit can be used to deliver blood directly to the celiac axis and superior mesenteric artery during their reattachment. The potential benefits of reducing hepatic and bowel ischemia include reduced risks of postoperative coagulopathy and bacterial translocation, respectively. Whenever possible, renal protection is achieved by perfusing the kidneys with cold (4°C [39.2°F]) crystalloid. In a randomized clinical trial, reduced kidney temperature was found to be associated with renal protection, and the use of cold crystalloid independently predicted preserved renal function.[93]

Hypothermic circulatory arrest can also be used during descending thoracic or thoracoabdominal aortic repairs.[94] At our center, the primary indication for this approach is the inability to clamp the aorta because of rupture, extremely large aneurysm size, or extension of the aneurysm into the distal transverse aortic arch, or because a prior endovascular repair hinders clamping.[55]

As discussed previously, complete repair of extensive aneurysms involving the ascending aorta, transverse arch, and

descending thoracic aorta generally requires staged operations. In such procedures, when the descending or thoracoabdominal component is symptomatic (e.g., causes back pain or has ruptured) or is disproportionately large (compared with the ascending aorta), the distal segment is treated during the initial operation, and repair of the ascending aorta and transverse aortic arch is performed as a second procedure. A reversed elephant trunk repair, in which a portion of the proximal end of the aortic graft is inverted down into the lumen, can be performed during the first operation; this technique facilitates the second-stage repair of the ascending aorta and transverse aortic arch (Fig. 22-13).[95]

Although spinal cord ischemia and renal failure receive the most attention, several other complications warrant consideration. The most common complication of extensive repairs is pulmonary dysfunction. With aneurysms adjacent to the left subclavian artery, the vagus and left recurrent laryngeal nerves are often adherent to the aortic wall and thus are susceptible to injury. Vocal cord paralysis should be

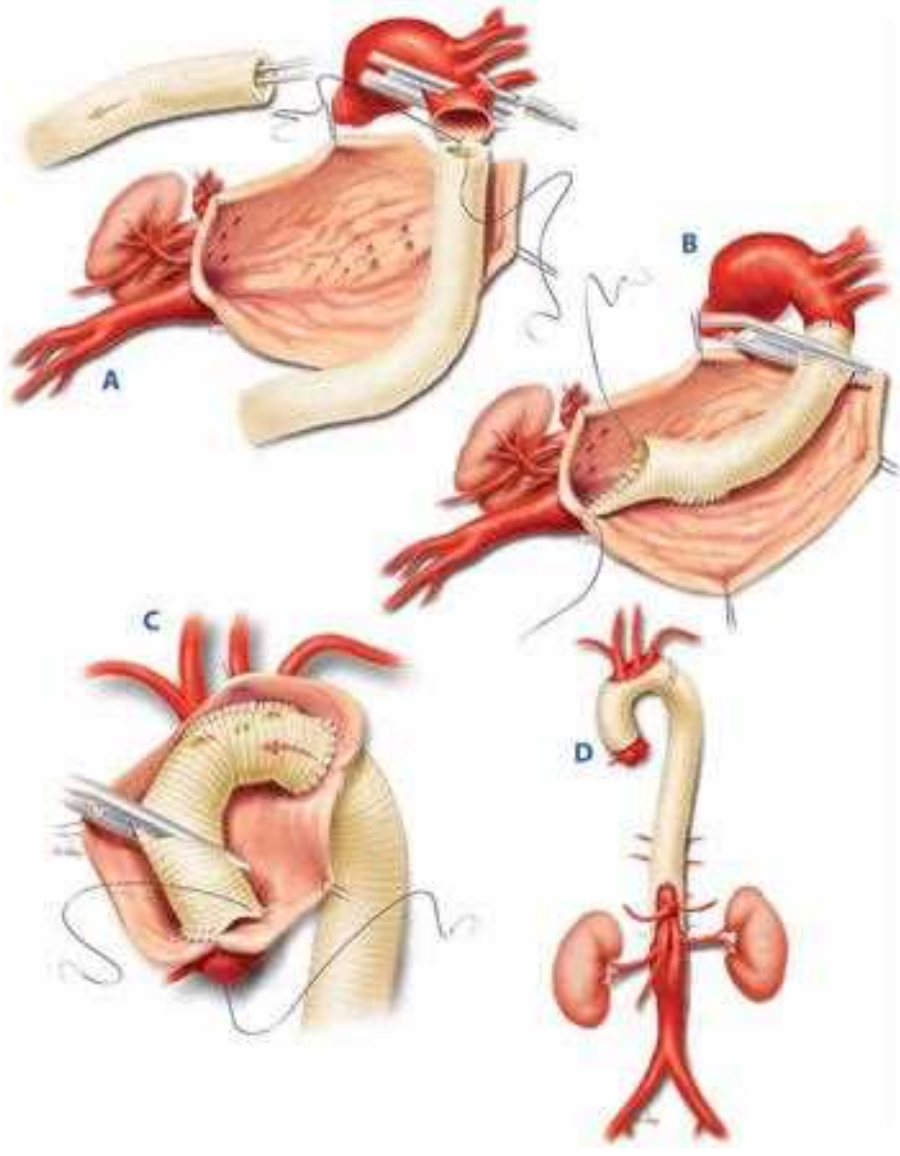

Figure 22-13. Illustration of the reversed elephant trunk technique using a traditional "island" approach to total aortic arch replacement. **A.** Stage 1: The distal aorta is repaired through a left thoracoabdominal approach. The aneurysm is opened after the aorta is clamped between the left common carotid artery and the left subclavian artery, which is also clamped. Before the proximal anastomosis is performed, the end of the graft is partly invaginated to leave a "trunk" for the subsequent repair. Proximal intercostal arteries are oversewn. **B.** After the proximal suture line is completed, the clamps are repositioned to restore blood flow to the left subclavian artery. The repair is completed by reattaching patent intercostal arteries to an opening in the side of the graft and creating a beveled distal anastomosis at the level of the visceral branches. **C.** Stage 2: The proximal aorta is repaired through a median sternotomy. The aortic arch is opened under hypothermic circulatory arrest. The "trunk" is pulled out and used to replace the aortic arch and ascending aorta. This eliminates the need for a new distal anastomosis and simplifies the procedure. Circulatory arrest and operative time, along with their attendant risks, are reduced. **D.** The completed two-stage repair of the entire thoracic aorta. *(Reproduced with permission from Coselli JS, LeMaire SA, Carter SA, et al: The reversed elephant trunk technique used for treatment of complex aneurysms of the entire thoracic aorta.* Ann Thorac Surg *2005; 80:2166, Figs. 2, 3, 7, and 8. Copyright The Society of Thoracic Surgeons.)*

suspected in patients who have postoperative hoarseness, and the presence of nerve damage should be confirmed by endoscopic examination. Vocal cord paralysis can be treated effectively by direct cord medialization (type 1 thyroplasty). Injury to the esophagus during the proximal anastomosis can have catastrophic consequences. Carefully separating the proximal descending thoracic aorta from the underlying esophagus before performing the proximal anastomosis minimizes the risk of a secondary aortoesophageal fistula. In patients who have previously undergone coronary artery bypass with a left internal thoracic artery graft, clamping proximal to the left subclavian artery can precipitate severe myocardial ischemia and cardiac arrest. When the need to clamp at this location is anticipated in these patients, a left common carotid to subclavian bypass is performed to prevent cardiac complications (Fig. 22-14).[96]

Endovascular Repair

Descending Thoracic Aortic Aneurysms Stent graft repair of descending thoracic aortic aneurysms has become an accepted treatment option for selected patients.[86] Although aortic repair with a self-fixing endoprosthesis was reported by Volodos[97] in the mid-1980s, it was the report by Parodi and associates[98] of using endovascular stent grafting to repair abdominal aortic aneurysms that helped popularize this approach. Only 3 years after this seminal report was published, Dake and colleagues[99] reported performing endovascular descending thoracic aortic repair with "homemade" stent grafts in 13 patients.

Although endografting was initially approved to treat degenerative descending thoracic aortic aneurysms, recently some newer devices have been approved for use in blunt aortic injury, as well as for penetrating aortic ulcers (see *Penetrating Aortic Ulcer* discussed later). However, in practice, off-label use of stent-grafts is exceedingly common, and they are frequently used in patients with aortic dissection or ruptured aneurysm. Although the use of stent-grafts in cases of aortic infection is not ideal, patients with fistula or mycotic aneurysm may be treated endovascularly as a bridge to open repair. Reporting standards to uniformly describe the endovascular repair process have been recently introduced,[100] as have guidelines for the use of endovascular repair in thoracic aortic disease.[40]

In elderly patients with severe comorbidity and patients who have undergone previous complex thoracic aortic procedures, endovascular repair is a particularly attractive alternative to standard surgical procedures. The patients tend to have a lower incidence of intraoperative complications, a shorter length of stay, and a higher likelihood of being discharged to home than those who undergo open repair.[49] As mentioned previously, appropriate patient selection depends on specific measurements taken from preoperative CT angiograms.

To protect patients against spinal cord ischemia during these endovascular repairs, many surgeons use cerebrospinal

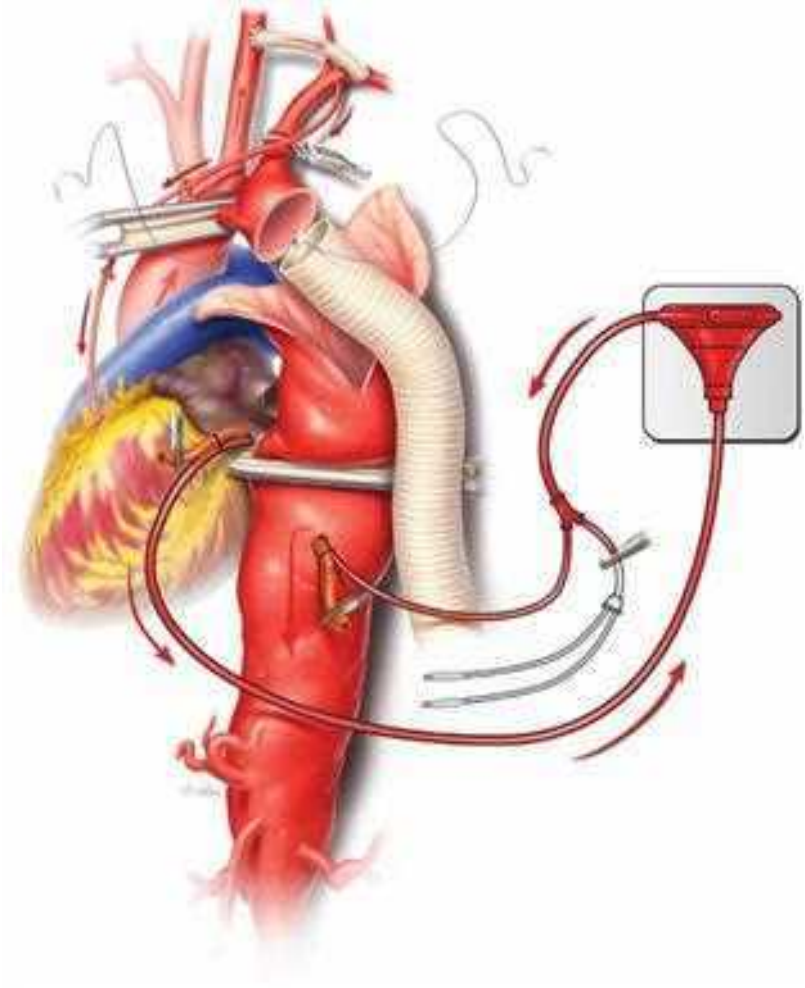

Figure 22-14. Illustration of a thoracoabdominal aortic aneurysm repair in a patient with a patent left internal thoracic artery–to–left anterior descending coronary artery graft. The proximal anastomosis is being performed while the aorta is clamped between the left common carotid and subclavian arteries. Myocardial perfusion is maintained through the carotid-subclavian bypass graft. *(Reproduced with permission from Jones et al,[96] Fig. 2. Copyright The Society of Thoracic Surgeons.)*

fluid drainage. The first step in the repair procedure is to obtain appropriate vascular access for the insertion of the thoracic stent graft. If the femoral artery will not accommodate the necessary sheath, then an iliac artery is exposed. A graft can be sewn to the iliac artery in an end-to-side fashion to facilitate the deployment of the endograft. After 5000 to 10,000 units of heparin are administered, a guidewire and the delivery sheath are typically inserted into the access artery under fluoroscopic guidance; recently, sheathless stent-grafts have been introduced, which are less bulky. The endograft is then advanced into the aorta and suitably positioned. Note that the best view of the distal arch and descending thoracic aorta is usually in the left anterior oblique position at an angle of approximately 40 to 50 degrees. The device is then deployed, and the proximal and distal ends are expanded by using a balloon catheter ("ballooned"), which optimizes the seal between the device and the aortic wall at this landing zone. An aortogram is then taken to rule out any endoleak, and protamine is administered.

Although it is not uncommon to cover the left subclavian artery with the endograft to lengthen the proximal landing zone,[101] findings suggest that the risk of spinal cord complications is heightened when the subclavian artery is covered and not revascularized, presumably because of a loss of collateral circulation to the spinal cord.[102] To prevent this complication, a carotid-to-subclavian bypass can be easily constructed to maintain vertebral artery blood flow and minimize neurologic injury (Fig. 22-15).[103,104] In addition, new generations of stent grafts are being designed with side branches that can be placed within the left subclavian artery. This feature is particularly attractive if the proximal neck is short or if the patient has a patent left internal thoracic artery–to–left anterior descending coronary artery bypass. Because a significant number of patients have coexisting coronary artery disease, care must be taken to avoid left subclavian artery occlusion in patients with previous coronary surgery unless a carotid-to-subclavian bypass has been performed.

Elephant Trunk Completion In select patients, elephant trunk completion repairs may be done endovascularly (Fig. 22-8C), rather than by an open approach through a thoracotomy.[105] Recall that an elephant trunk is used when an aortic aneurysm extends from the distal arch to the descending thoracic aorta. An endograft can be deployed at the time of elephant trunk construction or during a separate, subsequent procedure.[84,106] When the stent is deployed in a retrograde manner in such a second-stage procedure, the procedure is facilitated by placing radiopaque markers at the end of the elephant trunk during the first-stage procedure. This allows the distal end of the trunk to be identified via fluoroscopy. A guidewire can then be manipulated into the trunk and advanced into the ascending aorta to stabilize it during stent deployment. Note that advancing a wire in retrograde fashion from the femoral artery into the elephant trunk can be challenging. Occasionally, the wire must be advanced in an antegrade fashion from a brachial artery. Variations of this approach include the frozen elephant trunk, but this technique is most commonly used in patients with extensive aortic dissection (see *Acute Dissection* discussed later).

Thoracoabdominal Aortic Aneurysms Although endovascular thoracoabdominal aortic aneurysm repair remains experimental, it has been shown to be feasible in a few specialized centers. Endovascular thoracoabdominal aortic aneurysm repairs are quite complex, because at least one of the visceral arteries is incorporated into the repair. The number of visceral branches that need to be addressed varies with the extent of aortic coverage.[107] The types of stent grafts used include fenestrated grafts, reinforced fenestrated grafts, branched or cuffed grafts, modular combinations of grafts, and multilayer stents.[108] Graft fenestrations and branch vessels are typically aligned by using inflatable angioplasty balloons. Procedure time is not insignificant, nor is the amount of contrast medium required to obtain the highly detailed images needed to plan these procedures. In addition, some of the stent grafts used in endovascular thoracoabdominal aortic aneurysm repair are custom-made in advance and thus may take several weeks to obtain; therefore, their use is limited to cases of elective repair.[84] In efforts to hasten repair and utilize off-the-shelf devices, parallel graft approaches, which use a combination of large- and small-diameter stents, have been reported.[109] And, although some centers now propose distal coverage of the celiac axis[110] for extent I thoracoabdominal aortic aneurysm repairs, this potentially risky approach is not widely used.

It should be noted that, like open thoracoabdominal aortic aneurysm repair, endovascular repair carries risks of paraplegia, renal failure, stroke, and death, despite the apparent benefits of its being a less invasive procedure. Notably, reports from centers experienced in endovascular thoracoabdominal aortic repair primarily describe limited extent IV repairs.[54] For the near future, endovascular thoracoabdominal aortic aneurysm repair should be considered investigational.

Hybrid Repair As discussed previously, hybrid aortic repairs are extremely heterogeneous. For extensive distal aortic repairs, approaches such as the hybrid elephant trunk (described previously) are not feasible because the aneurysm extends beyond the visceral arteries. However, extensive hybrid thoracoabdominal aortic aneurysm repair[111,112] may be a life-saving option in patients at high surgical risk, such as those who have limited physiologic reserve, are of advanced age, or have significant comorbidities. Hybrid procedures use open surgical techniques to reroute blood supply to the visceral arteries so that their aortic origins can be covered by stent grafts without causing visceral ischemia (see Fig. 22-16). Endovascular methods are then used (either as part of the same procedure or at a later stage) to repair the aortic aneurysm, often with simple tube stent grafts; such devices are more readily available than the customized, modular stent grafts deployed in strictly endovascular repairs. Overall, results for hybrid thoracoabdominal aortic aneurysm repair have been somewhat disappointing.[113] However, a few centers report acceptable outcomes in high-risk patients, particularly when a staged hybrid approach is used.[114]

Postoperative Considerations

Open Procedures Aortic anastomoses are often extremely fragile during the early postoperative period. Even brief episodes of postoperative hypertension can disrupt suture lines and precipitate severe bleeding or pseudoaneurysm formation. Therefore, during the initial 24 to 48 hours, meticulous blood pressure control is maintained to protect the integrity of the anastomoses. Generally, we liberally use IV vasoactive agents to keep the mean arterial blood pressure between 80 and 90 mmHg. In patients with extremely friable aortic tissue, such as those with Marfan syndrome, we lower the target range to between 70 and 80 mmHg. It is a delicate balancing act, because one must be mindful of spinal cord perfusion and avoid periods of relative hypotension while maintaining these low pressures.

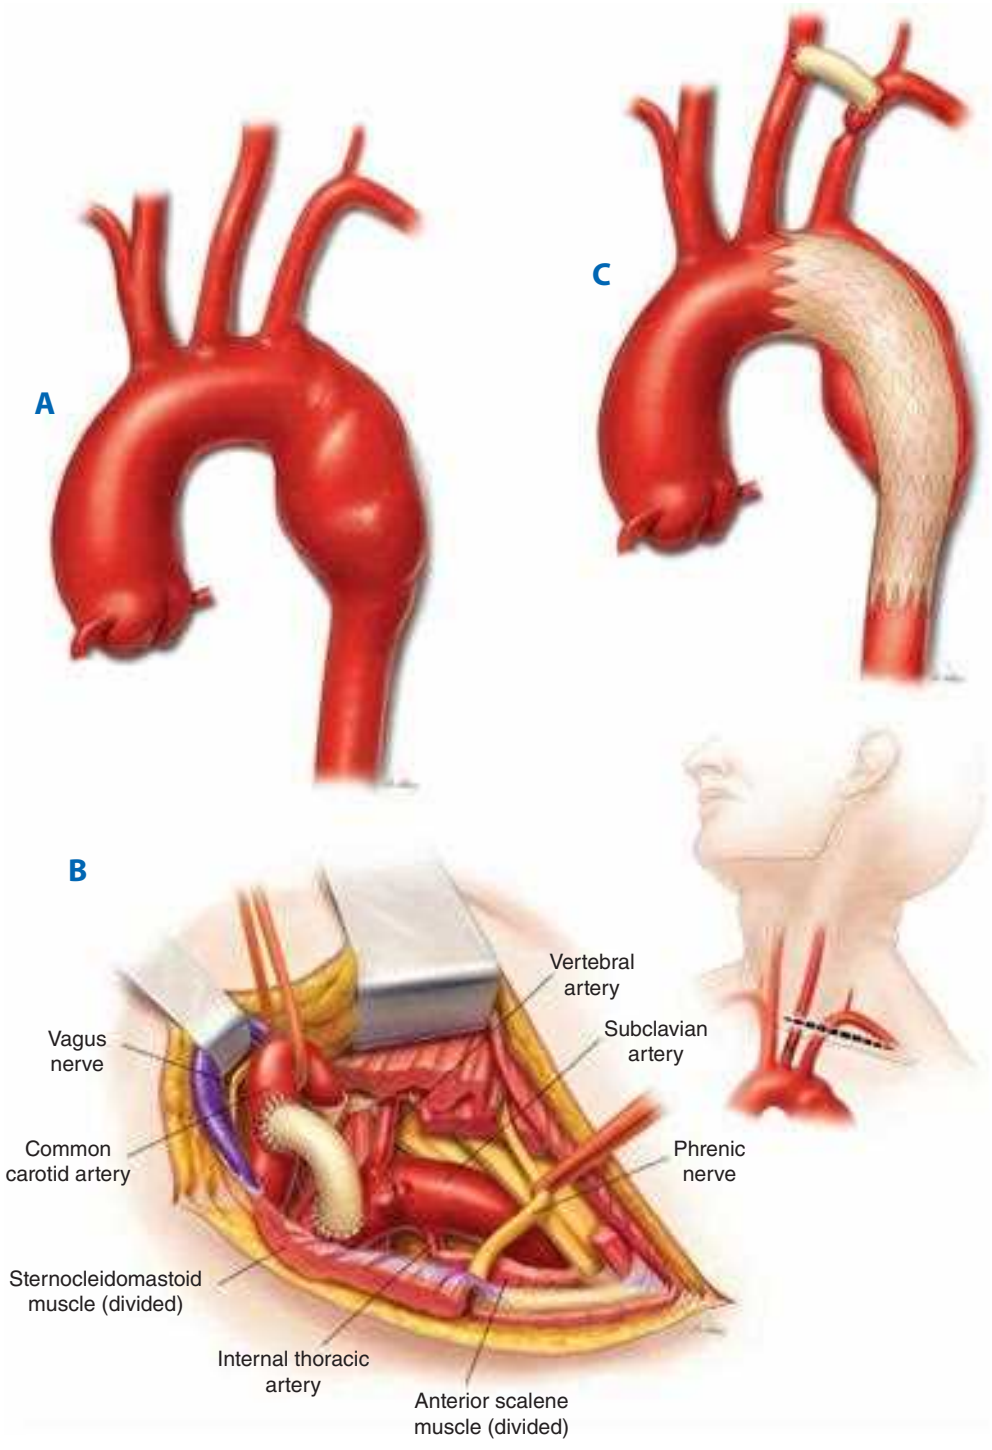

Figure 22-15. Illustration of a hybrid repair of the proximal descending thoracic aorta. **A.** The preoperative representation of the aneurysm shows that establishing a 2-cm proximal landing zone for a stent graft will require covering the origin of the left subclavian artery. **B.** Through a supraclavicular approach, a bypass from the left common carotid artery to the left subclavian artery is performed to reroute circulation and create a landing zone for the stent graft. After the bypass is completed, the left subclavian artery is ligated proximal to the graft. **C.** In the completed zone 2 hybrid repair, the aneurysm has been excluded successfully by a stent graft that covers the origin of the left subclavian artery, and blood flow to the left vertebral artery and arm is preserved by the bypass graft. *(Reproduced with permission from Bozinovski et al,[103] Figs. 9, 10, and 11. Copyright The Society of Thoracic Surgeons.)*

Endovascular Procedures As experience with descending thoracic aortic stent grafts continues to accumulate, so too do reports of both early and late complications.[55,115,116] Many of these complications are directly related to manipulation of the delivery system within the iliac arteries and aorta.[117] Patients with small, calcified, tortuous iliofemoral arteries are at particularly high risk for life-threatening iliac artery rupture. Although aortic rupture appears to be rare during thoracic stent graft procedures, acute iatrogenic retrograde dissection into the aortic arch and ascending aorta is a relatively common and life-threatening

Figure 22-16. Illustration of a hybrid approach—which combines open and endovascular techniques—for repair of an extensive aortic aneurysm. Debranching the arch and thoracoabdominal segments allows the use of a series of endovascular stent grafts to exclude the entire aneurysm.

complication that requires emergency repair of the ascending aorta and aortic arch via sternotomy and cardiopulmonary bypass. There are many reports of this complication, and it appears most common in off-label applications[55] such as hybrid arch approaches[84] and the treatment of descending thoracic aortic dissection.[118] Retrograde proximal dissection converts a localized descending thoracic aortic aneurysm into an acute problem involving the entire thoracic aorta. Of note, retrograde aortic dissection may also occur several months after initial repair.[119]

Another significant complication of descending thoracic aortic stent grafting is endoleak. An endoleak occurs when there is a persistent flow of blood (visible on radiologic imaging) into the aneurysm sac, and it may occur during the initial procedure or develop over time. Although endoleaks are a relatively common complication,[120] they are not benign, because they lead to continual pressurization of the sac, which can cause expansion or even rupture. These complications are categorized (Table 22-4) according to the site of the leak.[100] Although all endoleaks may progress such that they can be considered life-threatening, type I and type III endoleaks generally necessitate early and aggressive intervention. Recently published reporting guidelines aid standardized reporting.[100]

Other complications include stent graft misdeployment, device migration, endograft kinking, and stent-graft infection, including fistula. Although not all complications related to stent grafts are fatal, endovascular repairs should be performed by expert teams qualified to address the variety of problems that may arise; some patients may need to have these devices removed and replaced with polyester grafts.[55,115,116] Complications of endovascular repair are relatively common, so regularly scheduled radiologic imaging surveillance is of the utmost importance.

Table 22-4

Classification of and common treatment strategies for endoleak

Type I
- Incomplete seal between stent graft and aorta at the proximal landing site (Type Ia), the distal landing site (Type Ib), or branch module, fenestration, or plug (Type Ic)
- Early reintervention to improve seal or conversion to open surgery

Type II
- Retrograde perfusion of sac from excluded collateral arteries
- Surveillance; as-needed occlusion with percutaneous or other interventions

Type III
- Incomplete seal between overlapping stent graft or module (Type IIIa), or tear in graft fabric (Type IIIb)
- Early reintervention to cover gap or tear or conversion to open surgery

Type IV
- Perfusion of sac due to porosity of material
- Surveillance; as-needed reintervention to reline stent graft

Type V
- Expansion of sac with no identifiable source
- Surveillance; as-needed reintervention to reline stent graft

AORTIC DISSECTION

Pathology and Classification

Aortic dissection, the most common catastrophic event involving the aorta, is a progressive separation of the aortic wall layers that usually occurs after a tear forms in the intima and inner media. As the separation of the layers of the media propagates, at least two channels form (Fig. 22-17): the original lumen, which remains lined by the intima and which is called the *true lumen*, and the newly formed channel within the layers of the media, which is called the *false lumen.* The dissecting membrane separates the true and false lumens. Additional tears in the dissecting membrane that allow communication between

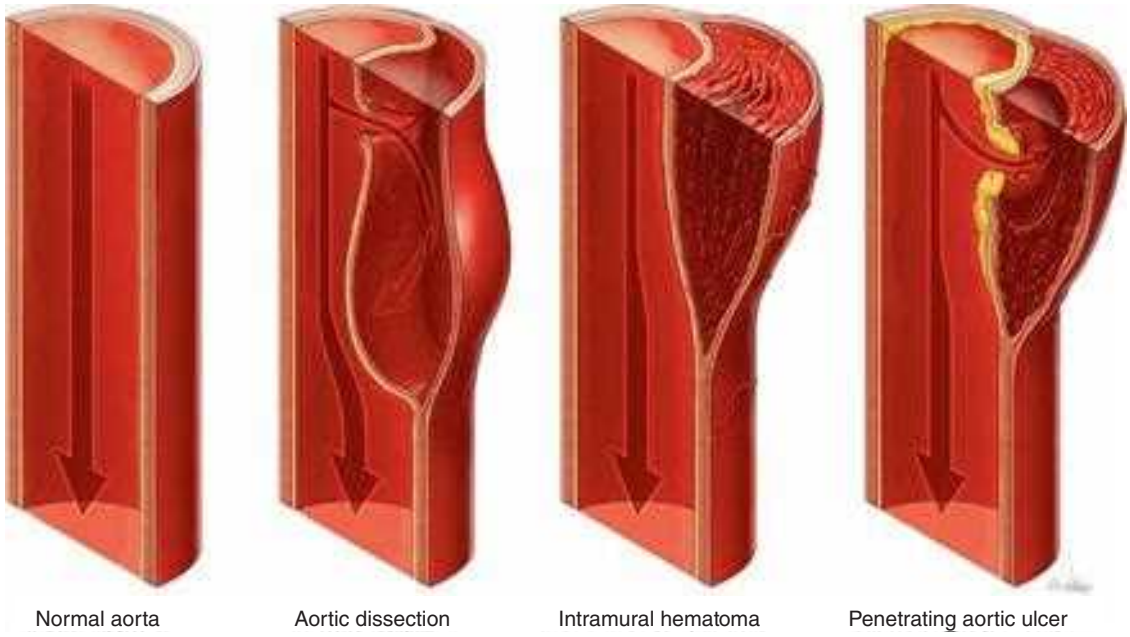

Figure 22-17. Illustration of longitudinal sections of the aortic wall and lumen. Blood flows freely downstream in normal aortic tissue. In classic aortic dissection, blood entering the media through a tear creates a false channel in the wall. Intramural hematomas arise when hemorrhage from the vasa vasorum causes blood to collect within the media; the intima is intact. Penetrating aortic ulcers are deep atherosclerotic lesions that burrow into the aortic wall and allow blood to enter the media. In each of these conditions, the outer aortic wall is severely weakened and prone to rupture.

the two channels are called *reentry sites.* Although the separation of layers primarily progresses distally along the length of the aorta, it can also proceed in a proximal direction; this process often is referred to as *proximal extension* or *retrograde dissection*.

The extensive disruption of the aortic wall has severe anatomic consequences (Fig. 22-18). First, the outer wall of the false lumen is extremely thin, inflamed, and fragile, which makes it prone to expansion or rupture in the face of ongoing hemodynamic stress. Second, the expanding false lumen can compress the true lumen and cause *malperfusion syndrome* by interfering with blood flow in the aorta or any of its branch vessels, including the coronary, carotid, intercostal, visceral, renal, and iliac arteries. Finally, when the separation of layers occurs within the aortic root, the aortic valve commissures can become unhinged, which results in acute valvular regurgitation. The clinical consequences of each of these sequelae are addressed in detail in the section on clinical manifestations.

Dissection vs. Aneurysm. The relationship between dissection and aneurysmal disease requires clarification. Dissection and aneurysm are separate entities, although they often coexist and are mutual risk factors. In most cases, dissection occurs in patients without aneurysms. The subsequent progressive dilatation of the weakened outer aortic wall results in an aneurysm. On the other hand, in patients with degenerative aneurysms, the ongoing deterioration of the aortic wall can lead to a superimposed dissection. The overused term *dissecting aneurysm* should be reserved for this specific situation.

Classification. For management purposes, aortic dissections are classified according to their location and chronicity. Improvements in imaging have increasingly revealed variants of aortic dissection that probably represent different forms along the spectrum of this condition.

Location To guide treatment, dissections are categorized according to their anatomic location and extent. The two traditional classification schemes that remain in common use are the DeBakey and the Stanford classification systems (Fig. 22-19).[121,122] In their current forms, both of these schemes describe the segments of aorta that are involved in the dissection, rather than the site of the initial intimal tear. The main drawback of the Stanford classification system is that it does not distinguish between patients with isolated ascending aortic dissection and patients with dissection involving the entire aorta. Both types of patients would be classified as having type A dissections, despite the fact that their treatment, follow-up, and prognosis are substantially different.

Additional classification schemas include that by Borst and associates,[123] in which the ascending and descending aorta are considered independently; the recent modification of the DeBakey classification by Tsagakis et al,[124] which extends type II dissection into the aortic arch; and the Penn modification of the Stanford classification,[125,126] which expands the classification to include the presence of tissue and global malperfusion. These modifications may help to better streamline the primary surgical intervention; patients with isolated proximal aortic dissection usually undergo emergent operation, as do patients with both proximal and distal aortic dissection. Patients with isolated distal aortic dissection are typically treated medically, unless complications requiring surgery develop. Additionally, these changes are reflective of a shift in some aortic centers from the more traditional approach that is primarily focused on emergent surgical repair of the ascending aorta toward one that, in select patients, additionally treats distal dissection entry points with off-label endovascular therapy.[127]

Chronicity Aortic dissection also is categorized according to the time elapsed since the initial tear. Dissection is considered

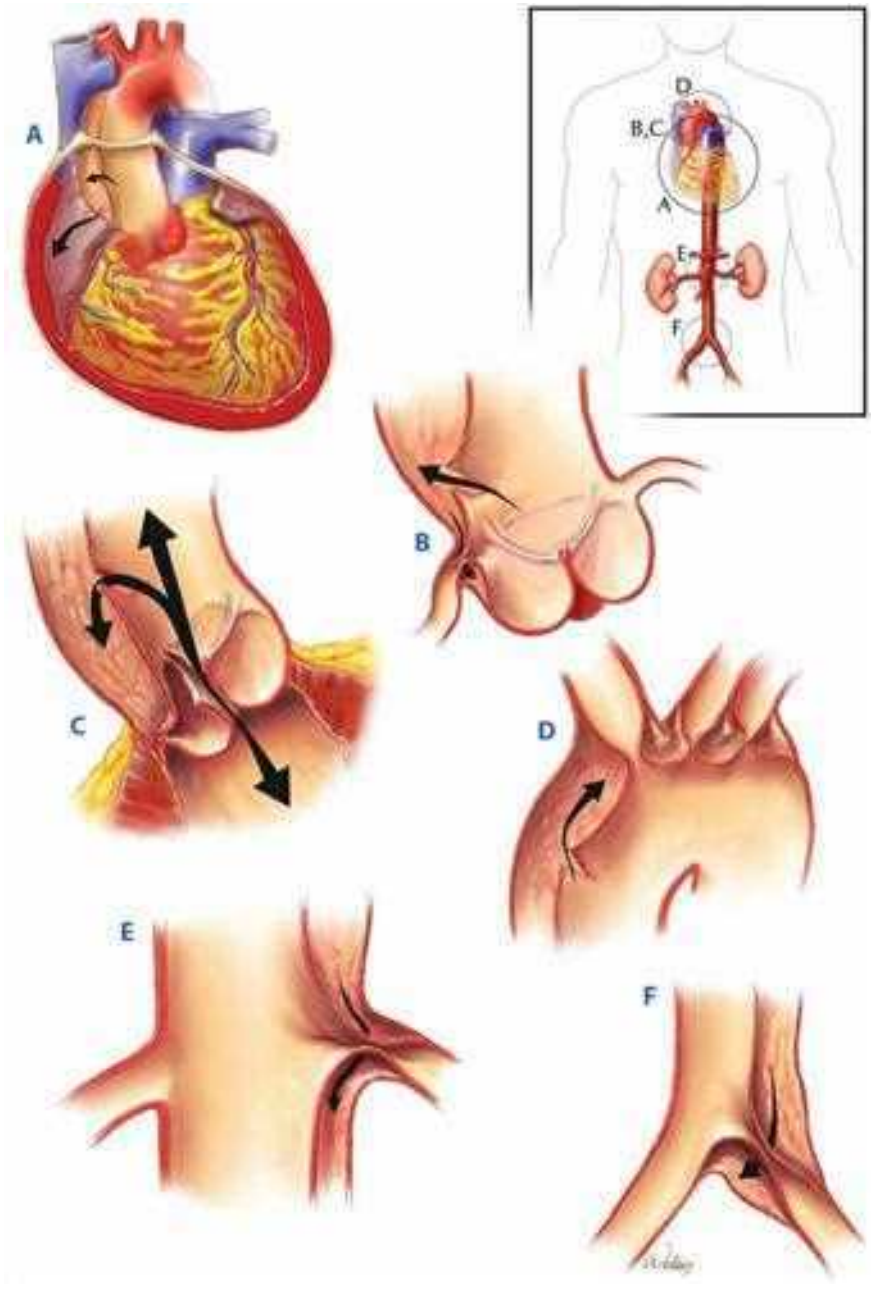

Figure 22-18. Illustration of the potential anatomic consequences of aortic dissection, with a mapped diagram of affected regions (*inset*). **A.** Ascending aortic rupture and cardiac tamponade. **B.** Disruption of coronary blood flow. **C.** Injury to the aortic valve causing regurgitation. **D, E,** and **F.** Compromised blood flow to branch vessels, causing ischemic complications. *(Images adapted from Creager MA, Dzau VS, Loscalzo J, eds.* Vascular Medicine. *Philadelphia: WB Saunders; 2006. Copyright © Saunders/Elsevier, 2006. Fig. 35-1.)*

acute within the first 14 days after the initial tear; after 14 days, the dissection is considered chronic. Although arbitrary, the distinction between acute and chronic dissections has important implications, not only for decision-making about perioperative management strategies and operative techniques, but also for evaluating surgical results. Figure 22-20 provides an algorithm for the management of acute aortic dissection. In light of the importance of acuity, Borst and associates[123] have proposed a third phase—termed *subacute*—to describe the transition between the acute and chronic phases. The subacute period encompasses days 15 through 60 after the initial tear. Although this is past the traditional 14-day acute phase, patients with subacute dissection continue to have extremely fragile aortic tissue, which may complicate operative treatment and increase the risks associated with surgery.

Variants As noted earlier, advancements in noninvasive imaging of the aorta have revealed variants of aortic dissection (see Fig. 22-17). The recently introduced term *acute aortic syndrome* encompasses classic aortic dissection and its variants. Other aortic syndromes, which were once thought to be rare, include *intramural hematoma* (*IMH*) and *penetrating aortic ulcer* (*PAU*). Although the issue is somewhat controversial, the current consensus is that, in most cases, these variants of dissection should be treated identically to classic dissection.

An IMH is a collection of blood within the aortic wall, without an intimal tear, that is believed to be due to rupture of the vasa vasorum within the media. The accumulation of blood can result in a secondary intimal tear that ultimately leads to a dissection.[128] Because IMH and aortic dissection represent a continuum, it is possible that IMH is seen less frequently than aortic dissection because IMH rapidly progresses to true dissection. The prevalence of IMH among patients with acute aortic syndromes is approximately 6%, and 16% progress to full dissection.[129] An IMH can be classified according to its location (i.e., ascending or descending) and should be treated analogously to classic dissection.[130]

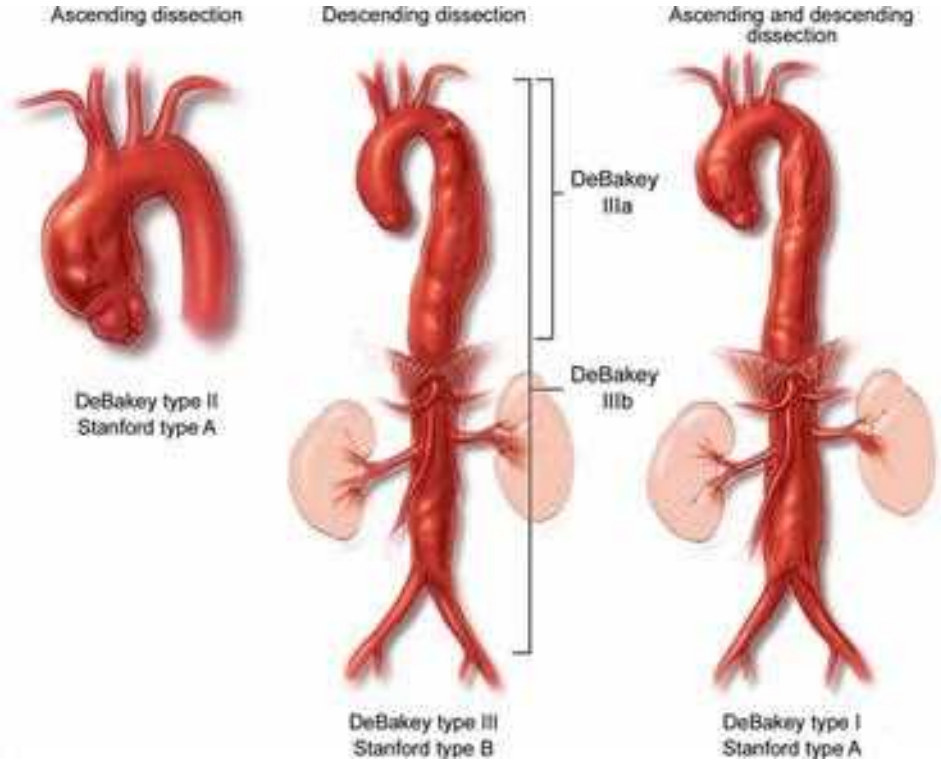

Figure 22-19. Illustration of the classification schemes for aortic dissection based on which portions of the aorta are involved. Dissection can be confined to the ascending aorta (*left*) or descending aorta (*middle*), or it can involve the entire aorta (*right*). *(Reproduced with permission from Creager MA, Dzau VS, Loscalzo J, eds.* Vascular Medicine. *Philadelphia: WB Saunders; 2006. Copyright © Saunders/Elsevier, 2006, Fig. 35-2).*

A PAU is essentially a disrupted atherosclerotic plaque that projects into the aortic wall and is associated with surrounding hematoma. Eventually, the ulcer can penetrate the aortic wall, which leads to dissection or rupture. The rate of disease progression is higher than that of IMH alone.[131]

Causes and Clinical History

Aortic dissection is a lethal condition with a reported incidence of 3.5 per 100,000 in the United States.[132] Without appropriate modern medical or surgical treatment, most patients (approximately 90%) die within 3 months of dissection, mostly from rupture.[133,134]

Although several risk factors for aortic dissection have been identified, the specific causes remain unknown. Ultimately, any condition that weakens the aortic wall increases the risk of aortic dissection. Common general cardiovascular risk factors, such as smoking, hypertension, atherosclerosis, and hypercholesterolemia, are associated with aortic dissection. Patients with connective tissue disorders, aortitis, bicuspid aortic valve, or preexisting medial degenerative disease are at risk for dissection, especially if they already have a thoracic aortic aneurysm.[21] Aortic injury during cardiac catheterization, surgery, or endovascular aortic repair is a common cause of iatrogenic dissection. Other conditions that are associated with aortic dissection include cocaine and amphetamine abuse,[135] as well as severe emotional stress or extreme physical exertion such as during weightlifting.[136] Advances in the understanding of the molecular mechanisms behind abdominal aortic aneurysms have prompted similar investigations of thoracic aortic dissection.[137-139]

Clinical Manifestations

The onset of dissection often is associated with severe chest or back pain, classically described as "tearing," that migrates distally as the dissection progresses along the length of the aorta. The location of the pain often indicates which aortic segments are involved. Pain in the anterior chest suggests involvement of the ascending aorta, whereas pain in the back and abdomen generally indicates involvement of the descending and thoracoabdominal aorta. Additional clinical sequelae of acute aortic dissection vary substantially and are best considered in terms of the dissection's potential anatomic manifestations at each level of the aorta (see Fig. 22-18 and Table 22-5). Thus, potential complications of dissection of the aorta (and involved secondary arteries) may include cardiac ischemia (coronary artery) or tamponade, stroke (brachiocephalic arteries), paraplegia or paraparesis (intercostal arteries), mesenteric ischemia (superior mesenteric artery), kidney failure (renal arteries), and limb ischemia or loss of motor function (brachial or femoral arteries).

Ascending aortic dissection can directly injure the aortic valve, causing regurgitation. The severity of the regurgitation varies with the degree of commissural disruption, which ranges from partial separation of only one commissure, producing mild valvular regurgitation, to full separation of all three commissures and complete prolapse of the valve into the left ventricle, producing severe acute heart failure. Patients with acute aortic valve regurgitation may report worsening dyspnea.

Ascending dissections also can extend into the coronary arteries or shear the coronary ostia off of the true lumen, causing acute coronary occlusion; when this occurs, it most often involves the right coronary artery. The sudden disruption of coronary blood flow can cause a myocardial infarction. This presentation of acute myocardial ischemia can mask the presence of aortic dissection, which results in delayed diagnosis and treatment.[140]

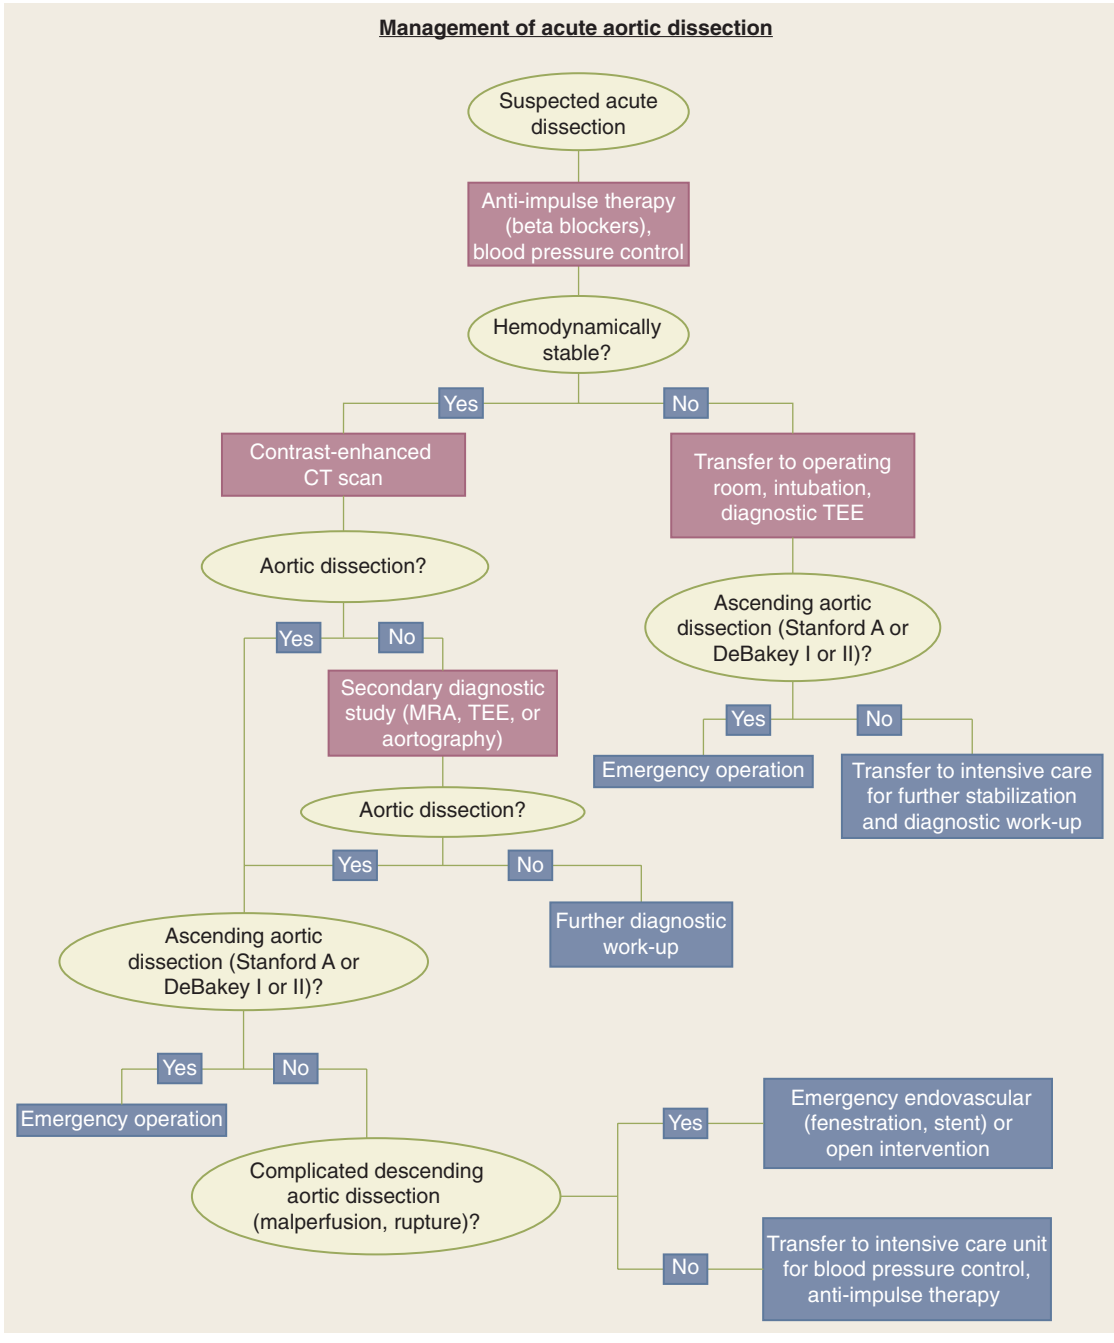

Figure 22-20. Algorithm used to facilitate decisions regarding treatment of acute aortic dissection. CT = computed tomography; MRA = magnetic resonance angiography; TEE = transesophageal echocardiography.

The thin and inflamed outer wall of a dissected ascending aorta often produces a serosanguineous pericardial effusion that can accumulate and cause tamponade. Suggestive signs include jugular venous distention, muffled heart tones, pulsus paradoxus, and low-voltage electrocardiogram (ECG) tracings. Free rupture into the pericardial space produces rapid tamponade and is generally fatal.

As the dissection progresses, any branch vessel from the aorta can become involved, which results in compromised blood flow and ischemic complications (i.e., malperfusion). Therefore, depending on which arteries are involved, the dissection can produce acute stroke, paraplegia, hepatic failure, bowel infarction, renal failure, or a threatened ischemic limb.

Diagnostic Evaluation

Because of the variations in severity and the wide variety of potential clinical manifestations, the diagnosis of acute aortic dissection can be challenging.[141-143] Only 3 out of every 100,000 patients who present to an emergency department with acute chest, back, or abdominal pain are eventually diagnosed with aortic dissection. Not surprisingly, diagnostic delays are common; delays beyond 24 hours after hospitalization occur in up to 39% of cases. Unfortunately, delays in diagnosis lead to delays in treatment, which can have disastrous consequences. The European Society of Cardiology Task Force on Aortic Dissection stated, "The main challenge in managing acute aortic dissection is to suspect and thus diagnose the disease as early

Table 22-5

Anatomic complications of aortic dissection and their associated symptoms and signs

ANATOMIC MANIFESTATION	SYMPTOMS AND SIGNS
Aortic valve insufficiency	Dyspnea Murmur Pulmonary rales Shock
Coronary malperfusion	Chest pain with characteristics of angina Nausea/vomiting Shock Ischemic changes on electrocardiogram Elevated cardiac enzymes
Pericardial tamponade	Dyspnea Jugular venous distension Pulsus paradoxus Muffled cardiac tones Shock Low-voltage electrocardiogram
Subclavian or iliofemoral artery malperfusion	Cold, painful extremity Extremity sensory and motor deficits Peripheral pulse deficit
Carotid artery malperfusion	Syncope Focal neurologic deficit (transient or persistent) Carotid pulse deficit Coma
Spinal malperfusion	Paraplegia Incontinence
Mesenteric malperfusion	Nausea/vomiting Abdominal pain
Renal malperfusion	Oliguria or anuria Hematuria

as possible."[141] A recent study by the International Registry of Acute Aortic Dissection examined the reasons for delayed diagnosis and found that diagnosis lagged in women, as well as in patients with atypical symptoms, such as fever or mild pain (rather than severe pain).[140] A high index of suspicion is critical, particularly in younger, atypical patients, who may have connective tissue disorders or other, less common risk factors.

Most patients with acute aortic dissection (80%–90%) experience severe pain in the chest, back, or abdomen.[141-143] The pain usually occurs suddenly, has a sharp or tearing quality, and often migrates distally as the dissection progresses along the aorta. For classification purposes (acute vs. subacute vs. chronic), the onset of pain is generally considered to represent the beginning of the dissection process. Most of the other common symptoms either are nonspecific or are caused by the secondary manifestations of dissection.

A discrepancy between the extremities in pulse, blood pressure, or both is the classic physical finding in patients with aortic dissection. It often occurs because of changes in flow in the true and false lumens, and it does not necessarily indicate extension into an extremity branch vessel. Involvement of the aortic arch often creates differences between the right and left arms, whereas descending aortic dissection often causes differences between the upper and lower extremities. Like symptoms, most of the physical signs after dissection are related to the secondary manifestations and therefore vary considerably (Table 22-5). For example, signs of stroke or a threatened ischemic limb may dominate the physical findings in patients with carotid or iliac malperfusion, respectively.

Unfortunately, laboratory studies are of little help in diagnosing acute aortic dissection. There has been continued interest in using D-dimer level to aid in making this diagnosis.[144] Several reports indicate that D-dimer is an extremely sensitive indicator of acute aortic dissection; elevated levels are found in approximately 97% of affected patients.[145] Tests that are commonly used to detect acute coronary events—including ECG and tests for serum markers of myocardial injury—deserve special consideration and need to be interpreted carefully. Normal ECGs and serum marker levels in patients with acute chest pain should raise suspicion about the possibility of aortic dissection. It is important to remember that ECG changes and elevated serum marker levels associated with myocardial infarction do not exclude the diagnosis of aortic dissection, because dissection can cause coronary malperfusion. Of note, abnormal ECGs have recently been shown to delay the diagnosis of aortic dissection, and the possibility of aortic dissection should not be prematurely ruled out.[140,146] Similarly, although CXRs may show a widened mediastinum or abnormal aortic contour, up to 16% of patients with dissection have a normal-appearing CXR.[142] The value of the CXR for detecting aortic dissection is limited, with a sensitivity of 67% and a specificity of 86%.[147]

Once the diagnosis of dissection is considered, the thoracic aorta should be imaged with CT, MRA, or echocardiography. The accuracy of these noninvasive imaging tests has all but eliminated the need for diagnostic aortography in most patients with suspected aortic dissection. Currently, the diagnosis of aortic dissection is usually established with contrast-enhanced CT, which has a sensitivity of 98% and a specificity of 87%, and, acquires images swiftly.[148] The classic diagnostic feature is a double-lumen aorta (Fig. 22-21). In addition, CT scans provide essential information about the segments of the aorta involved; the acuity of the dissection; aortic dilatation, including the presence of preexisting degenerative aneurysms; and the development of threatening sequelae, including pericardial effusion, early aortic rupture, and branch vessel compromise. Although MRA also provides excellent imaging (with both a sensitivity and specificity of 98%), the MR suite is not well suited for critically ill patients. In patients who cannot undergo contrast-enhanced CT or MRA, transthoracic echocardiography can be used to establish the diagnosis.

Transesophageal echocardiography (TEE) is excellent for detecting dissection, aneurysm, and IMH in the ascending aorta. In appropriate hands, TEE has a demonstrated sensitivity and specificity as high as 98% and 95%, respectively.[149] Furthermore, TEE offers important information about ventricular function and aortic valve competency. Finally, TEE is the diagnostic modality of choice for hemodynamically unstable patients in whom the diagnosis of ascending dissection is suspected; ideally, these patients should be taken to the operating room, where the TEE can be performed and, if the TEE is confirmatory, surgery can be started immediately.

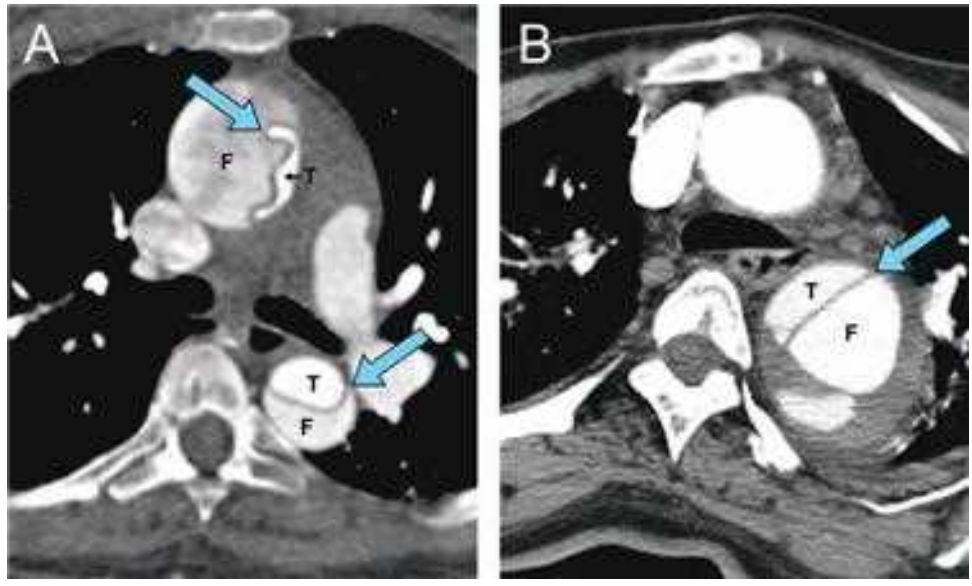

Figure 22-21. Computed tomographic scans showing that the aorta has been separated into two channels—the true (T) and false (F) lumens—in two patients with different phases of aortic dissection. **A.** An acute DeBakey type I aortic dissection. The dissecting membrane appears wavy (arrows) in the early phase of dissection. Here, the true lumen of the proximal aorta can be seen to be extensively compressed. This may lead to malperfusion of the heart. **B.** A chronic DeBakey type III aortic dissection. In the chronic phase, the membrane appears straighter and less mobile (arrow) because it has stabilized over time. *(Used with permission of Baylor College of Medicine.)*

In selected patients with ascending aortic dissection (i.e., those who have evidence of preexisting coronary artery disease), coronary angiography can be considered before surgery. Specific relative indications in these patients include a history of angina or myocardial infarction, a recent myocardial perfusion study with abnormal results, previous coronary artery bypass or angioplasty, and acute ischemic changes on ECG. Contraindications include hemodynamic instability, aortic rupture, and pericardial effusion.[150] In our practice, patients with acute aortic dissections rarely undergo coronary angiography. However, all patients presenting for elective repair of chronic ascending dissections have diagnostic coronary angiograms taken.

Of note, when malperfusion of the renal, visceral, or lower extremity arteries develops, the patient is usually treated in an angiography suite or hybrid operating room.[127] Although the dissection usually is diagnosed on CT scan, these patients also undergo aortography, during which the mechanism of the malperfusion is ascertained and, if possible, corrected. Hence, catheter-based aortography may be obsolete as a diagnostic test for dissection, but it remains beneficial for patients with malperfusion.

Treatment

Initial Assessment and Management. Regardless of the location of the dissection, the initial treatment is the same for all patients with suspected or confirmed acute aortic dissection (see Fig. 22-20). Furthermore, because of the potential for rupture before the diagnosis is confirmed, aggressive pharmacologic management is started once there is clinical suspicion of dissection, and this treatment is continued during the diagnostic evaluation. The goals of pharmacologic treatment are to stabilize the dissection and prevent rupture.

Patients are monitored closely in an intensive care unit. Indwelling radial arterial catheters are used to monitor blood pressure and optimize titration of antihypertensive agents. In cases of limb malperfusion, blood pressures in the affected limb can underrepresent the central aortic pressure; therefore, blood pressure is measured in the arm with the better pulse. Central venous catheters ensure reliable IV access for delivering vasoactive medications. Pulmonary artery catheters are reserved for patients with severe cardiopulmonary dysfunction.

In addition to confirming the diagnosis of dissection and defining its acuity and extent, the initial evaluation focuses on determining whether any of several life-threatening complications are present. Particular attention is paid to changes in neurologic status, peripheral pulses, and urine output. Serial laboratory studies—including arterial blood gas concentrations, complete blood cell count, prothrombin and partial thromboplastin times, and serum levels of electrolytes, creatinine, blood urea nitrogen, and liver enzymes—are useful for detecting organ ischemia and optimizing management.

The initial management strategy, commonly described as *anti-impulse therapy* or *blood pressure control,* focuses on reducing aortic wall stress, the force of left ventricular ejection, chronotropy, and the rate of change in blood pressure (dP/dT). Reductions in dP/dT are achieved by lowering both cardiac contractility and blood pressure. The drugs initially used to accomplish these goals include IV beta-adrenergic blockers, direct vasodilators, calcium channel blockers, and angiotensin-converting enzyme inhibitors. These agents are used to achieve a heart rate between 60 and 80 bpm, a systolic blood pressure between 100 and 110 mmHg, and a mean arterial blood pressure between 60 and 75 mmHg. These hemodynamic targets are maintained as long as urine output remains adequate and neurologic function is not impaired. Achieving adequate pain control with IV opiates, such as morphine and fentanyl, is important for maintaining acceptable blood pressure control.

Beta antagonists are administered to all patients with acute aortic dissections unless there are strong contraindications, such as severe heart failure, bradyarrhythmia, high-grade atrioventricular

conduction block, or bronchospastic disease. Esmolol can be useful in patients with bronchospastic disease because it is a cardioselective, ultrafast-acting agent with a short half-life. Labetalol, which causes both nonselective beta blockade and postsynaptic alpha$_1$-blockade, reduces systemic vascular resistance without impairing cardiac output. Doses of beta antagonists are titrated to achieve a heart rate of 60 to 80 bpm. In patients who cannot receive beta antagonists, calcium channel blockers such as diltiazem are an effective alternative. Nitroprusside, a direct vasodilator, can be administered once beta blockade is adequate. When used alone, however, nitroprusside can cause reflex increases in heart rate and contractility, elevated dP/dT, and progression of aortic dissection. Enalapril and other angiotensin-converting enzyme inhibitors are useful in patients with renal malperfusion. These drugs inhibit renin release, which may improve renal blood flow.

Treatment of Ascending Aortic Dissection

Acute Dissection Because of the risk of aortic rupture, acute ascending aortic dissection is usually considered an absolute indication for emergency surgical repair. However, specific patient groups may benefit from nonoperative management or delayed operation.[151] Delayed repair should be considered for patients who (a) present with severe acute stroke or mesenteric ischemia, (b) are elderly and have substantial comorbidity, (c) are in stable condition and may benefit from transfer to specialized centers, or (d) have undergone a cardiac operation in the remote past. Regarding the last group, it is important that the previous operation not be too recent; dissections that occur during the first 3 weeks after cardiac surgery pose a high risk of rupture and tamponade, and such dissections warrant early operation.[152]

In the absence of the circumstances listed earlier, most patients with acute ascending aortic dissection undergo emergent graft replacement of the ascending aorta. Operative repair is similar to that for aneurysm of the transverse aortic arch (described previously) because hypothermic circulatory arrest is commonly used regardless of the extent of repair. Immediately before the operation begins, intraoperative TEE is commonly performed to further assess baseline myocardial and valvular function and, if necessary, to confirm the diagnosis. The operation is performed via a median sternotomy with cardiopulmonary bypass and hypothermic circulatory arrest (Fig. 22-22). In preparation for circulatory arrest, cannulas are placed in the right axillary artery (to provide arterial inflow) and in the right atrium (to provide venous drainage).[77] After an appropriate level of cooling has been achieved (usually between 22°C and 24°C), cardiopulmonary bypass is stopped, and the ascending aorta is opened. The innominate artery is then occluded with a clamp or snare, and flow from the axillary artery cannula is used to provide ACP. A separate perfusion catheter can be placed in the left common carotid artery to ensure perfusion of the left side of the brain. This strategy of performing the distal anastomosis during a brief period of circulatory arrest, often termed *open distal anastomosis*, obviates the need to place a clamp across the fragile aorta, avoiding further aortic damage. Also, it allows the surgeon to carefully inspect the aortic arch for intimal tears. Traditionally, the entire arch is replaced only if a primary intimal tear is located in the arch or if the arch is aneurysmal; most commonly, repair is limited to replacement of the entire ascending aorta or to a beveled "hemiarch" repair.[153] Conservative repair has been shown to increase the likelihood of early survival.[154] The distal aortic cuff is prepared by tacking the inner and outer walls together and using surgical adhesive to obliterate the false lumen and strengthen the tissue. A polyester tube graft is sutured to the distal aortic cuff. The anastomosis between the graft and the aorta is fashioned so that blood flow will be directed into the true lumen; this often alleviates any distal malperfusion problems that were present preoperatively. After the distal anastomosis is reinforced with additional adhesive, the graft is de-aired and clamped, full cardiopulmonary bypass is resumed, rewarming is initiated, and the proximal portion of the repair is started. In the absence of annuloaortic ectasia or connective tissue disorders—which generally necessitate aortic root replacement—aortic valve regurgitation can be corrected by resuspending the commissures onto the outer aortic wall.[155] The proximal aortic cuff is prepared with tacking sutures and surgical adhesive before the proximal aortic anastomosis is performed.

In the majority of patients who undergo surgical repair of acute ascending dissection, the dissection persists distal to the site of the operative repair; the residually dissected aorta, which generally includes at least a portion of the transverse aortic arch as well as a large portion of the distal aorta, is susceptible to dilatation over time. Extensive dilatation of the arch or distal aorta develops in 25% to 40% of survivors[156,157] and often necessitates further aortic repair. Additionally, long-term survival after acute proximal aortic dissection is generally poor, and rupture of the dilated distal aorta is a common cause of late death in these patients.[154,156-158]

The challenges that survivors of acute proximal aortic dissection commonly face over time have led to the development of alternate acute dissection strategies such as total arch replacement[159] and hybrid arch strategies to extend proximal aortic repair into the distal aorta. The goal of hybrid arch approaches in acute dissection is to thrombose the residual false lumen by compressing it with the radial force that is exerted by a stent-graft placed in the true lumen, thereby facilitating remodeling and preventing late aneurysm formation.[160] However, in such repairs, the compressed false lumen may continue to be perfused in a retrograde fashion.

In Europe, Japan, and elsewhere, one-piece hybrid prostheses are now available that incorporate a polyester graft for the proximal repair and a stent-graft component for the descending aorta. These devices are deployed in an antegrade fashion after the arch has been resected; this procedure is termed a "frozen elephant trunk" repair.[161] In the United States, such devices are unavailable, so this repair is commonly done by concomitantly deploying a commercially available stent-graft in an antegrade fashion after fully or partly[162] replacing the ascending aorta and aortic arch. In some variations of this off-label approach, the stent-graft is directly sutured to the distal aspect of the proximal open repair, whereas in others, there may be a gap of native tissue between the open and endovascular repair. Although this technique appears to be extensively used outside the United States, and with early and midterm success,[160,163-165] only a few U.S. reports describe its use.[162,166,167] Emerging reports describe an enhanced risk of spinal cord ischemia, a risk that is not usually associated with open arch repair. This is probably due to the extensive coverage of the intercostal vessels by the stent-graft. Uncertainties in the frozen elephant trunk procedure need to be addressed before it becomes a standard recommendation for this subset of patients.[168]

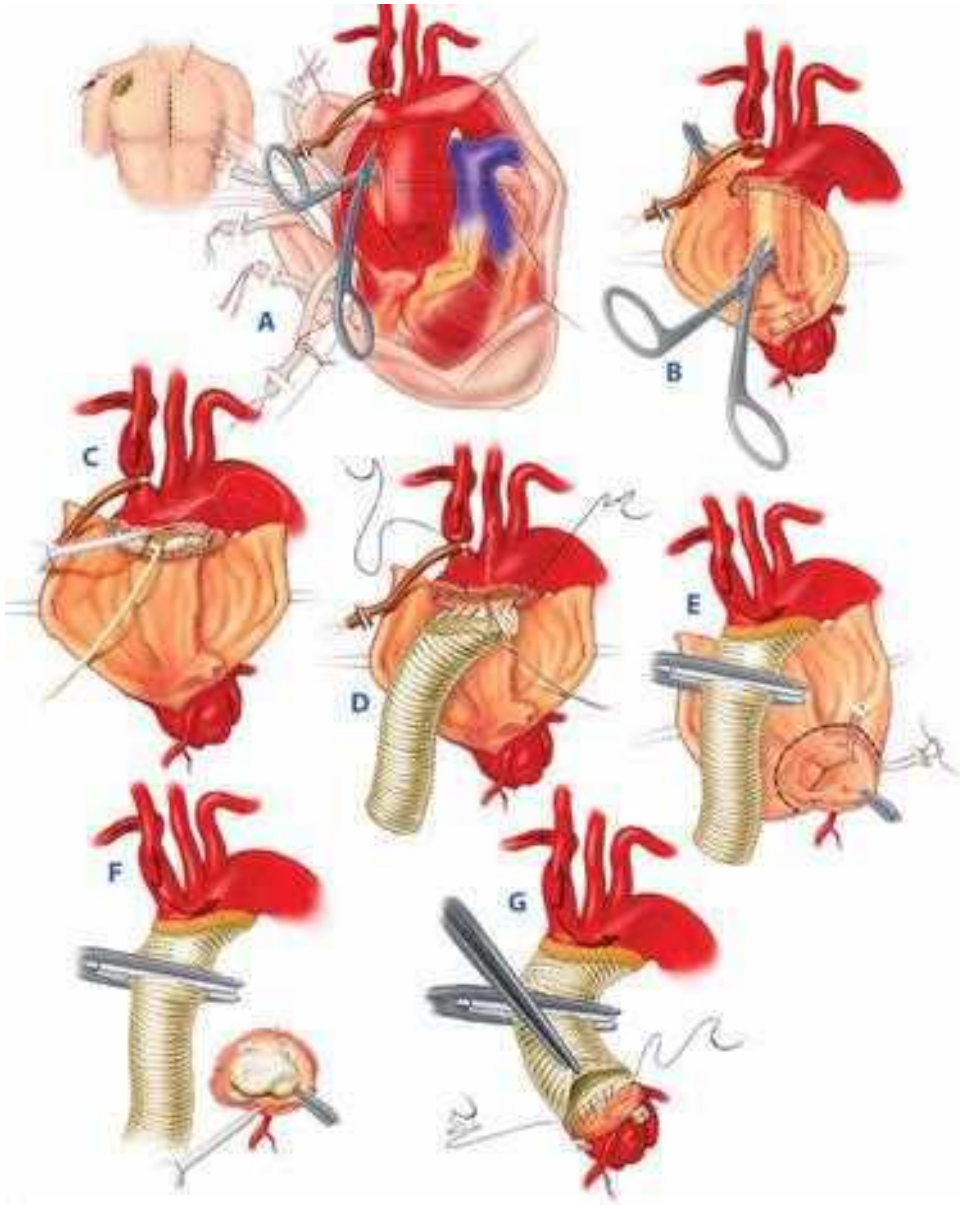

Figure 22-22. Illustration of proximal aortic repair for acute ascending aortic dissection. **A.** This repair requires a median sternotomy and cardiopulmonary bypass. The ascending aorta is opened during hypothermic circulatory arrest, while antegrade cerebral perfusion is delivered via an axillary artery graft (see Fig. 22-8). **B.** The dissecting membrane is removed to expose the true lumen. **C.** Surgical adhesive is used to obliterate the false lumen and strengthen the aorta for the distal anastomosis. A 30-mL balloon catheter is placed in the true lumen to compress the distal false lumen; this helps keep the adhesive (which strengthens the repair) within the proximal false lumen and prevents distal embolization of the adhesive through re-entry sites. A moist gauze sponge is placed in the true lumen to prevent the adhesive from running into the brachiocephalic vessels. **D.** An open distal anastomosis prevents clamp injury of the arch tissue and allows inspection of the arch lumen. A balloon perfusion catheter in the left common carotid artery ensures antegrade perfusion of the left cerebral circulation. If the origin of the dissection (i.e., intimal tear or disruption) does not extensively involve the greater curvature of the aortic arch, and if there is no evidence of a preexisting arch aneurysm, a beveled, hemi-arch repair is carried out, preserving most of the greater curvature of the arch. The aorta is transected, beginning at the greater curvature immediately proximal to the origin of the innominate artery and extending distally toward the lesser curvature to the level of the left subclavian artery. Consequently, most of the transverse aortic arch, except for the dorsal segment containing the brachiocephalic arteries, is removed. An appropriately sized, sealed (with collagen or gelatin) Dacron tube graft is selected, and the beveled distal anastomosis is made with continuous 3-0 or 4-0 monofilament suture. **E.** After the anastomosis is covered with additional adhesive and cardiopulmonary bypass is resumed, the aortic valve is assessed. Disrupted commissures are resuspended with pledgeted mattress sutures to restore valvular competence. **F.** The aorta is generally transected at the sinotubular junction, and adhesive is used to obliterate the false lumen within the proximal aortic stump. A moist gauze sponge is placed within the true lumen to prevent the adhesive from injuring the aortic valve leaflets or entering the coronary artery ostia. **G.** After the adhesive has set, the proximal anastomosis is carried out at the sinotubular junction, incorporating the distal margin of the commissures. *(Reproduced with permission from Creager MA, Dzau VS, Loscalzo J, eds.* Vascular Medicine. *Philadelphia: WB Saunders; 2006. Chronic Dissection Occasionally, patients with ascending aortic dissection present for repair in the chronic phase. In most respects, the operation is similar to that for acute dissection repair. One notable difference is that the tissue is stronger in chronic dissection than in acute dissection, which makes suturing safer. In addition, the false lumen is not obliterated at the distal anastomosis; instead, the dissecting membrane is fenestrated into the arch to ensure perfusion of both lumens and to prevent postoperative malperfusion complications. Unlike operations for acute dissection, operations for chronic dissection are often aggressive repairs that extend into the arch and root, because the tissues are much less fragile.

Treatment of Descending Aortic Dissection

Nonoperative Management Nonoperative, pharmacologic management of acute descending aortic dissection results in lower morbidity and mortality rates than traditional surgical treatment does.[142] The most common causes of death during nonoperative treatment are aortic rupture and end-organ malperfusion. Therefore, patients are continually reassessed for new complications. At least two serial CT scans—usually obtained on day 2 or 3 and on day 8 or 9 of treatment—are compared with the initial scan to rule out significant aortic expansion.

Once the patient's condition has been stabilized, pharmacologic management is gradually shifted from IV to oral medications. Oral therapy, which usually includes a beta antagonist, is initiated when systolic pressure is consistently between 100 and 110 mmHg and the neurologic, renal, and cardiovascular systems are stable. Many patients can be discharged after their blood pressure is well controlled with oral agents and after serial CT scans confirm the absence of aortic expansion.

Long-term pharmacologic therapy is important for patients with chronic aortic dissection. Beta blockers remain the drugs of choice.[169] In a 20-year follow-up study, DeBakey and colleagues[170] found that inadequate blood pressure control was associated with late aneurysm formation. Aneurysms developed in only 17% of patients with "good" blood pressure control, compared with 45% of patients with "poor" control.

Aggressive imaging follow-up is recommended for all patients with chronic aortic dissection.[171] Both contrast-enhanced CT and MRA scans provide excellent aortic imaging and facilitate serial comparisons to detect progressive aortic expansion. The first surveillance scan is obtained approximately 6 weeks after the onset of dissection. Subsequent scans are obtained at least every 3 months for the first year, every 6 months for the second year, and annually thereafter. Scans are obtained more frequently in high-risk patients, such as those with Marfan syndrome, and in those in whom significant aortic expansion is detected. For patients who have undergone graft repair of descending aortic dissection, annual CT or MRA scans are also obtained to detect false aneurysm formation or dilatation of unrepaired segments of aorta. Early detection of worrisome changes allows timely, elective intervention before rupture or other complications develop; rupture of the distal aorta is relatively common in patients with chronic aortic dissection and often results in death.[158]

Indications for Surgery In the acute phase, surgery has been traditionally reserved for patients who experience complications.[172] In general terms, such intervention is intended to prevent or repair ruptures and relieve life-threatening ischemic manifestations.

During the acute phase of a dissection, the specific indications for operative intervention include aortic rupture, increasing periaortic or pleural fluid volume, rapidly expanding aortic diameter, uncontrolled hypertension, and persistent pain despite adequate medical therapy. Aortic rupture may be contained by nearby tissues (such as a localized periaortic hematoma detected on imaging studies) or it may be free and uncontained (presenting as a hemothorax, hemoperitoneum, or massive retroperitoneal hematoma accompanied by shock). Acute dissection superimposed on a preexisting aneurysm is considered a life-threatening condition and is therefore another indication for operation. Finally, patients who have a history of noncompliance with medical therapy may ultimately benefit more from surgical treatment if they are otherwise reasonable operative candidates.

Acute malperfusion syndromes also warrant intervention. In the recent past, visceral and renal malperfusion were considered indications for operation. Percutaneous interventions, however, have largely replaced open surgery for treatment of these complications. When the endovascular approach is unavailable or unsuccessful, surgical options can be used.

In the chronic phase, the indications for operative intervention for aortic dissections are similar to those for degenerative thoracic aortic aneurysms, although a slightly lower threshold of repair is now recommended. Guidelines for thoracic aortic disease[40] recommend elective operation in otherwise healthy patients when the affected segment has reached a diameter of 5.5 cm, especially in patients with connective tissue disorders. Rapid aortic enlargement (>1 cm per year) and other factors that increase the likelihood of aortic rupture may also be considered.

Endovascular Treatment

Malperfusion Syndrome Endovascular therapy is routinely used in patients with descending aortic dissection complicated by visceral malperfusion.[173] Abdominal malperfusion syndrome often is fatal; prompt identification of visceral ischemia and expedited treatment to restore hepatic, gastrointestinal, and renal perfusion are imperative for a positive outcome. As described in a later section, several open surgical techniques can be used to re-establish blood flow to compromised organs. However, in acute cases, open surgery is associated with poor outcomes. Therefore, endovascular intervention is the preferred initial approach in such cases. In one endovascular technique known as *endovascular fenestration*, a balloon is used to create a tear in the dissection flap, which allows blood to flow in both the true and false lumens. This technique can be used when a visceral branch is being supplied by an underperfused true or false lumen. Placement of a stent graft in the true lumen of the aorta can resolve a "dynamic" malperfusion. Occasionally, a small stent must be placed directly in the lumen of a visceral or renal artery because the dissection has propagated into the branch, resulting in "static" malperfusion at the origin.

Iliofemoral malperfusion causing limb-threatening leg ischemia also can be treated via an endovascular approach. However, direct surgical revascularization—usually by placing a femoral-to-femoral arterial bypass graft—is a better option whenever the endovascular procedure cannot be performed expeditiously.

Acute Dissection Although surgery has been traditionally recommended for patients with complicated acute descending aortic dissection, many centers have shifted toward using endovascular stent grafts as the preferred approach in these cases,[174] even though this is an off-label application of stent grafts. Evidence suggests that emergent endovascular repair in patients with true

lumen collapse and complications such rupture or dynamic malperfusion may be lifesaving in these difficult-to-treat patients. However, these patients remain at risk of further complication or future reintervention. Although endovascular repair in patients with connective tissue disorder is generally not recommended, this technique may be used as a bridge to later definitive repair in such life-threatening circumstances.

Less convincing is the evidence in support of using endovascular stent grafts to treat uncomplicated acute descending dissection. The goal of this treatment strategy is to use the stent graft to cover the intimal tear, seal the entry site of the dissection, and eventually cause thrombosis of the false lumen to aid in aortic remodeling and reduce late aortic expansion. However, whether this approach is more effective than conventional nonoperative management remains controversial. Moreover, inadvertent retrograde perfusion or pressurization of the endovascularly repaired aortic section is still a risk; therefore, at this time, the use of endografts in patients with uncomplicated, classic dissection remains investigational.[175,176] Such procedures take place in a hybrid operating room, where access to the true lumen is gained through the femoral arteries. An aortogram is taken, and the intimal tear is identified. Note that the diameter of the true lumen is measured on both the aortogram and a preoperative contrast-enhanced CT scan. A stent graft approximately 10% wider in diameter than the true lumen is selected for these cases. Unlike stents deployed to treat most descending thoracic aortic aneurysms, stents deployed to treat descending aortic dissections must *not* be ballooned, because ballooning can cause a new intimal tear, retrograde dissection into the ascending aorta, or even aortic rupture.

Chronic Dissection Endovascular treatment of chronic descending aortic dissection is also controversial and remains under investigation.[174,177] These dissections are particularly challenging because the relative rigidity of the dissecting membrane and the presence of multiple re-entry sites make it difficult to exclude the false lumen. Furthermore, interfering with false lumen perfusion may cause ischemic complications, such as bowel infarction or renal failure. Until the safety and effectiveness of endovascular repair for this condition have been demonstrated, patients with chronic descending aortic dissection should be treated with conventional nonoperative management until indications for open surgical repair develop.

Penetrating Aortic Ulcer Unlike patients with classic descending aortic dissection, those with PAUs appear to be very well suited for endovascular intervention. Covering the focal ulceration with a stent graft has been shown to be an effective treatment.[178] In a recent study by Patel and colleagues,[179] endovascular repair of PAU was associated with better early outcomes than open repair. However, when PAU was associated with adjacent hematoma within the aortic wall, rates of subsequent reintervention were increased.

Open Repair

Acute Dissection In patients with acute aortic dissection, surgical repair of the descending thoracic or thoracoabdominal aorta is traditionally associated with high morbidity and mortality.[142] Therefore, the primary goals of surgery are to prevent fatal rupture and to restore branch vessel perfusion.[172] A limited graft repair of the life-threatening aortic lesion achieves these goals while minimizing risks. Because the most common site of rupture in descending aortic dissection is in the proximal third of the descending thoracic aorta, the upper half of the descending thoracic aorta is usually repaired. The distal half also may be replaced if it exceeds 4 cm in diameter. Graft replacement of the entire thoracoabdominal aorta is not attempted in such cases unless a large coexisting aneurysm mandates this radical approach. Similarly, the repair is not extended into the aortic arch unless the arch is aneurysmal, even if the primary tear is located there. Patients with chronic dissection who require emergency repair because of acute pain or rupture also undergo limited graft replacement of the symptomatic segment.

Because repairing acute dissections entails an increased risk of paraplegia, adjuncts that provide spinal cord protection, such as cerebrospinal fluid drainage and left heart bypass, are used liberally during such repairs,[180] even if the repair is confined to the upper descending thoracic aorta. Proximal control usually is obtained between the left common carotid and left subclavian arteries; any mediastinal hematoma near the proximal descending thoracic aorta is avoided until proximal control is established. After the aorta is opened, the dissecting membrane is excised from the section undergoing graft replacement. The proximal and distal anastomoses use all layers of the aortic wall, thereby excluding the false lumen in the suture lines and directing all blood flow into the true lumen. Although the relative lack of mural thrombus ensures the presence of multiple patent intercostal arteries, extreme tissue fragility may preclude their reattachment.

Malperfusion Syndrome Lower-extremity ischemia is commonly addressed with surgical extra-anatomic revascularization techniques, such as femoral-to-femoral bypass grafting. In patients with abdominal organ ischemia, flow to the compromised bed must be re-established swiftly. When an endovascular approach is unavailable or unsuccessful, open surgery is necessary. Although they are considered second-line therapies, multiple techniques are available, including graft replacement of the aorta (with flow redirected into the true lumen), open aortic fenestration, and visceral or renal artery bypass.

Chronic Dissection A more aggressive replacement usually is performed during elective aortic repairs in patients with chronic dissection. In many regards, the operative approach used in these patients is identical to that used for descending thoracic and thoracoabdominal aortic aneurysms, as described in the first half of this chapter (Fig. 22-23). One key difference is the need to excise as much dissecting membrane as possible to clearly identify the true and false lumens and to locate all important branch vessels. When the dissection extends into the visceral or renal arteries, the membrane can be fenestrated, or the false lumen can be obliterated with sutures or intraluminal stents. Asymmetric expansion of the false lumen can create wide separation of the renal arteries. This problem is addressed by reattaching the mobilized left renal artery to a separate opening in the graft or by performing a left renal artery bypass with a side graft. Wedges of dissecting membrane also are excised from the aorta adjacent to the proximal and distal anastomoses, which allows blood to flow through both true and false lumens. When placing the proximal clamp is not technically feasible, hypothermic circulatory arrest can be used to facilitate the proximal portion of the repair.

OUTCOMES

Improvements in anesthesia, surgical techniques, and perioperative care have led to substantial improvements in outcome after thoracic aortic aneurysm repair. When performed in specialized centers, these operations are associated with excellent survival

rates and acceptable morbidity rates. The interpretation of outcomes data is complicated by site-specific variables, such as the number of years reported and whether data are taken from single-practice centers or from pooled, multicenter, or national registries, and by patient-specific variables, such as type of enrollment, urgency and extent of repair, concomitant procedures performed, and the presence of preexisting risk factors such as advanced age, previous cardiovascular repair, disease of any system or organ, or connective tissue disorder.

Repair of Proximal Aortic Aneurysms

Risks associated with the open repair of the proximal aorta vary by extent of repair and are greatest for repairs involving total arch replacement. All varieties of aortic root replacement have shown acceptable early mortality rates and few complications. Two groups with 20 and 27 years' experience with composite valve graft replacement reported early mortality rates of 5.6% and 1.9%, respectively; the more recent repairs had better outcomes.[181,182] Early mortality rates for stentless porcine

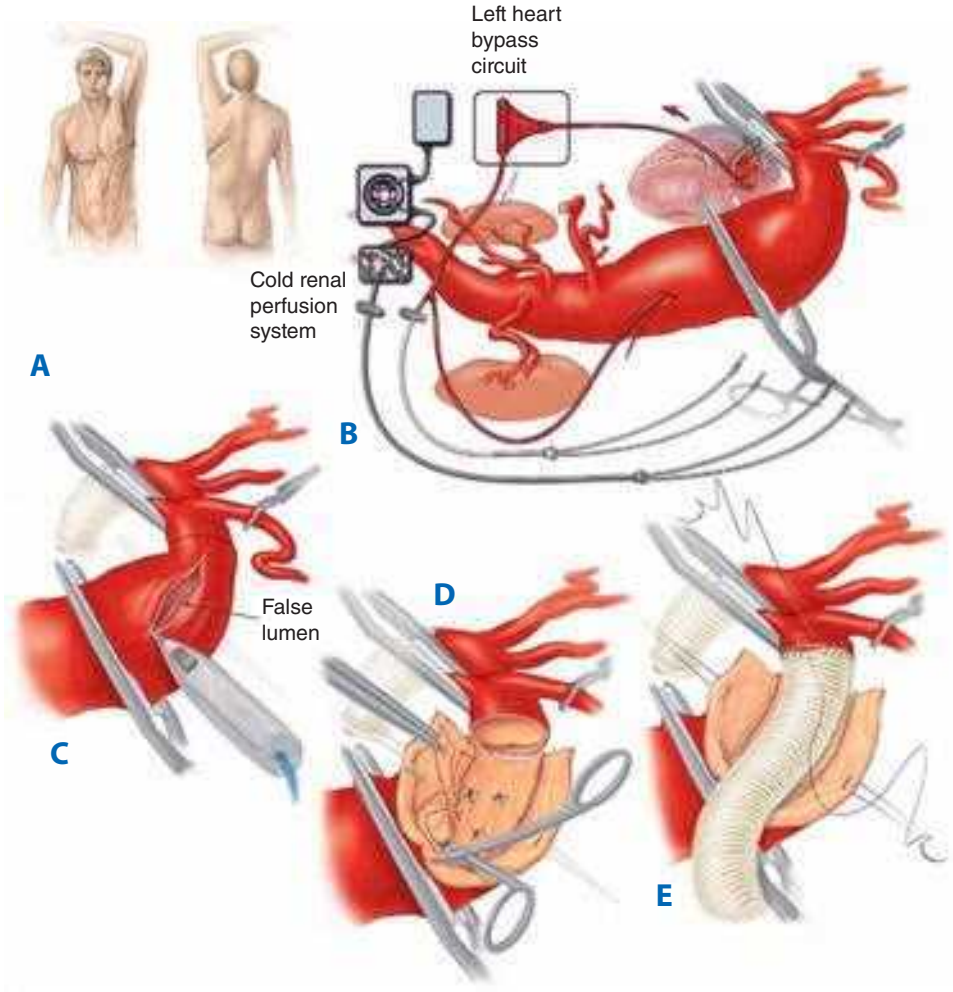

Figure 22-23. Illustration of distal aortic repair of a chronic dissection. **A.** Thoracoabdominal incision. **B.** Extent II thoracoabdominal aortic aneurysm resulting from chronic aortic dissection. The patient has previously undergone composite valve graft replacement of the aortic root and ascending aorta. After left heart bypass is initiated, the proximal portion of the aneurysm is isolated by placing clamps on the left subclavian artery, between the left common carotid and left subclavian arteries, and across the middle descending thoracic aorta. **C.** The isolated segment of aorta is opened by using electrocautery. **D.** The dissecting membrane is excised, and bleeding intercostal arteries are oversewn. The aorta is prepared for proximal anastomosis by transecting it distal to the proximal clamp and separating this portion from the esophagus (not shown). **E.** The proximal anastomosis between the aorta and an appropriately sized Dacron graft is completed with continuous polypropylene suture. **F.** After left heart bypass has been stopped and the distal aortic cannula has been removed, the proximal clamp is repositioned onto the graft, the other two clamps are removed, and the remainder of the aneurysm is opened. **G.** The rest of the dissecting membrane is excised, and the openings to the celiac, superior mesenteric, and renal arteries are identified. **H.** Selective visceral perfusion with oxygenated blood from the bypass circuit is delivered through balloon perfusion catheters placed in the celiac and superior mesenteric arterial ostia. Cold crystalloid is delivered to the renal arteries. The critical intercostal arteries are reattached to an opening cut in the graft. **I.** To minimize spinal cord ischemia, the proximal clamp is repositioned distal to the intercostal reattachment site. A second oval opening is fashioned in the graft adjacent to the visceral vessels. Selective perfusion of the visceral arteries continues during their reattachment to the graft. A separate anastomosis is often required to reattach the left renal artery. **J.** After the balloon perfusion catheters are removed and the visceral anastomosis is completed, the clamp is again moved distally, restoring blood flow to the celiac, renal, and superior mesenteric arteries. The final anastomosis is created between the graft and the distal aorta. *(Reproduced with permission from Creager MA, Dzau VS, Loscalzo J, eds.* Vascular Medicine. *Philadelphia: WB Saunders; 2006. Figure 22-23. (*Continued*)

tissue root replacements are also low, ranging from 3.6% to 6.0%.[183-187] Early mortality rates for contemporary valve-sparing approaches to aortic root replacement are quite low (1%–2%) in experienced centers.[66,188,189] Late survival rates after valve-sparing root procedures range from 97% to 99% at 5 years[66,188,189] and approach 94% at 10 years.[66]

Repairs incorporating the ascending aorta and aortic arch have acceptable outcomes; risk increases with patient-specific factors such as severe atherosclerosis[190] or as larger sections of the aortic arch are incorporated into the repair.[191,192] A revised surgical strategy—such as the use of hypothermic circulatory arrest—is often needed to avoid clamping atherosclerotic sections in the "porcelain" aorta. In Zingone and colleagues' series[190] of 64 patients who underwent replacement of atherosclerotic ascending aorta, hypothermic circulatory arrest was used in 61 patients (95%). Even though these patients had substantial comorbidity and 83% underwent concomitant cardiac repairs, acceptable rates of early mortality (11%) and stroke (6%) were obtained. Other studies indicate that the enhanced risk of neurocognitive disturbances in ascending repairs using circulatory arrest are not offset by lower rates of early mortality.[193,194] Regarding extended proximal repair, reported early mortality rates after traditional stage 1 elephant trunk repairs (primarily using island reattachment strategies) range from 2.3% to 13.9%.[195-199]

Contemporary mortality rates for extensive proximal aortic repair have improved as new strategies and modified adjuncts have been adopted. For example, by adopting contemporary approaches, we have reduced early mortality for stage 1 elephant trunk repairs from 12% to 2% in our patients.[73,196] Similarly, in a report by Kazui and colleagues[200] covering 20 years of experience and 472 consecutive patients who underwent aortic arch repair with selective ACP, operative mortality was 16.0% for early repairs and 4.1% for more recent repairs. Other contemporary reports of the use of techniques such as moderate hypothermia and Y-graft approaches[201-204] indicate similarly improved outcomes; early mortality ranges from 1% to 7%, stroke rates range from 1% to 6%, and no cases of paraplegia are reported. Although paraplegia has traditionally been an unusual and infrequent complication of aortic arch repair, it has been reported as a complication of "long" elephant trunk approaches[205] and frozen elephant trunk approaches.[206]

Because of the heterogeneity of hybrid arch approaches and the tendency to use these approaches in high-risk patients, results of hybrid arch repair are difficult to interpret. A meta-analysis conducted by Koullias and Wheatley[82] of data from

15 studies with 463 patients found an average 30-day mortality rate of 8.3%; stroke, 4.4%; paraplegia, 3.9%; and endoleak, 9.2%. Of note, relatively few repairs (30%) were performed "off-pump," and the majority of repairs used cardiopulmonary bypass or hypothermic circulatory arrest. Additionally, several reports of small series (ranging from 33 to 66 patients) have documented a substantial risk of acute retrograde aortic dissection during hybrid arch repairs; rates range from 3.0% to 7.5%, and these patients face significant mortality risk (ranging from 33% to 100%) should this occur.[85,207-209]

Treatment of Acute Ascending Aortic Dissection

The International Registry of Acute Aortic Dissection (IRAD) provides the most comprehensive data on contemporary outcomes in patients with acute aortic dissection. This registry was established in 1996 and has accumulated data from >3000 patients treated for acute aortic dissection at 30 centers in 11 countries. A recent IRAD analysis of data from 776 patients who underwent surgical repair of acute ascending aortic dissection revealed an in-hospital mortality rate of 23.8%.[210] The investigators identified several preoperative predictors of early mortality, including age >70 years, previous cardiac surgery, hypotension or shock at presentation, abrupt onset of symptoms, migrating pain, cardiac tamponade, preoperative renal failure, pulse deficit, and evidence of myocardial ischemia or infarction on ECG.[210,211] The German Registry for Acute Aortic Dissection (GERAADA) has collected data on more than 2500 patients from 52 centers since 2006. In a report of 1436 patients with acute proximal dissection that was surgically repaired using hypothermic circulatory arrest with or without unilateral and bilateral ACP, the early mortality rates ranged from 13.9% to 19.4%; the 628 patients with unilateral ACP had the lowest rate of early death.[212]

Repair of Distal Aortic Aneurysms

Endovascular Repair of Descending Thoracic Aortic Aneurysms. In the earliest series of endovascular repairs of descending thoracic aortic aneurysms, mortality and morbidity were difficult to assess. Most of the reported series were small and included a large proportion of high-risk patients with substantial comorbidity. For example, in the Stanford experience with "first-generation" stent grafts in 103 patients with descending thoracic aortic aneurysms, the operative mortality rate was 9%, the stroke rate was 7%, the paraplegia/paraparesis rate was 3%, and actuarial survival was only 73 ± 5% at 2 years. However, 62 patients (60%) were not considered candidates for thoracotomy and open surgical repair; as expected, this group experienced the majority of the morbidity and mortality.[213] In a follow-up series, the Stanford group reported survival rates of 74% at 1 year and 31% at 5 years after stent grafting in patients who were deemed not to be surgical candidates; in contrast, survival rates were 93% at 1 year and 78% at 5 years ($P<0.001$) after stent grafting in patients who were deemed reasonable candidates for conventional open repair.[214] This study also found a 30% incidence of late aortic complications, which stresses the necessity for appropriate follow-up.

Evidence from pivotal, nonrandomized trials that compared patients who underwent endograft exclusion with historical or concurrent patients who underwent open repair[215-217] shows that the stent graft groups had significantly less morbidity and early mortality than the open repair groups, although in two of the trials, a nonsignificant between-group difference was observed in the rate of stroke.[215,217] Available 5-year comparative data show that the two groups differed significantly in their aneurysm-related mortality rates (2.8% for endovascular patients and 11.7% for open repair patients) but not in their rates of all-cause mortality (which were 32% and 31%, respectively).[218] Additional pivotal trial 5-year outcomes[219] indicate the growing disparity between aneurysm-related (96.1%) and all-cause survival (58.5%) in patients with endovascular repair, leading some to comment on the possible futility of repair in many patients.[174]

Although the feasibility of endovascular treatment of chronic descending thoracic aortic dissection has been shown in small series,[148,220] the efficacy of such repairs has not been established. The eagerly anticipated initial outcomes of the INSTEAD trial (INvestigation of STEnt grafts in patients with type B Aortic Dissection), which involves 136 patients with uncomplicated chronic descending aortic dissection, show no survival benefit of stent grafting over standard medical antihypertensive therapy in the first 2 years after randomization.[221] However, it appears that the extended study may find a survival advantage at 5 years.[174] Likewise, the ADSORB (A Prospective Randomized Trial in Acute Uncomplicated Type B Dissections) trial[222] is currently underway, and once complete, it may help elucidate whether endovascular repair in patients with uncomplicated descending dissection provides an advantage over standard medical antihypertensive therapy as pertains to its study endpoints—thrombosis of the false lumen, aortic enlargement, and aortic rupture. Thus, at present, the use of stent grafts to treat chronic descending aortic dissection should be considered experimental.

Open Repair of Descending Thoracic and Thoracoabdominal Aortic Aneurysms. Contemporary results of open repairs of descending thoracic aortic aneurysms, including those performed in select patients with chronic dissection, indicate that early mortality rates range from 4.1% to 8.0%, renal failure rates range from to 4.2% to 7.5%, and paraplegia rates range from 2.3% to 5.7%; stroke rates are generally lower, ranging from 1.8% to 2.1%.[223-225] In our series, although the risk of paraplegia increased with the extent of repair, the risk of mortality was greatest for those undergoing repair of the proximal two thirds of the descending aorta.[223] As expected, stroke rates after distal aortic repairs were highest when the clamp site was near the left subclavian artery.

Several studies have compared endovascular and surgical approaches to descending thoracic aortic repair. Some studies found no significant differences in rates of early death, stroke, and paraplegia,[217,226,227] whereas others found that surgical patients had higher rates of early mortality (27%)[228] and paraplegia (14%).[215] However, a recent study of Medicare patients showed that the early survival advantage associated with stent grafts is soon lost in the majority of patients.[229]

Contemporary series of open thoracoabdominal aortic repairs show acceptable survival. Reported outcome rates range from 5% to 12% for early mortality, 3.8% to 9.5% for paraplegia, 1.7% to 5.2% for stroke, and 6% to 12% for renal complications.[230-234] Many of these series summarize 10 to 20 years of surgical experience,[231-234] although some present a shorter but more contemporary experience.[230] Even for complex thoracoabdominal aortic repairs, such as stage 2 elephant trunk repairs, several centers report acceptable early mortality rates ranging from 0% to 10%.[195-199] Worse outcomes are also documented, as in a statewide, nonfederal analysis of data from 1010 patients whose early mortality rate was 25%. Of note, 40% of these patients

were treated at centers averaging only one thoracoabdominal aortic aneurysm repair per year.[235] Cowan and colleagues,[236] who examined the influence of familiarity with the procedure on rates of mortality and morbidity after thoracoabdominal aortic aneurysm repair, reported that patients treated at low-volume centers fared less well. Replacing the entire thoracoabdominal aorta (i.e., performing an extent II repair) carries the highest risk of death, bleeding, renal failure, and paraplegia.[92,231,232] Early survival has been estimated at 79% at 2 years,[237] and midterm survival has been estimated at 63% at 5 years.[234]

Treatment of Acute Descending Aortic Dissection

Nonoperative Management. The in-hospital mortality rate is nearly 10% for patients with acute descending aortic dissection who receive nonoperative treatment[142]; however, when IRAD stratified patients according to clinical presentation, the mortality rate for patients with uncomplicated dissection was less than 4%, whereas the mortality rate for patients with complicated dissection was more than 20%.[142,238] The primary causes of death during nonoperative management are rupture, malperfusion, and cardiac failure. Risk factors associated with treatment failure—defined as death or need for surgery—include an enlarged aorta, persistent hypertension despite maximal treatment, oliguria, and peripheral ischemia. Among patients who receive nonoperative treatment for descending aortic dissection and who survive the acute period, approximately 90% remain alive 1 year later, and approximately 76% are alive 3 years later.[239]

Endovascular Treatment. For malperfusion of the visceral or renal arteries, an endovascular approach is ideal. The Stanford group reported a 93% technical success rate for endovascular reperfusion of an ischemic bed.[240] Their experience with the use of first-generation stents to treat acute complicated descending dissections was also encouraging: Complete thrombosis of the false lumen occurred in 79% of patients. The early mortality rate was 16%, comparable to that associated with open techniques.[241] A meta-analysis of observational studies of endovascular stenting, which included 248 patients with acute descending aortic dissection, found a 30-day mortality rate of 9.8%.[242] Compared with early mortality rates obtained from IRAD data,[142] this rate is substantially lower than the rate associated with open surgical treatment but is similar to the rate achieved with nonoperative management. However, patients with complicated acute descending dissection remain susceptible to late events; at 1 year, survival is approximately 70%, and reintervention is needed in about 10% of survivors.[243]

Open Repair. We recently reported our contemporary experience with 32 patients with acute complicated descending aortic dissection, including 7 patients (22%) with aortic rupture. Complexities included dangerously large aneurysms in the majority of patients (69%), which implied either rapid expansion or an aneurysm superimposed on the dissection. Malperfusion was present in one patient; this patient had an open fenestration procedure. A substantial number of patients (n = 7, 22%) had connective tissue disorders. The operative mortality rate was 6% overall.[244] There were 3 cases of permanent spinal cord complications (10%), 1 stroke (3%), and 2 cases of permanent renal failure (6%). In recent multicenter studies by IRAD, investigators found a 29% in-hospital mortality rate among 70 patients with acute dissection who underwent open surgical replacement of the descending thoracic aorta[238] and a 22% in-hospital mortality rate among 18 patients who underwent open fenestration procedures. Another study found that, of patients who survived surgical treatment of acute descending aortic dissection, approximately 96% were alive at 1 year and approximately 83% were alive at 3 years after the procedure,[239] which is substantially better than 1-year survival after endovascular repair in acute complicated distal dissection.[239,243]

CONCLUSIONS

Aortic aneurysm may present as localized or extensive disease. The availability and development of adjuncts and endovascular techniques have supported the constant evolution of surgical strategies to tackle these complex problems. Repair strategies range from isolated, totally endovascular aortic repair for descending thoracic aneurysms to extensive total aortic and staged replacements with a combination of both open and endovascular techniques. Regardless of the difficulty of accurately assessing the risks associated with aortic repair, surgical repair of the thoracoabdominal aorta clearly remains the most challenging aortic repair in terms of mortality and morbidity. Accordingly, replacing the entire thoracoabdominal aorta (i.e., performing an extent II repair) carries the highest risk of death, renal failure, and paraplegia.[89,221,226]

ACKNOWLEDGMENTS

The authors wish to thank Susan Y. Green, MPH, and Stephen N. Palmer, PhD, ELS, for editorial assistance; Scott A. Weldon, MA, CMI, and Carol P. Larson, CMI, for creating the illustrations; and Kapil Sharma, MD, for his substantial contributions to the chapter published in the 9th edition of the textbook, on which this updated chapter was based.

chapter 23

Arterial Disease

Peter H. Lin, Mun Jye Poi, Jesus Matos, Panagiotis Kougias, Carlos Bechara, and Changyi Chen

Key Points

1. Carotid intervention as a preventive strategy should be performed in patients with 50% or greater symptomatic internal carotid artery stenosis and those with 80% or greater asymptomatic internal carotid artery stenosis. Carotid intervention for asymptomatic stenosis between 60% and 79% remains controversial and is a function of an operator's stroke rate. The choice of intervention—carotid endarterectomy versus carotid stenting—remains controversial; currently, carotid endarterectomy appears to be associated with lower stroke rate, whereas carotid stenting is more suitable under certain anatomic or physiologic conditions.
2. Abdominal aortic aneurysms should be repaired when the risk of rupture, determined mainly by aneurysm size, exceeds the risk of death due to perioperative complications or concurrent illness. Endovascular repair is associated with less perioperative morbidity and mortality compared to open reconstruction and is preferred for high-risk patients who meet specific anatomic criteria.
3. Symptomatic mesenteric ischemia should be treated to improve quality of life and prevent bowel infarction. Operative treatment—bypass—is superior to endovascular intervention, although changes in wire and stent technology have improved the results of mesenteric stenting in recent series.
4. Aortoiliac occlusive disease can be treated with either endovascular means or open reconstruction, depending on patient risk stratification, occlusion characteristics, and symptomatology.
5. Claudication is a marker of extensive atherosclerosis and is mainly managed with risk factor modification and pharmacotherapy. Only 5% of patients with claudication will need intervention because of disabling extremity pain. The 5-year mortality of a patient with claudication approaches 30%. Patients with rest pain or tissue loss need expeditious evaluation and vascular reconstruction to ameliorate the severe extremity pain and prevent limb loss.

GENERAL APPROACH TO THE VASCULAR PATIENT

Since the vascular system involves every organ system in our body, the symptoms of vascular disease are as varied as those encountered in any medical specialty. Lack of adequate blood supply to target organs typically presents with pain; for example, calf pain with lower extremity claudication, postprandial abdominal pain from mesenteric ischemia, and arm pain with axillo-subclavian arterial occlusion. In contrast, stroke and transient ischemic attack (TIA) are the presenting symptoms from middle cerebral embolization as a consequence of a stenosed internal carotid artery. The pain syndrome of arterial disease is usually divided clinically into acute and chronic types, with all shades of severity between the two extremes. Sudden onset of pain can indicate complete occlusion of a critical vessel, leading to more severe pain and critical ischemia in the target organ, resulting in lower limb gangrene or intestinal infarction. Chronic pain results from a slower, more progressive atherosclerotic occlusion, which can be totally or partially compensated by developing collateral vessels. Acute on chronic is another pain pattern in which a patient most likely has an underlying arterial stenosis that suddenly occludes; for example, the patient with a history of calf claudication who now presents with sudden, severe acute limb-threatening ischemia. The clinician should always try to understand and relate the clinical manifestations to the underlying pathologic process.

The Vascular History

Appropriate history should be focused based on the presenting symptoms related to the vascular system (Table 23-1). Of particular importance in the previous medical history is noting prior vascular interventions (endovascular or open surgical), and all vascular patients should have inquiry made about their prior cardiac history and current cardiac symptoms. Approximately 30% of vascular patients will be diabetic. A history of prior and current smoking status should be noted.

Table 23-1

Pertinent elements in vascular history

- History of stroke or transient ischemic attack
- History of coronary artery disease, including previous myocardial infarction and angina
- History of peripheral arterial disease
- History of diabetes
- History of hypertension
- History of tobacco use
- History of hyperlipidemia

The patient with carotid disease in most cases is completely asymptomatic, having been referred based on the finding of a cervical bruit or duplex finding of stenosis. Symptoms of carotid territory TIAs include transient monocular blindness (amaurosis), contralateral weakness or numbness, and dysphasia. Symptoms persisting longer than 24 hours constitute a stroke. In contrast, the patient with chronic mesenteric ischemia is likely to present with postprandial abdominal pain and weight loss. The patient fears eating because of the pain, avoids food, and loses weight. It is very unlikely that a patient with abdominal pain who has not lost weight has chronic mesenteric ischemia.

The patient with lower extremity pain on ambulation has intermittent claudication that occurs in certain muscle groups; for example, calf pain upon exercise usually reflects superficial femoral artery disease, while pain in the buttocks reflects iliac disease. In most cases, the pain manifests in one muscle group below the level of the affected artery, occurs only with exercise, and is relieved with rest only to recur at the same location, hence the term "window gazer's disease." Rest pain (a manifestation of severe underlying occlusive disease) is constant and occurs in the foot (not the muscle groups), typically at the metatarsophalangeal junction, and is relieved by dependency. Often the

patient is prompted to sleep with their foot hanging off one side of the bed to increase the hydrostatic pressure.

The Vascular Physical Examination

Specific vascular examination should include abdominal aortic palpation, carotid artery examination, and pulse examination of the lower extremity (femoral, popliteal, posterior tibial, and dorsalis pedis arteries). The abdomen should be palpated for an abdominal aortic aneurysm, detected as an expansile pulse above the level of the umbilicus. It should also be examined for the presence of bruits. Because the aorta typically divides at the level of the umbilicus, an aortic aneurysm is most frequently palpable in the epigastrium. In thin individuals, a normal aortic pulsation is palpable, while in obese patients, even large aortic aneurysms may not be detectable. Suspicion of a clinically enlarged aorta should lead to the performance of an ultrasound scan for a more accurate definition of aortic diameter.

The carotids should be auscultated for the presence of bruits, although there is a higher correlation with coronary artery disease than underlying carotid stenosis. A bruit at the angle of the mandible is a significant finding, leading to follow-up duplex scanning. The differential diagnosis is a transmitted murmur from a sclerotic or stenotic aortic valve. The carotid is palpable deep to the sternocleidomastoid muscle in the neck. Palpation, however, should be gentle and rarely yields clinically useful information.

Upper extremity examination is necessary when an arteriovenous graft is to be inserted in patients who have symptoms of arm pain with exercise. Thoracic outlet syndrome (TOS) can result in occlusion or aneurysm formation of the subclavian artery. Distal embolization is a manifestation of TOS; consequently, the fingers should be examined for signs of ischemia and ulceration. The axillary artery enters the limb below the middle of the clavicle, where it can be palpated in thin patients. It is usually easily palpable in the axilla and medial upper arm. The brachial artery is most easily located at the antecubital fossa immediately medial to the biceps tendon. The radial artery is palpable at the wrist anterior to the radius.

For lower extremity vascular examination, the femoral pulse is usually palpable midway between the anterior superior iliac spine and the pubic tubercle. The popliteal artery is palpated in the popliteal fossa with the knee flexed to 45° and the foot supported on the examination table to relax the calf muscles. Palpation of the popliteal artery is a bimanual technique. Both thumbs are placed on the tibial tuberosity anteriorly and the fingers are placed into the popliteal fossa between the two heads of the gastrocnemius muscle. The popliteal artery is palpated by compressing it against the posterior aspect of the tibia just below the knee. The posterior tibial pulse is detected by palpation 2 cm posterior to the medial malleolus. The dorsalis pedis is detected 1 cm lateral to the hallucis longus extensor tendon, which dorsiflexes the great toe and is clearly visible on the dorsum of the foot. Pulses can be graded using either the traditional four-point scale or the basic two-point scale system (Table 23-2). The foot should also be carefully examined for pallor on elevation and rubor on dependency, as these findings are indicative of chronic ischemia. Note should also be made of nail changes and loss of hair. Ulceration and other findings specific to disease states are described in relevant sections later in this chapter.

After reconstructive vascular surgery, the graft may be available for examination, depending on its type and course.

Table 23-2

Grading scales for peripheral pulses

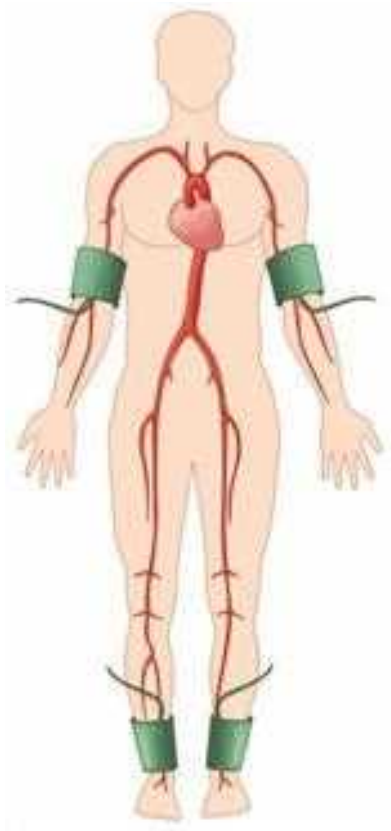
TRADITIONAL SCALE		BASIC SCALE	
4+	Normal	2+	Normal
3+	Slightly reduced	1+	Diminished
2+	Markedly reduced	0	Absent
1+	Barely palpable		

The in situ lower extremity graft runs in the subcutaneous fat and can be palpated along most of its length. A change in pulse quality, aneurysmal enlargement, or a new bruit should be carefully noted. Axillofemoral grafts, femoral-to-femoral grafts, and arteriovenous access grafts can usually be easily palpated as well.

Noninvasive Diagnostic Evaluation of the Vascular Patient

Ankle-Brachial Index. There is increasing interest in the use of the ankle-brachial index (ABI) to evaluate patients at risk for cardiovascular events. An ABI less than 0.9 correlates with increased risk of myocardial infarction and indicates significant, although perhaps asymptomatic, underlying peripheral vascular disease. The ABI is determined in the following ways. Blood pressure is measured in both upper extremities using the highest systolic blood pressure as the denominator for the ABI. The ankle pressure is determined by placing a blood pressure cuff above the ankle and measuring the return to flow of the posterior tibial and dorsalis pedis arteries using a pencil Doppler probe over each artery. The ratio of the systolic pressure in each vessel divided by the highest arm systolic pressure can be used to express the ABI in both the posterior tibial and dorsalis pedis arteries (Fig. 23-1). Normal is more than 1. Patients with claudication typically have an ABI in the 0.5 to 0.7 range, and those with rest pain are in the 0.3 to 0.5 range. Those with gangrene have an ABI of less than 0.3. These ranges can vary depending on the degree of compressibility of the vessel. The test is less reliable in patients with heavily calcified vessels. Due to noncompressibility, some patients, such as diabetics and those with end-stage renal disease, may have ABI ≥1.40 and require additional noninvasive diagnostic testing to evaluate for peripheral artery disease. Alternative tests include toe-brachial pressures, pulse volume recordings, transcutaneous oxygen measurements, or vascular imaging (duplex ultrasound).

Segmental Limb Pressures. By placing serial blood pressure cuffs down the lower extremity and then measuring the pressure with a Doppler probe as flow returns to the artery below the cuff, it is possible to determine segmental pressures down the leg. This data can then be used to infer the level of the occlusion. The systolic pressure at each level is expressed as a ratio, with the highest systolic pressure in the upper extremities as the denominator. Normal segmental pressures commonly show high thigh pressures 20 mmHg or greater in comparison to the brachial artery pressures. The low thigh pressure should be equivalent to brachial pressures. Subsequent pressures should fall by no more than 10 mmHg at each level. A pressure gradient of 20 mmHg between two subsequent levels is usually indicative of occlusive disease at that level. The most frequently used



Right ABI = ratio of

Higher of the right ankle systolic pressures (posterior tibial or dorsalis pedis)

Higher arm systolic pressure (left or right arm)

Left ABI = ratio of

Higher of the left ankle systolic pressures (posterior tibial or dorsalis pedis)

Higher arm systolic pressure (left or right arm)

Figure 23-1. Calculating the ankle-brachial index (ABI).

index is the ratio of the ankle pressure to the brachial pressure, the ABI. Normally, the ABI is greater than 1.0, and a value of less than 0.9 indicates some degree of arterial obstruction and has been shown to be correlated with an increased risk of coronary heart disease.[1] Limitations of relying on segmental limb pressures include: (a) missing isolated moderate stenoses (usually iliac) that produce little or no pressure gradient at rest; (b) falsely elevated pressures in patients with diabetes and end-stage renal disease; and (c) the inability to differentiate between stenosis and occlusion.[2] Patients with diabetes and end-stage renal disease have calcified vessels that are difficult to compress, thus rendering this method inaccurate, due to recording of falsely elevated pressure readings. Noncompressible arteries yield ankle systolic pressures ≥250 mmHg and ABIs >1.40. In this situation, absolute toe and ankle pressures can be measured to gauge critical limb ischemia. Ankle pressures less than 50 mmHg or toe pressures less than 30 mmHg are indicative of critical limb ischemia. The toe pressure is normally 30 mmHg less than the ankle pressure, and a toe-brachial index (TBI) <0.70 is abnormal. False-positive results with the TBI are unusual. The main limitation of this technique is that it may be impossible to measure pressures in the first and second toes due to pre-existing ulceration.

Pulse Volume Recording. In patients with noncompressible vessels, segmental plethysmography can be used to determine underlying arterial occlusive disease. Cuffs placed at different levels on the leg detect changes in blood volume and produce a pulse volume recording (PVR) when connected to a plethysmograph (Fig. 23-2). To obtain accurate PVR waveforms, the cuff is inflated to 60 to 65 mmHg, so as to detect volume changes without causing arterial occlusion. Pulse volume tracings are suggestive of proximal disease if the upstroke of the pulse is not brisk, the peak of the wave tracing is rounded, and there is disappearance of the dicrotic notch.

Although isolated segmental limb pressures and PVR measurements are 85% accurate when compared with angiography in detecting and localizing significant atherosclerotic lesions, when used in combination, accuracy approaches 95%.[3] For this reason, it is suggested that these two diagnostic modalities be used in combination when evaluating peripheral artery disease.

Radiologic Evaluation of the Vascular Patient

Ultrasound. Ultrasound examinations are relatively time consuming, require experienced technicians, and may not visualize all arterial segments. Doppler waveform analysis can suggest atherosclerotic occlusive disease if the waveforms in the insonated arteries are biphasic, monophasic, or asymmetrical. B-mode ultrasonography provides black and white, real-time images. B-mode ultrasonography does not evaluate blood flow; thus, it cannot differentiate between fresh thrombus and flowing blood, which have the same echogenicity. Calcification in atherosclerotic plaques will cause acoustic shadowing. B-mode ultrasound probes cannot be sterilized. Use of the B-mode probe intraoperatively requires a sterile covering and gel to maintain an acoustic interface. Experience is needed to obtain and interpret images accurately. Duplex ultrasonography entails performance of B-mode imaging, spectral Doppler scanning, and color-flow duplex scanning. The caveat to performance of duplex ultrasonography is meticulous technique by a certified vascular ultrasound technician, so that the appropriate 60° Doppler angle is maintained during insonation with the ultrasound probe. Alteration of this angle can markedly alter waveform appearance and subsequent interpretation of velocity measurements. Direct imaging of intra-abdominal vessels with duplex ultrasound is less reliable because of the difficulty in visualizing the vessels through overlying bowel. These disadvantages currently limit the applicability of duplex scanning in the evaluation of aortoiliac and infrapopliteal disease. In a recent study, duplex ultrasonography had lower sensitivity in the calculation of infrapopliteal vessel stenosis in comparison to conventional digital subtraction or computed tomography angiography.[4] Few surgeons rely solely on duplex ultrasonography for preoperative planning in lower extremity revascularizations; but with experience, lower extremity arteries can be insonated to determine anatomy, and the functional significance of lesions can be determined by calculation of degree of stenosis from velocity ratios. Duplex scanning is unable to evaluate recently implanted polytetrafluoroethylene (PTFE) and polyester (Dacron) grafts because they contain air, which prevents ultrasound penetration.

Computed Tomography Angiography. Computed tomography angiography (CTA) is a noninvasive, contrast-dependent method for imaging the arterial system. It depends on intravenous infusion of iodine-based contrast agents. The patient is advanced through a rotating gantry, which images serial transverse

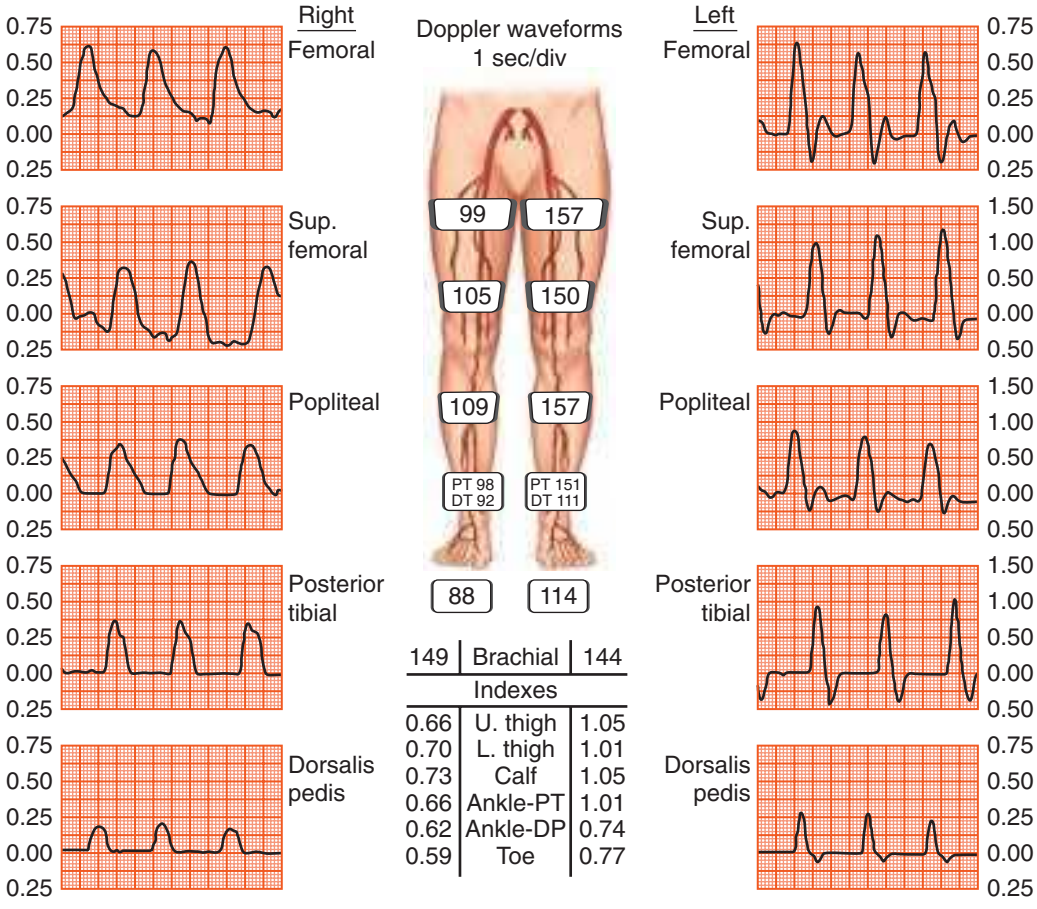


Figure 23-2. Typical report of peripheral vascular study with arterial segmental pressure measurement plus Doppler evaluation of the lower extremity.

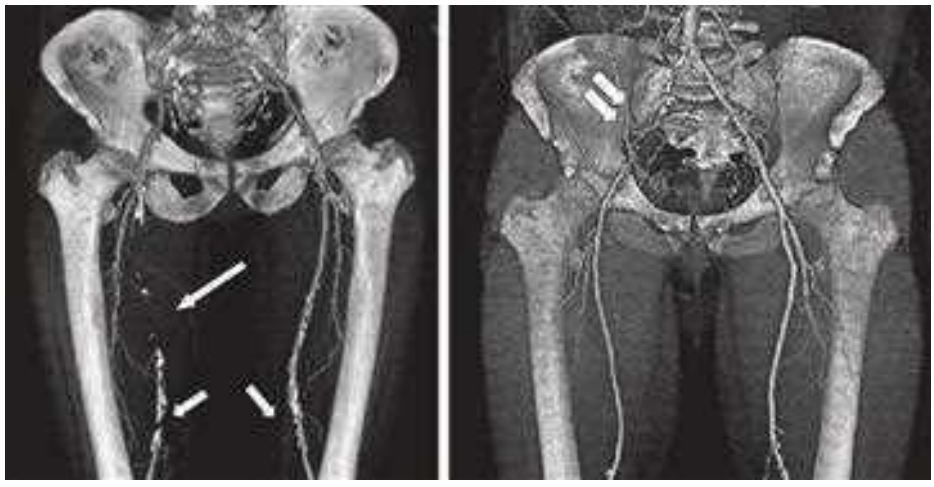

A B

Figure 23-3. A multidetector computed tomography angiography with three-dimensional reconstruction of the iliofemoral arterial circulation in two patients with lower leg claudication. **A.** A 50-year-old male with an occluded right superficial femoral artery (*single long arrow*) with reconstituted superficial femoral artery at the level of mid-thigh. Arterial calcifications (*single short arrows*) are present in the bilateral distal superficial femoral arteries. **B.** A 53-year-old male with occluded right common iliac artery (*double arrows*).

slices. The contrast-filled vessels can be extracted from the slices and rendered in three-dimensional format (Fig. 23-3). The extracted images can also be rotated and viewed from several different directions during postacquisition image processing. This technology has been advanced as a consequence of aortic endografting. CTA provides images for postprocessing that can be used to display the aneurysm in a format that demonstrates thrombus, calcium, lumen, and the outer wall, and allows "fitting" of a proposed endograft into the aneurysm (Fig. 23-4). CTA is increasingly being used to image the carotid bifurcation, and as computing power increases, the speed of image acquisition and resolution will continue to increase. The major limitations of multidetector CTA are use of contrast and presence of artifacts caused by calcification and stents. CTA can overestimate the degree of in-stent stenosis, while heavy calcification can limit the diagnostic accuracy of the method by causing a "blooming artifact."[5] The artifacts can be overcome with alteration in image acquisition technique. There are no randomized trials to document the superiority of multidetector CTA over traditional angiography, but there is emerging evidence to support the claim that multidetector CTA has sensitivity, specificity, and accuracy that rival invasive angiography.[5]

Magnetic Resonance Angiography. Magnetic resonance angiography (MRA) has the advantage of not requiring iodinated contrast agents to provide vessel opacification (Fig. 23-5). Gadolinium is used as a contrast agent for MRA studies, and because it is generally not nephrotoxic, it can be used in patients with elevated creatinine. MRA is contraindicated in patients with pacemakers, defibrillators, spinal cord stimulators, intracerebral shunts, cochlear implants, and cranial clips. Patients with claustrophobia may require sedation to be able to complete the test. The presence of metallic stents causes artifacts and signal drop-out; however, these can be dealt with using alternations in image acquisition and processing. Nitinol stents produce minimal artifact.[6] Compared to other modalities, MRA is relatively slow and expensive. However, due to its noninvasive nature and decreased nephrotoxicity, MRA is being used more frequently for imaging vasculature in various anatomic distributions.

Diagnostic Angiography. Diagnostic angiography is considered the gold standard in vascular imaging. In many centers, its use is rapidly decreasing due to the development of noninvasive imaging modalities such as duplex arterial mapping, CTA, and MRA. Nevertheless, contrast angiography still remains in

Figure 23-4. Three-dimensional computed tomography angiogram of an abdominal aortic aneurysm that displays various aneurysm components including thrombus, aortic calcification, blood circulation, and aneurysm wall.

Figure 23-5. Magnetic resonance angiogram of aortic arch and carotid arteries. This study can provide a three-dimensional analysis of vascular structure such as aortic arch branches and carotid and vertebral arteries.

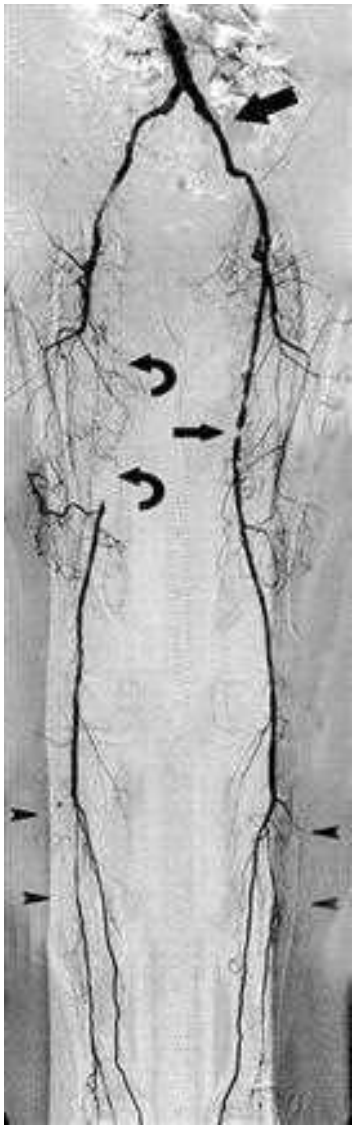

Figure 23-6. Digital subtraction angiography (DSA) provides excellent visualization of intravascular circulation with intra-arterial contrast administration. As depicted in this DSA study, multilevel lesions are demonstrated, which include a focal left iliac artery stenosis (*large arrow*), right superficial femoral occlusion (*curved arrows*), left superficial femoral stenosis (*small arrow*), and multiple tibial artery stenoses (*arrowheads*).

widespread use. The essential aspects of angiography are vascular access and catheter placement in the vascular bed that requires examination. The imaging system and the contrast agent are used to opacify the target vessel. Although in the past this function has largely been delegated to the interventional radiology service, an increasing number of surgeons are performing this procedure and following the diagnostic imaging with immediate surgical or endovascular intervention. There are several considerations when relying on angiography for imaging.

Approximately 70% of atherosclerotic plaques occur in an eccentric location within the blood vessel; therefore, images can be misleading when trying to evaluate stenoses because angiography is limited to a uniplanar "lumenogram." With increased use of intravascular stent deployment, it has also been noted that assessment of stent apposition and stent position in relation to surrounding branches may be inaccurate. Furthermore, angiography exposes the patient to the risks of both ionizing radiation and intravascular contrast. Nevertheless, contrast angiography remains the most common invasive method of vascular investigation for both diagnostic and therapeutic intervention. The angiogram usually provides the final information needed to decide whether or not to proceed with operation or endovascular interventions.

Digital subtraction angiography (DSA) offers some advantages over conventional cut-film angiography such as excellent visualization despite use of lower volumes of contrast media. In particular, when multilevel occlusive lesions limit the amount of contrast reaching distal vessels, supplemental use of digital subtraction angiographic techniques may enhance visualization and definition of anatomy. Intra-arterial DSA uses a portable, axially rotatable imaging device that can obtain views from different angles. DSA also allows for real-time video replay (Fig. 23-6). An entire extremity can be filmed with DSA using repeated injections of small amounts of contrast agent to obtain sequential angiographic images, the so-called pulse-chase technique.

Preoperative Cardiac Evaluation

The most important and most controversial aspect of preoperative evaluation in patients with atherosclerotic disease requiring surgical intervention is the detection and subsequent management of associated coronary artery disease.[7] Several studies

have documented the existence of significant coronary artery disease in 40% to 50% or more of patients requiring peripheral vascular reconstructive procedures, 10% to 20% of whom may be relatively asymptomatic largely because of their inability to exercise.[8] Myocardial infarction is responsible for the majority of both early and late postoperative deaths. Most available screening methods lack sensitivity and specificity to predict postoperative cardiac complications. There have been conflicting reports regarding the utility of preoperative dipyridamole-thallium nuclear imaging or dobutamine-echocardiography to stratify vascular patients in terms of perioperative cardiac morbidity and mortality. In nearly half of patients, thallium imaging proves to be unnecessary because cardiac risk can be predicted by clinical information alone.[7] Even with coronary angiography, it is difficult to relate anatomic findings to functional significance and, hence, surgical risk. There are no data confirming that percutaneous coronary interventions or surgical revascularization prior to vascular surgical procedures impact mortality or incidence of myocardial infarctions. In fact, coronary angiography is associated with its own inherent risks, and patients undergoing coronary artery bypass grafting or coronary percutaneous transluminal angioplasty (PTA) before needed aortoiliac reconstructions are subjected to the risks and complications of both procedures.

The Coronary Artery Revascularization Prophylaxis (CARP) trial showed that coronary revascularization in patients with peripheral vascular disease and significant coronary artery disease, who are considered high risk for perioperative complications, did not reduce overall mortality or perioperative myocardial infarction.[9] Additionally, patients who underwent prophylactic coronary revascularization had significant delays prior to undergoing their vascular procedure and increased limb morbidity compared to patients who did not. Studies do support improvement in cardiovascular and overall prognosis with medical optimization of patients. Therefore, use of perioperative β-blockade, as well as use of antiplatelet medication, statins, and angiotensin-converting enzyme inhibitors, is encouraged in vascular patients.[10,11]

BASIC PRINCIPLES OF ENDOVASCULAR THERAPY

Cardiovascular disease remains a major cause of mortality in the developed world since the beginning of the twenty-first century. Although surgical revascularization has played a predominant role in the management of patients with vascular disease, the modern treatment paradigms have evolved significantly with increased emphasis of catheter-based percutaneous interventions over the past two decades. The increasing role of this minimally invasive vascular intervention is fueled by various factors, including rapid advances in imaging technology, reduced morbidity and mortality in endovascular interventions, and faster convalescence following percutaneous therapy when compared to traditional operations. There is little doubt that with continued device development and refined image-guided technology, endovascular intervention will provide improved clinical outcomes and play an even greater role in the treatment of vascular disease.

The technique of percutaneous access for both the diagnostic and therapeutic management of vascular disease has resulted in tremendous changes in the practice of several subspecialties, including interventional radiology, invasive cardiology, and vascular surgery. The development of catheter and endoscopic instrumentation allows the vascular surgeon to operate via an intra- or extraluminal route. Endovascular techniques are now able to treat the full spectrum of vascular pathology, including stenoses and occlusions resulting from several etiologies, aneurysmal pathology, and traumatic lesions. Many of these procedures have only recently been developed and, as such, have not been investigated in a manner that would enable an accurate comparison with the more traditional methods of open surgical intervention. Long-term follow-up for these procedures is frequently lacking; however, because of the potential to treat patients with decreased mortality and morbidity, endovascular skills and techniques are being adopted into mainstream vascular surgery.

Needles and Access

Needles are used to achieve percutaneous vascular access. The size of the needle will be dictated by the diameter of the guidewire used. Most often, an 18-gauge needle is used, as it will accept a 0.035-inch guidewire. A 21-gauge micropuncture needle will accept a 0.018-inch guidewire. The most popular access needle is the Seldinger needle, which can be used for single- and double-wall puncture techniques.

Femoral arterial puncture is the most common site for access. The common femoral artery (CFA) is punctured over the medial third of the femoral head, which is landmarked using fluoroscopy. The single-wall puncture technique requires a sharp, beveled needle tip and no central stylet. The anterior wall of the vessel is punctured with the bevel of the needle pointing up, and pulsatile back-bleeding indicates an intraluminal position. This method is most useful for graft punctures, patients with abnormal clotting profiles, or if thrombolytic therapy is anticipated. Once the needle assumes an intraluminal position, verified by pulsatile back-bleeding, the guidewire may be advanced. This is always passed gently and under fluoroscopic guidance to avoid subintimal dissection or plaque disruption. Double-wall puncture techniques are performed with a blunt needle that has a removable inner cannula. The introducer needle punctures both walls of the artery and is withdrawn until bleeding is obtained to confirm intraluminal position prior to advancing a guidewire. There can be troublesome bleeding from the posterior arterial wall puncture; therefore, single puncture techniques are preferred.

Retrograde femoral access is the most common arterial access technique (Fig. 23-7). The advantages of this technique include the size and fixed position of the CFA, as well as the relative ease of compression against the femoral head at the end of the procedure. Care should be taken to avoid puncturing the external iliac artery above the inguinal ligament because this can result in retroperitoneal hemorrhage secondary to ineffective compression of the puncture site. Likewise, puncturing too low, at or below the CFA bifurcation, can result in thrombosis or pseudoaneurysm formation of the superficial femoral artery (SFA) or profunda femoris artery (PFA). Antegrade femoral access is more difficult than retrograde femoral access, and there is a greater tendency to puncture the SFA, but it is invaluable when the aortic bifurcation cannot be traversed or when devices are not long enough to reach a lesion from a contralateral femoral access approach. Occasionally, when the distal aorta or bilateral iliac arteries are inaccessible because of the extent of atherosclerotic lesions, scarring, or presence of bypass conduits, the brachial artery must be used to obtain access for diagnostic and therapeutic interventions. The left brachial artery is punctured because this avoids the origin of the carotid artery

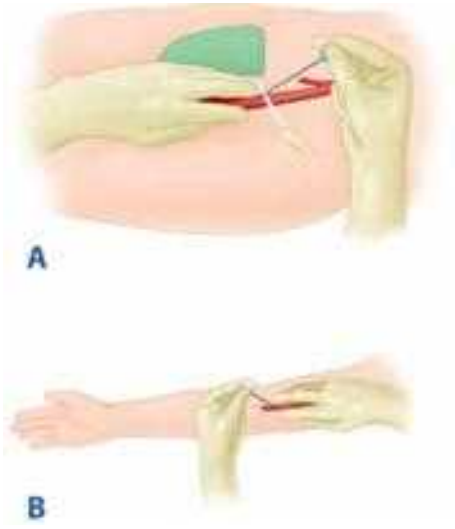

Figure 23-7. **A.** Antegrade femoral artery access. The needle is inserted just below the inguinal ligament in the common femoral artery whereby the guidewire is inserted in the ipsilateral superficial femoral artery. **B.** Brachial artery approach. The needle is inserted in a retrograde fashion in the brachial artery just above the antecubital fossa, whereby the guidewire is next inserted in the brachial artery.

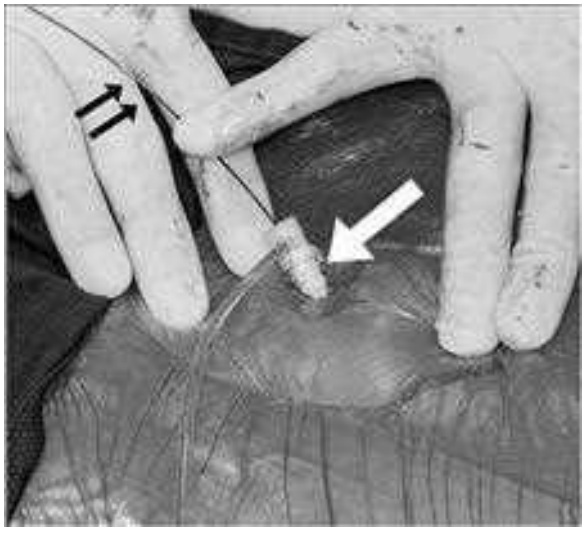

Figure 23-8. All percutaneous endovascular procedures are performed through an introducer sheath (*large arrow*), which provides an access conduit from skin to intravascular compartment. The sheath also acts to protect the vessel from injury as guidewires (*small arrows*) and catheters are introduced.

and thus decreases the risk of catheter-related emboli to the brain. The artery is accessed with a micropuncture needle just proximal to the antecubital crease. The use of brachial access is associated with a higher risk of thrombosis and nerve injuries than femoral access.

Guidewires

Guidewires are used to introduce, position, and exchange catheters. A guidewire generally has a flexible and stiff end. In general, only the flexible end of the guidewire is placed in the vessel. All guidewires are composed of a stiff inner core and an outer tightly coiled spring that allows a catheter to track over the guidewire. There are five essential characteristics of guidewires: size, length, stiffness, coating, and tip configuration.

Guidewires come in different maximum transverse diameters, ranging from 0.011 to 0.038 inches. For most aortoiliac procedures, a 0.035-inch wire is most commonly used, whereas the smaller diameter 0.018-inch guidewires are reserved for selective small vessel angiography such as infrageniculate or carotid lesions. In addition to diameter size, guidewires come in varying lengths, usually ranging from 180 to 260 cm in length. Increasing the length of the wire always makes it more difficult to handle and increases the risk of contamination. While performing a procedure, it is important to maintain the guidewire across the lesion until the completion arteriogram has been satisfactorily completed.

The stiffness of the guidewire is also an important characteristic. Stiff wires allow for passage of large aortic stent graft devices without kinking. They are also useful when trying to perform sheath or catheter exchanges around a tortuous artery. An example of a stiff guidewire is the Amplatz wire. Hydrophilic coated guidewires, such as the Glidewire, have become invaluable tools for assisting in difficult catheterizations. The coating is primed by bathing the guidewire in saline solution. The slippery nature of this guidewire along with its torque capability significantly facilitate in difficult catheterizations. Guidewires also come in various tip configurations. Angled tip wires like the angled Glidewire can be steered to manipulate a catheter across a tight stenosis or to select a specific branch of a vessel. The Rosen wire has a soft curled end, which makes it ideal for renal artery stenting. The soft curl of this wire prevents it from perforating small renal branch vessels.

Hemostatic Sheaths

The hemostatic sheath is a device through which endovascular procedures are performed. The sheath acts to protect the vessel from injury as wires and catheters are introduced (Fig. 23-8). A one-way valve prevents bleeding through the sheath, and a side-port allows contrast or heparin flushes to be administered during the procedure. Sheaths are sized by their inner diameter. The most commonly used sheaths for percutaneous access have a 5- to 9-French inner diameter, but with open surgical exposure of the CFA, sheaths as large as 26 French can be introduced. Sheaths also vary in length, and long sheaths are available so that interventions remote from the site of arterial access can be performed.

Catheters

A wide variety of catheters exist that differ primarily in the configuration of the tip. The multiple shapes permit access to vessels of varying dimensions and angulations. Catheters are used to perform angiography and protect the passage of balloons and stents, and can be used to direct the guidewire through tight stenoses or tortuous vessels.

Angioplasty Balloons

Angioplasty balloons differ primarily in their length and diameter, as well as the length of the catheter shaft. As balloon technology has advanced, lower profiles have been manufactured (i.e., the size that the balloon assumes upon deflation). Balloons are used to perform angioplasty on vascular stenoses, to deploy stents, and to assist with additional expansion after insertion of self-expanding stents (Fig. 23-9). Besides length and diameter,

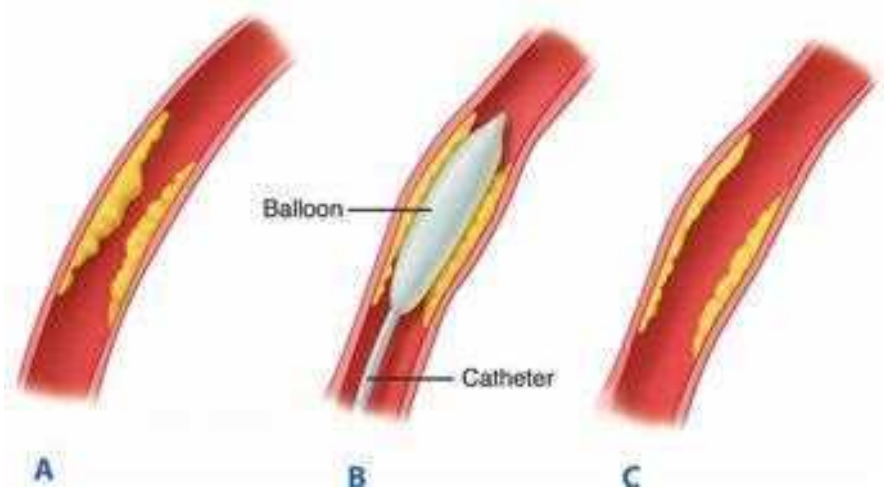

Figure 23-9. A. An artery with luminal narrowing caused by plaque. **B.** A balloon angioplasty catheter is positioned within the diseased artery, which is inflated to enlarge the intravascular channel. **C.** The plaque is compressed with widened flow lumen as the result of balloon angioplasty.

operators need to be familiar with several other balloon characteristics. Noncompliant and low-compliance balloons tend to be inflated to their preset diameter and offer greater dilating force at the site of stenosis. Low-compliance balloons are the mainstay for peripheral intervention. Lower profile balloons are less likely to get caught during passage through stents and are easier to pull out of sheaths. Under fluoroscopic guidance, balloon inflation is performed until the waist of the atherosclerotic lesion disappears and the balloon is at the full profile. The duration of balloon inflation and pressures used for the angioplasty depend on the indication for the intervention and the location and characteristics of the lesion being treated. Frequently, several inflations are required to achieve a full profile of the balloon. Occasionally, a lower profile balloon is needed to predilate the tight stenosis so that the selected balloon catheter can cross the lesion. After inflation, most balloons do not regain their preinflation diameter and assume a larger profile. Trackability, pushability, and crossability of the balloon should all be considered when choosing a particular balloon. Lastly, shoulder length is an important characteristic to consider when selecting a balloon because of the potential to cause injury during performance of PTA in adjacent arterial segments. There is always risk of causing dissection or rupture during PTA; thus a completion angiogram is performed while the wire is still in place. Leaving the wire in place provides access for repeating the procedure, placing a stent or stent graft if warranted.

Stents

Vascular stents are commonly used after an inadequate angioplasty with dissection or elastic recoil of an arterial stenosis. They serve to buttress collapsible vessels and help prevent atherosclerotic restenosis. Appropriate indications for primary stenting of a lesion without an initial trial of angioplasty alone are evolving in manners that are dependent on the extent and site of the lesion. Stents are manufactured from a variety of metals including stainless steel, tantalum, cobalt-based alloy, and nitinol. Vascular stents are classified into two basic categories: balloon-expandable stents and self-expanding stents.

Self-expanding stents (Fig. 23-10) are deployed by retracting a restraining sheath and usually consist of Elgiloy (a cobalt, chromium, nickel alloy) or nitinol (a shape memory alloy composed of nickel and titanium), the latter of which will contract and assume a heat-treated shape above a transition temperature that depends on the composition of the alloy. Self-expanding stents will expand to a final diameter that is determined by stent geometry, hoop strength, and vessel size. The self-expanding stent is mounted on a central shaft and is placed inside an outer sheath. It relies on a mechanical spring-like action to achieve expansion. With deployment of these stents, there is some degree of foreshortening that has to be taken into account when choosing the area of deployment. In this way, self-expanding stents are more difficult to place with absolute precision. There are several advantages related to self-expanding stents. Self-expanding stents generally come in longer lengths than balloon-expandable stents and are therefore used to treat long and tortuous lesions. Their ability to continually expand after delivery allows them to accommodate adjacent vessels of different size. This makes these stents ideal for placement in the internal carotid artery. These stents are always oversized by 1 to 2 mm relative to the largest diameter of normal vessel adjacent to the lesion in order to prevent immediate migration.

Balloon-expandable stents are usually composed of stainless steel, mounted on an angioplasty balloon, and deployed by balloon inflation (Fig. 23-11). They can be manually placed on a chosen balloon catheter or obtained premounted on a balloon catheter. The capacity of a balloon-expandable stent to shorten in length during deployment depends on both stent geometry and the final diameter to which the balloon is expanded. These stents are more rigid and are associated with a shorter time to complete endothelialization. They are often of limited flexibility and have a higher degree of crush resistance when compared to self-expanding stents. This makes them ideal for short-segment lesions, especially those that involve the ostia such as proximal common iliac or renal artery stenosis.

The most exciting area of development in stents is the evolution of drug-eluting stents (DES). These stents are usually composed of nitinol and have various anti-inflammatory drugs bonded to them. Over time, the stents release the drug into the surrounding arterial wall and help prevent restenosis. Numerous randomized controlled trials have proven their benefit in coronary arteries.[12] Clinical studies have similarly proved early efficacy of DES in the treatment of peripheral arterial disease.[13,14]

Stent Grafts

The combination of a metal stent covered with fabric gave birth to the first stent grafts. Covered stents have been designed

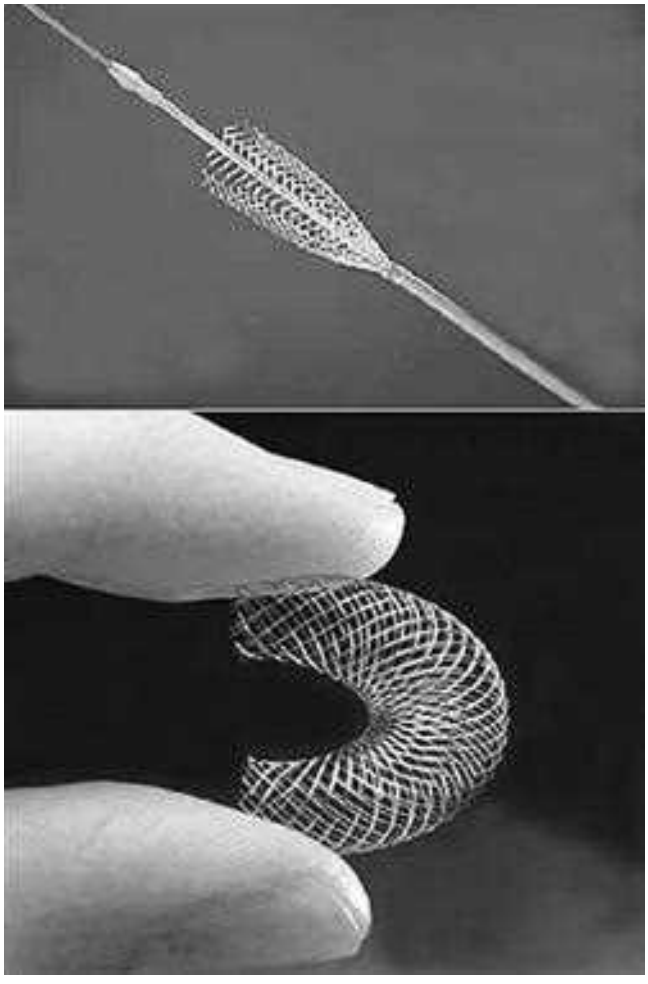

Figure 23-10. Self-expanding stents are made of tempered stainless steel or nitinol, an alloy of nickel and titanium, and are restrained when folded inside a delivery catheter. After being released from the restraining catheter, the self-expanding stents will expand to a final diameter that is determined by stent geometry, hoop strength, and vessel size.

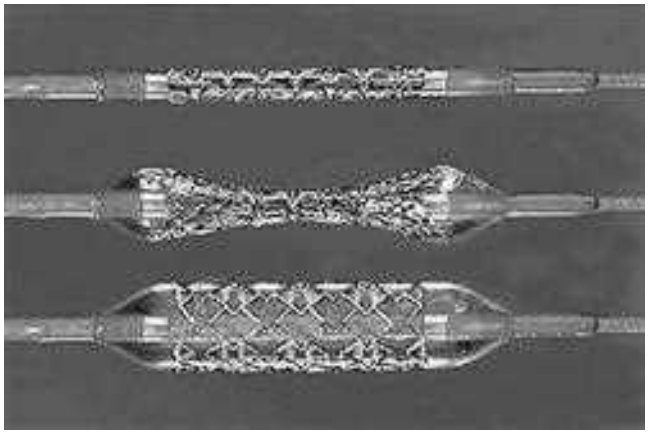

Figure 23-11. In a balloon-expandable stent, the stent is premounted on a balloon catheter. The balloon stretches the stent members beyond their elastic limit. The stent is deployed by full balloon expansion. This type of stent has a higher degree of crush resistance when compared to self-expanding stents, which is ideal for short-segment calcified ostial lesions.

with either a surrounding PTFE or polyester fabric and have been used predominantly for treatment of traumatic vascular lesions, including arterial disruption and arteriovenous fistulas (Fig. 23-12). However, these devices may well find a growing role in treatment of iliac or femoral arterial occlusive disease as well as popliteal aneurysms.

Endovascular aneurysm repair using the concept of stent grafts was initiated by Parodi in 1991.[15] Since that time, a large number of endografts have been inserted under the auspice of clinical trials initially and now as Food and Drug Administration (FDA)–approved devices. Current available FDA-approved devices include the following: (a) AneuRx device (Medtronic/AVE, Santa Rosa, CA); (b) Gore Excluder device (WL Gore & Associates, Flagstaff, AZ); (c) Endologix Powerlink device (Endologix Inc., Irvine, CA); (d) Zenith device (Cook Inc., Bloomington, IN); (e) Talent device (Medtronic/AVE, Santa Rosa, CA); and (f) Endurant device (Medtronic/AVE, Santa Rosa, CA) for the treatment of abdominal aortic aneurysms. All of these devices require that patients have an infrarenal aneurysm with at least a 15-mm proximal aortic neck below the renal arteries and not greater than 60° of angulation. For those patients with associated common iliac artery aneurysmal disease, endovascular treatment can be achieved by initial coil embolization of the ipsilateral hypogastric artery with extension of the endovascular device into the external iliac artery. Newer generation endografts, including devices such as AFX Endovascular AAA System (Endologix Inc., Irvine, CA), Aorfix Flexible Stent (Lombard Medical Inc., Framingham, MA), and Ovation Prime Stent (TriVascular Inc., Santa Rosa, CA), are designed to overcome previous challenges of difficult anatomy by incorporating more flexible stents and lower profile delivery systems. Clinical trials are under way with devices that will expand indications to aneurysms involving the visceral segment of the abdominal aorta. The FDA has similarly approved several thoracic endograft devices for the treatment of descending thoracic aortic aneurysm. Early studies have demonstrated short-term efficacy of thoracic aortic devices in the treatment of traumatic aortic transections and aortic dissections.[16-18] More experience with these devices exists in both Europe and Asia, and trials are under way in the United States with several devices.

CAROTID ARTERY DISEASE

Atherosclerotic occlusive plaque is by far the most common pathology seen in the carotid artery bifurcation. Thirty percent to 60% of all ischemic strokes are related to atherosclerotic carotid bifurcation occlusive disease. In the following section, we first focus our discussion on the clinical presentation, diagnosis, and management, including medical therapy, surgical carotid endarterectomy, and stenting, of atherosclerotic carotid occlusive disease. In the second part of the section, we provide a review on other less common nonatherosclerotic diseases involving the extracranial carotid artery, including kink and coil, fibromuscular dysplasia, arterial dissection, aneurysm, radiation arteritis, Takayasu's arteritis, and carotid body tumor.

Epidemiology and Etiology of Carotid Occlusive Disease

Approximately 700,000 Americans suffer a new or recurrent stroke each year.[19] Eighty-five percent of all strokes are ischemic, and 15% are hemorrhagic. Hemorrhagic strokes are caused by head trauma or spontaneous disruption of intracerebral blood

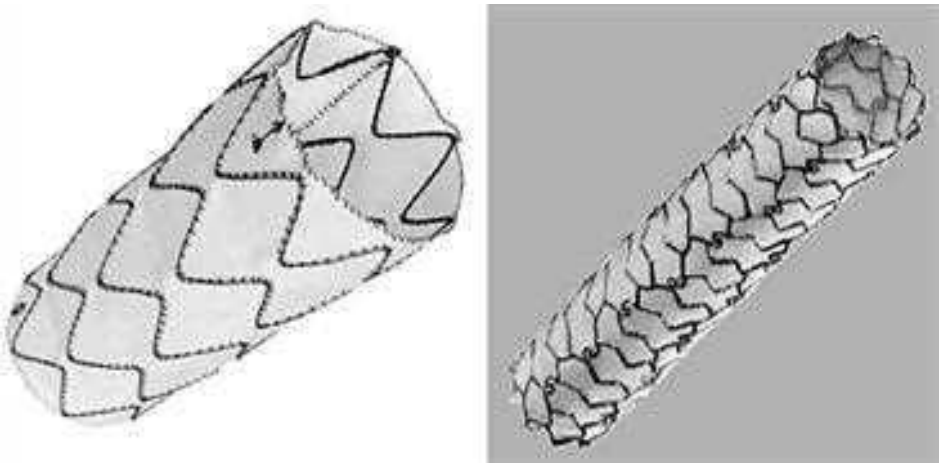

Figure 23-12. A stent graft is a metal stent covered with fabric that is commonly used for aneurysm exclusion.

vessels. Ischemic strokes are due to hypoperfusion from arterial occlusion or, less commonly, to decreased flow resulting from proximal arterial stenosis and poor collateral network. Common causes of ischemic strokes are cardiogenic emboli in 35%, carotid artery disease in 30%, lacunar in 10%, miscellaneous in 10%, and idiopathic in 15%.[19] The term *cerebrovascular accident* is often used interchangeably to refer to an ischemic stroke. A transient ischemic attack (TIA) is defined as a temporary focal cerebral or retinal hypoperfusion state that resolves spontaneously within 24 hours after its onset. However, the majority of TIAs resolve within minutes, and longer lasting neurologic deficits more likely represent a stroke. Recently, the term *brain attack* has been coined to refer to an acute stroke or TIA, denoting the condition as a medical emergency requiring immediate attention, similar to a heart attack.

Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli (Fig. 23-13). The carotid bifurcation is an area of low flow velocity and low shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. Characteristically, atherosclerotic plaque forms in the outer wall opposite to the flow divider (Fig. 23-14). Atherosclerotic plaque formation is complex, beginning with intimal injury, platelet deposition, smooth muscle cell proliferation, and fibroplasia, and leading to subsequent luminal narrowing. With increasing degree of stenosis in the internal carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates. The severity of stenosis is commonly divided into three categories according to the luminal diameter reduction: mild (<50%), moderate (50%–69%), and severe (70%–99%). Severe carotid stenosis is a strong predictor for stroke.[20] In turn, a prior history of neurologic symptoms (TIA or stroke) is an important determinant for recurrent ipsilateral stroke. The risk factors for the development of carotid artery bifurcation disease are similar to those causing atherosclerotic occlusive disease in other vascular beds. Increasing age, male gender, hypertension, tobacco smoking, diabetes mellitus, homocysteinemia, and hyperlipidemia are well-known predisposing factors for the development of atherosclerotic occlusive disease.

Clinical Manifestations of Cerebral Ischemia

TIA is a focal loss of neurologic function, lasting for less than 24 hours. Crescendo TIAs refer to a syndrome comprising repeated TIAs within a short period of time that is characterized by complete neurologic recovery in between. At a minimum, the term should probably be reserved for those with either daily events or multiple resolving attacks within 24 hours. Hemodynamic TIAs represent focal cerebral events that are aggravated by exercise or hemodynamic stress and typically occur after short bursts of physical activity, postprandially, or after getting out of a hot bath. It is implied that these are due to severe

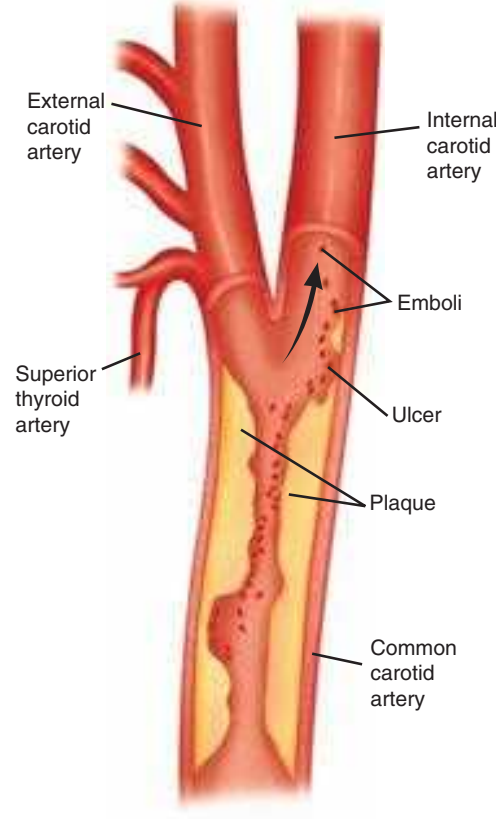

Figure 23-13. Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli arising from the internal carotid artery, which provides the majority of blood flow to the cerebral hemisphere. With increasing degree of stenosis in the carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates.

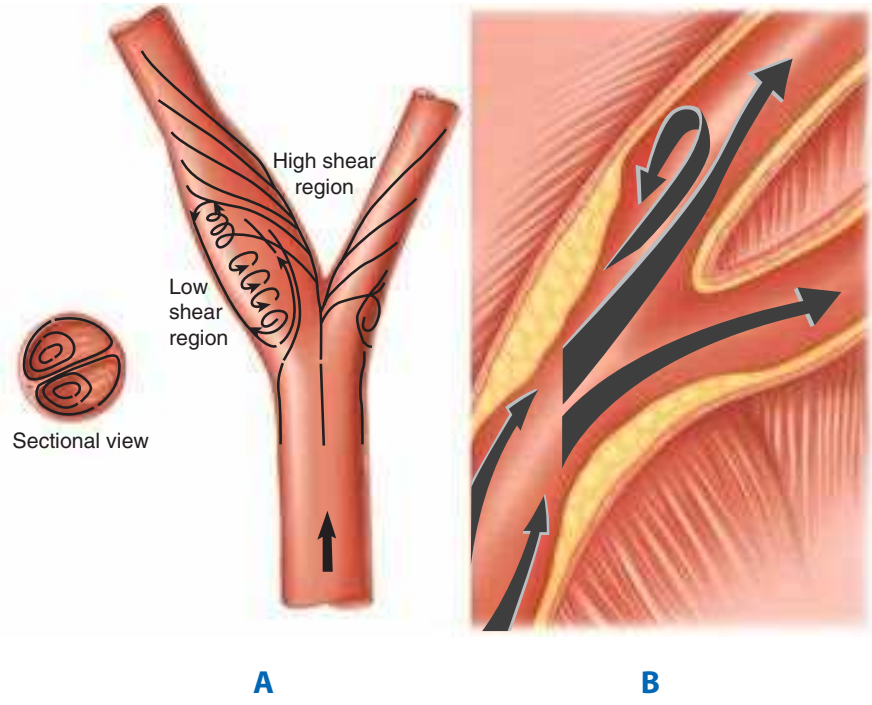

Figure 23-14. **A.** The carotid bifurcation is an area of low flow velocity and low shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. **B.** The carotid atherosclerotic plaque typically forms in the outer wall opposite to the flow divider due in part to the effect of the low shear stress region, which also creates a transient reversal of flow during the cardiac cycle.

extracranial disease and poor intracranial collateral recruitment. *Reversible ischemic neurologic deficits* refer to ischemic focal neurologic symptoms lasting longer than 24 hours but resolving within 3 weeks. When a neurologic deficit lasts longer than 3 weeks, it is considered a *completed stroke*. *Stroke in evolution* refers to progressive worsening of the neurologic deficit, either linearly over a 24-hour period or interspersed with transient periods of stabilization and/or partial clinical improvement.

Patients who suffer cerebrovascular accidents typically present with three categories of symptoms including ocular symptoms, sensory/motor deficit, and/or higher cortical dysfunction. The common ocular symptoms associated with extracranial carotid artery occlusive disease include amaurosis fugax and presence of Hollenhorst plaques. Amaurosis fugax, commonly referred to as transient monocular blindness, is a temporary loss of vision in one eye that patients typically describe as a window shutter coming down or grey shedding of the vision. This partial blindness usually lasts for a few minutes and then resolves. Most of these phenomena (>90%) are due to embolic occlusion of the main artery or the upper or lower divisions. Monocular blindness progressing over a 20-minute period suggests a migrainous etiology. Occasionally, the patient will recall no visual symptoms while the optician notes a yellowish plaque within the retinal vessels, which is also known as Hollenhorst plaque. These plaques are frequently derived from cholesterol embolization from the carotid bifurcation and warrant further investigation. Additionally, several ocular symptoms may be caused by microembolization from extracranial carotid diseases including monocular visual loss due to retinal artery or optic nerve ischemia, the ocular ischemia syndrome, and visual field deficits secondary to cortical infarction and ischemia of the optic tracts. Typical motor and/or sensory symptoms associated with cerebrovascular accidents are lateralized or focal neurologic deficits. Ischemic events tend to have an abrupt onset, with the severity of the insult being apparent from the onset and not usually associated with seizures or paresthesia. In contrast, they represent loss or diminution of neurologic function. Furthermore, motor or sensory deficits can be unilateral or bilateral, with the upper and lower limbs being variably affected depending on the site of the cerebral lesion. The combination of a motor and sensory deficit in the same body territory is suggestive of a cortical thromboembolic event as opposed to lacunar lesions secondary to small vessel disease of the penetrating arterioles. However, a small proportion of the latter may present with a sensorimotor stroke secondary to small vessel occlusion within the posterior limb of the internal capsule. Pure sensory and pure motor strokes and those strokes where the weakness affects one limb only or does not involve the face are more typically seen with lacunar as opposed to cortical infarction. A number of higher cortical functions, including speech and language disturbances, can be affected by thromboembolic phenomena from the carotid artery, with the most important clinical example for the dominant hemisphere being dysphasia or aphasia and visuospatial neglect being an example of nondominant hemisphere injury.

Diagnostic Evaluation

Duplex ultrasonography is the most widely used screening tool to evaluate for atherosclerotic plaque and stenosis of the extracranial carotid artery. It is also commonly used to monitor patients serially for progression of disease or after intervention (carotid endarterectomy or angioplasty). Duplex ultrasound of the carotid artery combines B-mode gray scale imaging and Doppler waveform analysis. Characterization of the carotid plaque on gray scale imaging provides useful information about its composition. However, there are currently no universal recommendations that can be made based solely on the sonographic appearance of the plaque. On the other hand, criteria have been developed and well refined for grading the degree of carotid stenosis based primarily on Doppler-derived velocity waveforms.

The external carotid artery has a high-resistance flow pattern with a sharp systolic peak and a small amount of flow in

diastole. In contrast, a normal internal carotid artery will have a low-resistance flow pattern with a broad systolic peak and a large amount of flow during diastole. The flow pattern in the common carotid artery resembles that in the internal carotid artery, as 80% of the flow is directed to the internal carotid artery, with waveforms that have broad systolic peaks and moderate amount of flow during diastole. Conventionally, velocity measurements are recorded in the common, external, carotid bulb, and the proximal, mid, and distal portions of the internal carotid artery. Characteristically, the peak systolic velocity is increased at the site of the vessel stenosis. The end-diastolic velocity is increased with greater degree of stenosis. In addition, stenosis of the internal carotid artery can lead to color shifts with color mosaics indicating a poststenotic turbulence. Dampening of the Doppler velocity waveforms is typically seen in areas distal to severe carotid stenosis where blood flow is reduced. It is well known that occlusion of the ipsilateral internal carotid artery can lead to a "falsely" elevated velocity on the contralateral side due to an increase in compensatory blood flow. In the presence of a high-grade stenosis or occlusion of the internal carotid artery, the ipsilateral common carotid artery displays high flow resistance waveforms, similar to those seen in the external carotid artery. If there is a significant stenosis in the proximal common carotid artery, its waveforms may be dampened with low velocities.

The Doppler grading systems of carotid stenosis were initially established by comparison to angiographic findings of disease. Studies have shown variability in the measurements of the duplex properties by different laboratories, as well as heterogeneity in the patient population, study design, and techniques. One the most commonly used classifications was established at the University of Washington School of Medicine in Seattle. Diameter reduction of 50% to 79% is defined by peak systolic velocity greater than 125 cm/s with extensive spectral broadening. For stenosis in the range of 80% to 99%, the peak systolic velocity is greater than 125 cm/s, and peak diastolic velocity is greater than 140 cm/s. The ratio of internal carotid to common carotid artery peak systolic velocity has also been part of various ultrasound diagnostic classifications. A ratio greater than 4 is a great predictor of angiographic stenosis of 70% to 99%. A multispecialty consensus panel has developed a set of criteria for grading carotid stenosis by duplex examination (Table 23-3).[21]

MRA is increasingly being used to evaluate for atherosclerotic carotid occlusive disease and intracranial circulation. MRA is noninvasive and does not require iodinated contrast agents. MRA uses phase contrast or time-of-flight, with either two-dimensional or three-dimensional data sets for greater accuracy. Three-dimensional contrast-enhanced MRA allows data to be obtained in coronal and sagittal planes with improved image qualities due to shorter study time. In addition, the new MRA techniques allow for better reformation of images in various planes to allow better grading of stenosis. There have been numerous studies comparing the sensitivity and specificity of MRA imaging for carotid disease to duplex and selective contrast angiography.[22] Magnetic resonance imaging (MRI) of the brain is essential in the assessment of acute stroke patients. MRI with diffusion-weighted imaging can differentiate areas of acute ischemia, areas still at risk for ischemia (penumbra), and chronic cerebral ischemic changes. However, computed tomography (CT) imaging remains the most expeditious test in the evaluation of acute stroke patients to rule out intracerebral hemorrhage. Recently, multidetector CTA has gained increasing popularity in the evaluation of carotid disease.[23] This imaging modality can provide volume rendering, which allows rotation of the object with accurate anatomic structures from all angles (Fig. 23-15). The advantages of CTA over MRA include faster data acquisition time and better spatial resolution. However, grading of carotid stenosis by CTA requires further validation at the time of this writing before it can be widely applied.

Historically, DSA has been the gold standard test to evaluate the extra- and intracranial circulation (Fig. 23-16). This is an invasive procedure, typically performed via a transfemoral puncture, and involves selective imaging of the carotid and vertebral arteries using iodinated contrast. The risk of stroke during cerebral angiography is generally reported at approximately 1% and is typically due to atheroembolization related to wire and catheter manipulation in the arch aorta or proximal branch vessels. Over the last few decades, however, the incidence of neurologic complications following angiography has been reduced, due to the use of improved guidewires and catheters, better resolution digital imaging, and increased experience. Local access complications of angiography are infrequent and include development of hematoma, pseudoaneurysm, distal embolization, and acute vessel thrombosis. Currently, selective angiography is particularly used for patients with suspected intracranial

Table 23-3

Carotid duplex ultrasound criteria for grading internal carotid artery stenosis

DEGREE OF STENOSIS (%)	ICA PSV (CM/S)	ICA/CCA PSV RATIO	ICA EDV (CM/S)	PLAQUE ESTIMATE (%)[a]
Normal	<125	<2.0	<40	None
<50	<125	<2.0	<40	<50
50–69	125–230	2.0–4.0	40–100	≥50
≥70 to less than near occlusion	>230	>4.0	>100	≥50
Near occlusion	High, low, or not detected	Variable	Variable	Visible
Total occlusion	Not detected	Not applicable	Not detected	Visible, no lumen

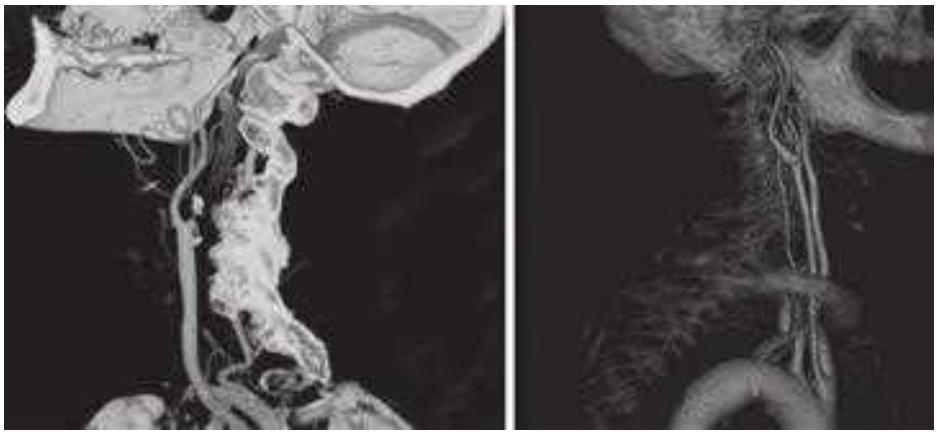
CCA = common carotid artery; EDV = end-diastolic velocity; ICA = internal carotid artery; PSV = peak systolic velocity.



A B

Figure 23-15. A. Carotid computed tomography angiography is a valuable imaging modality that can provide a three-dimensional image reconstruction with high image resolution. A carotid artery occlusion is noted in the internal carotid artery **B.** The entire segment of extracranial carotid artery is visualized from the thoracic compartment to the base of skull.

disease and for patients in whom percutaneous revascularization is considered. The techniques of carotid angioplasty and stenting for carotid bifurcation occlusive disease are described in detail later in this chapter. We generally use CTA or MRA to get information about the aortic arch anatomy and presence of concomitant intracranial disease and collateral pathway in planning our strategy for carotid stenting or endarterectomy.

Treatment of Carotid Occlusive Disease

Conventionally, patients with carotid bifurcation occlusive disease are divided into two broad categories: patients without prior history of ipsilateral stroke or TIA (asymptomatic) and those with prior or current ipsilateral neurologic symptoms (symptomatic). It is estimated that 15% of all strokes are preceded by a TIA. The 90-day risk of a stroke in a patient presenting with a TIA is 3% to 17%.[19] According to the Cardiovascular Health Study, a longitudinal population-based study of coronary artery disease and stroke in men and women, the prevalence of TIA in men was 2.7% for ages of 65 and 69 and 3.6% for ages 75 to 79; the prevalence in women was 1.4% and 4.1%, respectively.[24] There have been several studies reporting on the effectiveness of stroke prevention with medical treatment and carotid endarterectomy for symptomatic patients with moderate to severe carotid stenosis. Early and chronic aspirin therapy has been shown to reduce stroke recurrence rate in several large clinical trials.[25]

1▶

Figure 23-16. A carotid angiogram reveals an ulcerated carotid plaque (*arrow*) in the proximal internal carotid artery, which also resulted in a high-grade internal carotid artery stenosis.

Symptomatic Carotid Stenosis. Currently, most stroke neurologists prescribe both aspirin and clopidogrel for secondary stroke prevention in patients who have experienced a TIA or stroke.[19] In patients with symptomatic carotid stenosis, the degree of stenosis appears to be the most important predictor in determining risk for an ipsilateral stroke. The risk of a recurrent ipsilateral stroke in patients with severe carotid stenosis approaches 40%. Two large multicenter randomized clinical trials, the European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET), have both shown a significant risk reduction in stroke for patients with symptomatic high-grade stenosis (70%–99%) undergoing carotid endarterectomy when compared to medical therapy alone.[26,27] There has been much discussion regarding the different methodology used in the measurement of carotid stenosis and calculation of the life-table data between the two studies, yet they both studies had similar results.[28] Findings of these two landmark trials have also been reanalyzed in many subsequent publications. The main conclusions of the trials remain validated and widely acknowledged. Briefly, the NASCET study showed that for high-grade carotid stenosis, the cumulative risk of ipsilateral stroke was 26% in the medically treated group and 9% in the surgically treated group at 2 years. For patients with moderate carotid artery stenosis (50%–69%), the benefit of carotid endarterectomy is less but still favorable when compared to medical treatment alone; the 5-year fatal or nonfatal ipsilateral stroke rate was 16% in the surgically treated group versus 22% in the medically treated group.[29] The risk of stroke was similar for the remaining group of symptomatic patients with less than 50% carotid stenosis, whether they had

endarterectomy or medical treatment alone. The ECST reported similar stroke risk reduction for patients with severe symptomatic carotid stenosis and no benefit in patients with mild stenosis, when carotid endarterectomy was performed versus medical therapy.[27]

The optimal timing of carotid intervention after acute stroke, however, remains debatable. Earlier studies showed an increased rate of postoperative stroke exacerbation and conversion of a bland to hemorrhagic infarction when carotid endarterectomy was carried out within 5 to 6 weeks after acute stroke. The dismal outcome reported in the early experience was likely related to poor patient selection. The rate of stroke recurrence is not insignificant during the interval period and may be reduced with early intervention for symptomatic carotid stenosis. Contemporary series have demonstrated acceptable low rates of perioperative complications in patients undergoing carotid endarterectomy within 4 weeks after acute stroke.[29] In a recent retrospective series, carotid artery stenting when performed early (<2 weeks) after the acute stroke was associated with higher mortality than when delayed (>2 weeks).[30]

Asymptomatic Carotid Stenosis. Whereas there is universal agreement that carotid revascularization (endarterectomy or stenting) is effective in secondary stroke prevention for patients with symptomatic moderate and severe carotid stenosis, the management of asymptomatic patients remains an important controversy to be resolved. Generally, the detection of carotid stenosis in asymptomatic patients is related to the presence of a cervical bruit or based on screening duplex ultrasound findings. In one of the earlier observational studies, the authors showed that the annual occurrence rate of neurologic symptoms was 4% in a cohort of 167 patients with asymptomatic cervical bruits followed prospectively by serial carotid duplex scan.[31] The mean annual rate of carotid stenosis progression to a greater than 50% stenosis was 8%. The presence of or progression to a greater than 80% stenosis correlated highly with either the development of a total occlusion of the internal carotid artery or new symptoms. The major risk factors associated with disease progression were cigarette smoking, diabetes mellitus, and age. This study supported the contention that it is prudent to follow a conservative course in the management of asymptomatic patients presenting with a cervical bruit.

One of the first randomized clinical trials on the treatment of asymptomatic carotid artery stenosis was the Asymptomatic Carotid Atherosclerosis Study (ACAS), which evaluated the benefits of medical management with antiplatelet therapy versus carotid endarterectomy.[32] Over a 5-year period, the risk of ipsilateral stroke in individuals with a carotid artery stenosis greater than 60% was 5.1% in the surgical arm. On the other hand, the risk of ipsilateral stroke in patients treated with medical management was 11%. Carotid endarterectomy produced a relative risk reduction of 53% over medical management alone. The results of a larger randomized trial from Europe, the Asymptomatic Carotid Surgery Trial (ACST), recently confirmed similar beneficial stroke risk reduction for patients with asymptomatic, greater than 70% carotid stenosis undergoing endarterectomy versus medical therapy.[33] An important point derived from this latter trial was that even with improved medical therapy, including the addition of statin drugs and clopidogrel, medical therapy was still inferior to endarterectomy in the primary stroke prevention for patients with high-grade carotid artery stenosis. It is generally agreed that asymptomatic patients with severe carotid stenosis (80%–99%) are at significantly increased risk for stroke and stand to benefit from either surgical or endovascular revascularization. However, revascularization for asymptomatic patients with a less severe degree of stenosis (60%–79%) remains controversial.

Carotid Endarterectomy versus Angioplasty and Stenting

Currently, the argument is no longer whether medical therapy alone is inferior to surgical endarterectomy in stroke prevention for severe carotid stenosis. Rather, the debate now revolves around whether carotid angioplasty and stenting produce the same benefits demonstrated by carotid endarterectomy. Since carotid artery stenting was approved by the FDA for clinical application in 2004, this percutaneous procedure has become a treatment alternative in patients who are deemed "high risk" for endarterectomy (Table 23-4). In contrast to many endovascular peripheral arterial interventions, percutaneous carotid stenting represents a much more challenging procedure, because it requires complex catheter-based skills using the 0.014-inch guidewire system and distal protection device. Moreover, current carotid stent devices predominantly use the monorail guidewire system, which requires more technical agility compared with the over-the-wire catheter system that is routinely used in peripheral interventions. This percutaneous intervention often

Table 23-4

Conditions qualifying patients as high surgical risk for carotid endarterectomy

ANATOMIC FACTORS	PHYSIOLOGIC FACTORS
• High carotid bifurcation (above C2 vertebral body)	• Age ≥80 years • Left ventricular ejection fraction ≤30%
• Low common carotid artery (below clavicle) • Contralateral carotid occlusion • Restenosis of ipsilateral prior carotid endarterectomy • Previous neck irradiation	• New York Heart Association class III/IV congestive heart failure • Unstable angina: Canadian Cardiovascular Society class III/IV angina pectoris • Recent myocardial infarction
• Prior radical neck dissection • Contralateral laryngeal nerve palsy • Presence of tracheostomy	• Clinically significant cardiac disease (congestive heart failure, abnormal stress test, or need for coronary revascularization) • Severe chronic obstructive pulmonary disease • End-stage renal disease on dialysis

requires balloon angioplasty and stent placement through a long carotid guiding sheath via a groin approach. Poor technical skills can result in devastating treatment complications such as stroke, which can occur in part due to plaque embolization during the balloon angioplasty and stenting of the carotid artery. Because of these various procedural components that require high technical proficiency, many early clinical investigations of carotid artery stenting, which included physicians with little or no carotid stenting experience, resulted in alarmingly poor clinical outcomes. A recent Cochrane review noted that, before 2006, a total of 1269 patients had been studied in five randomized controlled trials comparing percutaneous carotid intervention and surgical carotid reconstruction.[34] Taken together, these trials revealed that carotid artery stenting had a greater procedural risk of stroke and death when compared to carotid endarterectomy (odds ratio, 1.33; 95% confidence interval, 0.86 to 2.04). Additionally, a greater incidence of carotid restenosis was noted in the stenting group than the endarterectomy cohorts.

However, the constant improvement of endovascular devices, procedural techniques, and adjunctive pharmacologic therapy will likely improve the treatment success of percutaneous carotid intervention. Critical appraisals of several prospective randomized trials comparing the efficacy of carotid stenting versus endarterectomy are available for review.[35] Two recently published randomized controlled trial, the Carotid Revascularization Endarterectomy Versus Stent Trial (CREST) and the International Carotid Stenting Study (ICSS) have reported somewhat differing results.[36] CREST compared the efficacy of carotid endarterectomy and carotid stenting in both symptomatic and asymptomatic patients.[37] Primary end points included 30-day periprocedural composite death, stroke, myocardial infarction, or any ipsilateral stroke up to 4 years. CREST investigators reported no difference between stenting (5.2%) and endarterectomy (4.5%) in terms of primary end point. When each variable was independently analyzed, there was a higher rate of stroke in the stenting group at 30 days (4.1% vs. 2.3%) and a higher rate of myocardial infarction in the endarterectomy group (2.3% vs. 1.1%). The ICSS was a multicenter, international, randomized controlled trial comparing carotid stenting versus endarterectomy in patients with symptomatic carotid stenosis.[38] The risk of stroke, death, and myocardial infarction in the stenting group (8.5%) was significantly higher than in the surgical arm (5.2%). The finding that carotid endarterectomy is safer than carotid stenting is also supported by the results of an MRI substudy, which showed significantly more new lesions by diffusion-weighted imaging in the carotid stenting than the carotid endarterectomy patients.

All available randomized studies have provided some answers and raised some questions. Some ongoing clinical trials will undoubtedly provide more insights on the efficacy of carotid stenting in the near future. Currently, the Society for Vascular Surgeons recommends carotid endarterectomy as first-line treatment for most symptomatic patients with stenosis of 50% to 99% and asymptomatic patients with stenosis of 60% to 99%.[39] The perioperative risk of stroke and death in asymptomatic patients must be below 3% to ensure benefit for the patient. Carotid artery stenting should be reserved for symptomatic patients with stenosis of 50% to 99% at high risk for carotid endarterectomy for anatomic or medical reasons. Carotid artery stenting is not recommended for asymptomatic patients at this time. Asymptomatic patients at high risk for intervention or with a life expectancy of less than 3 years should be considered for medical management as the first-line therapy.

Surgical Techniques of Carotid Endarterectomy

Although carotid endarterectomy is one of the earliest vascular operations ever described and its techniques have been perfected in the last two decades, surgeons continue to debate many aspects of this procedure. For instance, there is no universal agreement with regard to the best anesthetic of choice, the best intraoperative cerebral monitoring, whether to "routinely" shunt, open versus eversion endarterectomy, and patch versus primary closure. Various anesthetic options are available for patient undergoing carotid endarterectomy including general, local, and regional anesthesia. Typically the anesthesia of choice depends on the preference of the surgeon, anesthesiologist, and patient. However, depending on the anesthetic given, the surgeon must decide whether intraoperative cerebral monitoring is necessary or intra-arterial carotid shunting will be used. In general, if the patient is awake, then his or her abilities to respond to commands during carotid clamp period determine the adequacy of collateral flow to the ipsilateral hemisphere. On the other hand, intraoperative electroencephalogram (EEG) or transcranial power Doppler (TCD) has been used to monitor for adequacy of cerebral perfusion during the clamp period for patients undergoing surgery under general anesthesia. Focal ipsilateral decreases in amplitudes and slowing of EEG waves are indicative of cerebral ischemia. Similarly, a decrease to less than 50% of baseline velocity in the ipsilateral middle cerebral artery is a sign of cerebral ischemia. For patients with poor collateral flow exhibiting signs of cerebral ischemia, intra-arterial carotid shunting with removal of the clamp will restore cerebral flow for the remaining part of the surgery. Stump pressures have been used to determine the need for intra-arterial carotid shunting. Some surgeons prefer to shunt all patients on a routine basis and do not use intraoperative cerebral monitoring.

The patient's neck is slightly hyperextended and turned to the contralateral side, with a roll placed between the shoulder blades. An oblique incision is made along the anterior border of the sternocleidomastoid muscle centered on top of the carotid bifurcation (Fig. 23-17). The platysma is divided completely. Typically tributaries of the anterior jugular vein are ligated and

Figure 23-17. To perform carotid endarterectomy, the patient's neck is slightly hyperextended and turned to the contralateral side. An oblique incision is made along the anterior border of the sternocleidomastoid muscle centered on top of the carotid bifurcation.

divided. The dissection is carried medial to the sternocleidomastoid. The superior belly of the omohyoid muscle is usually encountered just anterior to the common carotid artery. This muscle can be divided. The carotid fascia is incised, and the common carotid artery is exposed. The common carotid artery is mobilized cephalad toward the bifurcation. The dissection of the carotid bifurcation can cause reactive bradycardia related to stimulation of the carotid body. This reflex can be blunted with injection of lidocaine 1% into the carotid body or reversed with administration of intravenous atropine. A useful landmark in the dissection of the carotid bifurcation is the common facial vein. This vein can be ligated and divided. Frequently the 12th cranial nerve (hypoglossal nerve) traverses the carotid bifurcation just behind the common facial vein. The external carotid artery is mobilized just enough to get a clamp across. Often, a branch of the external carotid artery crossing to the sternocleidomastoid can be divided to allow further cephalad mobilization of the internal carotid artery. For high bifurcation, division of the posterior belly of the digastric muscle is helpful in establishing distal exposure of the internal carotid artery.

Intravenous heparin sulfate (1 mg/kg) is routinely administered just prior to carotid clamping. The internal carotid artery is clamped first using a soft noncrushing vascular clamp to prevent distal embolization. The external and common carotid arteries are clamped subsequently. A longitudinal arteriotomy is made in the distal common carotid artery and extended into the bulb and past the occlusive plaque into the normal part of the internal carotid artery. Endarterectomy is carried out to remove the occlusive plaque (Fig. 23-18). If necessary, a temporary shunt can be inserted from the common carotid artery to the internal carotid artery to maintain continuous antegrade cerebral blood flow (Fig. 23-19). Typically, a plane is teased

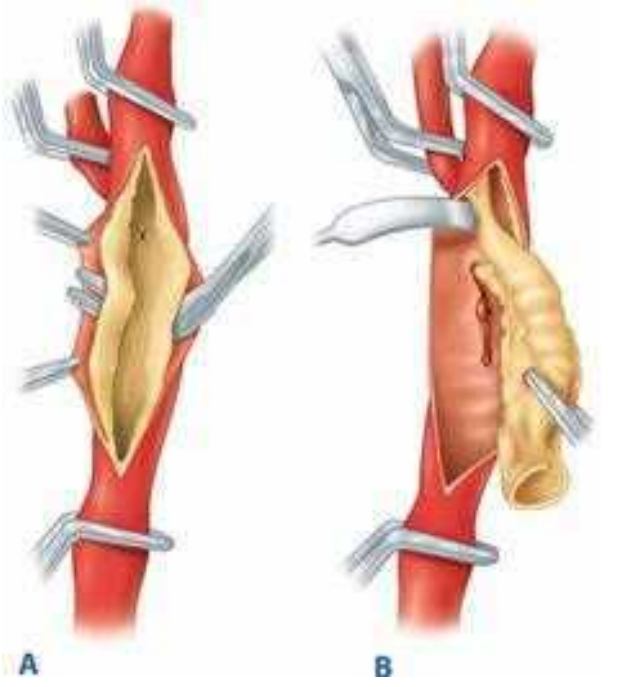


Figure 23-18. **A.** During carotid endarterectomy, vascular clamps are applied in the common carotid, external carotid, and internal carotid arteries. Carotid plaque is elevated from the carotid lumen. **B.** Carotid plaque is removed, and the arteriotomy is closed either primarily or with a patch angioplasty.

Figure 23-19. A temporary carotid shunt is inserted from the common carotid artery (*long arrow*) to the internal carotid artery (*short arrow*) during carotid endarterectomy to provide continuous antegrade cerebral blood flow.

out from the vessel wall, and the entire plaque is elevated and removed. The distal transition line in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures are placed when an intimal flap remains in this transition to ensure no obstruction to flow (Fig. 23-20). The occlusive plaque is usually removed from the origin of the external carotid artery using the eversion technique. The endarterectomized surface is then irrigated and any debris removed. A patch (autogenous saphenous vein, synthetic such as polyester, PTFE, or biologic material) is sewn to close the arteriotomy (Fig. 23-21). Whether patch closure is necessary in all patients and which patch is the best remain controversial. However, most surgeons agree that patch closure is indicated particularly for the small vessel (<7 mm). The eversion technique has also been advocated for removing the plaque from the internal carotid artery. In the eversion technique, the internal carotid artery is transected at the bulb, the edges of the divided vessel are everted, and the occluding plaque is "peeled"

Figure 23-20. The distal transition line (*left side of the picture*) in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures (*arrows*) are placed when an intimal flap remains in this transition to ensure no obstruction to flow.

off the vessel wall. The purported advantages of the eversion technique are no need for patch closure and a clear visualization of the distal transition area. Reported series have not shown a clear superiority of one technique over the others.[40] Surgeons will likely continue to use the technique of their choice. Just prior to completion of the anastomosis to close the arteriotomy, we thoroughly flush the vessels of any potential debris. When the arteriotomy is closed, flow is restored to the external carotid artery first and to the internal carotid artery second. Intravenous protamine sulfate can be given to reverse the effect of heparin anticoagulation following carotid endarterectomy. The wound is closed in layers. After surgery, the patient's neurologic condition is asserted in the operating room prior to transfer to the recovery area.

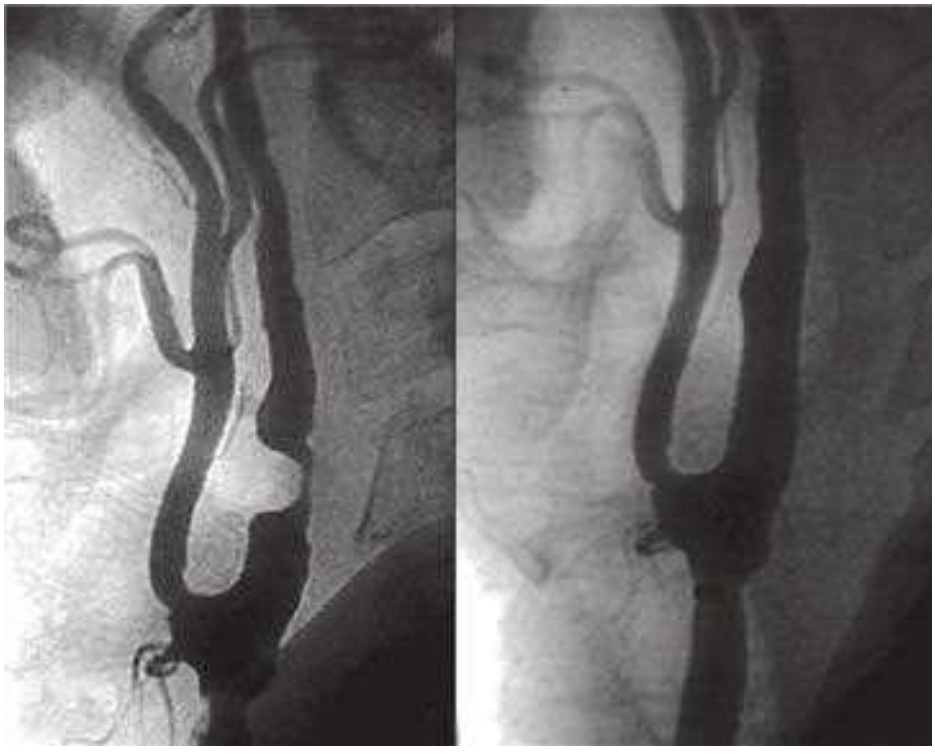
Complications of Carotid Endarterectomy. Most patients tolerate carotid endarterectomy very well and typically are discharged home within 24 hours after surgery. Complications after endarterectomy are infrequent but can be potentially life-threatening or disabling. Acute ipsilateral stroke is a dreaded complication following carotid endarterectomy. Cerebral ischemia can be due to either intraoperative or postoperative events. Embolizations from the occlusive plaque or prolonged cerebral ischemia are potential causes of intraoperative stroke. The most common cause of postoperative stroke is due to embolization. Less frequently, acute carotid artery occlusion can cause acute postoperative stroke. This is usually due to carotid artery thrombosis related to closure of the arteriotomy, an occluding intimal flap, or distal carotid dissection. When patients experience acute symptoms of neurologic ischemia after endarterectomy, immediate intervention may be indicated. Carotid duplex scan can be done expeditiously to assess patency of the extracranial internal carotid artery. Re-exploration is mandated for acute carotid artery occlusion. Cerebral angiography can be useful if intracranial revascularization is considered.

Local complications related to surgery include excessive bleeding and cranial nerve palsies. Postoperative hematoma in the neck after carotid endarterectomy can lead to devastating airway compromise. Any expanding hematoma should be evacuated and active bleeding stopped. Securing an airway is critical and can be extremely difficult in patients with large postoperative neck hematoma. The reported incidence of postoperative cranial nerve palsies after carotid endarterectomy varies from 1% to 30%.[41] Well-recognized injuries involve the marginal mandibular, vagus, hypoglossal, superior laryngeal, and recurrent laryngeal nerves. Often these are traction injuries but can also be due to severance of the respective nerves.

Techniques of Carotid Angioplasty and Stenting

Percutaneous carotid artery stenting has become an accepted alternative treatment in the management of patients with carotid bifurcation disease (Fig. 23-22). The perceived advantages of percutaneous carotid revascularization are related to the minimal invasiveness of the procedure compared to surgery. There are anatomic conditions based on angiographic evaluation in which carotid artery stenting should be avoided due to increased procedure-related risks (Table 23-5). In preparation for carotid stenting, the patient should be given oral clopidogrel 3 days prior to the intervention if the patient was not already taking the drug. The procedure is done in either the operating room with angiographic capabilities or in a dedicated angiography room. The patient is placed in the supine position. The patient's blood pressure and cardiac rhythm are closely monitored.

To gain access to the carotid artery, a retrograde transfemoral approach is most commonly used as the access site for carotid intervention. Using the Seldinger technique, we insert a diagnostic 5- or 6-French sheath in the CFA. A diagnostic arch aortogram is obtained. The carotid artery to be treated is then selected using a 5-French diagnostic catheter, and contrast is injected to show the carotid anatomy. It is important to assess the contralateral carotid artery, vertebrobasilar, and intracranial circulation if these are not known based on the preoperative noninvasive studies. Once the decision is made to proceed with carotid artery stenting, with the tip of the diagnostic catheter still in the common carotid artery, a 0.035-inch, 260-cm long stiff guidewire is placed in the ipsilateral external carotid artery. Anticoagulation with intravenous bivalirudin bolus (0.75 mg/kg) followed by an infusion rate of 2.5 mg/kg/h for the remainder of the procedure is routinely administered. Next the diagnostic catheter is withdrawn and a 90-cm, 6-French guiding sheath is advanced into the common carotid artery over the stiff glide wire. It is critical not to advance the sheath beyond the occlusive plaque in the carotid bulb. The stiff wire is then removed, and preparation is made to deploy the distal embolic protection device (EPD). Several distal EPDs are available (Table 23-6). The EPD device is carefully deployed beyond the target lesion. With regard to the carotid stents, there are several stents that have received approval from the FDA and are commercially available for carotid revascularization (Table 23-7). All current carotid stents use the rapid-exchange monorail 0.014-inch platform. The size selection is typically based on the size of common carotid artery. Predilatation using a 4-mm balloon may be necessary to allow passage of the stent delivery catheter. Once



A B

Figure 23-22. **A.** Carotid angiogram demonstrating a high-grade stenosis of the left internal carotid artery. **B.** Completion angiogram demonstrating a satisfactory result following a carotid stent placement.

the stent is deployed across the occlusive plaque, postdilatation is usually performed using a ≤5.5-mm balloon. It is noteworthy that balloon dilation of the carotid bulb may lead to immediate bradycardia due to stimulation of the glossopharyngeal nerve. The EPD is then retrieved and the procedure is completed with removal of the sheath from the femoral artery. The puncture site is closed using available closure device or with manual compression. Throughout the procedure, the patient's neurologic function is closely monitored. The bivalirudin infusion is stopped and the patient is kept on clopidogrel (75 mg daily) for at least 1 month and aspirin indefinitely.

Complications of Carotid Stenting. Although there have been no randomized trials comparing carotid stenting with and without EPD, the availability of EPDs appears to have reduced the risk of distal embolization and stroke. The results of the various clinical trials and registries of carotid stenting have been reported and compared. It is well known that distal embolization as detected by TCD is much more frequent with carotid stenting even with EPD, when compared with carotid endarterectomy. However, the clinical significance of the distal embolization detected by TCD is not clear because most are asymptomatic. Acute carotid stent thrombosis is rare. The incidence of in-stent carotid restenosis is not well known but is estimated at 10% to 30%. Duplex surveillance shows elevated peak systolic velocities within the stent after carotid stenting not infrequently. However, velocity criteria are being formulated to determine the severity of in-stent restenosis after carotid stenting by ultrasound duplex.[42] It appears that systolic velocities exceeding 300 to 400 cm/s would represent >70% to 80% restenosis. Bradycardia and hypotension occur in up to 20% of patients undergoing carotid stenting.[43] Systemic administration of atropine is usually effective in reversing the bradycardia. Other technical complications

Table 23-5

Unfavorable carotid angiographic appearance in which carotid stenting should be avoided

- Extensive carotid calcification
- Polypoid or globular carotid lesions
- Severe tortuosity of the common carotid artery
- Long-segment stenoses (>2 cm in length)
- Carotid artery occlusion
- Severe intraluminal thrombus (angiographic defects)
- Extensive middle cerebral artery atherosclerosis

of carotid stenting are infrequent and include carotid artery dissection and access site complications, such as groin hematoma, femoral artery pseudoaneurysm, distal embolization, and acute femoral artery thrombosis.

Nonatherosclerotic Disease of the Carotid Artery

Carotid Coil and Kink. A carotid coil consists of an excessive elongation of the internal carotid artery producing tortuosity of the vessel (Fig. 23-23). Embryologically, the carotid artery is derived from the third aortic arch and dorsal aortic root and is uncoiled as the heart and great vessels descend into the mediastinum. In children, carotid coils appear to be congenital in origin. In contrast, elongation and kinking of the carotid artery in adults are associated with the loss of elasticity and an abrupt angulation of the vessel. Kinking is more common in women than men. Cerebral ischemic symptoms caused by kinks of the carotid artery are similar to those from atherosclerotic carotid lesions but are more likely due to due to cerebral hypoperfusion than embolic episodes. Classically, sudden head rotation, flexion, or extension can accentuate the kink and provoke ischemic symptoms. Most carotid kinks and coils are found incidentally on carotid duplex scan. However, interpretation of the Doppler frequency shifts and spectral analysis in tortuous carotid arteries can be difficult because of the uncertain angle of insonation. Cerebral angiography, with multiple views taken in neck flexion, extension, and rotation, is useful in the determination of the clinical significance of kinks and coils.

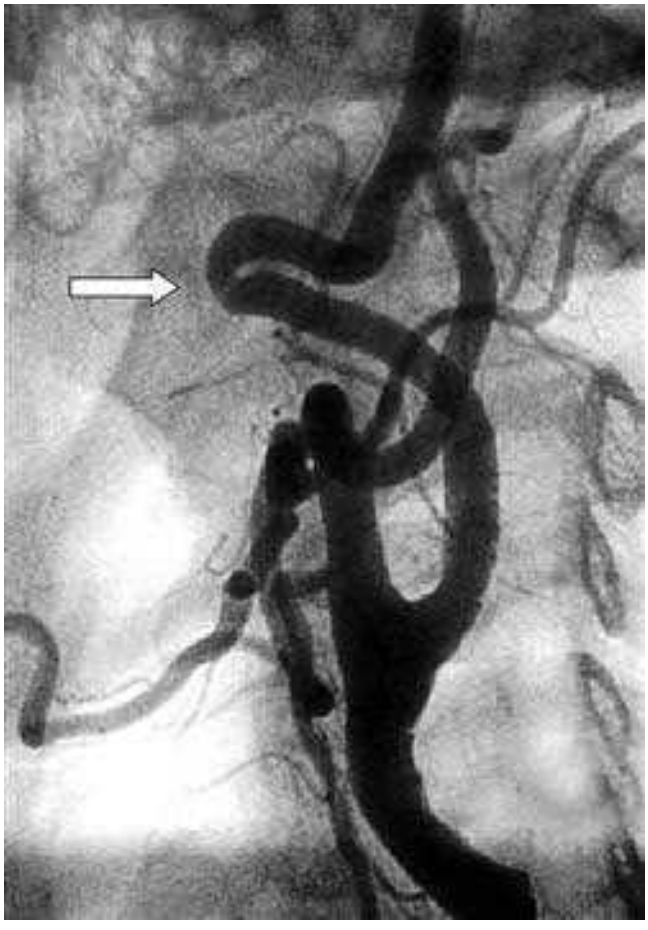

Figure 23-23. Excessive elongation of the carotid artery can result in carotid kinking (*arrow*), which can compromise cerebral blood flow and lead to cerebral ischemia.

Fibromuscular Dysplasia. Fibromuscular dysplasia (FMD) usually involves medium-sized arteries that are long and have few branches (Fig. 23-24). Women in the fourth or fifth decade of life are more commonly affected than men. Hormonal effects on the vessel wall are thought to play a role in the pathogenesis of FMD. FMD of the carotid artery is commonly bilateral, and in about 20% of patients, the vertebral artery is also involved.[44] An intracranial saccular aneurysm of the carotid siphon or middle cerebral artery can be identified in up to 50% of the patients with FMD. Four histologic types of FMD have been described in the literature. The most common type is medial fibroplasia, which may present as a focal stenosis or multiple lesions with intervening aneurysmal outpouchings. The disease involves the media with the smooth muscle being replaced by fibrous connective tissue. Commonly, mural dilations and microaneurysms can be seen with this type of FMD. Medial hyperplasia is a rare type of FMD, with the media demonstrating excessive amounts of smooth muscle. Intimal fibroplasia accounts for 5% of all cases and occurs equally in both sexes. The media and adventitia remain normal, and there is accumulation of subendothelial mesenchymal cells with a loose matrix of connective tissue causing a focal stenosis in adults. Finally, premedial dysplasia represents a type of FMD with elastic tissue accumulating between the media and adventitia. FMD can also involve the renal and external iliac arteries. It is estimated that approximately 40% of patients with FMD present with a TIA due to embolization of platelet aggregates.[44] DSA demonstrates the

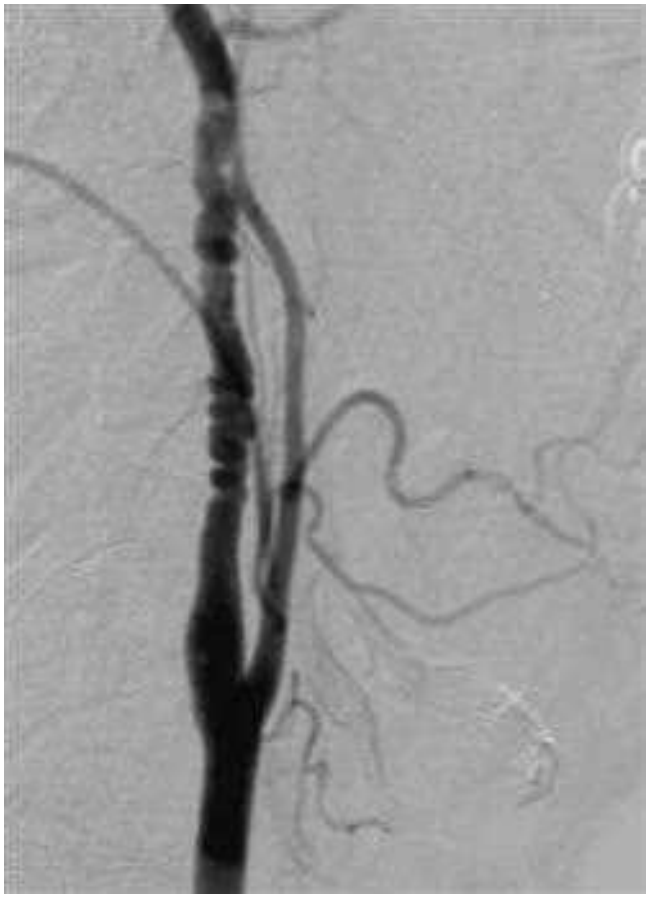

Figure 23-24. A carotid fibromuscular dysplasia with typical characteristics of multiple stenoses with intervening aneurysmal outpouching dilatations. The disease involves the media, with the smooth muscle being replaced by fibrous connective tissue.

characteristic "string of beads" pattern, which represents alternating segments of stenosis and dilatation. The string of beads can also be shown noninvasively by CTA or MRA. FMD should be suspected when an increased velocity is detected across a stenotic segment without associated atherosclerotic changes on carotid duplex ultrasound. Antiplatelet medication is the generally accepted therapy for asymptomatic lesions. Endovascular treatment is recommended for patients with documented lateralizing symptoms. Surgical correction is rarely indicated.

Carotid Artery Dissection. Dissection of the carotid artery accounts for approximately 20% of strokes in patients younger than 45 years of age. The etiology and pathogenesis of spontaneous carotid artery dissection remain incompletely understood. Arterial dissection involves hemorrhage within the media, which can extend into the subadventitial and subintimal layers. When the dissection extends into the subadventitial space, there is an increased risk of aneurysm formation. Subintimal dissections can lead to intramural clot or thrombosis. Traumatic dissection is typically a result of hyperextension of the neck during blunt trauma, neck manipulation, strangulation, or penetrating injuries to the neck. Even in supposedly spontaneous cases, a history of preceding unrecognized minor neck trauma is not uncommon. Connective disorders, such as Ehlers-Danlos syndrome, Marfan's syndrome, α_1-antitrypsin deficiency, or FMD, may predispose to carotid artery dissection. Iatrogenic dissections can also occur due to catheter manipulation or balloon angioplasty.

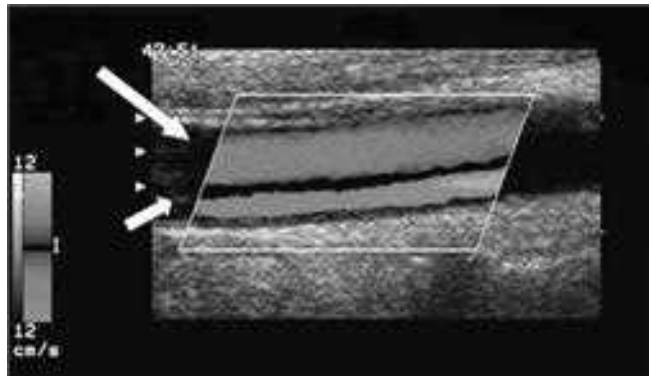

Figure 23-25. Carotid ultrasound reveals a patient with a carotid artery dissection in which carotid flow is separated in the true flow lumen (*long arrow*) from the false lumen (*short arrow*).

Typical clinical features of carotid artery dissection include unilateral neck pain, headache, and ipsilateral Horner's syndrome in up to 50% of patients, followed by manifestations of the cerebral or ocular ischemia and cranial nerve palsies. Neurologic deficits can result either because of hemodynamic failure (caused by luminal stenosis) or by an artery-to-artery thromboembolism. The ischemia may cause TIAs or infarctions, or both. Catheter angiography has been the method of choice to diagnose arterial dissections, but with the advent of duplex ultrasonography, MRI/MRA, and CTA, most dissections can now be diagnosed using noninvasive imaging modalities (Fig. 23-25). The dissection typically starts in the internal carotid artery distal to the bulb. Uncommonly, the dissection can start in the common carotid artery or is an extension of a more proximal aortic dissection. Medical therapy has been the accepted primary treatment of symptomatic of carotid artery dissection. Anticoagulation (heparin and warfarin) and antiplatelet therapy have been commonly used, although there have not been any randomized studies to evaluate their effectiveness. The prognosis depends on the severity of neurologic deficit but is generally good in extracranial dissections. The recurrence rate is low. Therapeutic interventions have been reserved for recurrent TIAs or strokes or failure of medical treatment. Endovascular options include intra-arterial stenting, coiling of associated pseudoaneurysms, or, more recently, deployment of covered stents.

Carotid Artery Aneurysms. Carotid artery aneurysms are rare, encountered in less than 1% of all carotid operations (Fig. 23-26). The true carotid artery aneurysm is generally due to atherosclerosis or medial degeneration. The carotid bulb is involved in most carotid aneurysms, and bilaterality is present in 12% of the patients. Patients typically present with a pulsatile neck mass. The available data suggest that, untreated, these aneurysms lead to neurologic symptoms from embolization. Thrombosis and rupture of the carotid aneurysm are rare. Pseudoaneurysms of the carotid artery can result from injury or infection. Mycotic aneurysms often involved syphilis in the past, but are now more commonly associated with peritonsillar abscesses caused by *Staphylococcus aureus* infection. FMD and spontaneous dissection of the carotid artery can lead to the formation of true aneurysms or pseudoaneurysms. Whereas conventional surgery has been the primary mode of treatment in the past, carotid aneurysms are currently being treated more commonly using endovascular approaches.[45]

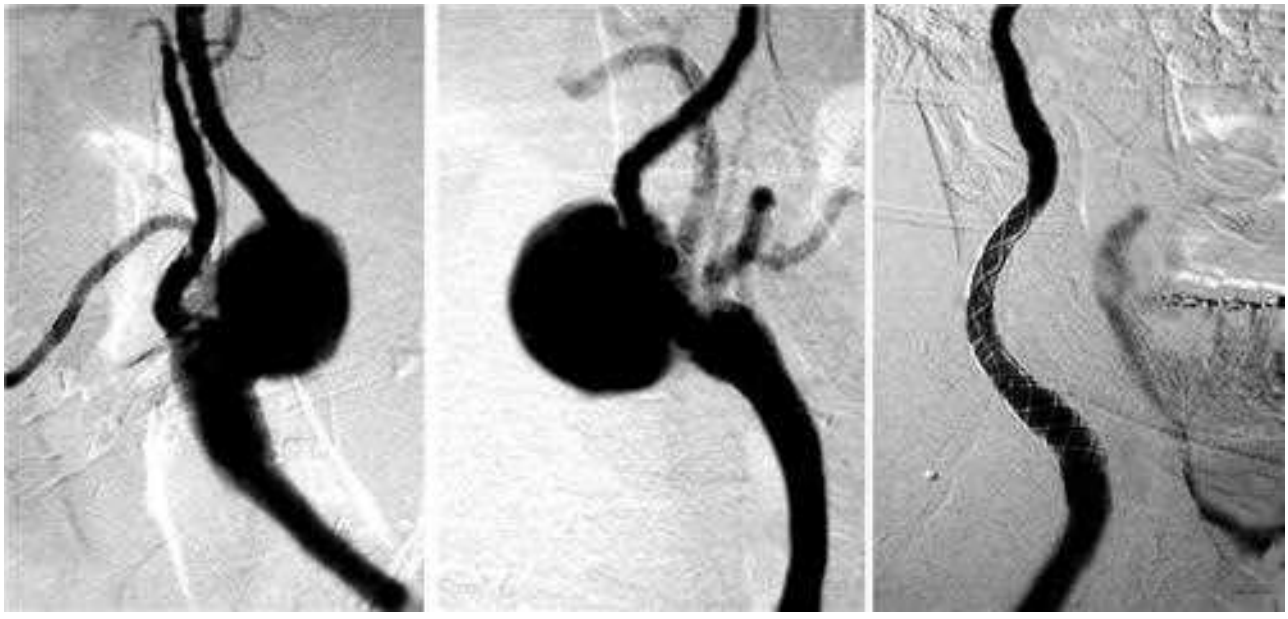

Figure 23-26. **A.** An anteroposterior angiogram of the neck revealing a carotid artery aneurysm. **B.** A lateral projection of the carotid artery aneurysm. **C.** Following endovascular placement, the carotid artery aneurysm is successfully excluded.

Carotid Body Tumor. The carotid body originates from the third branchial arch and from neuro-ectodermal derived neural crest lineage. The normal carotid body is located in the adventitia or periadventitial tissue at the bifurcation of the common carotid artery (Fig. 23-27). The gland is innervated by the glossopharyngeal nerve. Its blood supply is derived predominantly from the external carotid artery but can also come from the vertebral artery. Carotid body tumor is a rare lesion of the neuroendocrine system. Other glands of neural crest origin are seen in the neck, parapharyngeal spaces, mediastinum, retroperitoneum, and adrenal medulla. Tumors involving these structures have been referred to as paraganglioma, glomus tumor, or chemodectoma. Approximately 5% to 7% of carotid body tumors are malignant. Although chronic hypoxemia has been invoked as a stimulus for hyperplasia of carotid body, approximately 35% of carotid body tumors are hereditary. The risk of malignancy is greatest in young patients with familial tumors.

Symptoms related to the endocrine products of the carotid body tumor are rare. Patients usually present between the fifth and seventh decades of life with an asymptomatic lateral neck

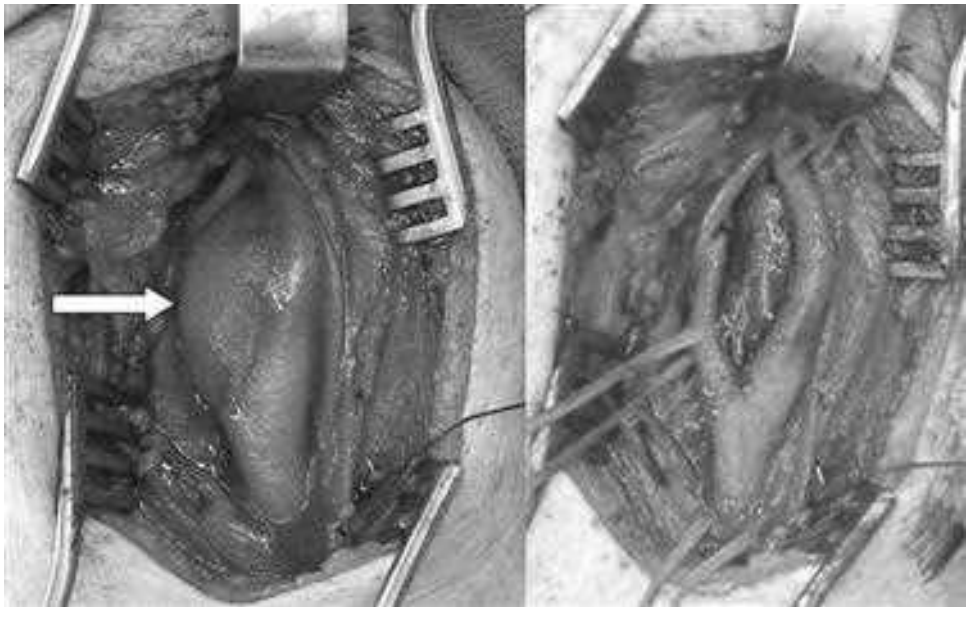

Figure 23-27. **A.** A carotid body tumor (*arrow*) located adjacent to the carotid bulb. **B.** Following periadventitial dissection, the carotid body tumor is removed.

mass. The diagnosis of carotid body tumor requires confirmation on imaging studies. Carotid duplex scan can localize the tumor to the carotid bifurcation, but CT or MRI is usually required to further delineate the relationship of the tumor to the adjacent structures. Classically, a carotid body tumor will widen the carotid bifurcation. The Shamblin classification describes the tumor extent: I, tumor is less than 5 cm and relatively free of vessel involvement; II, tumor is intimately involved but does not encase the vessel wall; and III, tumor is intramural and encases the carotid vessels and adjacent nerves.[46] With good-resolution CT and MRI, arteriography is usually not required. However, arteriography can provide an assessment of the vessel invasion and intracranial circulation and allows for preoperative embolization of the feeder vessels, which has been reported to reduce intraoperative blood loss. Surgical resection is the recommended treatment for suspected carotid body tumor.

Carotid Trauma. Blunt or penetrating trauma to the neck can cause injury to the carotid artery. Notwithstanding the massive bleeding from carotid artery transection, injury to the carotid artery can result in carotid dissection, thrombosis, or pseudoaneurysm formation. Carotid duplex ultrasound can be useful to locate the site of injury in the cervical segment of the carotid artery. Spiral CTA has become the modality of choice to detect extracranial carotid artery injury. Confirmation of carotid injury by contrast cerebral angiography remains the gold standard diagnostic test. Injuries to the cervical segment of the common and internal carotid arteries can be repaired surgically. Acute carotid artery thrombosis is usually treated medically with anticoagulation if the patient is asymptomatic. Revascularization should be considered for patients presenting with ongoing cerebral ischemia related to carotid artery thrombosis. Traumatic carotid artery dissection can cause cerebral ischemia due to thromboembolization, decreased flow, or thrombosis. Commonly, the dissection involves the distal portion of the cervical and petrous segment of the internal carotid artery. Medical management with antiplatelet or anticoagulation therapy is usually adequate for uncomplicated traumatic carotid dissection. In patients with pseudoaneurysms of the carotid artery that are located in a segment that is out of surgical reach, the use of selective coil embolization of the pseudoaneurysm or exclusion of the pseudoaneurysm by a covered stent graft has been reported. Bare metal stent has been used with success in the treatment of traumatic carotid artery dissection.

ABDOMINAL AORTIC ANEURYSM

Despite more than 50,000 patients undergoing elective repair of abdominal aortic aneurysm (AAA) each year in the United States, approximately 15,000 patients die annually as a result of ruptured aneurysm, making it the 10th leading cause of death in men in this country.[47] The incidence appears to be increasing, and this is due in part to improvements in diagnostic imaging and, more importantly, a growing elderly population. With early diagnosis and timely intervention, aneurysm rupture–related death is largely preventable. Conventional treatment of an AAA involves replacing the aneurysmal segment of the aorta with a prosthetic graft, with the operation performed through a large abdominal incision. Techniques for this open abdominal surgery have been refined, adapted, and extensively studied by vascular surgeons over the past four decades. Despite a well-documented low perioperative mortality rate of 2% to 3% in large academic institutions, the thought of undergoing an open abdominal aortic operation often provokes a sense of anxiety in many patients due in part to the postoperative pain associated with the large abdominal incision as well as the long recovery time needed before the patient can return to normal physical activity.

The most common location of aortic aneurysms is the infrarenal aorta. Endovascular stent graft placement represents a revolutionary and minimally invasive treatment for infrarenal AAAs that only requires 1 to 2 days of hospitalization, and the patient can return to normal physical activity within 1 week. The concept of using an endoluminal device in the management of vascular disease was first proposed by Dotter and colleagues, who successfully treated a patient with iliac occlusion using transluminal angioplasty in 1964.[48] Nearly two decades later, Parodi and colleagues reported the first successful endovascular repair of AAA using a stent graft device.[15] Since then, a variety of stent graft technologies have been developed to treat AAA. The rapid innovation of this new treatment modality has undoubtedly captured the attention of patients with aortic aneurysms as well as physicians who practice endovascular therapy. Physicians in general should be knowledgeable regarding available treatment options of AAA in order to provide adequate evaluation and education to patients and their families. The purpose of this section is to outline the treatment options for AAAs, including conventional repair and endovascular approach. Advantages and potential complications of these treatments will also be addressed.

Causes and Risk Factors

The pathogenesis of aneurysmal disease of the aorta is complex and multifactorial. A degenerative process in the aortic wall is the most common cause of AAA development.[49] Matrix metalloproteinases (MMP), proteolytic enzymes, are found abundantly in the wall of AAA. Atherosclerotic disease, age, male sex, smoking history, family history, hypertension, coronary artery disease, and chronic obstructive pulmonary disease are associated with the development of AAA.[50,51] Diabetes and black race have negative association with AAA.[50] Other less common causes include inflammation, infection, and connective tissue disease. Inflammatory AAA accounts for 5% to 10% of all AAAs.[52] In contrast to atherosclerotic AAA, the inflammatory variant is characterized pathologically by marked thickening of the aneurysm wall, fibrosis of the adjacent retroperitoneum, and rigid adherence of the adjacent structures to the anterior aneurysm wall.[53] Male sex and smoking are even stronger risk factors in inflammatory AAA.[54] Smoking cessation is the first step of medical therapy, followed by surgical repair. Infectious or mycotic AAA is rare but is associated with high mortality.[55] Patients with connective tissue disorders such as Marfan's syndrome and Ehlers-Danlos syndrome tend to have more extensive and larger aneurysms at a younger age.[56]

Natural History of Aortic Aneurysm

The natural history of an AAA is to expand and rupture. AAA exhibits a "staccato" pattern of growth, where periods of relative quiescence may alternate with expansion. Therefore, although an individual pattern of growth cannot be predicted, average aggregate growth is approximately 3 to 4 mm/year. There is some evidence to suggest that larger aneurysms may expand faster than smaller aneurysms, but there is significant overlap between the ranges of growth rates at each strata of size.

Rupture risk appears to be directly related to aneurysm size as predicted by Laplace's Law. Although more sophisticated

Table 23-8

Annualized risk of rupture of abdominal aortic aneurysm (AAA) based on size

DESCRIPTION	DIAMETER OF AORTA (CM)	ESTIMATED ANNUAL RISK OF RUPTURE (%)	ESTIMATED 5-YEAR RISK OF RUPTURE (%)[a]
Normal aorta	2–3	0	0 (unless AAA develops)
Small AAA	4–5	1	5–10
Moderate AAA	5–6	2–5	30–40
Large AAA	6–7	3–10	>50
Very large AAA	>7	>10	Approaching 100

[a]The estimated 5-year risk is more than five times the estimated annual risk because over that 5 years, the AAA, if left untreated, will continue to grow in size.

methods of assessing rupture risk based on finite element analysis of wall stress are under active investigation, maximum transverse diameter remains the standard method of risk assessment for aneurysm rupture. In the past, AAA rupture risk has been overestimated. More recently, two landmark studies have served to better define the natural history of AAA.[57,58] Based on best available evidence, the annualized risk of rupture is given in Table 23-8. The rupture risk is quite low below 5.5 cm and begins to rise exponentially thereafter. This size can serve as an appropriate threshold for recommending elective repair provided one's surgical mortality is below 5%. For each size strata, however, women appear to be at higher risk for rupture than men, and a lower threshold of 4.5 to 5.0 cm may be reasonable in good-risk patients. Although data are less compelling, a pattern of rapid expansion of >0.5 cm within 6 months can be considered a relative indication for elective repair. Aneurysms that fall below these indications may safely be followed with CT or ultrasound at 6-month intervals, with long-term outcomes equivalent to earlier surgical repair. Interestingly, in the Aneurysm Detection and Management (ADAM) study, 80% of all AAAs that were followed in this manner eventually came to repair within 5 years.[58]

2▶

Unless symptomatic or ruptured, AAA repair is a prophylactic repair. The rationale for recommending repair is predicated on the assumption that the risk of aneurysm rupture exceeds the combined risk of death from all other causes such as cardiopulmonary disease and cancer. On the other hand, our limitation in predicting timing and cause of death is underscored by the observation that over 25% of patients who were deemed unfit for surgical repair because of their comorbidities died from rupture of their aneurysms within 5 years.

Clinical Manifestations

Most AAAs are asymptomatic and are usually found incidentally during workup for chronic back pain or kidney stones. Physical examination is neither sensitive nor specific except in thin patients. Large aneurysms may be missed in the obese, while normal aortic pulsations may be mistaken for an aneurysm in thin individuals. Rarely patients present with back pain and/or abdominal pain with a tender pulsatile mass. Patients with these symptoms must be treated as a rupture until proven otherwise. If the patient is hemodynamically stable and the aneurysm is intact on a CT scan, the patient is admitted for blood pressure control with intravenous antihypertensive agents and undergoes repair usually within 12 to 24 hours or at least during the same hospitalization. In contrast, patients who are hemodynamically unstable with a history of acute back pain and/or syncope and a known unrepaired AAA or a pulsatile abdominal mass should be immediately taken to the operating room with a presumed diagnosis of a ruptured AAA.

Overall mortality of AAA rupture is 71% to 77%, which includes all out-of-hospital and in-hospital deaths, as compared with 2% to 6% for elective open surgical repair.[59] Nearly half of all patients with ruptured AAA will die before reaching the hospital. For the remainder, surgical mortality is 45% to 50% and has not substantially changed in the last 30 years.

Relevant Anatomy

An AAA is defined as a pathologic focal dilation of the aorta that is greater than 30 mm or 1.5 times the adjacent diameter of the normal aorta (Fig. 23-28). Male aortas tend to be larger

Figure 23-28. An operative view of an infrarenal aortic aneurysm.

than female aortas, and there is generalized growth of the aortic diameter with each decade of life. Ninety percent of AAAs are infrarenal in location and have a fusiform morphology. There is a higher predilection for juxtarenal and suprarenal AAAs in women compared with men. Concomitant common iliac and/or hypogastric artery aneurysms can be found in 20% to 25% of patients. Although the etiology of most aortic aneurysms is atherosclerotic, clinically significant peripheral occlusive disease is unusual and present in less than 10% of all cases.

Although extravascular anatomy is important for open surgical repair of AAA, intravascular anatomy and aortoiliac morphology are important for endovascular repair. Pertinent anatomic dimensions include the diameter of the proximal nondilated infrarenal aortic neck, which can range from 18 to 30 mm; common iliac artery, which can range from 8 to 16 mm; and external iliac arteries, which can range from 6 to 10 mm. Morphologically, the aortic neck can manifest complex angulation above and below the renal arteries due to combination of elongation and anterolateral displacement by the posterior bulge of the aneurysmal aorta. Furthermore, the shape of the proximal neck is rarely tubular, but often is conical, reverse conical, or barrel-shaped. Distally, the iliac arteries can have severe tortuosity with multiple compound turns. Although significant from hemodynamic standpoint, severe iliac calcifications combined with extreme tortuosity can pose a formidable challenge during endovascular repair.

Diagnostic Evaluation

Preoperative evaluation should include routine history and physical exam with particular attention to (a) any symptoms referable to the aneurysm, which may impact the timing of repair; (b) history of pelvic surgery or radiation, in the event retroperitoneal exposure is required or interruption of hypogastric circulation is planned; (c) claudication suggestive of significant iliac occlusive disease; (d) lower extremity bypass or other femoral reconstructive procedures; and (e) chronic renal insufficiency or contrast allergy.

Cross-sectional imaging is required for definitive evaluation of AAA. Although ultrasound is safe, widely available, relatively accurate, and inexpensive and thus the screening modality of choice, CT scan remains the gold standard for determination of anatomic eligibility for endovascular repair. Size of AAA may differ up to 1 cm between CT and ultrasound, and during longitudinal follow-up, comparisons should be made between identical modalities. With modern multirow detector scanners, a timed-bolus intravenous contrast-enhanced, 2.5- to 3.0-mm slice spiral CT of the chest, abdomen, and pelvis can be performed in less than 30 seconds with a single breath hold. Extremely high-resolution images are obtained with submillimeter spatial resolution (Fig. 23-29). Proper window level and width (brightness and contrast) are important for discrimination among aortic wall, calcific plaque, thrombus, and lumen. The only major drawback to CT is the risk of contrast nephropathy in diabetics and in patients with renal insufficiency.

The spiral technique further affords the ability for three-dimensional reconstruction. Three-dimensional reconstructions can yield important morphologic information that is critical to endovascular therapy. Using third-party software, these images can be viewed and manipulated on one's desktop computer, and so-called "center-line" (transverse slices perpendicular to the central flow lumen of the aorta) diameter and length measurements obtained. Conventional angiography has a minimal role in the current management of AAA. Angiography is invasive with an increased risk of complications. Indications for angiography are isolated to concomitant iliac occlusive disease (present in <10% of patients with AAA) and unusual renovascular anatomy.

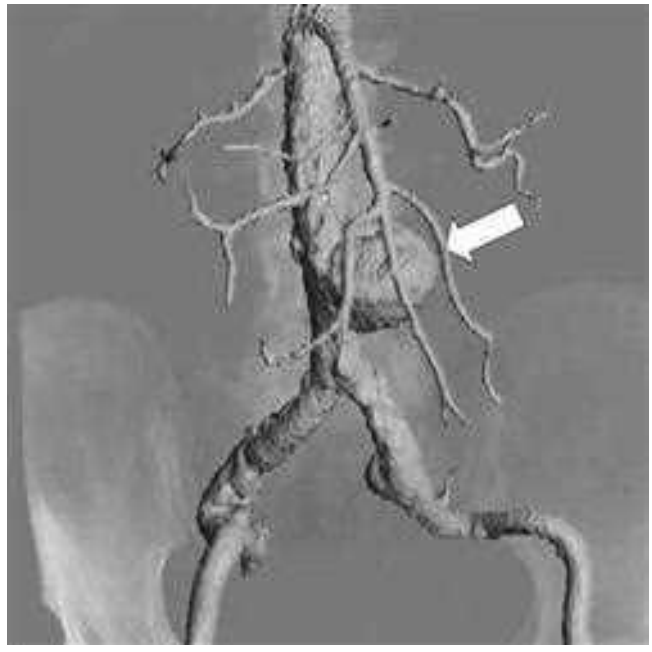

Figure 23-29. High resolution of image displaying an aortic aneurysm (*arrow*) can be achieved with multidetector computed tomography angiography.

Surgical Repair of Abdominal Aortic Aneurysm

General anesthesia is necessary when performing a conventional open AAA repair. While a retroperitoneal incision is a well-accepted surgical approach, a midline transabdominal incision remains the more common approach for open aortic aneurysm operation. Since the abdominal incision can lead to significant pain and discomfort, an epidural catheter can be placed prior to the operation for postoperative analgesic infusion to provide pain control. Once the abdominal cavity is opened, the small intestines and transverse colon are retracted to expose the retroperitoneum overlying the AAA. The retroperitoneum is next divided, followed by isolation of both proximal and distal segments of the AAA. Intravenous heparin (100 IU/kg) is given followed by clamping of the proximal and distal segments of the aneurysm. The aneurysm sac is open next, and a prosthetic graft is used to reconstruct the aorta. If the aneurysm only involves the abdominal aorta, a tube graft can be used to replace the aorta (Fig. 23-30). If the aneurysm extends distally to the iliac arteries, a prosthetic bifurcated graft is used for either an aorto-bi-iliac or aorto-bi-femoral bypass reconstruction (Fig. 23-31). The overlying aneurysm sac and the retroperitoneum are closed to cover the prosthetic bypass graft to minimize potential bowel contact to the graft. Small and large intestines are returned to the abdominal cavity followed by the closure of the abdominal fascia and skin.

Advantages and Risks of Open Abdominal Aortic Aneurysm Repair. The main advantage of a conventional open repair is that the AAA is permanently eliminated because it is entirely replaced by a prosthetic aortic graft. The risk of aneurysm

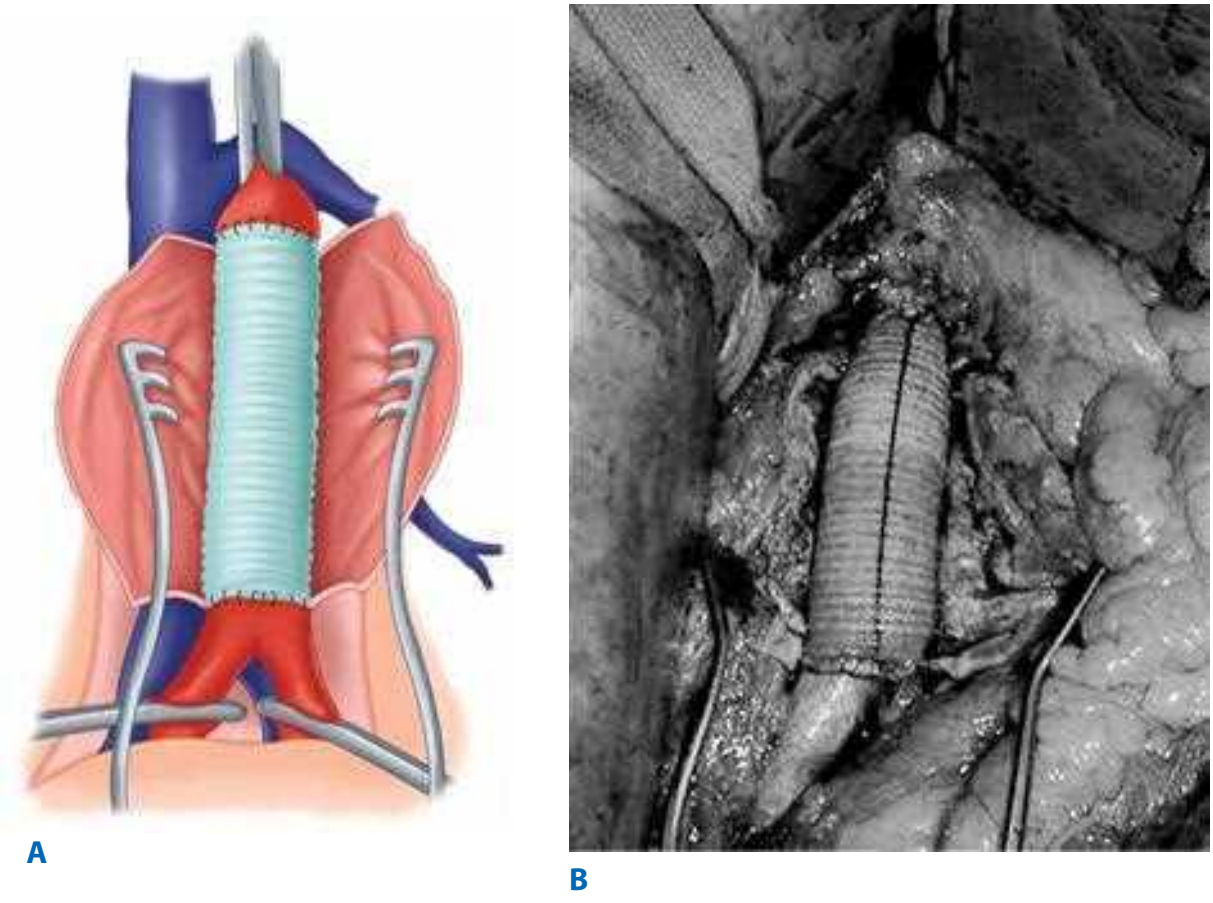

Figure 23-30. **A.** Schematic depiction of an aortic tube graft used to repair an aortic aneurysm. **B.** Intraoperative image of an aortic tube graft reconstruction.

recurrence or delayed rupture no longer exists. As a result, long-term imaging surveillance is not needed with these patients. In contrast, the long-term efficacy of endovascular repair remains unclear. Consequently, long-term imaging surveillance is critical to ensure that the aortic aneurysm remains properly sealed by the stent graft. Other potential advantages of open repair include direct assessment of the circulatory integrity of the colon. If signs of colonic ischemia become evident after aortic bypass grafting, a concomitant mesenteric artery bypass can be performed to revascularize the colonic circulation. In addition, open repair permits the surgeons to explore for other abdominal pathologies, such as gastrointestinal tumors, liver mass, or cholelithiasis.

As for the risks associated with open repair, cardiac complications, in the form of either myocardial infarction or arrhythmias, remain the most common morbidity, with an incidence between 2% and 6%.[60] Another significant complication is renal failure or transient renal insufficiency as a result of perioperative hypotension, atheromatous embolization, inadvertent injury to the ureter, preoperative contrast-induced nephropathy, or suprarenal aortic clamping. Although the incidence of renal failure is less than 2% in elective aneurysm repair, it can occur in more than 20% of patients after repair of a ruptured AAA.[60]

Ischemic colitis is a devastating potential complication after open repair. The likelihood of such a complication is highest in those who had a prior colon resection and undergo repair of a ruptured AAA, due to the loss of collateral blood supply to the rectosigmoid colon. It is estimated that 5% of patients who undergo elective aneurysm repair will develop partial-thickness ischemic colitis but without significant clinical sequelae.[61] However, if the partial-thickness ischemia progresses to full-thickness gangrene and peritonitis, mortality can be as high as 90%.[61]

The incidence of prosthetic graft infection ranges between 1% and 4% after open repair.[61] It is more common in those who undergo repair of a ruptured AAA. If the prosthetic graft is not fully covered by the aneurysm sac or retroperitoneum, intestinal adhesion with subsequent bowel erosion may occur, resulting in an aortoenteric fistula. The predominant sign of such a complication is massive hematemesis, and it typically occurs years after the operation. Despite these potential complications, however, the majority of patients who undergo successful elective open repair have an uneventful recovery.

Endovascular Repair of Abdominal Aortic Aneurysm

Over a decade has passed since the first report of human implantation of a homemade stent graft for endovascular repair of an AAA by Parodi in 1991.[3] Several prospective clinical trials across different devices and analysis of large Medicare administrative databases and meta-analyses of published literature have consistently demonstrated significantly decreased operative time, blood loss, hospital length of stay, and overall perioperative morbidity and mortality of endovascular repair compared with open surgical repair. For patients who are at increased risk for surgery because of age or comorbidity, endovascular repair is a superior minimally invasive alternative.

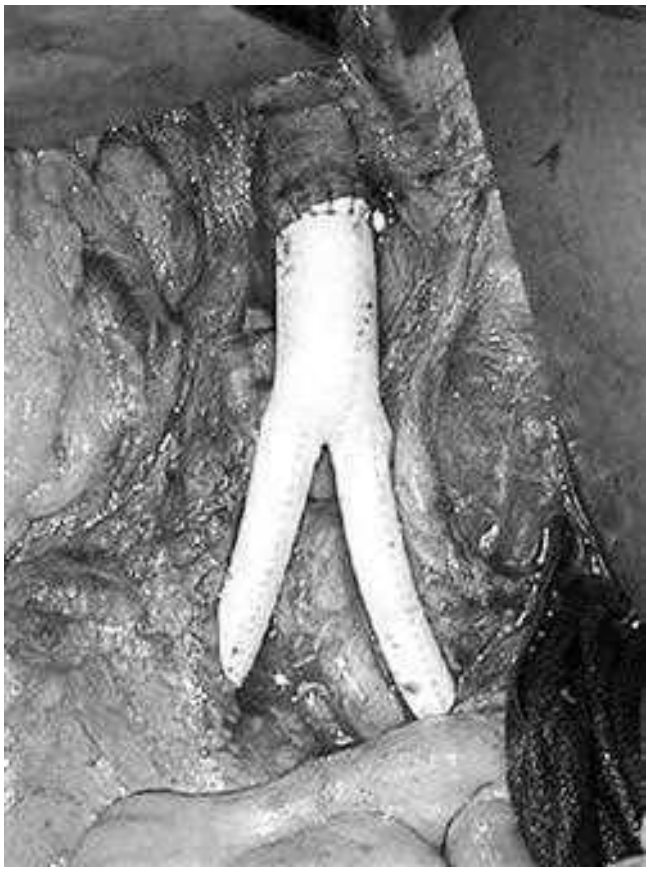

Figure 23-31. Intraoperative view of a bifurcated graft used to repair an aortic aneurysm.

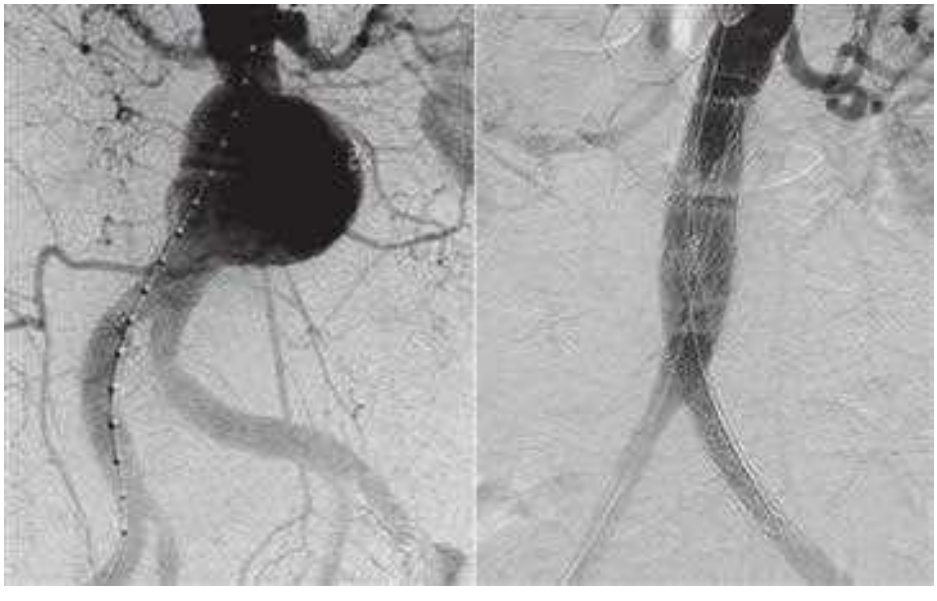
The principle of endovascular repair of AAA involves the implantation of an aortic stent graft that is fixed proximally and distally to nonaneurysmal aortoiliac segment and thereby endoluminally excluding the aneurysm from the aortic circulation (Fig. 23-32). Unlike open surgical repair, the aneurysm sac is not resected, which is subjected for potential aneurysm expansion or even rupture. Importantly, aortic branches, such as lumbar arteries or the inferior mesenteric artery (IMA), are occluded, which can lead to persistent aneurysm pressurization and aneurysm expansion. Currently, the following nine devices are available for elective repair of intact infrarenal AAA: AneuRx device (Medtronic/AVE, Santa Rosa, CA), Gore Excluder device (WL Gore & Associates, Flagstaff, AZ), Endologix Powerlink device (Endologix Inc., Irvine, CA), Zenith device (Cook Inc., Bloomington, IN), Talent device (Medtronic/AVE, Santa Rosa, CA), Endurant device (Medtronic/AVE, Santa Rosa, CA), AFX Endovascular AAA System (Endologix Inc., Irvine, CA), Aorfix Flexible Stent (Lombard Medical Inc., Framingham, MA), and Ovation Prime Stent (TriVascular Inc., Santa Rosa, CA). Despite some differences in physical appearance, mechanical properties, and materials, they will be discussed collectively for this chapter. Most of these devices are modular devices consisting of a primary device or main body and one or two iliac limbs that insert into the main body to complete the repair. Depending on the device, there are varying degrees of flexibility in the choice of iliac limbs that can be matched to the main body, which can impact the customizability for a particular anatomy.

A severe limitation of the endovascular repair devices is the need for adequate proximal neck to achieve a durable sealing zone. Several techniques have been proposed to overcome this limitation. These include fenestrated or branched endografts and the "chimney," "snorkel," and "periscope" techniques. The fenestrated stent grafts rely on precise alignment between the fenestration and the corresponding visceral artery.[62] Multiple clinical trials using customized fenestrated stent graft for the treatment of short-necked and juxtarenal aortic aneurysm repair have shown promising short- and mid-term results.[63,64] However, restricted access to these investigational devices and the delays due to device customization limit the current use of these devices to a few centers. Alternatively, some centers have reported good results with intraoperative surgeon-modified endograft to create fenestrations for the treatment of complex aortic aneurysms in high-risk patients.[65] Further development



A B

Figure 23-32. A. An aortogram demonstrating a large infrarenal abdominal aortic aneurysm. **B.** Following endovascular stent graft implantation, the aortic aneurysm is successfully excluded.

of the fenestrated techniques also opens the way for endovascular treatment of suprarenal and thoracoabdominal aneurysm.[66] Recently, an "off-the-shelf" Zenith Fenestrated AAA endovascular graft has been approved by the FDA. This device has fenestrations or scallops in the graft material to allow the proximal edge of the stent graft to be placed above the renal arteries while still permitting blood flow to vessels accommodated by the fenestrations or scallops. The "chimney" technique involves placing renal or mesenteric stents parallel to the aortic stent graft to preserve blood flow in the visceral aortic branches.[67] This technique has been suggested as a rescue procedure for visceral arteries that have been covered by the stent graft during endovascular repair.[68] The review of literature showed that open surgery remains a safe and effective treatment option for good-risk patients with juxtarenal aortic aneurysm.[69] Fenestrated endovascular repair is associated with low mortality and compares favorably with open surgery in terms of morbidity, especially renal function impairment and cardiac complications.[69] The "chimney" technique demonstrated feasibility, but because of the limited number of reports and the lack of long-term data, it should be considered only in acute poor surgical risk patients and in case of unintentional visceral artery coverage or elective poor surgical cases for fenestrated endovascular repair.[69]

Patient Selection for Endovascular Aortic Aneurysm Repair. Anatomic eligibility for endovascular repair is mainly based on three areas: the proximal aortic neck, common iliac arteries, and external iliac and common femoral arteries, which relate to the proximal and distal landing zones or fixation sites and the access vessels, respectively. The requirements for the proximal aortic neck are a diameter of 18 to 28 mm and a minimum length of 15 mm (Table 23-9). Usually, multiple measurements of the diameter are taken along the length of the neck to assess its shape. All diameter measurements are mid-wall to mid-wall of the vessel. Secondary considerations include mural calcifications (<50% circumference), luminal thrombus (<50% circumference), and angulation (<45°). Presence of a significant amount of any one of these secondary features in combination with a relatively short proximal neck may compromise successful short- and long-term fixation of the stent graft and exclusion of the aneurysm. The usual distal landing zone is the common iliac artery. The external iliac artery may serve as an alternate site when the ipsilateral common iliac artery is aneurysmal or ectatic. The treatable diameters of common iliac arteries range from 8 to 20 mm, and there should be at least 20 mm of patent artery of uniform diameter to allow adequate fixation. Finally, at least one of two common femoral and external iliac arteries must be at least 7 mm in diameter in order to safely introduce the main delivery sheath. Slightly smaller iliac diameters may be tolerated depending on the specific device and in the absence of severe tortuosity and calcific disease. Difficult access is one of the main causes of increased procedural time and intraoperative complications. Using these criteria, approximately 60% of all AAAs are anatomic candidates for endovascular repair.

Table 23-9

Ideal characteristics of an aneurysm for endovascular abdominal aortic aneurysm repair

Neck length (mm)	>15
Neck diameter (mm)	>18, <32
Aortic Neck angle (degrees)	<60
Neck mural calcification (% circumference)	<50
Neck luminal thrombus (% circumference)	<50
Common iliac artery diameter (mm)	Between 8 and 20
Common iliac artery length (mm)	>20
External iliac artery diameter (mm)	>7

The next step in the preoperative planning is device selection. Typically, the proximal diameter of the main device is oversized by 10% to 20% of the nominal diameter of the aortic neck. Distally, the iliac limbs are oversized by 1 to 4 mm depending on the individual device's instructions for use. The biggest challenge to proper device selection remains determining the optimal length from the renal arteries to the hypogastric arteries. Despite availability of sophisticated three-dimensional reconstructions, the exact path that a device will take from the proximal aortic neck to the distal iliac arteries is difficult to predict. It is dependent on a host of factors related to the mechanical properties of the stent graft and the morphology of the aortoiliac flow lumen. "Plumb-line" measurements of axial CT images can be quite inaccurate, typically grossly underestimating the length, whereas center-line measurements usually overestimate the length. Angiographic measurements using a marker catheter are invasive, require contrast and radiation exposure, and are also inaccurate because they fail to account for the stiffness of the stent graft. The consequences of not choosing the correct length of the device include inadvertent coverage of the hypogastric artery if too long and the need for additional devices if too short.

Advantages and Risks of Endovascular Repair. The obvious advantage of an endovascular AAA repair is its minimally invasive nature. Typically, patients who undergo this procedure stay in the hospital for only 1 to 3 days, in contrast to the 5- to 10-day stay required after conventional open surgical repair. In our institution, patients who have had an endovascular repair are routinely transferred to a general vascular ward from the postanesthesia recovery unit, avoiding admission to a more costly intensive care unit.

Because an abdominal incision is not necessary in endovascular repair, the procedure is particularly beneficial in patients with severe pulmonary disease, such as chronic obstructive pulmonary disease or emphysema. Patients can sustain adequate breathing in the postoperative period, avoiding respiratory complications or prolonged mechanical ventilation. Because the abdominal cavity has not been entered, the risk of gastrointestinal complications, such as ileus, ventral hernia, or bowel obstruction due to intestinal adhesion, is also greatly reduced. Moreover, regional or epidural anesthesia can be used, avoiding the risks associated with general anesthesia in patients with severe cardiopulmonary dysfunction.

Despite its many advantages, endovascular repair does have potential complications. Since the stent graft device is attached endoluminally within the abdominal aorta, an endoleak due to incomplete stent graft exclusion of the aneurysm can occur. With this type of leak, blood flow persists outside the lumen of the endoluminal graft but within an aneurysm sac. A meta-analysis of 1118 patients who underwent successful endovascular repair found an endoleak incidence of 24%.[70] Although

a small endoleak usually poses little clinical significance because it will typically become thrombosed spontaneously, a large or persistent endoleak may lead to continuous aneurysm perfusion and ultimately to aneurysm rupture. The rupture rate following an endovascular AAA repair has been reported to be less than 0.8%.[71]

Stent graft iliac limb dysfunction resulting in thrombosis has been reported following endovascular repair.[18,70] One possible cause is aneurysm remodeling, resulting in a shortening in the aortic length, which can cause the stent graft to kink. Alternatively, progression of an underlying iliac atherosclerotic lesion may cause compression of the iliac limb and ultimately result in graft-limb occlusion. Treatment options include thrombolysis or graft thrombectomy to determine the underlying cause and possibly additional stent graft placement. Renal artery occlusion may occur due to improper stent graft positioning or migration.[18,60,70] Graft limb separation or dislocation has also been reported.[18,60,70]

In patients with AAA and concurrent iliac artery aneurysms who undergo preoperative coil embolization of the internal iliac artery, 20% to 45% experience symptoms of pelvic ischemia.[72] These symptoms may include buttock claudication, impotence, gluteal skin sloughing, and colonic ischemia. Other complications pertaining to endovascular repair relate to the access site and include groin hematoma and wound infection. Occasionally, the stent graft device can malfunction by either failing to deploy or dislodging during the deployment procedure.[18,71] If the device cannot be salvaged or rescued endoluminally, open surgical repair of the aneurysm may be necessary.

Technical Considerations of Endovascular Aortic Aneurysm Repair. Although endovascular AAA repair may be performed in any venue with appropriate digital fluoroscopic imaging capability, due to the need for absolute sterility and aseptic technique, it is most safely performed in a surgical suite. The patient is prepped and draped just as in open AAA repair. Patients with renal insufficiency should be started on perioperative oral *N*-acetylcysteine (Mucomyst) and sodium bicarbonate infusion to reduce the risk of contrast nephropathy. A variety of anesthetic options may be used. Regional anesthesia may be appropriate for patients with pulmonary disease. There are reports of success with local anesthetics alone, as the incisions are typically smaller than a typical open inguinal hernia repair.[73]

Bilateral transverse oblique incisions are made just below the inguinal ligament to expose approximately 2 to 3 cm of CFA and obtain proximal control. Special attention is paid to avoid the groin crease to decrease the risk of wound complications. Some have advocated a completely percutaneous access using the "pre-close" technique with the Perclose suture-mediated vascular closure device (Abbott Perclose, Redwood City, CA). Review of reported series on this technique suggest a technical success rate of 95% for medium-size sheaths ranging from 12 to 16 French, and 75% success for 18- to 24-French sizes.

Transfemoral access is obtained using standard Seldinger technique. Initial soft-tipped starter guidewires are exchanged for stiff guidewires that are advanced to the thoracic arch. Intravenous heparin at 80 IU/kg are administered, and the activated clotting time is maintained at 200 to 250 seconds. These guidewires provide the necessary support for the subsequent introduction of the large-diameter delivery catheters and devices. In the absence of special anatomic considerations, the primary device is inserted through the right side and the contralateral iliac limb is inserted through the left side. After administration of heparin, the delivery catheter or the introducer sheath is advanced to the L1-L2 vertebral space, which typically marks the location of the renal arteries. An angiographic catheter is advanced from the contralateral femoral artery to the same level.

A road-mapping aortogram is obtained to localize the renal arteries. The primary device is rotated to the desired orientation and deployed immediate below the lowest renal artery (Fig. 23-33). The angiographic catheter is replaced with a directional catheter and an angled guidewire, and the opening for the contralateral limb on the main device is cannulated. Intrastent passage of the guidewire is confirmed, and the angled guidewire is replaced with a stiff guidewire. The contralateral iliac limb is inserted into the docking opening of the primary device and deployed. A completion angiogram is performed looking for patency of the renal and hypogastric arteries, the device limbs, proximal and distal fixation, and endoleak. Adjunctive interventions including additional devices, balloons, and bare stents are performed as needed. The procedure is concluded with routine repairs of the femoral arteries and closure of the groin incisions. The patients recover in the recovery room for 2 to 4 hours and admitted to the general care floor. Although in the past, patients

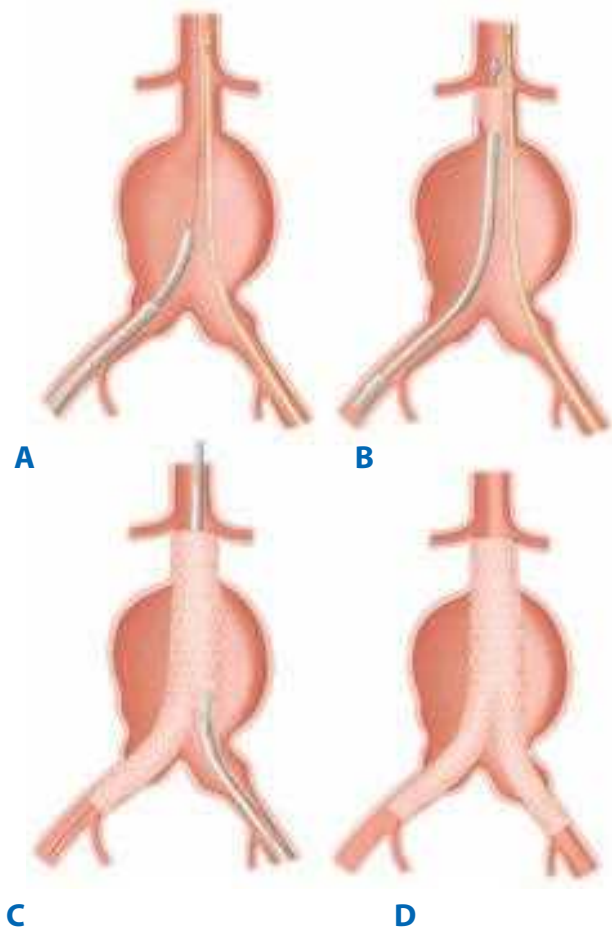


Figure 23-33. **A.** During an endovascular aortic aneurysm repair, the main endograft device is inserted through a femoral artery approach. **B.** The device is deployed in the aorta just below the renal arteries. **C.** A contralateral iliac endograft device is inserted through a contralateral gate opening, which is next deployed. **D.** Completion of deployment of the endograft device should fully exclude an aortic aneurysm while preserving flow of the renal and hypogastric arteries.

were admitted to the intensive care unit, this is rarely needed. Most patients can be started on a regular diet that evening and discharged the next morning.

Surveillance Following Endovascular Aortic Aneurysm Repair. Life-long follow-up is essential to the long-term success after endovascular AAA repair. Indeed, one may go so far as to say that absence of appropriate follow-up is tantamount to not having had a repair at all. A triple-phase (noncontrast, contrast, and delayed) spiral CT scan and a four-view (anteroposterior, lateral, and two obliques) abdominal x-ray should be obtained within the first month. Subsequent imaging can be obtained at 6-month intervals in the first 1 to 2 years and yearly thereafter. After the first 6 months, patients who cannot travel easily may obtain their studies locally and submit them for review. The CT scan is for detection of endoleaks, subtle proximal migrations, and changes in aneurysm size. The abdominal x-ray gives a "birds-eye" view of the overall morphology of the stent graft. Subtle changes in conformation of the iliac limbs relative to each other and/or the spine can provide early signs of impending component separation or loss of fixation. Further, stent fractures and/or suture breaks that can compromise long-term device integrity can sometimes only be detected on a plain film and not on a CT scan.

Results from Clinical Studies Comparing Endovascular versus Open Repair

The primary success rate after endovascular repair of AAA has been reported to be as high as 95%.[18,59] The less invasive nature of this procedure is appealing to many physicians and patients. In addition, virtually all reports indicate a decreased blood loss, transfusion requirements, and length of intensive care unit and hospital stay for endovascular repair of AAAs compared with the standard surgical approach.[18,59,74] With the advent of bifurcated grafts and improved delivery systems in the future, the only real limitation will be cost. When evaluating the literature for results from clinical series, it is important to look at a comparison of endoluminal versus open repair and device-specific outcome and cost analysis studies.

Early reports on results with endovascular repair were often flawed due to selection biases. This is because from its inception, endovascular repair has been used mostly in patients who are at higher risk for open repair. At the same time, only patients with favorable anatomy including less tortuosity and the presence of a suitable infrarenal neck were considered for endovascular repair. Randomization is also difficult because most patients who anatomically qualify for endovascular repair would withdraw from the study if randomized to open repair. Consequently, there are very few randomized controlled trials that have compared outcomes in patients with similar risk factors and anatomy who are eligible for both types of repair. Two such European trials have recently published short-term outcome data that are unbiased in design.

The DREAM trial is a multicenter randomized trial that compared open versus endovascular repair among a group of 345 patients at 28 European centers using multiple different devices including Gore, AneuRx, and Zenith.[75] Patients were included only if they were considered to be candidates for both types of repairs. The operative mortality rate was 4.6% in the operative group versus 1.2% in the endoluminal group at 30 days. When looking at the combined rate of operative mortality and severe complications, there was an incidence of 9.8% in the open repair group versus 4.7% in the endoluminal group. The difference here was largely due to the higher frequency of pulmonary complications seen in the open group. There was a higher incidence of graft-related complications in the endoluminal group. There was no difference in the nonvascular local complication rate among the two groups. The Endovascular Repair-1 (EVAR-1) trial is also a multicenter randomized trial that compared open to endoluminal repair.[74] This study was conducted on 1082 patients at 34 centers in the United Kingdom using all available devices. Short-term mortality at 30 days was 4.7% in the open group and 1.7% in the endoluminal group. The in-hospital mortality rate was also increased in the open when compared to the endoluminal group (6.2% vs. 2.1%). As expected, the secondary intervention rate was higher in the endoluminal group (9.8% vs. 5.8%). Complication rates were not reported in the EVAR-1 trial. Criticisms can be applied to both of these trials. Patients had to be eligible for either type of repair in order to be included in the study. Consequently, these findings cannot be generalized to patients who are too sick to undergo open surgery or to patients whose anatomy precludes them from undergoing endovascular repair.

The Open Versus Endovascular Repair (OVER) Veterans Affairs Cooperative Study Group randomly assigned 881 patients with asymptomatic AAAs who were candidates for both procedures to either endovascular repair (n = 444) or open repair (n = 437) and followed them for up to 9 years.[76] Reduction in perioperative mortality with endovascular repair was sustained at 3 years but not thereafter. There was no difference in primary outcome of all-cause mortality. Endovascular repair and open repair resulted in similar long-term survival. Six aneurysm ruptures were confirmed in the endovascular repair group versus none in the open repair group. Rupture after endovascular repair remains a concern. A significant interaction was observed between age and type of treatment. Endovascular repair led to increased long-term survival among younger patients but not among older patients, for whom a greater benefit from the endovascular approach had been expected.

Device-Specific Outcome. Matsumura and associates compared endoluminal versus open repair using the Excluder device.[77] In their review, they demonstrated a 30-day mortality rate of 1% along with endoleak rates of 17% and 20% at 1- and 2-year intervals, respectively.[77] The limb narrowing, limb migration, and trunk migration were all 1% at 2 years. There were no deployment failures or early conversions. There was an annual 7% reintervention rate. Aneurysm growth was demonstrated in 14% of patients at 2 years. The Zenith device by Cook has been studied by Greenberg and associates, who compared standard surgical repair with endoluminal repair in low-risk patients and endoluminal repair in high-risk patients.[78] They reported a 30-day mortality rate of 3.5%, which was equal to the open group. The endoleak rates were 7.4% and 5.4% at 1- and 2-year intervals, respectively. There was a 5.3% migration of 5 mm at 1 year. Freedom from rupture was 100% in the low-risk group and 98.9% in the high-risk endoluminal group at 2 years. Experience with the AneuRx device has been reported by Zarins.[79] In this 4-year review, they found a 30-day mortality rate of 2.8%. Endoleak rate at 4 years was 13.9%, aneurysm enlargement was 11.5%, and stent graft migration was 9.5%. Freedom from rupture was noted to be 98.4% at 4 years. Criado and associates have reported on their 1- year experience with the Talent LPS device by Medtronic.[80] They report a 30-day mortality rate of 0.8%. Endoleak rate was 10%. Three deployment failures were noted, and freedom from rupture was 100%.

Aneurysm growth and migration rates were divided into three different neck size groups. Patients with a wide neck (>26 mm) had a 3% growth and migration rate. Narrow-neck patients (<26 mm) had a 1% growth rate and a 2% migration neck. Interestingly, short-neck patients (<15 mm) had no aneurysm growths and a 2% migration rate.

Cost Analysis. The current climate of cost containment and limited reimbursement for healthcare services mandates a critical analysis of the economic impact of any new medical technology on the market. The in-hospital costs for both endovascular and open repair include graft cost, operating room fees, radiology, pharmacy, ancillary care, intensive care unit charges, and floor charges. Despite the improved morbidity and mortality rates, several early studies have reported no cost benefit with the application of endovascular repair.[81,82] The limiting factor appears to be the cost of the device. Despite commercialization of endovascular repair, the device costs are still in the range of $5000 to $6000 with no signs of abating. A recent report by Angle and associated further corroborates previous studies.[83] In their review, despite decreased hospital and intensive care unit stays and utilization of pharmacy and respiratory services, cost of endovascular repair was 1.74 times greater than the standard surgical approach. In addition, these cost analysis studies are centered on in-hospital costs and do not even begin to address secondary costs such as postoperative surveillance that is required with endovascular repair. In the OVER trial, endovascular repair was found to be a cost-effective alternative to open repair in the U.S. Veterans Affairs healthcare system for at least the first 2 years.[84] The primary outcomes were mean total healthcare cost per life-year and per quality-adjusted life-year. There were no differences found in survival, quality of life, and costs after 2 years between the endovascular and the open group. Although graft costs were higher in the endovascular group, length of stay was shorter, resulting in lower cost of AAA repair hospitalization in the endovascular group. Costs remained lower after 2 years in the endovascular group, but the difference was no longer significant.

Classification and Management of Endoleak

An endoleak is an extravasation of contrast outside the stent graft and within the aneurysm sac (Fig. 23-34). It can be present in up to 20% to 30% of all endovascular AAA repairs in the early postoperative period.[85] In general, over half of these endoleaks will resolve spontaneously during the first 6 months, resulting in a 10% incidence of chronic endoleaks in all cases

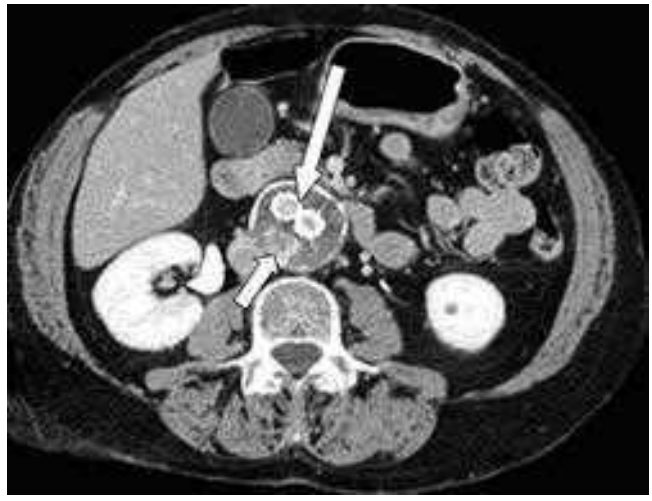

Figure 23-35. A computed tomography scan demonstrating an endoleak (*small arrow*) as evidenced by contrast flow outside the aortic endograft (*long arrow*).

beyond the first year of follow-up. Endoleaks can be detected using conventional angiography, contrast CT (Fig. 23-35), MRA, and color-flow duplex ultrasound. Although there is no recognized gold standard, in practice, angiography is considered the least sensitive but most specific for characterizing the source of the endoleak, whereas the CT scan is the most sensitive but least specific. Widespread availability and reliability that is relatively independent of technique have made the CT scan the de facto standard imaging modality for postoperative surveillance. Conversely, routine use of duplex ultrasound and MRA has been limited by the lack of proper equipment and local expertise. On the other hand, investigational techniques such as time-resolved MRA may provide greater sensitivity and specificity than either angiography or CT in the future.

Four types of endoleaks have been described (Table 23-10). Type I endoleak refers to fixation-related leaks that occur at the proximal or distal attachment sites. These represent less than 5% of all endoleaks and are seen as an early blush of contrast into the aneurysm sac from the proximal or distal ends of the device during completion angiography.[85,86] Although seen as marker of poor patient selection or inadequate repair, over 80% of these leaks spontaneously seal in the first 6 months. Persistent type I endoleaks, on the other hand, require prompt treatment. Type II

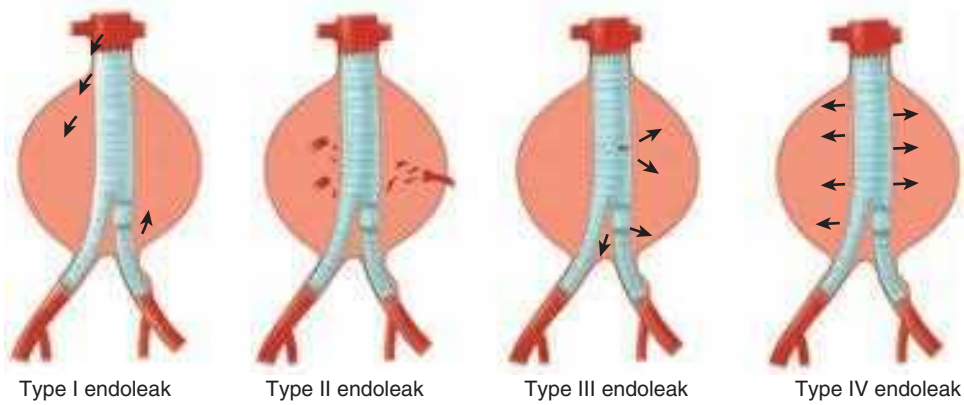

Figure 23-34. The four types of endoleak include the following: type I endoleak = attachment site leak; type II endoleak = side branch leak caused by lumbar or side branches; type III endoleak = endograft junctional leak due to overlapping device components; and type IV endoleak = endograft fabric or porosity leak.

Table 23-10

Endoleak classification

CLASSIFICATION	DESCRIPTION
Type I endoleak	Attachment site leak
Type II endoleak	Side branch leak caused by lumbar or inferior mesenteric arteries
Type III endoleak	Junctional leak (of overlapping endograft components) and graft fabric defect
Type IV endoleak	Endograft fabric porosity leak

endoleak refers to retrograde flow originating from a lumbar, inferior mesenteric, accessory renal, or hypogastric artery. They are the most common type of endoleak, accounting for 20% to 30% of all cases, and about half resolve spontaneously. On angiography, they are seen as a late filling of the aneurysm sac from a branch vessel(s). Type II endoleaks carry a relatively benign natural history and do not merit intervention unless associated with aneurysm growth. Type III endoleaks refer to failure of device integrity or component separation from modular systems. If detected intraoperatively or in the early perioperative period, it is usually from inadequate overlap between two stent grafts, whereas in the late period, the endoleak may be from a fabric tear or junctional separation from conformational changes of the aneurysm. Regardless of the etiology or timing, these should be promptly repaired. Finally, type IV endoleak refers to the diffuse, early blush seen during completion angiography due to graft porosity and/or suture holes of some Dacron-based devices. It does not have any clinical significance and usually cannot be seen after 48 hours and heparin reversal. Endoleaks that are initially considered type IV but persist become type III endoleaks by definition, because this indicates a more significant material defect than simple porosity or a suture hole.

Endotension Following Endovascular Aortic Aneurysm Repair. In approximately 5% of cases after an apparently successful endovascular repair, the aneurysm continues to grow without any demonstrable endoleak.[87] This phenomenon has been described as endotension. Although it was initially thought that an endoleak was really present but simply not detected, case have been reported where the aneurysm has been surgically opened and the contents were completely devoid of any blood and no extravasation could be found. The mechanism of continued pressurization of the aneurysm sac following successful exclusion from the arterial circulation remains unsolved at this time. One putative mechanism has been linked to a transudative process related to certain expanded PTFE graft materials.[88] More importantly, however, the natural history of these enlarging aneurysms without endoleaks is unknown, but to date, there has been no evidence to suggest that they carry an increased risk of rupture. Conservatively speaking, until further long-term data become available, if the patient is a suitable surgical risk, elective open conversion should be considered.

Secondary Interventions Following Endovascular Aortic Aneurysm Repair. There is approximately 10% to 15% per year risk of secondary interventions following endovascular AAA repair.[18,78,89] These procedures are critical in the long-term success of the primary procedure in prevention of aneurysm rupture and aneurysm-related death. These secondary procedures, in order of frequency, include proximal or distal extender placement for migrations, highly selective or translumbar embolization for type II endoleaks, direct surgical or laparoscopic branch vessel ligations, bridging cuffs for component separations, and late open surgical conversions.

Multiple large series have reported that an annual rupture rate of approximately 1% to 1.5% per year after endovascular repair.[18,78,89] The EUROSTAR registry reports a rupture rate of 2.3% over 15.4 months in patients with an endoleak, compared with 0.3% in those without.[90] Various causes of late ruptures have been reported in the literature, although presence of a persistent endoleak with aneurysm enlargement remains a common culprit for this complication. It has been shown that even successfully excluded aneurysms can lead to the development of attachment-site leaks and device failure, caused in part by aneurysm remodeling resulting in stent migration or kinking.[91] Mehta and colleagues reported that 63% of delayed AAA ruptures after endovascular repair were caused by type I endoleaks with endograft migration, 11% by type I without migration, 19% by type II, and the rest of unknown type.[92]

Treatment of rupture may be open conversion or endovascular stent graft placement. May and associates reported a mortality rate of 43% in those patients who underwent open conversion.[93] Emergent endovascular repair should be considered in these patients since it is potentially much faster and less likely to cause physiologic stress than open conversion. Several reports have shown that endovascular repair can be performed successfully in patients previously treated with endoluminal prostheses.[94,95]

MESENTERIC ARTERY DISEASE

Vascular occlusive disease of the mesenteric vessels is a relatively uncommon but potentially devastating condition that generally presents in patients over 60 years of age, is three times more frequent in women, and has been recognized as an entity since 1936.[96] The incidence of such a disease is low and represents 2% of the revascularization operations for atheromatous lesions. The most common cause of mesenteric ischemia is atherosclerotic vascular disease. Autopsy studies have demonstrated splanchnic atherosclerosis in 35% to 70% of cases.[97] Other etiologies exist and include FMD, panarteritis nodosa, arteritis, and celiac artery compression from a median arcuate ligament, but they are unusual and have an incidence of one in nine compared with that of atherosclerosis.

Chronic mesenteric ischemia is related to a lack of blood supply in the splanchnic region and is caused by disease in one or more visceral arteries: the celiac trunk, the superior mesenteric artery, and the IMA. Mesenteric ischemia is thought to occur when two of the three visceral vessels are affected with severe stenosis or occlusion; however, in as many as 9% of cases, only a single vessel is involved (SMA in 5% and celiac trunk in 4% of cases).[98] This disease process may evolve in a chronic fashion, as in the case of progressive luminal obliteration due to atherosclerosis. On the other hand, mesenteric ischemia can occur suddenly, as in the case of thromboembolism. Despite recent progress in perioperative management and better understanding of pathophysiology, mesenteric ischemia is considered one of the most catastrophic vascular disorders with mortality rates ranging from 50% to 75%. Delays in diagnosis

and treatment are the main contributing factors in its high mortality. It is estimated that mesenteric ischemia accounts for 1 in every 1000 hospital admissions in this country. The prevalence is rising due in part to the increased awareness of this disease, the advanced age of the population, and the significant comorbidity of these elderly patients. Early recognition and prompt treatment before the onset of irreversible intestinal ischemia are essential to improve the outcome.

Anatomy and Pathophysiology

Mesenteric arterial circulation is remarkable for its rich collateral network. Three main mesenteric arteries provide the arterial perfusion to the gastrointestinal system: the celiac artery (CA), the superior mesenteric artery (SMA), and the IMA. In general, the CA provides arterial circulation to the foregut (distal esophagus to duodenum), hepatobiliary system, and spleen; the SMA supplies the midgut (jejunum to mid-colon); and the IMA supplies the hindgut (mid-colon to rectum). The CA and SMA arise from the ventral surface of the infradiaphragmatic suprarenal abdominal aorta, whereas the IMA originates from the left lateral portion of the infrarenal aorta. These anatomic origins in relation to the aorta are important when a mesenteric angiogram is performed to determine the luminal patency. In order to fully visualize the origins of the CA and SMA, it is necessary to perform both an anteroposterior and a lateral projection of the aorta since most arterial occlusive lesions occur in the proximal segments of these mesenteric trunks.

Because of the abundant collateral flow between these mesenteric arteries, progressive diminution of flow in one or even two of the main mesenteric trunks is usually tolerated, provided that uninvolved mesenteric branches can enlarge over time to provide sufficient compensatory collateral flow. In contrast, acute occlusion of a main mesenteric trunk may result in profound ischemia due to lack of sufficient collateral flow. Collateral networks between the CA and the SMA exist primarily through the superior and inferior pancreaticoduodenal arteries. The IMA may provide collateral arterial flow to the SMA through the marginal artery of Drummond, the arc of Riolan, and other unnamed retroperitoneal collateral vessels termed meandering mesenteric arteries (Fig. 23-36). Lastly, collateral visceral vessels may provide important arterial flow to the IMA and the hindgut through the hypogastric arteries and the hemorrhoidal arterial network.

Regulation of mesenteric blood flow is largely modulated by both hormonal and neural stimuli, which characteristically regulate systemic blood flow. In addition, the mesenteric circulation responds to the gastrointestinal contents. Hormonal regulation is mediated by splanchnic vasodilators, such as nitric oxide, glucagon, and vasoactive intestinal peptide. Certain intrinsic vasoconstrictors, such as vasopressin, can diminish the mesenteric blood flow. On the other hand, neural regulation is provided by the extensive visceral autonomic innervation.

Clinical manifestation of mesenteric ischemia is predominantly postprandial abdominal pain, which signifies that the increased oxygen demand of digestion is not met by the gastrointestinal collateral circulation. The postprandial pain frequently occurs in the mid-abdomen, suggesting that the diversion of blood flow from the SMA to supply the stomach impairs perfusion to the small bowel. This leads to transient anaerobic metabolism and acidosis. Persistent or profound mesenteric ischemia will lead to mucosal compromise with release of intracellular contents and by-products of anaerobic metabolism to the splanchnic and systemic circulation. Injured bowel mucosa allows unimpeded influx of toxic substances from the bowel lumen with systemic consequences. If full-thickness necrosis occurs in the bowel wall, intestinal perforation ensues, which will lead to peritonitis. Concomitant atherosclerotic disease in cardiac or systemic circulation frequently compounds the diagnostic and therapeutic complexity of mesenteric ischemia.

Types of Mesenteric Artery Occlusive Disease

There are three major mechanisms of visceral ischemia involving the mesenteric arteries: (a) acute mesenteric ischemia, which can be either embolic or thrombotic in origin; (b) chronic mesenteric ischemia; and (c) nonocclusive mesenteric ischemia. Despite the variability of these syndromes, a common anatomic pathology is involved in these processes. The superior mesenteric artery (SMA) is the most commonly involved vessel in acute mesenteric ischemia. Acute thrombosis occurs in patients with underlying mesenteric atherosclerosis, which typically involves the origin of the mesenteric arteries while sparing the collateral branches. In acute embolic mesenteric ischemia, the emboli typically originate from a cardiac source and frequently occur in patients with atrial fibrillation or following myocardial infarction (Figs. 23-37 and 23-38). Nonocclusive mesenteric ischemia is characterized by a low flow state in otherwise normal mesenteric arteries and most frequently occurs in critically ill patients on vasopressors. Finally, chronic mesenteric ischemia is a functional consequence of a long-standing atherosclerotic process that typically involves at least two of the three main mesenteric vessels. The gradual development of the occlusive process allows the development of collateral vessels that prevent the manifestations of acute ischemia, but are not sufficient to meet the high postprandial intestinal oxygen requirements, giving rise to the classical symptoms of postprandial abdominal pain and the resultant food fear.

Figure 23-37. An anteroposterior view of a selective superior mesenteric artery angiogram shows an abrupt cutoff of the middle colic artery, which was caused by emboli (*arrow*) due to atrial fibrillation.

Several less common syndromes of visceral ischemia involving the mesenteric arteries can also cause serious debilitation. Chronic mesenteric ischemic symptoms can occur due to extrinsic compression of the celiac artery by the diaphragm, which is termed median arcuate ligament syndrome or celiac artery compression syndrome. Acute visceral ischemia may occur following an aortic operation, due to ligation of the IMA in the absence of adequate collateral vessels. Furthermore, acute visceral ischemia may develop in aortic dissection, which involves the mesenteric arteries, or after coarctation repair. Finally, other unusual causes of ischemia include mesenteric arteritis, radiation arteritis, and cholesterol emboli.

Figure 23-38. A lateral mesenteric angiogram showing an abrupt cutoff of the proximal superior mesenteric artery (SMA), which is consistent with SMA embolism (*arrow*).

Clinical Manifestations

Abdominal pain out of proportion to physical findings is the classic presentation in patients with acute mesenteric ischemia and occurs following an embolic or thrombotic ischemic event of the SMA. Other manifestations include sudden onset of abdominal cramps in patients with underlying cardiac or atherosclerotic disease, often associated with bloody diarrhea, as a result of mucosal sloughing secondary to ischemia. Fever, nausea, vomiting, and abdominal distention are some common but nonspecific manifestations. Diffuse abdominal tenderness, rebound, and rigidity are late signs and usually indicate bowel infarction and necrosis.

Clinical manifestations of chronic mesenteric ischemia are more subtle due to the extensive collateral development. However, when intestinal blood flow is unable to meet the physiologic gastrointestinal demands, mesenteric insufficiency ensues. The classical symptoms include postprandial abdominal pain, food fear, and weight loss. Persistent nausea and occasionally diarrhea may coexist. Diagnosis remains challenging, and most of the patients will undergo an extensive and expensive gastrointestinal tract workup for the above symptoms prior to referral to a vascular service.

The typical patient who develops nonocclusive mesenteric ischemia is an elderly patient who has multiple comorbidities, such as congestive heart failure, acute myocardial infarction with cardiogenic shock, hypovolemic or hemorrhagic shock, sepsis, pancreatitis, and administration of digitalis or vasoconstrictor agents such as epinephrine. Abdominal pain is only present in approximately 70% of these patients. When present, the pain is usually severe but may vary in location, character, and intensity. In the absence of abdominal pain, progressive abdominal distention with acidosis may be an early sign of ischemia and impending bowel infarction.

Abdominal pain due to narrowing of the origin of the CA may occur as a result of extrinsic compression or impingement by the median arcuate ligament (Fig. 23-39). This condition is known as celiac artery compression syndrome or median arcuate ligament syndrome. Angiographically, there is CA compression that augments with deep expiration and poststenotic dilatation. The celiac artery compression syndrome has been implicated in some variants of chronic mesenteric ischemia. Most patients are young females between 20 and 40 years of age. Abdominal symptoms are nonspecific, but the pain is localized in the upper abdomen, which may be precipitated by meals.

Diagnostic Evaluation

The differential diagnosis of acute mesenteric ischemia includes other causes of severe abdominal pain of acute onset, such as perforated viscus, intestinal obstruction, pancreatitis, cholecystitis, and nephrolithiasis. Laboratory evaluation is neither sensitive nor specific in distinguishing these various diagnoses. In the setting of mesenteric ischemia, complete blood count may reveal hemoconcentration and leukocytosis. Metabolic acidosis develops as a result of anaerobic metabolism. Elevated serum amylase may indicate a diagnosis of pancreatitis but is also common in the setting of intestinal infarction. Finally, increased lactate levels, hyperkalemia, and azotemia may occur in the late stages of mesenteric ischemia.

Plain abdominal radiographs may provide helpful information to exclude other causes of abdominal pain such as intestinal obstruction, perforation, or volvulus, which may exhibit symptoms mimicking intestinal ischemia. Pneumoperitoneum,

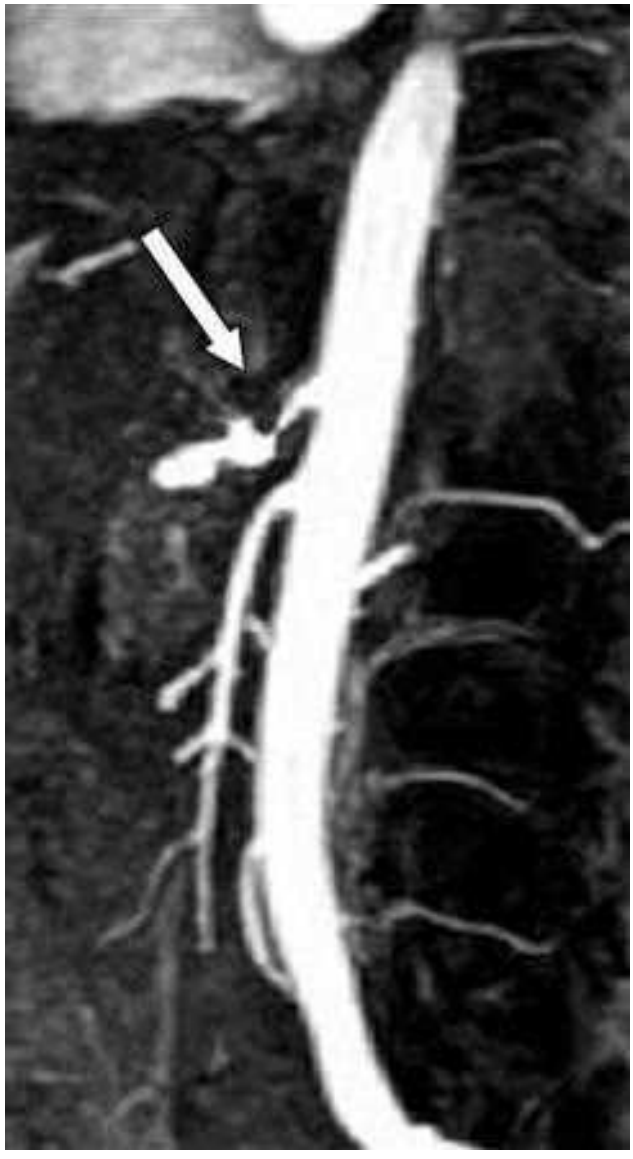

Figure 23-39. A lateral projection of the magnetic resonance angiography of the aorta showing a chronic compression of the celiac artery by the median arcuate ligament (*arrow*).

pneumatosis intestinalis, and gas in the portal vein may indicate infarcted bowel. In contrast, radiographic appearance of an adynamic ileus with a gasless abdomen is the most common finding in patients with acute mesenteric ischemia.

Upper endoscopy, colonoscopy, or barium radiography does not provide any useful information when evaluating acute mesenteric ischemia. Moreover, barium enema is contraindicated if the diagnosis of mesenteric ischemia is being considered. The intraluminal barium can obscure accurate visualization of mesenteric circulation during angiography. In addition, intraperitoneal leakage of barium can occur in the setting of intestinal perforation, which can lead to added therapeutic challenges during mesenteric revascularization.

Diagnosis of chronic mesenteric ischemia can be more challenging. Usually prior to the evaluation by a vascular service, the patients have undergone an extensive workup for the symptoms of chronic abdominal pain, weight loss, and anorexia. Rarely, the vascular surgeon is the first to encounter a patient with the above symptoms. In this situation, it is advisable to keep in mind that mesenteric ischemia is a rare entity and that a full diagnostic workup that should include CT scan of the abdomen and evaluation by gastroenterologist should be performed. Mesenteric occlusive disease may coexist with malignancy, and symptoms of mesenteric vessel stenosis may be the result of extrinsic compression by a tumor.

Duplex ultrasonography is a valuable noninvasive means of assessing the patency of the mesenteric vessels. Moneta and associates evaluated the use of duplex ultrasound in the diagnosis of mesenteric occlusive disease in a blinded prospective study.[99,100] A peak systolic velocity in the SMA >275 cm/s demonstrated a sensitivity of 92%, specificity of 96%, and overall accuracy of 96% for detecting >70% stenosis. The same authors found sensitivity and specificity of 87% and 82%, respectively, with an accuracy of 82% in predicting >70% celiac trunk stenosis. Duplex has been successfully used for follow-up after open surgical reconstruction or endovascular treatment of the mesenteric vessels to assess recurrence of the disease. Finally, spiral CT with three-dimensional reconstruction (Fig. 23-40) and MRA (Fig. 23-41) have been promising in providing clear radiographic assessment of the mesenteric vessels.

The definitive diagnosis of mesenteric vascular disease is made by biplanar mesenteric arteriography, which should be performed promptly in any patient with suspected mesenteric occlusion. It typically shows occlusion or near-occlusion of the CA and SMA at or near their origins from the aorta. In most

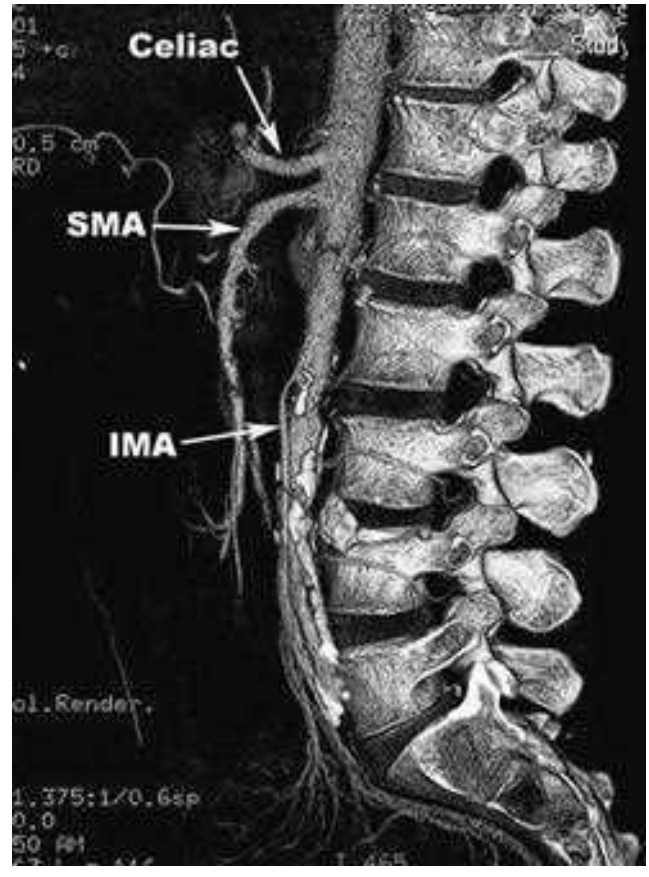

Figure 23-40. Computed tomography angiogram of the abdomen with three-dimensional reconstruction provides a clear view of the celiac artery, superior mesenteric artery (SMA), and inferior mesenteric artery (IMA).

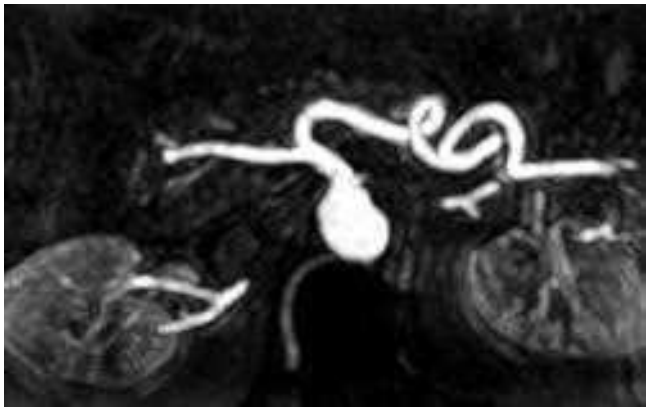

Figure 23-41. A cross-sectional view of a magnetic resonance angiogram provides a clear view of the luminal patency of the superior mesenteric artery.

cases, the IMA has been previously occluded secondary to diffuse infrarenal aortic atherosclerosis. The differentiation of the different types of mesenteric arterial occlusion may be suggested with biplanar mesenteric arteriogram. Mesenteric emboli typically lodge at the orifice of the middle colic artery, which creates a "meniscus sign" with an abrupt cutoff of a normal proximal SMA several centimeters from its origin on the aorta. Mesenteric thrombosis, in contrast, occurs at the most proximal SMA, which tapers off at 1 to 2 cm from its origin. In the case of chronic mesenteric occlusion, the appearance of collateral circulation is typically present. Nonocclusive mesenteric ischemia produces an arteriographic image of segmental mesenteric vasospasm with a relatively normal-appearing main SMA trunk (Fig. 23-42).

Figure 23-42. Mesenteric arteriogram showing nonocclusive mesenteric ischemia as evidenced by diffuse spasm of intestinal arcades with poor filling of intramural vessels.

Mesenteric arteriography can also play a therapeutic role. Once the diagnosis of nonocclusive mesenteric ischemia is made on the arteriogram, an infusion catheter can be placed at the SMA orifice, and vasodilating agents, such as papaverine, can be administered intra-arterially. The papaverine infusion may be continued postoperatively to treat persistent vasospasm, a common occurrence following mesenteric reperfusion. Transcatheter thrombolytic therapy has little role in the management of thrombotic mesenteric occlusion. Although thrombolytic agents may transiently recannulate the occluded vessels, the underlying occlusive lesions require definitive treatment. Furthermore, thrombolytic therapy typically requires a prolonged period of time to restore perfusion, during which the intestinal viability will be difficult to assess.

A word of caution would be appropriate here regarding patients with typical history of chronic intestinal angina who present with an acute abdomen and classical findings of peritoneal irritation. Arteriography is the gold standard for the diagnosis of mesenteric occlusive disease; however, it can be a time-consuming diagnostic modality. In this group of patients, immediate exploration for assessment of intestinal viability and vascular reconstruction is the best choice.

Surgical Repair

Acute Embolic Mesenteric Ischemia. Initial management of patients with acute mesenteric ischemia includes fluid resuscitation and systemic anticoagulation with heparin to prevent further thrombus propagation. Significant metabolic acidosis not responding to fluid resuscitation should be corrected with sodium bicarbonate. A central venous catheter, peripheral arterial catheter, and Foley catheter should be placed for hemodynamic status monitoring. Appropriate antibiotics are given prior to surgical exploration. The operative management of acute mesenteric ischemia is dictated by the cause of the occlusion. It is helpful to obtain a preoperative mesenteric arteriogram to confirm the diagnosis and to plan appropriate treatment options. However, the diagnosis of mesenteric ischemia frequently cannot be established prior to surgical exploration, and therefore, patients in a moribund condition with acute abdominal symptoms should undergo immediate surgical exploration, avoiding the delay required to perform an arteriogram.

The primary goal of surgical treatment in embolic mesenteric ischemia is to restore arterial perfusion with removal of the embolus from the vessel. The abdomen is explored through a midline incision, which often reveals variable degrees of intestinal ischemia from the mid-jejunum to the ascending or transverse colon. The transverse colon is lifted superiorly, and the small intestine is reflected toward the right upper quadrant. The SMA is approached at the root of the small bowel mesentery, usually as it emerges from beneath the pancreas to cross over the junction of the third and fourth portions of the duodenum. Alternatively, the SMA can be approached by incising the retroperitoneum lateral to the fourth portion of the duodenum, which is rotated medially to expose the SMA. Once the proximal SMA is identified and controlled with vascular clamps, a transverse arteriotomy is made to extract the embolus, using standard balloon embolectomy catheters. In the event the embolus has lodged more distally, exposure of the distal SMA may be obtained in the root of the small bowel mesentery by isolating individual jejunal and ileal branches to allow a more comprehensive thromboembolectomy. Following the restoration of SMA flow, an assessment of intestinal viability must be

made, and nonviable bowel must be resected. Several methods have been described to evaluate the viability of the intestine, which include intraoperative intravenous fluorescein injection and inspection with a Wood's lamp, and Doppler assessment of antimesenteric intestinal arterial pulsations. A second-look procedure should be considered in many patients and is performed 24 to 48 hours following embolectomy. The goal of the procedure is reassessment of the extent of bowel viability, which may not be obvious immediately following the initial embolectomy. If nonviable intestine is evident in the second-look procedure, additional bowel resections should be performed at that time.

Acute Thrombotic Mesenteric Ischemia. Thrombotic mesenteric ischemia usually involves a severely atherosclerotic vessel, typically the proximal CA and SMA. Therefore, these patients require a reconstructive procedure to the SMA to bypass the proximal occlusive lesion and restore adequate mesenteric flow. The saphenous vein is the graft material of choice, and prosthetic materials should be avoided in patients with nonviable bowel, due to the risk of bacterial contamination if resection of necrotic intestine is performed. The bypass graft may originate from either the aorta or iliac artery. Advantages from using the supraceliac infradiaphragmatic aorta as opposed to the infrarenal aorta as the inflow vessel include a smoother graft configuration with less chance of kinking and the absence of atherosclerotic disease in the supraceliac aortic segment. Exposure of the supraceliac aorta is technically more challenging and time consuming than that of the iliac artery, which unless calcified is an appropriate inflow. Patency rates are similar regardless of inflow vessel choice.[101]

Chronic Mesenteric Ischemia. The therapeutic goal in patients with chronic mesenteric ischemia is to revascularize mesenteric circulation and prevent the development of bowel infarction. Mesenteric occlusive disease can be treated successfully by either transaortic endarterectomy or mesenteric artery bypass. Transaortic endarterectomy is indicated for ostial lesions of patent CA and SMA. A left medial rotation is performed, and the aorta and the mesenteric branches are exposed. A lateral aortotomy is performed encompassing both the CA and SMA orifices. The visceral arteries must be adequately mobilized so that the termination site of endarterectomy can be visualized. Otherwise, an intimal flap may develop, which can lead to early thrombosis or distal embolization.

3▶

For occlusive lesions located 1 to 2 cm distal to the mesenteric origin, mesenteric artery bypass should be performed. Multiple mesenteric arteries are typically involved in chronic mesenteric ischemia, and both the CA and SMA should be revascularized whenever possible. In general, bypass grafting may be performed either antegrade from the supraceliac aorta or retrograde from either the infrarenal aorta or iliac artery. Both autogenous saphenous vein grafts and prosthetic grafts have been used with satisfactory and equivalent success. An antegrade bypass also can be performed using a small-caliber bifurcated graft from the supraceliac aorta to both the CA and SMA, which yields an excellent long-term result.[101]

Celiac Artery Compression Syndrome. The decision to intervene in patients with CA compression syndrome should be based on both an appropriate symptom complex and the finding of celiac artery compression in the absence of other findings to explain the symptoms. The treatment goal is to release the ligamentous structure that compresses the proximal CA and to correct any persistent stricture by bypass grafting. Some surgeons advocate careful celiac plexus sympathectomy in addition to arcuate ligament decompression to ensure good treatment outcome.[102] The patient should be cautioned that relief of the celiac compression cannot be guaranteed to relieve the symptoms. In a number of reports on endovascular management of chronic mesenteric ischemia, the presence of CA compression syndrome has been identified as a major factor of technical failure and recurrence. Therefore, angioplasty and stenting should not be undertaken if extrinsic compression of the CA by the median arcuate ligament is suspected based on preoperative imaging studies. Open surgical treatment should be performed instead.[103,104] A recent review of laparoscopic and open median arcuate ligament release cases in the literature by Jimenez and colleagues showed both approaches to be effective in symptom relief (85%), with no difference in late symptom recurrence rate (6.8% in the open group and 5.7% in the laparoscopic group).[105]

Endovascular Treatment

Chronic Mesenteric Ischemia. Endovascular treatment of mesenteric artery stenosis or short segment occlusion by balloon dilatation or stent placement represents a less invasive therapeutic alternative to open surgical intervention, particularly in patients whose medical comorbidities place them at a high operative risk category. Endovascular therapy is also suited in patients with recurrent disease or anastomotic stenosis following previous open mesenteric revascularization. Prophylactic mesenteric revascularization is rarely performed in the asymptomatic patient undergoing an aortic procedure for other indications.[106] However, the natural history of untreated chronic mesenteric ischemia may justify revascularization in some minimally symptomatic or asymptomatic patients if the operative risks are acceptable, since the first clinical presentation may be acute intestinal ischemia in as many as 50% of the patients, with a mortality rate that ranges from 15% to 70%.[106] This is particularly true when the SMA is involved. Mesenteric angioplasty and stenting is particularly suitable for this patient subgroup given its low morbidity and mortality. Because of the limited experience with stent use in mesenteric vessels, appropriate indications for primary stent placement have not been clearly defined. Guidelines generally include calcified ostial stenoses, high-grade eccentric stenoses, chronic occlusions, and significant residual stenosis >30% or the presence of dissection after angioplasty. Restenosis after PTA is also an indication for stent placement.[107]

Acute Mesenteric Ischemia. Catheter-directed thrombolytic therapy is a potentially useful treatment modality for acute mesenteric ischemia, which can be initiated with intra-arterial delivery of thrombolytic agent into the mesenteric thrombus at the time of diagnostic angiography. Various thrombolytic medications, including urokinase (Abbokinase; Abbott Laboratory, North Chicago, IL) or recombinant tissue plasminogen activator (Activase; Genentech, South San Francisco, CA), have been reported to be successful in a small series of case reports. Catheter-directed thrombolytic therapy has a higher probability of restoring mesenteric blood flow success when performed within 12 hours of symptom onset. Successful resolution of a mesenteric thrombus will facilitate the identification of the underlying mesenteric occlusive disease process. As a result, subsequent operative mesenteric revascularization or mesenteric balloon angioplasty and stenting may be performed

electively to correct the mesenteric stenosis. There are two main drawbacks with regard to thrombolytic therapy in mesenteric ischemia. Percutaneous catheter-directed thrombolysis does not allow the possibility to inspect the potentially ischemic intestine following restoration of the mesenteric flow. Additionally, a prolonged period of time may be necessary in order to achieve successful catheter-directed thrombolysis, due in part to serial angiographic surveillance to document thrombus resolution. An incomplete or unsuccessful thrombolysis may lead to delayed operative revascularization, which may further necessitate bowel resection for irreversible intestinal necrosis. Therefore, catheter-directed thrombolytic therapy for acute mesenteric ischemia should only be considered in selected patients under a closely scrutinized clinical protocol.

Nonocclusive Mesenteric Ischemia. The treatment of nonocclusive mesenteric ischemia is primarily pharmacologic with selective mesenteric arterial catheterization followed by infusion of vasodilatory agents, such as tolazoline or papaverine. Once the diagnosis is made on the mesenteric arteriography (see Fig. 23-42), intra-arterial papaverine is given at a dose of 30 to 60 mg/h. This must be coupled with the cessation of other vasoconstricting agents. Concomitant intravenous heparin should be administered to prevent thrombosis in the cannulated vessels. Treatment strategy thereafter is dependent on the patient's clinical response to the vasodilator therapy. If abdominal symptoms improve, mesenteric arteriography should be repeated to document the resolution of vasospasm. The patient's hemodynamic status must be carefully monitored during papaverine infusion as significant hypotension can develop in the event that the infusion catheter migrates into the aorta, which can lead to systemic circulation of papaverine. Surgical exploration is indicated if the patient develops signs of continued bowel ischemia or infarction as evidenced by rebound tenderness or involuntary guarding. In these circumstances, papaverine infusion should be continued intraoperatively and postoperatively. The operating room should be kept as warm as possible, and warm irrigation fluid and laparotomy pads should be used to prevent further intestinal vasoconstriction during exploration.

Techniques of Endovascular Interventions. To perform endovascular mesenteric revascularization, intraluminal access is performed via a femoral or brachial artery approach. Once an introducer sheath is placed in the femoral artery, an anteroposterior and lateral aortogram just below the level of the diaphragm is obtained with a pigtail catheter to identify the origin of the CA and SMA. Initial catheterization of the mesenteric artery can be performed using a variety of selective angled catheters, which include the RDC, Cobra-2, Simmons I (Boston Scientific/Meditech, Natick, MA), or SOS Omni catheter (Angiodynamics, Queensbury, NY). Once the mesenteric artery is cannulated, systemic heparin (5000 IU) is administered intravenously. A selective mesenteric angiogram is then performed to identify the diseased segment, which is followed by the placement of a 0.035-inch or less traumatic 0.014- to 0.018-inch guidewire to cross the stenotic lesion. Once the guidewire is placed across the stenosis, the catheter is carefully advanced over the guidewire across the lesion. In the event that the mesenteric artery is severely angulated as it arises from the aorta, a second stiffer guidewire (Amplatz or Rosen Guidewire, Boston Scientific) may be exchanged through the catheter to facilitate the placement of a 6-French guiding sheath (Pinnacle, Boston Scientific).

With the image intensifier angled in a lateral position to fully visualize the proximal mesenteric segment, a balloon angioplasty is advanced over the guidewire through the guiding sheath and positioned across the stenosis. The balloon diameter should be chosen based on the vessel size of the adjacent normal mesenteric vessel. Once balloon angioplasty is completed, a postangioplasty angiogram is necessary to document the procedural result. Radiographic evidence of either residual stenosis or mesenteric artery dissection constitutes suboptimal angioplasty results that warrants mesenteric stent placement. Moreover, atherosclerotic involvement of the proximal mesenteric artery or vessel orifice should be treated with balloon-expandable stent placement. These stents can be placed over a low-profile 0.014- or 0.018-inch guidewire system. It is preferable to deliver the balloon-mounted stent through a guiding sheath, which is positioned just proximal to the mesenteric orifice while the balloon-mounted stent is advanced across the stenosis. The stent is next deployed by expanding the angioplasty balloon to its designated inflation pressure. The balloon is then deflated and carefully withdrawn through the guiding sheath.

Completion angiogram is performed by hand injecting a small volume of contrast though the guiding sheath. It is critical to maintain the guidewire access until satisfactory completion angiogram is obtained. If the completion angiogram reveals suboptimal radiographic results, such as residual stenosis or dissection, additional catheter-based intervention can be performed through the same guidewire. These interventions may include repeat balloon angioplasty for residual stenosis or additional stent placement for mesenteric artery dissection. During the procedure, intra-arterial infusion of papaverine or nitroglycerine can be used to decrease vasospasm. Administration of antiplatelet agents is also recommended for at least 6 months or even indefinitely if other risk factors of cardiovascular disease are present.

Complications of Endovascular Treatment. Complications are not common and rarely become life threatening. These include access site thrombosis, hematomas, and infection. Dissection can occur during PTA and is managed with placement of a stent. Balloon-mounted stents are preferred over the self-expanding ones because of the higher radial force and the more precise placement. Distal embolization has also been reported, but it never resulted in acute intestinal ischemia, likely due to the rich network of collaterals already developed.[108]

Clinical Results of Interventions for Mesenteric Ischemia

The first successful percutaneous angioplasty of the SMA was reported in 1980.[109] Since 1995, multiple series and scattered case reports have reported results from endovascular management of mesenteric occlusive disease.[101,108] A literature review by AbuRahma and colleagues in 2003 showed that endovascular intervention had an overall technical success rate of 91%, early and late pain relief rates of 84% and 71%, respectively, and 30-day morbidity and mortality rates of 16.4% and 4.3%, respectively. The average patency was 63% during an average 26-month follow-up.[108]

In our review of the literature from published series since 1995, restenosis developed in 22% of patients during 24.5 months of average follow-up.[101] The long-term clinical relief without reintervention was 82%. Among the patients who experienced a technical failure, 15 were ultimately diagnosed

with median arcuate ligament syndrome and underwent successful surgical treatment, an observation that emphasizes the need for careful patient selection. Interestingly, the addition of selective stenting after PTA that was started in 1998, while it slightly increases the technical success rate, is not correlated with any substantial overall clinical benefit or improved long-term patency rates.

In contrast to endovascular treatment, open surgical techniques have achieved an immediate clinical success rate that approaches 100%, a surgical mortality rate of 0% to 17%, and an operative morbidity rate that ranges from 19% to 54% in a number of different series.[101,104,106] AbuRahma and colleagues reported their experience of endovascular interventions of 22 patients with symptomatic mesenteric ischemia due to either SMA or CA stenosis.[108] They noted an excellent initial technical and clinical success rates, which were 96% (23 of 24 patients) and 95% (21 of 22 patients), respectively, with no perioperative mortality or major morbidity. During a mean follow-up of 26 months (range, 1–54 months), the primary late clinical success rate was 61%, and freedom from recurrent stenosis was 30%. The freedom from recurrent stenosis rates at 1, 2, 3, and 4 years were 65%, 47%, 39%, and 13%, respectively. The authors concluded that mesenteric stenting, which provides excellent early results, is associated with a relative high incidence of late restenosis.[108]

Several studies have attempted to compare the endovascular with the standard open surgical approach.[110,111] The results of the open surgery appear to be more durable, but it tends to be associated with higher morbidity and mortality rates and an overall longer hospital stay. In one study that compared the clinical outcome of open revascularization with percutaneous stenting for patients with chronic mesenteric ischemia, 28 patients underwent endovascular treatment and 85 patients underwent open mesenteric bypass grafting.[111] With both patient cohorts having similar baseline comorbidities and symptom duration, there was no difference in early in-hospital complication or mortality rates. Moreover, both groups had similar 3-year cumulative recurrent stenosis and mortality rates. However, patients treated with mesenteric stenting had a significantly higher incidence of recurrent symptoms. The authors concluded that operative mesenteric revascularization should be offered to patients with low surgical risk.[111]

Based on the above results one could argue that mesenteric angioplasty and stenting demonstrate an inferior technical and clinical success rate. Long-term patency rates appear to also be superior with the open technique. There is a general consensus, however, that the endovascular approach is associated with lower morbidity and mortality rates and is therefore more suitable for high-risk patients. One should also keep in mind that practices representing standard of care for stent placement today were absent in the early era of endovascular experience. These include perioperative heparinization and short-term antiplatelet therapy, use of stents with higher radial force, routine use of postoperative surveillance with arterial duplex and early reintervention to prevent a high-grade stenosis from progressing to occlusion, and placement of drug-eluting stents. One such example is a recent nonrandomized study to compare the outcomes of mesenteric angioplasty using covered stents or bare metal stents in patients undergoing primary or reintervention for chronic mesenteric ischemia. The study showed that covered stents are associated with less restenosis (18% vs. 47%), symptom recurrence (18% vs. 50%), and reintervention (9% vs. 44%) at 24 months and better primary patency at 3 years (92% vs. 52%) than bare metal stents in the primary intervention group.[112] Similar results were found in the reintervention group as well.

RENAL ARTERY DISEASE

Obstructive lesions of the renal artery can produce hypertension, resulting in a condition known as renovascular hypertension, which is the most common form of hypertension amenable to therapeutic intervention, and affects 5% to 10% of all hypertensive patients in the United States.[113] Patients with renovascular hypertension are at an increased risk for irreversible end-organ dysfunction, including permanent kidney damage, if inadequate pharmacologic therapies are used to control the blood pressure. The majority of patients with renal artery obstructive disease have vascular lesions of either atherosclerotic disease or fibrodysplasia involving the renal arteries. The proximal portion of the renal artery represents the most common location for the development of atherosclerotic disease. It is well established that renal artery intervention, either by surgical or endovascular revascularization, provides an effective treatment for controlling renovascular hypertension as well as preserving renal function. The decision for intervention is complex and needs to consider a variety of anatomic, physiologic, and clinical features, unique for the individual patient.

Etiology

Approximately 80% of all renal artery occlusive lesions are caused by atherosclerosis, which typically involves a short segment of the renal artery ostia and represents spillover disease from a severely atheromatous aorta (Fig. 23-43).[114] Atherosclerotic lesions are bilateral in two thirds of patients. Individuals with this disease commonly present during the sixth decade of life. Men are affected twice as frequently as women. Atherosclerotic lesions in other territories such as the coronary, mesenteric, cerebrovascular, and peripheral arterial circulation are common. When a unilateral lesion is present, the disease process equally affects the right and left renal arteries.[115]

The second most common cause of renal artery stenosis is FMD, which accounts for 20% of cases and is most frequently encountered in young, often multiparous women.[116] FMD of

Figure 23-43. Occlusive disease of the renal artery typically involves the renal ostium (*arrow*) as a spillover plaque extension from aortic atherosclerosis.

Figure 23-44. Abdominal aortogram reveals a left renal artery fibromuscular dysplasia (*arrows*) with a characteristic "string of beads" appearance.

the renal artery represents a heterogeneous group of lesions that can produce histopathologic changes in the intima, media, or adventitia. The most common variety consists of medial fibroplasia, in which thickened fibromuscular ridges alternate with attenuated media producing the classic angiographic "string of beads" appearance (Figs. 23-44 and 23-45). The cause of medial fibroplasia remains unclear. Most common theories involve a modification of arterial smooth muscle cells in response to estrogenic stimuli during the reproductive years, unusual traction forces on affected vessels, and mural ischemia from impairment of vasa vasorum blood flow.[116] Fibromuscular hyperplasia usually affects the distal two thirds of the main renal artery, and the right renal artery is affected more frequently than the left. Other less common causes of renal artery stenosis include renal artery aneurysm (compressing the adjacent normal renal artery), arteriovenous malformations, neurofibromatosis, renal artery dissections, renal artery trauma, Takayasu's arteritis, and renal arteriovenous fistula.

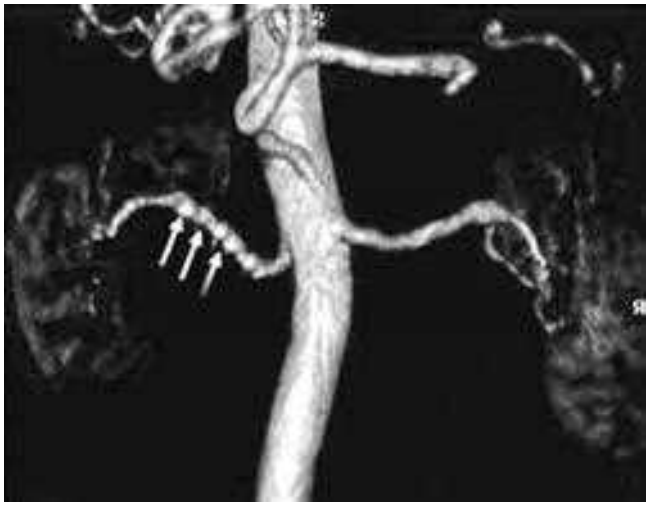

Figure 23-45. Magnetic resonance angiography of the abdominal aorta reveals the presence of a left renal artery fibromuscular dysplasia (*arrows*).

Clinical Manifestations

Renovascular hypertension is the most common sequela of renal artery occlusive disease. Its prevalence varies from 2% in patients with diastolic blood pressure greater than 100 mmHg to almost 30% in those with diastolic blood pressure over 125 mmHg.[114] Clinical features that may indicate the presence of renovascular hypertension include the following: (a) systolic and diastolic upper abdominal bruits; (b) diastolic hypertension of greater than 115 mmHg; (c) rapid onset of hypertension after the age of 50 years; (d) a sudden worsening of mild to moderate essential hypertension; (e) hypertension that is difficult to control with three or more antihypertensives; (f) development of renal insufficiency after angiotensin-converting enzyme inhibitors; and (g) development of hypertension during childhood.

All patients with significant hypertension, especially elevated diastolic blood pressure, must be considered as suspect for renovascular disease. Young adults with hypertension have a great deal to gain by avoiding lifelong treatment if renovascular hypertension is diagnosed and corrected. Appropriate diagnostic studies and intervention must be timely instituted to detect the possibility of renovascular hypertension in patients with primary hypertension who present for clinical evaluation.

Diagnostic Evaluation

The diagnostic requisites for renovascular hypertension include both hypertension and renal artery stenosis. Impairment of the renal function may coexist, although the occurrence of renal insufficiency prior to the development of hypertension is uncommon. Nearly all diagnostic studies for renovascular hypertension evaluate either the anatomic stenosis or renal parenchymal dysfunction attributed to the stenosis. The following section provides an overview of the strengths and limitations of the most common tests used in the diagnostic evaluation of the patient with suspected renovascular hypertension prior to intervention.

Captopril renal scanning is a functional study that assesses renal perfusion before and after administration of the angiotensin-converting enzyme inhibitor captopril. Captopril inhibits the secretion of angiotensin II. Through this mechanism, it reduces the efferent arteriole vasoconstriction and, as a result, the glomerular filtration rate (GFR). The test consists of a baseline renal scan and a second renal scan after captopril administration. A positive result indicates that captopril administration (a) increases the time to peak activity to more than 11 minutes or (b) the GFR ratio between sides increases to greater than 1.5:1 compared to a normal baseline scan. Significant parenchymal disease limits the reliability of this study.

Renal artery duplex ultrasonography is a noninvasive test of assessing renal artery stenosis both by visualization of the vessel and measurement of the effect of stenosis on blood flow velocity and waveforms. The presence of a severe renal artery stenosis correlates with peak systolic velocities of greater than

Table 23-11

Renal duplex diagnostic criteria

RENAL ARTERY DIAMETER REDUCTION	RENAL ARTERY PSV	RAR
Normal	<180 cm/s	<3.5
<60%	≥180 cm/s	<3.5
≥60%	≥180 cm/s	≥3.5
Occlusion	No signal	No signal

PSV = peak systolic velocity; RAR = renal-to-aortic ratio.

180 cm/s and the ratio of these velocities to those in the aorta of greater than 3.5 (Table 23-11). Renal artery duplex is a technically demanding exam, requiring a substantial amount of operator expertise. In addition, the presence of bowel gas and obesity make the exam difficult to perform and interpret. However, in experienced hands and with appropriate patient selection, it can be a high-yield exam and is typically the initial screening test for patients with suspected renal artery occlusive disease.

Selective catheterization of the renal vein via a femoral vein approach for assessing renin activity is a more invasive test of detecting the physiologic sequelae of renal artery stenosis. If unilateral disease is present, the affected kidney should secrete high levels of renin while the contralateral kidney should have low renin production. A ratio between the two kidneys, or the renal vein renin ratio (RVRR), of greater than 1.5 is indicative of functionally important renovascular hypertension, and it also predicts a favorable response from renovascular revascularization. Since this study assesses the ratio between the two kidneys, it is not useful in patients with bilateral disease because both kidneys may secrete abnormally elevated renin levels.

The renal:systemic renin index (RSRI) is calculated by subtracting systemic renin activity from individual renal vein renin activity and dividing the remainder by systemic renin activity. This value represents the contribution of each kidney to renin production. In the absence of renal artery stenosis, the renal vein renin activity from each kidney is typically 24% or 0.24 higher than the systemic level. As the result, the total of both kidneys' renin activity is usually 48% greater than the systemic activity, a value that represents a steady state of renal renin activity. The RSRI of the affected kidney in patients with renovascular hypertension is greater than 0.24. In the case of unilateral renal artery stenosis with normal contralateral kidney, the increase in ipsilateral renin release is normally balanced by suppression of the contralateral kidney renin production, which results in a drop in its RSRI to less than 0.24. Bilateral renal artery disease may negate the contralateral compensatory response, and the autonomous release of renin from both diseased kidneys may result in the sum of the individual RSRIs to be considerably greater than 0.48. The prognostic value of RSRI remains limited in that approximately 10% of patients with favorable clinical response following renovascular revascularization do not exhibit contralateral renin suppression. As a result, the use of RSRI must be applied with caution in the management of patients with renovascular hypertension.

MRA with intravenous gadolinium contrast enhancement has been increasingly used for renal artery imaging because of its ability to provide high-resolution images (Figs. 23-46 and 23-47) while using a minimally nephrotoxic agent. Flow void may be inaccurately interpreted as occlusion or stenosis in MRA. Therefore, unless the quality of the image analysis software is superior, MRA should be interpreted with caution and used in conjunction with other modalities prior to making plans for operative or endovascular treatment.

Figure 23-46. Magnetic resonance angiography of the abdominal aorta reveals bilateral normal renal arteries.

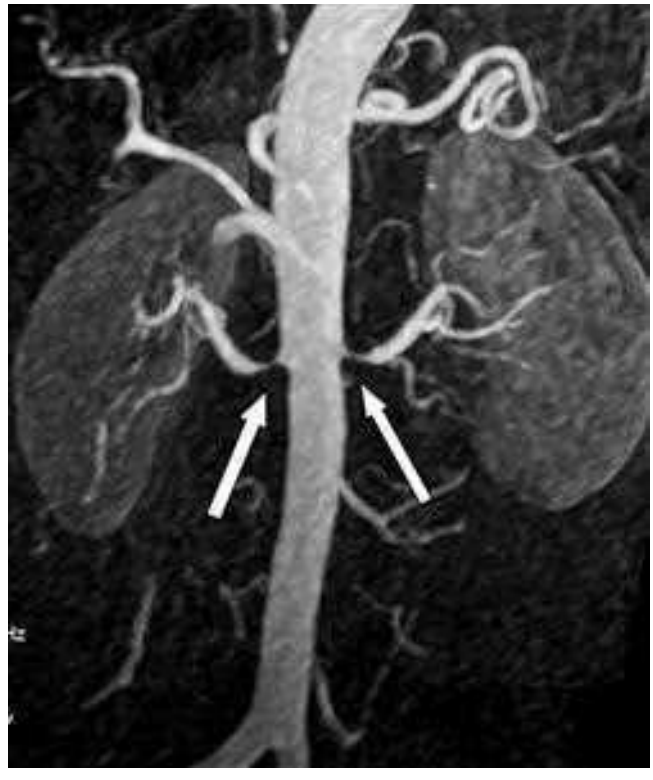

Figure 23-47. Magnetic resonance angiography of the abdominal aorta reveals bilateral ostial renal artery stenosis (*arrows*).

DSA remains the gold standard to assess renal artery occlusive disease. A flush aortogram is performed first so that any accessory renal arteries can be detected and the origins of all the renal arteries are adequately displayed. The presence of collateral vessels circumventing a renal artery stenosis strongly supports the hemodynamic importance of the stenosis. A pressure gradient of 10 mmHg or greater is necessary for collateral vessel development, which is also associated with activation of the renin-angiotensin cascade.

Treatment Indications

The therapeutic goals in patients with renovascular disease include: (a) improved blood pressure control, in order to prevent end-organ damage on systems such as the cerebral, coronary, pulmonary, and peripheral circulations; and (b) preservation and possibly improvement of the renal function (Table 23-12).

The indications for endovascular treatment for renal artery occlusive disease include 70% or greater stenosis of one or both renal arteries and at least one of the following clinical criteria:

- Inability to adequately control hypertension despite appropriate antihypertensive regimen.
- Chronic renal insufficiency related to bilateral renal artery occlusive disease or stenosis to a solitary functioning kidney.
- Dialysis-dependent renal failure in a patient with renal artery stenosis but without another definite cause of end-stage renal disease.
- Recurrent congestive heart failure or flash pulmonary edema not attributable to active coronary ischemia.

Prior to 1990, the most common treatment modality in patients with renal artery occlusive disease is surgical revascularization, with either renal artery bypass grafting or renal artery endarterectomy. The advancement of endovascular therapy in the past decade has led to various minimally invasive treatment strategies such as renal artery balloon angioplasty or stenting to control hypertension or to preserve renal function.

Table 23-12

Indications for renal artery revascularization

Angiography Criteria
• Documented renal artery stenosis (>70% diameter reduction)
• Fibromuscular dysplasia lesion
• Pressure gradient >20 mmHg
• Affected/unaffected kidney renin ratio >1.5 to 1
Clinical Criteria
• Refractory or rapidly progressive hypertension
• Hypertension associated with flash pulmonary edema without coronary artery disease
• Rapidly progressive deterioration in renal function
• Intolerance to antihypertensive medications
• Chronic renal insufficiency related to bilateral renal artery occlusive disease or stenosis to a solitary functioning kidney
• Dialysis-dependent renal failure in a patient with renal artery stenosis but without another definite cause of end-stage renal disease
• Recurrent congestive heart failure or flash pulmonary edema not attributable to active coronary ischemia

Surgical Reconstruction

The typical approach for surgical renal artery revascularization involves a midline xiphoid-to-pubis incision. The posterior peritoneum is incised, and the duodenum is mobilized to the right, starting at the ligament of Treitz. The left renal hilum can be exposed by extending the retroperitoneal dissection to the left along the avascular plane along the inferior border of the pancreas. Mobilization of the left renal vein is essential in these cases and can be achieved by dividing the gonadal, iliolumbar, and adrenal veins. The proximal portion of the right renal artery can be exposed through the base of the mesentery by retraction of the left renal vein cephalad and the vena cava to the right. Accessing the most distal portion of the right renal artery requires a Kocher maneuver and duodenal mobilization. Another approach useful for treating bilateral renal artery lesions involves mobilization of the entire small bowel and the right colon, with a dissection that starts at the ligament of Treitz and proceeds toward the cecum and then along the line of Todd in the right paracolic gutter. Simultaneous dissection along the inferior border of the pancreas provides additional visualization of the left renal artery. Finally, division of the diaphragmatic crura that encircle the suprarenal aorta may sometimes be necessary to achieve suprarenal clamping.

Types of Surgical Reconstruction. Aortorenal bypass is the most frequently performed reconstruction of ostial occlusive renal artery disease. After proximal and distal control is obtained, an elliptical segment of the aorta is excised, and the proximal anastomosis is performed in end-to-side fashion. Autologous vein is the preferred conduit. If the vein is not suitable, then prosthetic material can be used. An end-to-end anastomosis is then performed between the conduit of choice and the renal artery using either a 6-0 or 7-0 polypropylene suture. The length of the arteriotomy needs to be at least three times the diameter of the renal artery to prevent anastomotic restenosis. In the event that the surgeon plans to perform a side-to-side anastomosis between the conduit and the renal artery, this is performed first, and the aortic anastomosis follows.

Endarterectomy, either transrenal or transaortic, is an alternative to bypass for short ostial lesions or in patients with multiple renal arteries. The transrenal endarterectomy is performed with a transverse longitudinal incision on the aorta that extends into the diseased renal artery. After plaque removal, the arteriotomy is closed with a prosthetic patch. Transaortic endarterectomy is well suited for patients with multiple renal arteries and short ostial lesions. The aorta is opened longitudinally and aortic sleeve endarterectomy is performed, followed by eversion endarterectomy of the renal arteries. Adequate mobilization of the renal arteries is essential for a safe and complete endarterectomy.

Hepatorenal and splenorenal bypass are alternative options of revascularization for patients who might not tolerate aortic clamping or for those with calcified aorta that precludes adequate control. For hepatorenal bypass, a right subcostal incision is used, and the hepatic artery is exposed with an incision in the lesser omentum. A Kocher maneuver is performed, the right renal vein is identified and mobilized, and the right renal artery is identified and controlled posteriorly to the vein. Greater saphenous vein is the conduit of choice. The anastomosis is performed end-to-side with the common hepatic artery, and end-to-end with the renal artery anterior to the inferior vena cava.

The splenorenal bypass is performed via a left subcostal incision. The splenic artery is mobilized from the lesser sac, brought through a retropancreatic plane, and anastomosed end-to-end to the renal artery.

Reimplantation of the renal artery is an attractive option of reconstruction in children or in adults with ostial lesions. A redundant renal artery is a prerequisite for the procedure. After mobilization, the artery is transected and spatulated, eversion endarterectomy is performed if necessary, and an end-to-side anastomosis with the aorta is created.

Clinical Results of Surgical Repair

Results reflect the need for performance of renal artery bypass in high-volume and experienced centers. In a review from a large tertiary center, 92% of the patients with nonatherosclerotic vascular disease had improvement in hypertension, but only 43% were completely cured and taken off antihypertensives.[117] Patients younger than age 45 fair better, with a cure rate of 68% and improvement rate of 32%. In patients with atherosclerotic renal artery disease, the cure rate was even smaller (12%), and the overall response to hypertension rate was 85%. The operative mortality rates were 3.1% and 0% in the atherosclerotic and nonatherosclerotic groups, respectively.

Renal function improvement occurs within the first week of the operation in approximately two thirds of patients. A progressive decrease in the GFR is seen after this initial improvement, but the rate of decrease is less compared with patients who did not respond at all to operative intervention. Up to three quarters of patients were permanently removed from dialysis in a large series.[118] Favorable response of renal function to revascularization improves overall survival.

Endovascular Treatment

Endovascular treatment of renal artery occlusive disease was first introduced by Grüntzig who successfully dilated a renal artery stenosis using a balloon catheter technique. This technique requires passage of a guidewire under fluoroscopic control typically from a femoral artery approach to across the stenosis in the renal artery. A balloon dilating catheter is passed over the guidewire and positioned within the area of stenosis and inflated to produce a controlled disruption of the arterial wall. Alternatively, a balloon-mounted expandable stent can be used to primarily dilate the renal artery stenosis. Completion angiography is usually performed to assess the immediate results. The technical aspect of an endovascular renal artery revascularization is discussed below.

Techniques of Renal Artery Angioplasty and Stenting.

Access to the renal artery for endovascular intervention is typically performed via a femoral artery approach, although a brachial artery approach can be considered in the event of severe aortoiliac occlusive disease, aortoiliac aneurysm, or severe caudal renal artery angulation. Once an introducer sheath is placed in the femoral artery, an aortogram is performed with a pigtail catheter placed in the suprarenal aorta. Additional oblique views are frequently necessary to more precisely visualize the orifice of the stenosed renal artery and thoroughly assess the presence of accessory renal arteries. Noniodinated contrast agents, such as carbon dioxide and gadolinium, can be used in endovascular renal intervention in patients with renal dysfunction or history of allergic reaction.

After systemic heparinization, catheterization of the renal artery can be performed using a variety of selective angled catheters, including the RDC, Cobra-2, Simmons I, or SOS Omni catheter. A selective renal angiogram is then performed to confirm position, and the lesion is crossed with either 0.035-inch or a 0.018- to 0.014-inch guidewires. It is important to maintain the distal wire position without movement in the tertiary renal branches during guiding sheath placement to reduce the possibility of parenchymal perforation and spasm. A guiding sheath or a guiding catheter is then advanced at the orifice of the renal artery and provides a secure access for balloon and stent deployment.

Balloon angioplasty is performed with a balloon sized to the diameter of the normal renal artery adjacent to the stenosis. Choosing a balloon with diameter 4 mm is a reasonable first choice. The luminal diameter of the renal artery can be further assessed by comparing it to the fully inflated balloon. Such a comparison may provide a reference guide to determine whether renal artery dilatation with a larger diameter angioplasty balloon is necessary.

Once balloon angioplasty of the renal artery is completed, an angiogram is performed to document the procedural result. Radiographic evidence of either residual stenosis or renal artery dissection constitutes suboptimal angioplasty results, which warrants an immediate renal artery stent placement. Moreover, atherosclerotic involvement of the very proximal renal artery that involves the vessel orifice typically requires stent placement. A balloon-expandable stent is typically used and is positioned in such a way that it protrudes into the aorta by 1 to 2 mm. The size of the stent is determined by the size of the renal artery, taking into account a desirable 10% to 20% oversizing. After the stent deployment, the angiogram is repeated, and upon a satisfactory result, the devices are withdrawn. It is critical to maintain the guidewire access across the renal lesion until satisfactory completion angiogram is obtained. Spasm of the branches of the renal artery will usually respond to nitroglycerin 100 to 200 µg administered through the guiding sheath directly into the renal artery.

While endovascular therapy of renal artery occlusive disease is considerably less invasive than conventional renal artery bypass operation, complications relating to this treatment modality can occur. In a study in which Guzman and colleagues compared the complications following renal artery angioplasty and surgical revascularization, the authors noted that major complication rates following endovascular and surgical treatment were 17%, and 31 %, respectively.[119] In contrast, significantly greater minor complications were associated with the endovascular cohort, with a minor complication rate of 48% compared with 7% in the surgical group.[119] In a prospective randomized study that compared the clinical outcome of renal artery balloon angioplasty versus stenting for renal ostial atherosclerotic lesion, comparable complications rates were found in the two groups (39% vs. 43%, respectively). However, the incidence of restenosis at 6 months was significantly higher in the balloon angioplasty cohort than the stenting group (48% vs. 14%, respectively). This study underscores the clinical superiority of renal stenting compared to renal balloon angioplasty alone in patients with ostial stenosis.[120]

Deterioration in renal function, albeit transient, is a common complication following endovascular renal artery intervention. This is most likely the combined result of the use of iodinated contrast and the occurrence of renal parenchymal embolism due to wire and catheter manipulation. In most cases, this is a temporary problem, as supportive care with adequate

fluid hydration is sufficient to reverse the renal dysfunction. However, transient hemodialysis may become necessary in approximately 1% of patients. Other complications include vascular access complications (bleeding, hematoma, femoral nerve injury, arteriovenous fistula, and pseudoaneurysm), target vessel dissection, perinephric hematoma, early postoperative renal artery thrombosis, and extremity atheroembolism from thrombus in the aorta or the iliac arteries.

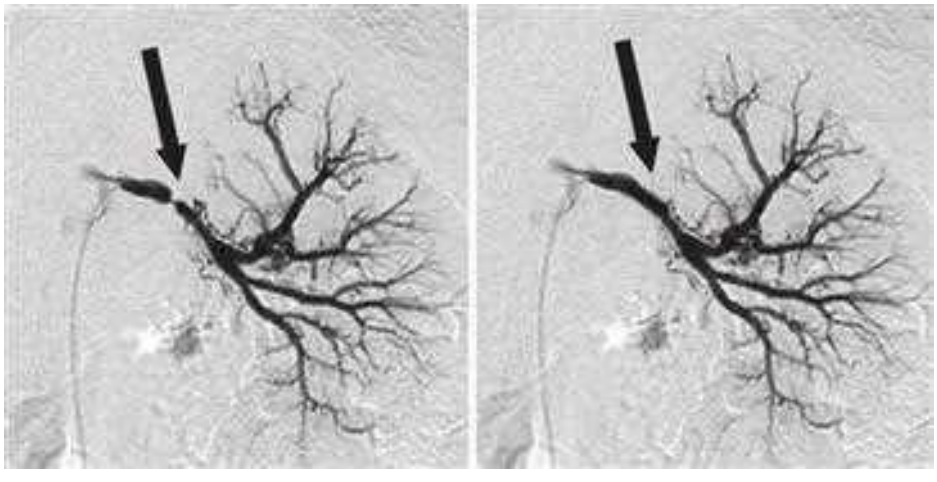
Clinical Results of Endovascular Interventions

Percutaneous Transluminal Balloon Angioplasty. FMD of the renal artery is the most common treatment indication for percutaneous transluminal balloon angioplasty. Patients with symptomatic FMD such as hypertension or renal insufficiency usually respond well to renal artery balloon angioplasty alone.[121] In contrast, balloon angioplasty generally is not an effective treatment for patients with renal artery stenosis or proximal occlusive disease of the renal artery, due to the high incidence of restenosis with balloon angioplasty alone. In the latter group of patients, primary stent placement is the preferred endovascular treatment. The long-term benefit of renal artery balloon angioplasty in patients with FMD was reported by Surowiec and colleagues.[121] They followed 14 patients who underwent 19 interventions on 18 renal artery segments. The technical success rate of balloon angioplasty for FMD was 95%. Primary patency rates were 81%, 69%, 69%, and 69% at 2, 4, 6, and 8 years, respectively. Assisted primary patency rates were 87%, 87%, 87%, and 87% at 2, 4, 6, and 8 years, respectively. The restenosis rate was 25% at 8 years. Clinical benefit, as defined by either improved or cured hypertension, was found in 79% of patients overall, with two thirds of patients having maintained this benefit at 8 years. The authors concluded that balloon angioplasty is highly effective in symptomatic FMD with excellent durable functional benefits.[121]

The utility of balloon angioplasty alone in the treatment of renovascular hypertension appears to be limited. van Jaarsveld and associates performed a prospective study in which patients with renal artery stenosis were randomized to either drug therapy or balloon angioplasty treatment.[122] A total of 106 patients with 50% diameter stenosis or greater plus hypertension or renal insufficiency were randomized in the study. At 3 months, there was no difference in the degree to which blood pressure was controlled between the two groups. However, the degree and dose of antihypertensive medications were slightly lowered in the balloon angioplasty group. The above advantage of the angioplasty group completely disappeared at 12 months, making the authors conclude that in the treatment of patients with hypertension and renal artery stenosis, percutaneous transluminal balloon angioplasty alone offers minimal advantage over antihypertensive drug therapy.

Renal Artery Stenting. Endovascular stent placement is the treatment of choice for patients with symptomatic or high-grade renal artery occlusive disease (Fig. 23-48) This is due in part to the high incidence of restenosis with balloon angioplasty alone, particularly in the setting of ostial stenosis. Renal artery stenting is also indicated for renal artery dissection caused by balloon angioplasty or other catheter-based interventions. Numerous studies have clearly demonstrated the clinical efficacy of renal artery stenting when compared to balloon angioplasty alone in patients with high-grade renal artery stenosis.

White and colleagues conducted a study to evaluate the role of renal artery stenting in patients with poorly controlled hypertension and renal artery lesions that did not respond well to balloon angioplasty alone.[123] The technical success of the procedure was 99%. The mean blood pressure values were 173 ± 25/88 ± 17 mmHg prior to stent implantation and 146 ± 20/77 ± 12 mmHg 6 months after renal artery stenting (P <0.01). Angiographic follow-up with 67 patients (mean 8.7 ± 5 months) demonstrated that restenosis, as defined by 50% or greater luminal narrowing, occurred in 15 patients (19%). The study concluded that renal artery stenting is a highly effective treatment for renovascular hypertension, with a low angiographic restenosis rate. In another similar study, Blum and colleagues prospectively performed renal artery stenting in 68 patients (74 lesions) with ostial renal artery stenosis and suboptimal balloon angioplasty.[124] Patients were followed for a mean of 27 months with measurements of blood pressure and serum creatinine, duplex sonography, and intra-arterial angiography. Five-year patency was 84.5% (mean follow-up, 27 months). Restenosis occurred in 8 of 74 arteries (11%), but after reintervention, the secondary 5-year patency rate was 92.4%. Hypertension was cured or improved in 78% of patients. The authors concluded that primary



A B

Figure 23-48. Renal artery stenting. **A.** Focal lesion in the renal artery (*arrow*). **B.** Poststenting angiogram reveals a satisfactory result following a renal artery stenting placement (*arrow*).

stent placement is an effective treatment for renal artery stenosis involving the ostium.

The clinical utility of renal artery stenting in renal function preservation was analyzed by several studies, which measured serial serum creatinine levels to determine the response of renal function following endovascular intervention.[125] In a study reported by Harden and colleagues who performed 33 renal artery stenting procedures in 32 patients with renal insufficiency, they noted that renal function improved or stabilized in 22 patients (69%).[126] In a similar study, Watson and associates evaluated the effect of renal artery stenting on renal function by comparing the slopes of the regression lines derived from the reciprocal of serum creatinine versus time.[125] A total of 61 renal stenting procedures were performed in 33 patients, and the authors found that after stent placement, the slopes of the reciprocal of the serum creatinine (1/Scr) were positive in 18 patients and less negative in 7 patients. The study concluded that in patients with chronic renal insufficiency due to obstructive renal artery stenosis, renal artery stenting is effective in improving or stabilizing renal function.

The clinical outcome of several large clinical studies of renal artery stenting in the treatment of renovascular hypertension or chronic renal insufficiency is shown in Table 23-13.[123,124,126-132] These studies uniformly demonstrated an excellent technical success rate with low incidence of restenosis or procedural-related complications. A similar analysis was reported by Leertouwer and colleagues who performed a meta-analysis of 14 studies comparing patients with renal arterial stent placement to those who underwent balloon angioplasty alone for renal arterial stenosis.[133] The study found that stent placement proved highly successful, with an initial technical success of 98%. The overall cure rate for hypertension was 20%, whereas hypertension was improved in 49%. Renal function improved in 30% of patients and stabilized in 38% of patients. The restenosis rate at follow-up of 6 to 29 months was 17%. Renal stenting resulted in a higher technical success rate and a lower restenosis rate when compared to balloon angioplasty alone.

AORTOILIAC OCCLUSIVE DISEASE

The distal abdominal aorta and the iliac arteries are common sites affected by atherosclerosis. The symptoms and natural history of the atherosclerotic process affecting the aortoiliac arterial segment are influenced by the disease distribution and extent. Atherosclerotic plaques may cause clinical symptoms by restricting blood flow due to luminal obstruction or by embolizing atherosclerotic debris to the lower extremity circulation. If the aortoiliac plaques reach sufficient mass and impinge on the arterial lumen, obstruction of blood flow to lower extremities occurs. Various risk factors exist that can lead to the development of aortoiliac occlusive disease. Recognition of these factors and understanding of this disease entity will enable physicians to prescribe the appropriate treatment strategy, which may alleviate symptoms and improve quality of life.

Diagnostic Evaluation

On clinical examination patients often have weakened femoral pulses and a reduced ABI. Verification of iliac occlusive disease is usually made by color duplex scanning, which reveals either a peak systolic velocity ratio ≥2.5 at the site of stenosis and or a monophasic waveform. Noninvasive tests such as pulse volume recordings (PVRs) of the lower extremity with estimation of the thigh-brachial pressure index may be suggestive of aortoiliac disease. MRA and multidetector CTA are increasingly being used to determine the extent and type of obstruction. DSA offers the interventionalist the benefit of making a diagnosis and the option of performing an endovascular treatment in a single session. Angiography provides important information regarding distal arterial runoff vessels as well as the patency of the PFA. Presence of pelvic and groin collaterals is important to provide crucial collateral flow in maintaining lower limb viability. It must be emphasized, however, that patients should be subjected to angiography only if their symptoms warrant surgical intervention.

Differential Diagnosis

Degenerative hip or spine disease, lumbar disk herniation, spinal stenosis, diabetic neuropathy, and other neuromuscular

problems can produce symptoms that may be mistaken for vascular claudication. Such cases can be distinguished from true claudication by the fact that the discomfort from neuromuscular problems is often relieved by sitting or lying down, as opposed to cessation of ambulation. In addition, complaints that are experienced upon standing suggest nonvascular causes. When confusion persists, the use of noninvasive vascular laboratory testing modalities, including treadmill exercise, can help establish the diagnosis.

Collateral Arterial Network

The principal collateral pathways in severe aortoiliac artery occlusive disease or chronic aortic occlusion that may provide blood flow distal to the aortoiliac lesion include: (a) the superior mesenteric artery to the distal IMA via its superior hemorrhoidal branch to the middle and inferior hemorrhoidals to the internal iliac artery (39%); (b) the lumbar arteries to the superior gluteal artery to the internal iliac system (37%); (c) the lumbar arteries to the lateral and deep circumflex arteries to the CFA (12%); and (d) Winslow's pathway from the subclavian to the superior epigastric artery to the inferior epigastric artery to the external iliac arteries at the groin (Fig. 23-49). In general, treatment indications for aortoiliac artery occlusive disease include disabling claudication, ischemic rest pain, nonhealing lower extremity tissue wound, and lower extremity microembolization that arises from aortoiliac lesions.

Disease Classification

Based on the atherosclerotic disease pattern, aortoiliac occlusive disease can be classified into three types (Fig. 23-50). Type I aortoiliac disease, which occurs in 5% to 10% of patients, is confined to the distal abdominal aorta and common iliac vessels (Fig. 23-51). Due to the localized nature of this type of aortic obstruction and formation of collateral blood flow around the occluded segment, limb-threatening symptoms are rare in the absence of more distal disease (Fig. 23-52). This type of aortoiliac occlusive disease occurs in a relatively younger group of patients (in their mid-50s), compared with patients who have more femoropopliteal disease. Patients with a type I disease pattern have a lower incidence of hypertension and diabetes, but a

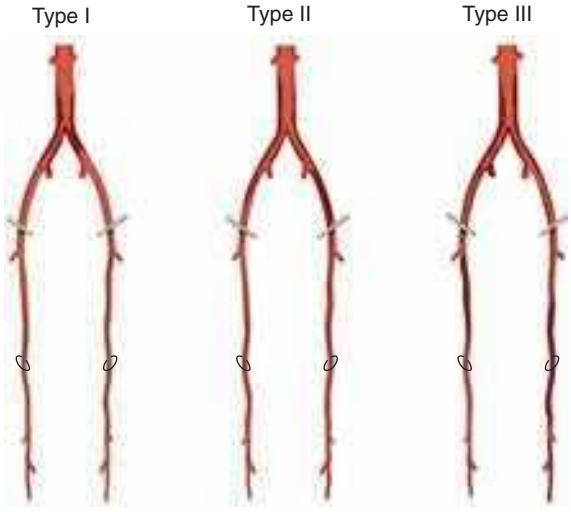

Figure 23-50. Aortoiliac disease can be classified into three types. Type I represents focal disease affecting the distal aorta and proximal common iliac artery. Type II represents diffuse aortoiliac disease above the inguinal ligament. Type III represents multisegment occlusive diseases involving aortoiliac and infrainguinal arterial vessels.

Figure 23-49. Pertinent collateral pathways are developed in the event of chronic severe aortoiliac occlusive disease. As illustrated in this multidetector computed tomography angiography, these collaterals include epigastric arteries (*large white arrows*), an enlarged inferior mesenteric artery (*arrowhead*), and enlarged lumbar arteries (*black arrows*).

Figure 23-51. Type I aortoiliac disease is confined to the distal abdominal aorta (*long arrow*) or proximal common iliac arteries. Due to the localized nature of this type of aortic obstruction and formation of collateral blood flow around the occluded segment (*short arrows*), limb-threatening symptoms are rare in the absence of more distal disease.

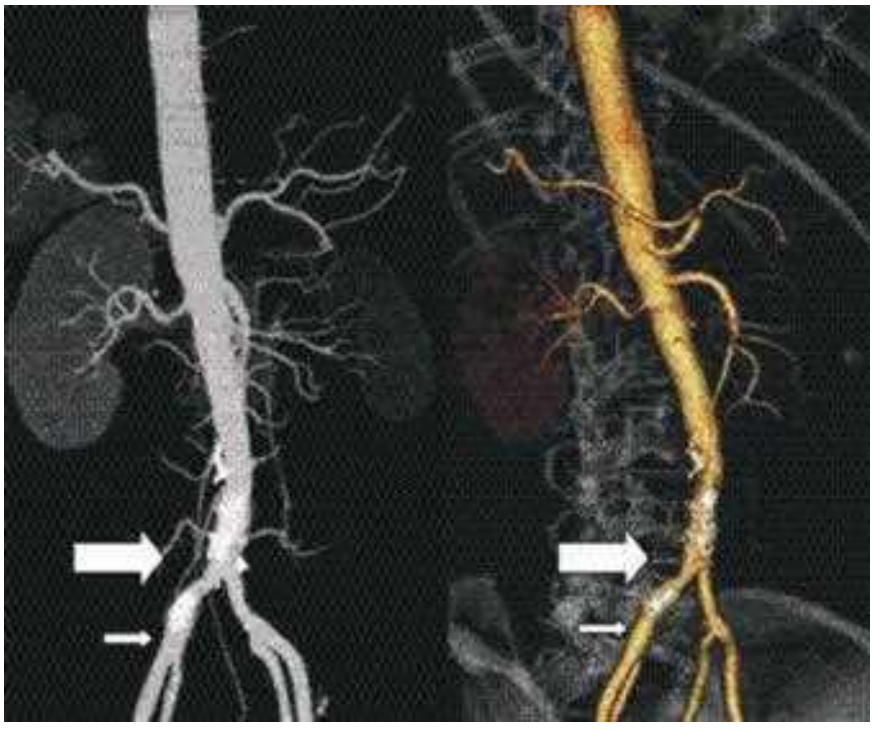

Figure 23-52. A. Multidetector computed tomography angiography of the aortoiliac artery circulation in a 63-year-old male with buttock claudication. **B.** Three-dimensional image reconstruction shows intra-arterial calcification of the aorta (*large arrow*) and right common iliac artery (*small arrow*). This is consistent with type I aortoiliac occlusive disease.

significant frequency of abnormal blood lipid levels, particularly type IV hyperlipoproteinemia. Symptoms typically consist of bilateral thigh or buttock claudication and fatigue. Men report diminished penile tumescence and may have complete loss of erectile function. These symptoms in the absence of femoral pulses constitute Leriche's syndrome. Rest pain is unusual with isolated aortoiliac disease unless distal disease coexists. Occasionally patients report a prolonged history of thigh and buttock claudication that recently becomes more severe. It is likely that this group has underlying aortoiliac disease that has progressed to acute occlusion of the terminal aorta. Others may present with "trash foot," which represents microembolization into the distal vascular bed (Fig. 23-53). Type II aortoiliac disease represents a more diffuse atherosclerotic progression that involves predominately the abdominal aorta with disease extension into the common iliac artery. This disease pattern affects approximately 25% patients with aortoiliac occlusive disease. Type III aortoiliac occlusive disease, which affects approximately 65% of patients with aortoiliac occlusive disease, is widespread disease that is seen above and below the inguinal ligament (Fig. 23-54). Patients with "multilevel" disease are older, more commonly male (with a male-to-female ratio of 6:1), and much more likely to have diabetes, hypertension, and associated atherosclerotic disease involving cerebral, coronary, and visceral arteries. Progression of the occlusive process is more likely in these patients than in those with localized aortoiliac disease. For these reasons, most patients with a type III pattern tend to present with symptoms of advanced ischemia and require revascularization for

Figure 23-53. Atherosclerotic disease involving the aortoiliac segment can result in microembolization of the lower leg circulation, resulting in trash foot or digital gangrene of toes.

Figure 23-54. Type III aortoiliac occlusive disease is a multilevel disease pattern that affects the aortoiliac segment as well as infrainguinal femoropopliteal vessels. Most patients with this disease pattern tend to present with symptoms of advanced ischemia and require revascularization for limb salvage rather than for claudication.

limb salvage rather than for claudication. These patients have a decreased 10-year life expectancy when compared to patients with localized aortoiliac disease.

The most commonly used classification system of iliac lesions has been set forth by the TransAtlantic Inter-Society Consensus (TASC) group with recommended treatment options. This lesion classification categorizes the extent of atherosclerosis and has suggested a therapeutic approach based on this classification (Table 23-14 and Fig. 23-55).[2] According to this consensus document, endovascular therapy is the treatment of choice for type A lesions, and surgery is the treatment of choice for type D lesions. Endovascular treatment is the preferred treatment for type B lesions, and surgery is the preferred treatment for good-risk patients with type C lesions. In comparison to the 2000 TASC document, the commission has not only made allowances for treatment of more extensive lesions, but also takes into account the continuing evolution of endovascular technology and the skills of individual interventionalists when stating that the patient's comorbidities, fully informed patient preference, and the local operator's long-term success rates must be considered when making treatment decisions for type B and type C lesions.[2,134]

General Treatment Considerations

There is no effective medical therapy for the management of aortoiliac disease, but control of risk factors may help slow progression of atherosclerosis. Patients should have hypertension, hyperlipidemia, and diabetes mellitus controlled. They should be advised to stop smoking. Most patients are empirically placed on antiplatelet therapy. A graduated exercise program may improve walking efficiency, endothelial function, and metabolic adaptations in skeletal muscle, but, there is usually minimal improvement in patients with aortoiliac disease who are treated with these measures. Failure to respond to exercise and/or drug therapy should prompt consideration for limb

Table 23-14

TASC classification of aortoiliac occlusive lesions

Type A lesions • Unilateral or bilateral stenoses of CIA • Unilateral or bilateral single short (≤3 cm) stenosis of EIA
Type B lesions • Short (≤3 cm) stenosis of infrarenal aorta • Unilateral CIA occlusion • Single or multiple stenosis totaling 3–10 cm involving the EIA not extending into the CFA • Unilateral EIA occlusion not involving the origins of internal iliac artery or CFA
Type C lesions • Bilateral CIA occlusions • Bilateral EIA stenoses 3–10 cm long not extending into the CFA • Unilateral EIA stenosis extending into the CFA • Unilateral EIA occlusion that involves the origins of internal iliac artery and/or CFA • Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac artery and/or CFA
Type D lesions • Infrarenal aortoiliac occlusion • Diffuse disease involving the aorta and both iliac arteries requiring treatment • Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA • Unilateral occlusions of both CIA and EIA • Bilateral occlusions of EIA • Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

AAA = abdominal aortic aneurysm; CFA = common femoral artery; CIA = common iliac artery; EIA = external iliac artery.

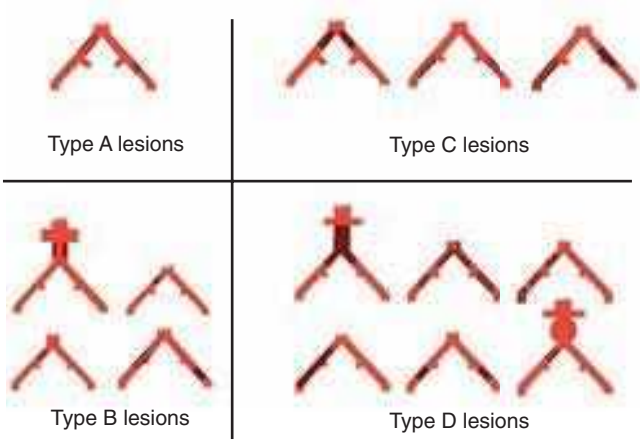

Figure 23-55. Schematic depiction of the TransAtlantic Inter-Society Consensus classification of aortoiliac occlusive lesions.

revascularization. Patients with buttock claudication and reduced or absent femoral pulses who fail to respond to exercise and drug therapy should be considered for revascularization because they are less likely than patients with more distal lesions to improve without concomitant surgical or endovascular intervention.

Surgical Reconstruction of Aortoiliac Occlusive Disease

Aortobifemoral Bypass. Surgical options for treatment of aortoiliac occlusive diseases consist of various configurations of aortobifemoral bypass grafting, various types of extra-anatomic bypass grafts, and aortoiliac endarterectomy. The procedure performed is determined by several factors, including anatomic distribution of the disease, clinical condition of the patient, and personal preference of the surgeon.

In most cases, aortobifemoral bypass is performed because patients usually have disease in both iliac systems. Although one side may be more severely affected than the other, progression does occur, and bilateral bypass does not complicate the procedure or add to the physiologic stress of the operation. Aortobifemoral bypass reliably relieves symptoms, has excellent long-term patency (approximately 70%–80% at 10 years), and can be completed with a tolerable perioperative mortality (2%–3%).[135]

Technical Considerations for Aortobifemoral Bypass. Both femoral arteries are initially exposed to ensure that they are adequate for the distal anastomoses. The abdomen is then opened in the midline, the small intestine is retracted to the right, and the posterior peritoneum overlying the aorta is incised. A retroperitoneal approach may be selected as an alternative in certain situations. This approach involves making a left flank incision and displacing the peritoneum and its contents to the right. Such an approach is contraindicated if the right renal artery is acutely occluded, since visualization from the left flank is very poor. Tunneling of a graft to the right femoral artery is also more difficult from a retroperitoneal approach, but can be achieved. The retroperitoneal approach has been reputed to be better tolerated than midline laparotomy for patients with multiple previous abdominal operations and with severe pulmonary disease. Further proposed advantages of the retroperitoneal approach include less gastrointestinal disturbance, decreased third space fluid losses, and ease with which the pararenal aorta can be accessed. There are randomized reports, however, that support and refute the superiority of this approach. A collagen-impregnated, knitted Dacron graft is used to perform the proximal aortic anastomosis, which can then be made in either an end-to-end or end-to-side fashion using 3-0 polypropylene suture. The proximal anastomosis should be made as close as possible to the renal arteries to decrease the incidence of restenosis from progression of the atherosclerotic occlusive process in the future.

An end-to-end proximal aortic anastomosis is necessary in patients with an aortic aneurysm or complete aortic occlusion extending up to the renal arteries (Fig. 23-56). Although in theory the end-to-end configuration allows for less turbulence and less chance of competitive flow with still patent host iliac vessels, there have not been consistent results to substantiate differences in patency between end-to-end and end-to-side grafts. Relative indications for an end-to-side proximal aortic anastomosis include the presence of large aberrant renal arteries, an unusually large IMA with poor back-bleeding suggesting

Figure 23-56. In an end-to-end proximal aortic anastomosis, the aorta is divided in half. The proximal end of the aorta is anastomosed to the end of a prosthetic graft, while the distal divided aortic stump is oversewn.

inadequate collateralization, and/or occlusive disease involving bilateral external iliac arteries. Under such circumstances, end-to-end bypass from the proximal aorta to the femoral level devascularizes the pelvic region because there is no antegrade or retrograde flow in the occluded external iliac arteries to supply the hypogastric arteries. As a result of the pelvic devascularization, there is an increased incidence of impotence, postoperative colon ischemia, buttock ischemia, and paraplegia secondary to spinal cord ischemia despite the presence of excellent femoral and distal pulses.

An end-to-side proximal aortic anastomosis can be associated with certain disadvantages, which include the potential for distal embolization when applying a partially occlusive aortic clamp (Fig. 23-57). Furthermore, the distal aorta often proceeds to total occlusion after an end-to-side anastomosis. There may also be a higher incidence of aortoenteric fistula following construction of end-to-side proximal anastomoses because the anterior projection makes subsequent tissue coverage and reperitonealization of the graft more difficult. The limbs of the

Figure 23-57. In an end-to-side aortic anastomosis, the end of a prosthetic graft is connected to the side of an aortic incision.

graft are tunneled through the retroperitoneum to the groin, where an end-to-side anastomosis is fashioned between the graft and the bifurcation of the CFA using 5-0 polypropylene suture. Endarterectomy or patch angioplasty of the profunda femoris may be required concurrently. Once the anastomoses have been fashioned and the graft thoroughly flushed, the clamps are removed and the surgeon carefully controls the degree of aortic occlusion until full flow is re-established. During this period, the patient must be carefully monitored for hypotension. Declamping hypotension is a complication of sudden restoration of aortic flow, particularly following prolonged occlusion. Once flow has been re-established, the peritoneum is carefully reapproximated over the prosthesis to prevent fistulization into the intestine.

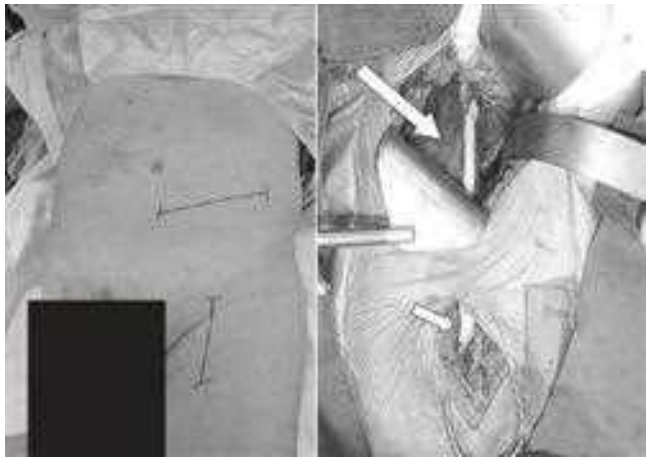
Despite the presence of multilevel disease in most patients, a properly performed aortobifemoral operation can provide arterial inflow and alleviate claudication symptoms in 70% to 80% of patients; however, 10% to 15% of patients will require simultaneous outflow reconstruction to address distal ischemia and facilitate limb salvage. The advantage of concomitant distal revascularization is avoidance of reoperation in a scarred groin. As a rule, if the profunda femoris can accept a 4-mm probe and if a No. 3 Fogarty embolectomy catheter can be passed distally for 20 cm or more, the PFA will be sufficient for outflow, and concomitant distal revascularization is not necessary.

Aortic Endarterectomy. Aortoiliac endarterectomy is rarely performed because it is associated with greater blood loss and greater sexual dysfunction and is more difficult to perform. Long-term patency is comparable with aortobifemoral grafting, and thus it remains a reasonable option in cases in which the risk of infection of a graft is excessive, because it involves no prosthetic tissue. Aortoiliac endarterectomy was useful when disease was localized to either the aorta or common iliac arteries; however, at present, aortoiliac PTA, stents, and other catheter-based therapies have become first-line treatment in this scenario. Endarterectomy should not be performed if the aorta is aneurysmal because of continued aneurysmal degeneration of the endarterectomized segment. If there is total occlusion of the aorta to the level of the renal arteries, aortic transection several centimeters below the renal arteries with thrombectomy of the aortic cuff followed by graft insertion is easier and more expeditious when compared to endarterectomy. Involvement of the external iliac artery makes aortic endarterectomy more difficult to complete because of decreased vessel diameter, increased length, and exposure issues. The ability to establish an appropriate endarterectomy plane is compromised due to the muscular and inherently adherent nature of the media in this location. There is a higher incidence of early thrombosis and late failure with extended aortoiliofemoral endarterectomy when compared to bypass grafting as a result of recurrent stenosis.

Axillofemoral Bypass. An axillofemoral bypass is an extra-anatomic reconstruction that derives arterial inflow from the axillary artery to the femoral artery. This is a treatment option for patients with medical comorbidities that prohibit an abdominal vascular reconstruction. It may be performed under local anesthesia and is used for limb salvage. Extra-anatomic bypasses have lower patency when compared to aortobifemoral and, therefore, are seldom recommended for claudication. Before performing this operation, the surgeon should check pulses and blood pressure in both arms to ensure that there is no obvious disease affecting flow through the axillary system. Angiography of the axillosubclavian vasculature is not necessary, but can be helpful if performed at the time of aortography. The axillary artery is exposed below the clavicle, and a 6- to 8-mm externally reinforced PTFE graft is tunneled subcutaneously down the lateral chest wall and lateral abdomen to the groin. It is anastomosed ipsilaterally at the CFA bifurcation into the SFA and PFA. A femorofemoral crossover graft using a 6- to 8-mm externally reinforced PTFE graft is then used to revascularize the opposite extremity if necessary. Reported patency rates over 5 years vary from 30% to 80%.[136] Paradoxically, although it is a less complex procedure than aortofemoral grafting, the mortality rate is higher (10%), reflecting the compromised medical status of these patients.[136]

Iliofemoral Bypass. One option for patients with unilateral occlusion of the distal common iliac or external iliac arteries is iliofemoral grafting (Fig. 23-58). Long-term patency is comparable to aortounifemoral bypass, and because the procedure can be performed using a retroperitoneal approach without clamping the aorta, the perioperative mortality is less.[136]

Femorofemoral Bypass. A femorofemoral bypass is another option for patients with unilateral stenosis or occlusion of the common or external iliac artery who have rest pain, tissue loss, or intractable claudication. The primary (assisted) patency at 5 years is reported to be 60% to 70%, and although this is inferior when compared to aortofemoral bypass, there are physiologic benefits, especially for patients with multiple comorbidities because it is not necessary to cross-clamp the aorta.[137] There are no studies supporting the superiority of unsupported or externally supported PTFE over Dacron for choice of conduit. The fear of the recipient extremity stealing blood from the extremity ipsilateral to the donor limb is not realized unless the donor iliac artery and donor outflow arteries are diseased.[137] Depending on the skills of the interventionalist or surgeon, many iliac lesions classified as TASC B, C, or D can now be addressed using an endovascular approach, thus obviating the need to perform a femorofemoral bypass. Additionally, femorofemoral bypass can be used as an adjuvant procedure after iliac inflow has been optimized with endovascular methods.



A B

Figure 23-58. **A.** Skin markings showing the incisions of an iliofemoral bypass. **B.** A prosthetic bypass graft is used for an iliofemoral artery bypass in which the proximal anastomosis is connected to the common iliac artery (*long arrow*) while the distal anastomosis is connected to the common femoral artery (*short arrow*).

Obturator Bypass. An obturator bypass is used to reconstruct arterial anatomy in patients with groin sepsis resulting from prior prosthetic grafting, intra-arterial drug abuse, groin neoplasm, or damage from prior groin irradiation. This bypass can originate from the common iliac artery, external iliac artery, or uninvolved limb of an aortobifemoral bypass. A conduit of Dacron, PTFE, or autologous vein is tunneled through the anteromedial portion of the obturator membrane to the distal SFA or popliteal artery. The obturator membrane must be divided sharply so as avoid injury to adjacent structures, and care must be taken to identify the obturator artery and nerve that pass posterolaterally. After the bypass is completed and the wounds isolated, the infected area is entered, the involved arteries are débrided to healthy tissue, and vascularized muscle flaps are mobilized to cover the ligated ends.[138] There have been varied results in terms of patency and limb salvage for obturator bypass. Some authors have reported 57% 5-year patency and 77% 5-year limb salvage rates, whereas others have shown a high rate of reinfection and low patency requiring reintervention.[138,139]

Thoracofemoral Bypass. The indications for thoracofemoral bypass are (a) multiple prior surgeries with a failed infrarenal aortic reconstruction and (b) infected aortic prosthesis. This procedure is more physiologically demanding than other extra-anatomic reconstructions because the patient must not only tolerate clamping the descending thoracic aorta but also performance of a left thoracotomy. The graft is tunneled to the left CFA from the left thorax posterior to the left kidney in the anterior axillary line using a small incision in the periphery of the diaphragm and an incision in the left inguinal ligament to gain access to the extraperitoneal space from below. The right limb is tunneled in the space of Retzius in an attempt to decrease kinking that is more likely to occur with subcutaneous, suprapubic tunneling. Thoracofemoral bypass has long-term patency comparable to aortofemoral bypass.

Complications of Surgical Aortoiliac Reconstruction

With current surgical techniques and conduits, early postoperative hemorrhage is unusual and occurs in 1% to 2%. It is usually the result of technical oversight or coagulation abnormality.[140] Acute limb ischemia occurring after aortoiliac surgery may be the result of acute thrombosis or distal thromboembolism. The surgeon can prevent thromboembolic events by (a) avoiding excessive manipulation of the aorta, (b) ensuring adequate systemic heparinization, (c) judicious placement of vascular clamps, and (d) thorough flushing prior to restoring blood flow. Acute thrombosis of an aortofemoral graft limb in the early perioperative period occurs in 1% to 3% of patients.[140] Thrombectomy of the graft limb is performed through a transverse opening in the hood of the graft at the femoral anastomosis. With this approach it is possible to inspect the interior of the anastomosis and pass embolectomy catheters distally to clear the superficial femoral and profunda arteries. Various complications may be encountered following aortoiliac or aortobifemoral reconstruction (Table 23-15).

Intestinal ischemia following aortic reconstruction occurs in approximately 2% of cases; however, with colonoscopy mucosal ischemia, which is a milder form, is seen more frequently. The surgeon can identify patients who require concomitant revascularization of the IMA, hypogastric arteries, or mesenteric arteries by examining the preoperative arteriogram for the presence of associated occlusive lesions in the celiac axis, the superior mesenteric arteries, or both. Likewise, patients with a patent and enlarged IMA or a history of prior colonic resections will benefit from IMA reimplantation.

Table 23-15

Perioperative complications of aortobifemoral bypass grafting

Medical Complications
• Perioperative myocardial infarction
• Respiratory failure
• Ischemia-induced renal failure
• Bleeding from intravenous heparinization
• Stroke
Procedure-Related Complications
Early
• Declamping shock
• Graft thrombosis
• Retroperitoneal bleeding
• Groin hematoma
• Bowel ischemia/infarction
• Peripheral embolization
• Erectile dysfunction
• Lymphatic leak
• Chylous ascites
• Paraplegia
Late
• Graft infection
• Anastomotic pseudoaneurysm
• Aortoenteric fistula
• Aortourinary fistula
• Graft thrombosis

In a comprehensive review of 747 patients who had aortoiliac operations for occlusive disease, secondary operations for late complications such as reocclusion, pseudoaneurysms, and infection were necessary in 21% over a 22-year period.[141] The most frequent late complication is graft thrombosis. Limb occlusion occurs in 5% to 10% of patients within 5 years of the index operation and in 15% to 30% of patients ≥10 years after the index operation.[140,141] Anastomotic pseudoaneurysms occur in 1% and 5% of femoral anastomoses in patients with aortofemoral grafts.[142] Predisposing factors to pseudoaneurysm formation include progression of degenerative changes within the host artery, excessive tension at the anastomosis, and infection.[142] Due to the associated risks of thrombosis, distal embolization, infection, and rupture, anastomotic aneurysms should be repaired expeditiously.

Infection following aortoiliac reconstruction is a devastating complication that occurs in 1% of cases. Femoral anastomoses of aortofemoral reconstructions and axillofemoral bypasses are prone to infection.[141,142] Use of prophylactic antibiotics and meticulous surgical technique are vital in preventing contamination of the graft at the time of implantation. If infection appears localized to a single groin, graft preservation and local measures such as antibiotic irrigation, aggressive debridement, and soft tissue coverage with rotational muscle flaps may prove successful. Most patients with infected aortoiliofemoral reconstructions usually require graft excision and revascularization via remote uncontaminated routes or the use of in situ replacement to clear the infective process and maintain limb viability. Aortoenteric

fistula and associated gastrointestinal hemorrhage are devastating complications, with a 50% incidence of death or limb loss. The incidence of aortoenteric fistula formation appears to be higher after an end-to-side proximal anastomosis, because it is more difficult to cover the prosthesis with viable tissue and avoid contact with the gastrointestinal tract with this configuration.[141,142] Treatment of aortoenteric fistula requires resection of all prosthetic material, closure of the infrarenal abdominal aorta, repair of the gastrointestinal tract, and revascularization by means of an extra-anatomic graft.

Endovascular Treatment for Aortic Disease

Although aortofemoral bypass surgery has excellent long-term patency and can be performed with low mortality rates, there are patients who are unable to withstand the physiologic stress of longer open procedures performed under general anesthesia, which require aortic cross-clamping and which are associated with greater blood loss. These patients are more suited to endovascular interventions despite the decreased durability and requirement for more frequent reinterventions.

Focal Aortic Stenosis. The endovascular technique used to treat infrarenal aortic stenoses is similar to that used for iliac artery disease. Bilateral CFA access is established followed by insertion of a 10-French sheath. The lesion is crossed using a hydrophilic wire and a supporting selective catheter and then changed for a stiffer guidewire. A self-expanding nitinol stent or a balloon-expandable stent mounted on a larger-caliber angioplasty balloon is implanted followed by adequate postdilation. At the physician's discretion, "kissing" stents, simultaneous bilateral proximal iliac stents, are deployed if the lesion is in the distal aorta in the proximity of the aortic bifurcation. The role of covered stents such as cuffs made for endoluminal AAA repair has not been rigorously studied. The aortic diameter should be sized with a calibrated catheter during the angiography or by preintervention CT scanning to avoid undersizing. Balloon size will range from 12 to 18 mm in most cases. A single stent is generally sufficient in most cases. Large Palmaz-type stents mounted on XXL balloons (Meditech, Westwood, MA) have been successfully used and may be inflated up to 25 mm in diameter if needed. Newer self-expanding stents have also been used. Concentric aortic stenosis may encroach upon the IMA, and coverage of this vessel may be unavoidable. Care should be taken to use low inflation pressures (5 mmHg) to minimize the risk of aortic rupture. Patient complaints of back or abdominal pain during balloon inflation should be taken seriously as they may suggest impending rupture. In case of a calcified small-caliber, hypoplastic aorta (≤12 mm, typically in female patients), it is recommend to use smaller diameter stents. To achieve clinical improvement, these patients can be recanalized to an aortic diameter of 8 or 9 mm. Distal embolization is one of the potential complications of endovascular treatment for aortic stenoses. Full heparinization, meticulous technique during wire and catheter manipulations, and primary stenting reduce the risk of this complication. Since calcified aortic stenoses are prone to rupture during dilation, it is recommended to be cognizant of the extent of the calcification with preoperative CT scans. In case of aortic rupture, as long as wire access has been maintained, an occlusion balloon can be inflated proximal to the disrupted segment to achieve hemostasis, and the rupture can be covered with a stent graft or repaired with open surgery.

Occlusive Lesions of the Aortic Bifurcation. Occlusive lesions are treated with the kissing balloon technique to avoid dislodging aortic plaque. Two angioplasty balloons of equal size are positioned across the ostia of the common iliac arteries, using a retrograde approach, and inflated. Simultaneous balloon dilatation at the origins of both common iliac arteries is advocated, even in the presence of unilateral lesion, to protect the contralateral common iliac artery from dissection or plaque embolization. Calcified lesions that typically occur at the aortic bifurcation are not amenable to balloon dilatation and frequently require that a distal aortic reconstruction be performed using "kissing stents." Fears that the proximal ends of the stents that extend into the distal aorta will become a nidus for thrombus formation or cause hemolysis have not been realized. The results are difficult to interpret because these bifurcation lesions are usually included in studies with iliac artery lesions. Patency rates for aortic bifurcation PTA range from 76% to 92% at 3 years.[143] The largest series reported to date includes 79 patients with aortic bifurcation lesions. The cumulative clinical success rate at a mean of 4 years was 93%.[144] In more recent years, stents have been used to reconstruct the aortic bifurcation.[145] The kissing stent technique is well-suited for orificial lesions. Technical success with kissing stents at the aortic bifurcation has been reported to be 95% to 100%.[145] In the largest series reported, the primary patency at 3 years was 79%.[146]

Endovascular Treatment for Iliac Artery Disease

Percutaneous Transluminal Angioplasty. PTA is most useful in the treatment of isolated iliac stenoses of less than 4 cm in length. When used for stenoses rather than occlusion, a 2-year patency of 86% can be achieved.[147] The complication rate is approximately 2%, consisting of distal embolization, medial dissection, and acute thrombosis.

Technical Considerations for Iliac Interventions. Crossing a high-grade stenosis or occlusion can be challenging in the iliac arteries. It is vital to image the lesion well because multiple views and use of the image intensifier will frequently uncover the anatomic reason for the difficulty. Frequently, the difficulty is the result of vessel tortuosity that cannot be appreciated on the original view. Use of an angled hydrophilic guidewire and an angled catheter can provide steering and add extra support for the wire trying to cross the lesion. Patience, persistence, and periodic reimaging will facilitate the crossing of a lesion in the great majority of cases. Guidewire traversal must be achieved for performance of endovascular iliac intervention. Over 90% of iliac occlusions can be passed with simple guidewire techniques. The preferred approach for recanalizing a common iliac artery occlusion is retrograde passage of devices from an ipsilateral CFA puncture because, in this manner, distance to the lesion is short and access is straighter. A stenosis is normally crossed using a combination of a soft-tip 0.035-inch guidewire (i.e., Bentson-type wire) or hydrophilic wire and a 5-French straight or selective catheter. One of the hazards of retrograde recanalization is that the guidewire stays in a subintimal location and cannot be redirected into the true lumen at the aortic bifurcation. There are several approaches that can be used to achieve re-entry of total chronic occlusions. Specialized catheters allow passage of a needle and guidewire across the intima distal to the occlusion. Intravascular ultrasound can be used for true lumen re-entry under fluoroscopic guidance. Another method of achieving true lumen re-entry involves performing the recanalization from an antegrade contralateral

CFA approach. A 4-French Berenstein catheter (Cordis Corp., Miami Lakes, FL) is used to probe the occlusion. The lesion can be crossed in most instances (5%–20% failure rate) with a hydrophilic guidewire or occasionally with its stiffer back end. As soon as the guidewire has crossed the obstruction and lies within the ipsilateral external iliac artery lumen, it is snared and partially pulled out of the ipsilateral CFA. A short catheter is then inserted in a retrograde fashion over the wire end into the abdominal aorta proximal to the lesion. The hydrophilic guidewire is then exchanged for a stiffer Amplatz (Boston Scientific, Natick, MA) guidewire to facilitate iliac stenting.

Obtaining arterial access when there are absent femoral pulsations is aided by the use of ultrasound guidance and "roadmap" imaging software, which is available on modern angiographic equipment. When the lesion is successfully crossed, balloons of an appropriate size and length are selected for the angioplasty. Most common iliac arteries will accommodate 8- to 10-mm diameter balloons, whereas most external iliac arteries will accommodate 6- to 8-mm diameter balloons. Inflation is performed with caution, especially if there is heavy calcification, and should be guided by patient discomfort, pressure gauge readings, and changes in balloon outline.

If guidewire traversal is straightforward, consideration should be given to the presence of an acute thrombosis that may benefit from catheter-directed thrombolysis. If guidewire traversal is challenging, it is unlikely that catheter-directed thrombolysis will be beneficial. Investigators have found that routine thrombolysis and balloon dilation of occluded arteries prior to stent placement are associated with an increased incidence of distal embolic events.[148] Stents should be placed after inadequate angioplasty. Stents are warranted when there is a greater than 30% residual stenosis, when there is a flow-limiting dissection, or when there is a pressure gradient of ≥5 mmHg across the treated segment.[149] Placement of stents can precipitate distal embolization in up to 10%, especially if lesions are friable and vulnerable to manipulation. Routine primary stent placement is not recommended because it has not been found to be superior to selective stenting in terms of outcomes or cost.[150]

Primary Stenting versus Selective Stenting in Iliac Arteries. Primary stenting rather than selective stenting should be considered for longer iliac lesions and for all TASC C and D lesions. The primary patency rates at 1, 2, and 3 years were 96%, 90%, and 72%, respectively, for longer lesions (>5 cm) that were primarily stented versus 46%, 46%, and 28%, respectively, with selective stenting.[150] Primary stenting is generally advocated for chronic iliac artery occlusions, recurrent stenosis after previous iliac PTA, and complex stenoses with eccentric, calcified, ulcerated plaques or plaques with spontaneous dissection. All of these lesions are prone to distal embolization during manipulation of wires and angioplasty balloons. Distal embolization with isolated PTA is not common for uncomplicated lesions, but can occur in up to 24% of cases, when treating ulcerated plaques, aortoiliac bifurcation lesions, or iliac occlusions.[150] It is believed that direct stent placement without predilation significantly reduces the risk of distal embolization by trapping potentially embologenic material between the arterial wall and the stent mesh. While PTA has demonstrated excellent results in focal stenoses of the abdominal aorta and iliacs, primary stenting in these locations is safe, improves patency rates, reduces the degree of restenosis when compared with PTA alone, and decreases the risk of distal embolization. Additional potential advantages of direct stenting include shorter procedural time and less radiation exposure. The Dutch Iliac Stent Trial has provided evidence that refutes the superiority of primary stenting over angioplasty alone.[151] Most interventionalists continue to perform angioplasty first and stent selectively for inadequate results. The approach to aortoiliac stenting is intuitive. Individual judgment and experience are important in the decision-making process, and there are lesions with unstable morphology such as long occlusions, ulceration, and dissection that warrant primary stenting.

Stent Graft Placement for Aortoiliac Interventions. Stent grafts have been used to treat complex iliac lesions in an attempt to exclude these sources of embolization. A recent report suggested that the use of stent grafts was beneficial for TASC C and D lesions.[152] Bosiers and colleagues published a series of 91 limbs with diseased iliacs that they treated with 107 stent grafts. They reported successful deployment in all patients without distal embolization or vessel rupture and a primary patency rate of 91.1% at 1 year.[153] The authors commented about their concerns of causing embolization during placement of the stent grafts and recommended that once an occlusion was traversed with the guidewire, to gently predilate with a 5-mm balloon, followed by smooth stent graft insertion into the newly created channel. The role of stent grafts in aortoiliac occlusive disease has not been fully elucidated yet.

Complications of Endovascular Aortoiliac Interventions

Iliac artery angioplasty is associated with a 2% to 4% major complication rate and 4% to 15% minor complication rate. Many of these minor complications are related to the arterial puncture site. The most frequent complications relate to access site cannulation. Hemorrhage can range from the more common access site hematoma to the rarer retroperitoneal and intraperitoneal hemorrhage. Distal embolization occurs in 2% to 10% of iliac PTA and stenting procedures.[140] Percutaneous catheter aspiration should be the initial treatment for calf vessel embolization, but, for larger emboli, such as those that lodge in the profunda femoris or common femoral arteries, surgical embolectomy may be required because the embolic material contains atherosclerotic plaque, which is not amenable to transcatheter aspiration or catheter-directed thrombolysis. The incidence of pseudoaneurysm formation at the puncture site is 0.5%. The treatment of choice for pseudoaneurysms >2 cm in diameter is percutaneous thrombin injection under ultrasound guidance. Arterial rupture may complicate the procedure in 0.3% of cases. Tamponade of the ruptured artery with an occlusion balloon should be performed, and a covered stent should be placed. In case of failure, surgical treatment is required.

Clinical Results Comparing Surgical and Endovascular Treatment of Aortoiliac Disease

The mortality risk of aortobifemoral bypass in patients with isolated, localized aortoiliac disease is relatively low, whereas for patients with concomitant atherosclerosis in coronary, carotid, and visceral vessels, mortality and morbidity are higher. For this reason, the cumulative long-term survival rate for patients receiving aortoiliac reconstruction remains 10 to 15 years less than anticipated for a normal age- and sex-matched population. Twenty-five percent to 30% of patients with concomitant atherosclerosis in other vascular distributions are dead within 5 years, and 50% to 60% will have died by 10 years.[142]

5▶

Compared with conventional aortobifemoral bypass, common iliac angioplasty was shown to have a 10% to 20% lower overall patency rate. It should be noted that these results were reported in early trials that used older generations of endovascular equipment. With continued progress and newer angioplasty balloons and stenting practices, more comparable outcomes are being reported. Review of the literature confirms that there is an 85% to 90% graft patency rate at 5 years and a 70% to 75% graft patency rate at 10 years after aortobifemoral reconstruction.[154] Due in part to factors including continued refinements in anesthetic management, intraoperative monitoring, and postoperative intensive care, low perioperative mortality rates for aortobifemoral bypass can be achieved commonly in today's clinical practice. The most recent systematic review and meta-analysis of 5358 patients who underwent direct open bypass or endovascular treatment for aortoiliac occlusive disease demonstrated superior durability for open bypass, although with longer length of stay and increased risk for complications and mortality, when compared to the endovascular approach.[155] In this study, poor preoperative runoff was greater in the open bypass group (50.0% vs. 24.6%). Mean length of hospital stay was 13 days for open bypass versus 4 days for endovascular treatment procedures. The open bypass group experienced more complications (18.0% vs. 13.4%) and greater 30-day mortality (2.6% vs. 0.7%). At 1, 3, and 5 years, pooled primary patency rates were greater in the open bypass group (94.8% vs. 86.0%, 86.0% vs. 80.0%, and 82.7% vs. 71.4%, respectively); the same was true for secondary patency (95.7% vs. 90.0%, 91.5 vs. 86.5%, and 91.0% vs. 82.5%, respectively).

Despite its lower long-term success, common iliac angioplasty is a useful procedure in patients with focal disease and mild symptoms in whom a major surgical revascularization is not justified. Angioplasty of the iliac vessels can be a useful adjunct to distal surgical bypass as well, increasing the success of distal revascularization and eliminating the risks associated with aortoiliac bypass. Thus, with long-term patency less than, but comparable to, open surgical bypass, and with more favorable morbidity rates, iliac angioplasty has become a well-accepted modality of treatment for iliac occlusive disease. Ideal iliac angioplasty lesions are nonocclusive and short. Patency after intervention is better when lesions occur in larger diameter vessels, when stenoses rather than occlusions are treated, when runoff vessels are patent, and when the indication for intervention is lifestyle-limiting claudication rather than critical limb ischemia.

Becker and colleagues estimated a 5-year patency rate of 72% in an analysis of 2697 cases of iliac angioplasty and noted a better patency (79%) in claudicants.[156] Less favorable results are obtained with long stenoses, external iliac stenoses, and tandem lesions. The reported technical and initial clinical success of balloon angioplasty in iliac artery stenoses exceeds 90% in most series, and the 5-year patency rates range from 54% to 92%.[157] The reported technical and initial clinical success of balloon angioplasty in iliac artery occlusions ranges from 78% to 98%, and the 3-year patency rates range from 48% to 85%.[157]

Factors reported to affect the patency of aortoiliac endovascular interventions adversely include quality of runoff vessels, severity of ischemia, and length of diseased segments treated. Likewise as vessel diameter and flow rates change, so do success rates after angioplasty. It was reported in the literature that location of the lesion at the external iliac artery adversely affects both primary and assisted-primary patency. Following angioplasty of the common iliac artery, patency rates were 81% and 52% at 1 and 6 years, respectively; whereas, after external iliac artery angioplasty, they were 74% and 48% at 1 and 4 years, respectively.[158] Although some literature supports location of the lesion in the external iliac artery as a factor that adversely affects both primary and assisted-primary patency, this has not been a universal finding.[158] Female patients are also reported to have lower patency rates than males following iliac PTA, with or without stent placement in the external iliac artery.[159]

Stenting of the iliac arteries provides a durable and curative treatment, with a 3-year patency rate of 41% to 92% for stenosis and a 3-year patency rate of 64% to 85% and 4-year patency rate of 54% to 78% for occlusions.[157] A meta-analysis of 2116 patients by Bosch and Hunink showed that aortoiliac stenting resulted in a 39% improvement in long-term patency compared to balloon angioplasty, despite the fact that complication rates and 30-day mortality rates did not differ significantly.[160] Park and colleagues presented long-term follow-up results in a cohort of patients with all four TASC types of iliac lesions. The authors presented primary patency rates of 87%, 83%, 61%, and 49% at 3, 5, 7, and 10 years, respectively, after the index intervention.[161] Leville and colleagues achieved primary and secondary patency rates of 76% and 90%, respectively, after 3 years, in a cohort of patients who received stents for iliac occlusions.[162] The authors postulated that endovascular treatment for iliac occlusive disease should be extended to type C and D lesions, because they observed no detectable differences between the four TASC classifications in terms of primary and secondary patency rates.[162] They concluded that presence of TASC C and D lesions should not preclude endovascular treatment and believe that endovascular attempts should be exhausted before open surgical repair of iliac occlusions is attempted because of the decreased perioperative morbidity and good midterm durability.

Not all results have been in favor of stenting, and at present, universal primary stenting cannot be recommended. Although stents are often used to improve the outcome of PTA, there is no general consensus that stenting should be mandatory in all iliac lesions. Complex, ulcerated iliac lesions with high embologenic potential or recanalized chronic iliac occlusions may be an exception. In the Dutch Iliac Stent Trial, primary stenting did not prove to be superior to iliac angioplasty and selective stenting. The researchers in this prospective randomized multicenter study concluded that balloon angioplasty with selective stenting had comparable 2-year patency rates with primary stenting (77% and 78%, respectively). It must be noted, however, that it was necessary to stent 43% of the patients in the PTA treatment group due to unsatisfactory angioplasty results.[151] The 5-year outcomes between the two groups were also similar, with 82% and 80% of the treated iliac segments remaining free of the need for new revascularization procedures after a mean follow-up of 5.6 ± 1.3 years.[151]

LOWER EXTREMITY ARTERIAL OCCLUSIVE DISEASE

The symptoms of lower extremity occlusive disease are classified into two large categories: acute limb ischemia (ALI) and chronic limb ischemia (CLI). Ninety percent of acute ischemia cases are either thrombotic or embolic. Frequently, sudden onset of limb-threatening ischemia may be the result of acute exacerbation of the pre-existing atherosclerotic disease. Chronic ischemia is largely due to atherosclerotic changes of the lower

extremity that manifest from asymptomatic to limb-threatening gangrene. As the population ages, the prevalence of chronic occlusive disease of the lower extremity is increasing, and it significantly influences lifestyle, morbidity, and mortality. In addition, multiple comorbid conditions increase risks of surgical procedures. Endovascular interventions become an important alternative in treating lower extremity occlusive disease. However, despite rapidly evolving endovascular technology, lower extremity endovascular intervention continues to be one of the most controversial areas of endovascular therapy.

Epidemiology

In a detailed review of the literature, McDaniel and Cronenwett concluded that claudication occurred in 1.8% of patients under 60 years of age, 3.7% of patients between 60 and 70 years of age, and 5.2% of patients over 70 years of age.[163] Leng and his colleagues scanned 784 subjects using ultrasound in a random sample of men and women age 56 to 77 years. Of the subjects who were scanned, 64% demonstrated atherosclerotic plaque.[164] However, a large number of patients had occlusive disease without significant symptoms. In a study by Schroll and Munck, only 19% of patients with peripheral vascular disease were symptomatic.[165] Using ABIs, Stoffers and colleagues scanned 3171 individuals between the ages of 45 and 75 and identified that 6.9% of patients had ABIs <0.95, only 22% of whom had symptoms.[166] In addition, they demonstrated that concomitant cardiovascular and cerebrovascular diseases were three to four times higher among the group with asymptomatic peripheral vascular diseases than those without peripheral vascular disease. Furthermore, they confirmed that 68% of all peripheral arterial obstructive diseases were unknown to the primary care physician, and this group mainly represented less advanced cases of atherosclerosis. However, among patients with an ABI ratio <0.75, 42% were unknown to the primary physicians.

Diagnostic Evaluation

The diagnosis of lower extremity occlusive disease is often made based on a focused history and physical examination and confirmed by the imaging studies. A well-performed physical examination often reveals the site of lesions by detecting changes in pulses, temperature, and appearances. The bedside ABIs using blood pressure cuff also aid in diagnosis. Various clinical signs and symptoms are useful to differentiate conditions of viable, threatened, and irreversible limb ischemia caused by arterial insufficiency (Table 23-16).

Noninvasive studies are important in documenting the severity of occlusive disease objectively. Ultrasound Dopplers measuring ABIs and segmental pressures are widely used in North America and Europe. Normal ABI is greater than 1.0. In patients with claudication, ABIs decrease to 0.5 to 0.9 and to even lower levels in patients with rest pain or tissue loss.[167] Segmental pressures are helpful in identifying the level of involvement. Decrease in segmental pressure between two segments indicates significant disease. Ultrasound duplex scans are used to identify the site of lesion by revealing flow disturbance and velocity changes. A meta-analysis of 71 studies by Koelemay and associates confirmed that duplex scanning is accurate for assessing arterial occlusive disease in patients suffering from claudication or critical ischemia with a accumulative sensitivity of 80% and specificity of over 95%.[168] Adding an ultrasound contrast agent further increases the sensitivity and specificity of ultrasound technology.[169] Other noninvasive imaging technologies, such as MRA and CTA, are rapidly evolving and gaining popularity in the diagnosis of lower extremity occlusive disease (Figs. 23-59 and 23-60).

Contrast angiography remains the gold standard imaging study. Using contrast angiography, interventionists can locate and size the anatomic significant lesions and measure the pressure gradient across the lesion, as well as plan for potential intervention. Angiography is, however, semi-invasive and should be confined to patients for whom surgical or percutaneous intervention is contemplated. Patients with borderline renal function may need to have alternate contrast agents, such as gadolinium or carbon dioxide, to avoid contrast-induced nephrotoxicity.

Differential Diagnosis

Arterial insufficiency frequently leads to muscle ischemic pain involving the lower extremity muscles, particularly during exercise. Intermittent claudication is pain affecting the calf and, less commonly, the thigh and buttock that is induced by exercise and relieved by rest. Symptom severity varies from mild to severe. Intermittent claudication occurs as a result of muscle ischemia during exercise caused by obstruction to arterial flow. Regarding the differential diagnosis of intermittent claudication, there are a variety of neurologic, musculoskeletal, and venous conditions that may produce symptoms of calf pain (Table 23-17). Additionally, various nonatherosclerotic conditions can also cause symptoms consistent with intermittent lower extremity claudication (Table 23-18). Nocturnal calf muscle spasms or night cramps are not indicative of arterial disease. They are common but are difficult to diagnose with certainty. Foot ulceration is not always the result of arterial insufficiency. Ischemic ulcers occur on the toes or lateral side of the foot and are painful. By comparison, venous ulcers, which are also common, occur above the

Table 23-16

Signs and symptoms of acute limb ischemia

	CATEGORY		
DESCRIPTION	VIABLE	THREATENED	IRREVERSIBLE
Clinical description	Not immediately threatened	Salvageable if promptly treated	Major tissue loss, amputation unavoidable
Capillary return	Intact	Intact, slow	Absent (marbling)
Muscle weakness	None	Mild, partial	Profound, paralysis (rigor)
Sensory loss	None	Mild, incomplete	Profound anesthetic
Arteriovenous Doppler finding	Audible	Inaudible or audible	Inaudible

medial malleolus, usually in an area with the skin changes of lipodermatosclerosis, and cause mild discomfort. Neuropathic ulcers are usually found on weight-bearing surfaces, have thick calluses, and are pain free. Ulcers may be the result of more than one etiology. Rest pain must be distinguished from peripheral neuropathy, which is prevalent in diabetic patients. Patients with diabetic neuropathy tend to have decreased vibration and position sense and decreased reflexes. Spinal stenosis causes pain that is exacerbated with standing and back extension.

Lower Extremity Occlusive Disease Classification

Lower extremity occlusive disease may range from exhibiting no symptoms to limb-threatening gangrene. There are two major classifications developed based on the clinical presentations.

The Fontaine classification uses four stages: Fontaine I is the stage when patients are asymptomatic; Fontaine II is when they have mild (IIa) or severe (IIb) claudication; Fontaine III is when they have ischemic rest pain; and Fontaine IV is when patients suffer tissue loss, such as ulceration or gangrene (Table 23-19).[170]

The Rutherford classification has four grades (0–III) and seven categories (0–6). Asymptomatic patients are classified into category 0; claudicants are stratified into grade I and divided into three categories based on the severity of the symptoms; patients with rest pain belong to grade II and category 4; and patients with tissue loss are classified into grade III and categories 5 and 6 based on the significance of the tissue loss.[2] These clinical classifications help to establish uniform standards in evaluating and reporting the results of diagnostic measurements and therapeutic interventions (Table 23-19).

The most clinically useful classification of lower extremity atherosclerotic disease should be based on the morphologic character of the lesions. The TASC taskforce published a guideline separating lower extremity arterial diseases into

Table 23-17

Differential diagnosis of intermittent claudication

CONDITION	LOCATION OF PAIN OR DISCOMFORT	CHARACTERISTIC DISCOMFORT	ONSET RELATIVE TO EXERCISE	EFFECT OF REST	EFFECT OF BODY POSITION	OTHER CHARACTERISTICS
Intermittent claudication (calf)	Calf muscles	Cramping pain	After same degree of exercise	Quickly relieved	None	Reproducible
Chronic compartment syndrome	Calf muscles	Tight, bursting pain	After much exercise (e.g., jogging)	Subsides very slowly	Relief speeded by elevation	Typically heavy-muscled athletes
Venous claudication	Entire leg, but usually worse in thigh and groin	Tight, bursting pain	After walking	Subsides slowly	Relief speeded by elevation	History of iliofemoral deep venous thrombosis, signs of venous congestion, edema
Nerve root compression (e.g., herniated disk)	Radiates down leg, usually posteriorly	Sharp lancinating pain	Soon, if not immediately after onset	Not quickly relieved (also often present at rest)	Relief may be aided by adjusting back position	History of back problems
Symptomatic Baker's cyst	Behind knee, down calf	Swelling, soreness, tenderness	With exercise	Present at rest	None	Not intermittent
Intermittent claudication (hip, thigh, buttock)	Hip, thigh, buttocks	Aching discomfort, weakness	After same degree of exercise	Quickly relieved	None	Reproducible
Hip arthritis	Hip, thigh, buttocks	Aching discomfort	After variable degree of exercise	Not quickly relieved (and may be present at rest)	More comfortable sitting, weight taken off legs	Variable, may relate to activity level, weather changes
Spinal cord compression	Hip, thigh, buttocks (follows dermatome)	Weakness more than pain	After walking or standing for same length of time	Relieved by stopping only if position changed	Relief by lumbar spine flexion (sitting or stooping forward) pressure	Frequent history of back problems, provoked by increased intra-abdominal pressure
Intermittent claudication (foot)	Foot, arch	Severe deep pain and numbness	After same degree of exercise	Quickly relieved	None	Reproducible
Arthritic, inflammatory process	Foot, arch	Aching pain	After variable degree of exercise	Not quickly relieved (and may be present at rest)	May be relieved by not bearing weight	Variable, may relate to activity level

Table 23-18

Nonatherosclerotic causes of intermittent claudication

- Aortic coarctation

- Popliteal entrapment
- Primary vascular tumors
- Pseudoxanthoma elasticum
- Remote trauma or radiation injury
- Takayasu's disease
- Thromboangiitis obliterans

femoropopliteal and infrapopliteal lesions (Table 23-20). This guideline is particularly useful in determining intervention strategies based on the disease classifications. Based on the guideline, femoropopliteal lesions are divided into four types: A, B, C, and D. Type A lesions are single focal lesions less than 3 cm in length and do not involve the origins of the SFA or the distal popliteal artery. Type B lesions are single lesions 3 to 5 cm in length not involving the distal popliteal artery or multiple or heavily calcified lesions less than 3 cm in length. Type C lesions are multiple stenoses or occlusions greater than 15 cm in length or recurrent stenoses or occlusions that need treatment after two endovascular interventions. Type D lesions are those with complete occlusion of CFA, SFA, or popliteal artery.[2]

In a similar fashion, infrapopliteal arterial diseases are classified into four types based on TASC guideline (Fig. 23-61). Type A lesions are single lesions less than 1 cm in length not involving the trifurcation. Type B lesions are multiple lesions less than 1 cm in length or single lesions shorter than 1 cm involving the trifurcation. Type C lesions are lesions that extensively involve trifurcation or 1- to 4-cm stenotic or 1- to 2-cm occlusive lesions. Type D lesions are occlusions longer than 2 cm or diffuse lesions.[2]

Etiology of Acute Limb Ischemia

ALI is defined as sudden loss of limb perfusion, and the term is applicable up to 2 weeks after an initiating event. While the instances of acute leg ischemia caused by emboli have decreased due to more effective treatment of rheumatic fever and atrial fibrillation, the incidence of thrombotic acute leg ischemia has increased. Even with the extensive use of newer endovascular techniques including thrombolysis, most published series report a 10% to 30% 30-day amputation rate.[2] The short-term mortality of patients presenting with acute ischemia is 15% to 20%. The most common etiologies of ALI include embolism, native vessel thrombosis, reconstruction thrombosis, trauma, and complications of peripheral aneurysm. Most cases of lower extremity ALI are the result of thrombosis of a prosthetic conduit. This stems from increased use of prosthetic conduits to address CLI.

Presenting symptoms in ALI are pain and loss of sensory or motor function. The abruptness and time of onset of the pain, its location and intensity, and change in severity over time should all be taken into consideration. The duration and intensity of the pain and presence of motor or sensory changes are very important in clinical decision making and urgency of revascularization. Thrombolysis may be less effective for thrombosis of ≥2 weeks in duration compared with acute thrombosis.[171]

Arterial Embolism. The heart is the most common source of distal emboli, which accounts for more than 90% of peripheral arterial embolic events. Atrial fibrillation is the most common source. Sudden cardioversion results in the dilated noncontractile atrial appendage regaining contractile activity, which can dislodge the contained thrombus. Other cardiac sources include mural thrombus overlying a myocardial infarction or thrombus forming within a dilated left ventricular aneurysm. Mural thrombi can also develop within a ventricle dilated by cardiomyopathy. Emboli that arise from a ventricular aneurysm or from a dilated cardiomyopathy can be very large and can lodge at the aortic bifurcation (saddle embolus), thus rendering both legs ischemic. Diseased valves are another source of distal embolization. Historically, this occurred as a result of rheumatic heart disease. Currently, subacute endocarditis and acute bacterial endocarditis are the more common causes. Infected emboli can seed the recipient vessel wall, creating mycotic aneurysms.

Table 23-19

Classification of peripheral arterial disease based on the Fontaine and Rutherford classifications

FONTAINE CLASSIFICATION		RUTHERFORD CLASSIFICATION		
STAGE	CLINICAL	GRADE	CATEGORY	CLINICAL
I	Asymptomatic	0	0	Asymptomatic
IIa	Mild claudication	I	1	Mild claudication
IIb	Moderate to severe claudication	I	2	Moderate claudication
		I	3	Severe claudication
III	Ischemic rest pain	II	4	Ischemic rest pain
IV	Ulceration or gangrene	III	5	Minor tissue loss
		III	6	Major tissue loss

Table 23-20

TransAtlantic Inter-Society Consensus classification of femoral popliteal occlusive lesions

Type A lesions • Single stenosis ≤10 cm in length • Single occlusion ≤5 cm in length
Type B lesions • Multiple lesions (stenoses or occlusions), each ≤5 cm • Single stenosis or occlusion ≤15 cm not involving the infrageniculate popliteal artery • Single or multiple lesions in the absence of continuous tibial vessels to improve inflow for a distal bypass • Heavily calcified occlusion ≤5 cm in length • Single popliteal stenosis
Type C lesions • Multiple stenoses or occlusions totaling >15 cm with or without heavy calcification • Recurrent stenoses or occlusions that need treatment after two endovascular interventions
Type D lesions • Chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery) • Chronic total occlusion of popliteal artery and proximal trifurcation vessels

CFA = common femoral artery; SFA = superficial femoral artery.

An electrocardiogram (ECG) will diagnose atrial fibrillation. A transthoracic or transesophageal echocardiogram should be performed looking for a cardiac source. It is important to seek other sources of the embolus using CT scanning of the descending thoracic and abdominal aorta. More unusual sources include mural thrombus from an aortic aneurysm, and occasionally, idiopathic arterial-to-arterial thrombus occurs, usually from thrombus that has formed in an atherosclerotic aortic arch or descending thoracic aorta. The presence of mobile plaque on transesophageal echocardiography is suggestive of this source.

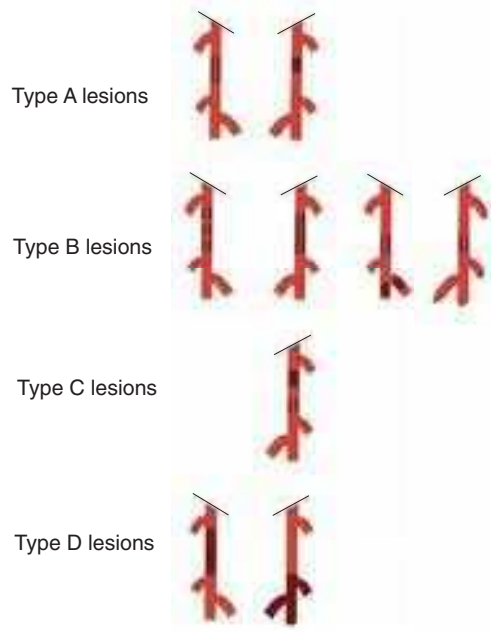

Figure 23-61. Schematic depiction of TransAtlantic Inter-Society Consensus classification of femoral popliteal occlusive lesions.

Paradoxical embolus occurs when a patient has a patent foramen ovale and an embolus from a deep venous thrombosis crosses through the atrial defect into the left side of the heart and passes into the peripheral circulation. This is diagnosed using a bubble echocardiography, in which air bubbles introduced into the venous circulation can be seen traversing the septal defect.

Arterial Thrombosis. Thrombosis can occur in native arteries and in arterial reconstructions. Patients with thrombosed arterial segments often have an underlying atherosclerotic lesion at the site of thrombosis or aneurysmal degeneration with mural thrombosis. It is important to obtain a history, determine risk factors for atherosclerosis and hypercoagulable status, and examine the contralateral extremity for circulatory problems. Patients with thrombosis of prior arterial reconstructions have limb incisions from previous surgery, and graft occlusion can be confirmed with duplex imaging.

Clinical Manifestations of Acute Limb Ischemia

Acute lower extremity ischemia manifests with the "five Ps": *p*ain, *p*allor, *p*aresthesias, *p*aralysis, and *p*ulselessness, to which some add a sixth "P"—*p*oikilothermia or "*p*erishing cold." Pain is the usual symptom that causes a patient to present to the emergency room. The most common location for an embolus to lodge in the leg is at the common femoral bifurcation. Typically a patient will complain of foot and calf pain. Pulses are absent, and there may be diminution of sensation. Inability to move the affected muscle group is a sign of very severe ischemia and necessitates urgent revascularization. During evaluation of the affected extremity, it is important to compare findings with the contralateral limb. Clinical evaluation is extremely important in determining the etiology and location of the obstruction. One of the most important pieces of information to obtain is whether the patient has had prior vascular procedures or if there is a history of lower extremity claudication. Either of these features suggests pre-existing vascular disease, renders revascularization more complicated, and usually mandates angiography to permit surgical planning. On the contrary, in a patient with no history suggestive of prior vascular disease, the etiology is most likely embolic, and simple thrombectomy is more likely to be successful.

Absent bilateral femoral pulses in a patient with bilateral lower extremity ischemia is most likely due to saddle embolus to the aortic bifurcation. A palpable femoral pulse and absent popliteal and distal pulses may either be due to distal common femoral embolus (the pulse being palpable above the level of occlusion) or embolus to the superficial femoral or popliteal arteries. Typically, emboli lodge at arterial bifurcations where they are trapped due to sudden reductions in arterial diameter. A popliteal trifurcation embolus will present with calf ischemia and absent pedal pulses, possibly with a popliteal pulse present. The finding of palpable contralateral pulses and the absence of ipsilateral pulses in the acutely ischemic leg are suggestive of an embolus, irrespective of presence of Doppler signals. Arteriography is not mandatory in patients without antecedent history suggestive of vascular disease; nevertheless, all patients should be positioned on the operating room table in such a way that fluoroscopic access to the entire inflow and outflow tract is possible if necessary.

The main question to be answered by the history and physical examination is the severity of the ALI, which is the major consideration in early management decisions. Patients with ALI should be evaluated in a fashion that considers the severity and duration of ischemia at the time of presentation. Ideally, all patients with acute ischemia should be investigated with imaging, especially if there is an antecedent vascular reconstruction; however, the clinical condition and access to resources must guide further investigations.[2] Unnecessary delays can result in amputation. Arteriography, if it can be performed in a timely fashion, is an excellent modality for localizing obstructions and deciding which type of intervention (endovascular, embolectomy, or bypass) patients will benefit more from. One of the goals of treatment for ALI is to prevent thrombus propagation; therefore, expedient anticoagulation with heparin is indicated as soon as the diagnosis is suspected.

Treatment Considerations for Acute Limb Ischemia

In the absence of any significant contraindication, the patient with an ischemic lower extremity should be immediately anticoagulated. This will prevent propagation of the clot into unaffected vascular beds. Intravenous fluid should be started and a Foley catheter inserted to monitor urine output. Baseline labs should be obtained and creatinine levels noted. A hypercoagulable workup should be performed prior to initiation of heparin if there is sufficient suspicion. According to results from randomized trials, there is no clear superiority for thrombolysis over surgery in terms of 30-day limb salvage or mortality. Access to each treatment option is a major issue in the decision-making process, as time is often critical. National registry data from the United States reveal that surgery is used three- to five-fold more frequently than thrombolysis. Three randomized studies have investigated the role of catheter-directed thrombolytic therapy in the treatment of ALI.[172]

Endovascular Treatment

The potential to reduce mortality and morbidity while achieving limb salvage is the impetus that makes thrombolysis preferable to open surgery as first-line treatment in patients with ALI (class I and IIa). Advantages of thrombolytic therapy over balloon embolectomy include the reduced endothelial trauma and potential for more gradual and complete clot lysis in branch vessels usually too small to access by embolectomy balloons. It is hoped that the more gradual clot dissolution with thrombolysis may decrease the incidence of reperfusion injury that is encountered after open surgical procedures where rapid return of blood flow may precipitate compartment syndrome. Skeletal muscle tissue appears to be most vulnerable to ischemia. Pathophysiologic studies reveal that irreversible damage to muscle tissue starts after 3 hours of ischemia and is nearly complete at 6 hours. Progressive microvascular damage appears to follow rather than precede skeletal muscle tissue damage. The more severe the cellular damage, the greater are the microvascular changes. When the musculature and microvasculature are severely damaged, amputation rather than attempts at revascularization may be the most prudent course to prevent wash-out of toxic by-product from the ischemic limb into the systemic circulation. The mortality rate associated with reperfusion syndrome is high, because of the development of concomitant adult respiratory distress syndrome, shock, disseminated intravascular coagulation, and renal failure.

Table 23-21

Contraindications to thrombolytic therapy

Absolute contraindications
Established cerebrovascular events (including transient ischemic attack) within last 2 months
Active bleeding diathesis
Recent (<10 days) gastrointestinal bleeding
Neurosurgery (intracranial or spinal) within last 3 months
Intracranial trauma within last 3 months
Intracranial malignancy or metastasis
Relative major contraindications
Cardiopulmonary resuscitation within last 10 days
Major nonvascular surgery or trauma within last 10 days
Uncontrolled hypertension (>180 mmHg systolic or >110 mmHg diastolic)
Puncture of noncompressible vessel
Intracranial tumor
Recent eye surgery
Minor contraindications
Hepatic failure, particularly with coagulopathy
Bacterial endocarditis
Pregnancy
Diabetic hemorrhagic retinopathy

Patients with small-vessel occlusion are poor candidates for surgery because they lack distal target vessels to use for bypass. These patients should be offered a trial of thrombolysis, unless they have contraindications to thrombolysis or their ischemia is so severe that the time needed to achieve adequate lysis is considered too long. The major contraindications of thrombolysis are recent stroke, intracranial primary malignancy, brain metastases, or intracranial surgical intervention. Relative contraindications for performance of thrombolysis include renal insufficiency, allergy to contrast material, cardiac thrombus, diabetic retinopathy, coagulopathy, and recent arterial puncture or surgery (Table 23-21).

Advances in clot removal techniques with percutaneous mechanical thrombectomy and thromboaspiration may extend the applicability of this intervention to patients with more advanced degrees of ALI (class IIb) and contraindications to thrombolysis. Several thrombectomy devices have received FDA approval for acute lower extremity arterial thrombosis. The utility of these thrombectomy devices is that they can be used as standalone therapy when there are contraindications for thrombolytic therapy. Additionally, these thrombectomy devices can be used in conjunction with thrombolytic agents, for pharmacomechanical thrombectomy, to enhance clot lysis and to limit the doses and time required for thrombolysis.[173,174]

Surgical Treatment

Embolectomy. When a decision is made to proceed with open surgical intervention, the abdomen, contralateral groin, and entire lower extremity are prepped in the field. The groin is opened through a vertical incision, exposing the CFA and its bifurcation. Frequently, the location of the embolus at the femoral bifurcation is readily apparent by the presence of a palpable proximal femoral pulse, which disappears distally. The artery is clamped and opened transversely over the bifurcation.

Thrombus is extracted by passing a Fogarty balloon embolectomy catheter. Good back-bleeding and antegrade bleeding suggest that the entire clot has been removed. Embolic material often forms a cast of the vessel and is sent for culture and histologic examination. Completion angiography is advisable to ascertain the adequacy of clot removal. The artery is then closed and the patient fully anticoagulated.

When an embolus lodges in the popliteal artery, in most cases it can be extracted via a femoral incision using the techniques previously described. A femoral approach is preferred because the larger diameter of the femoral artery results in decreased likelihood of arterial compromise when the arteriotomy is closed. The disadvantage with using the femoral approach for embolectomy is the greater difficulty involved in directing the embolectomy catheter into each of the infrapopliteal arteries. Use of fluoroscopic imaging and an over-the-wire thrombectomy catheter can overcome this problem. Alternatively, use of a separate incision to expose the popliteal bifurcation may be necessary to achieve a complete thrombectomy.

A more complex situation arises when a patient has antecedent peripheral vascular disease and in situ thrombosis develops on top of pre-existing atheroma because, frequently, embolectomy catheters will not pass through these occlusions. Similarly, when a bypass graft fails, it is usually due to progression of atheroma proximal or distal to the graft anastomoses or to intrinsic stenoses that develop within a vein graft. In these scenarios, expeditious angiography is useful to determine the extent of the occlusion, to search for inflow and distal outflow vessels, and to decide whether thrombolysis or surgery will be the better intervention. Although the surgeon's preference tends to dictate the approach selected, the decision is based on the presence or absence of good target vessels and availability of a suitable bypass conduit. If there are good distal vessels and the saphenous vein is suitable, surgical bypass is recommended, because it is fast, durable, and reliable. In the absence of a good distal target and saphenous vein, or in a patient at high risk for surgery, lysis is recommended.

Bypass Graft Thrombectomy. Bypass thrombectomy is more likely to succeed with prosthetic bypasses. Bypass graft revision or replacement is more appropriate for acute vein graft failures because they are less likely to respond to thrombolysis and require some type of revision, such as valve lysis, interposition, or extension. Thrombectomy of autogenous grafts is prone to failure unless an anatomic cause for failure such as a retained valve or unligated side branch is found and corrected. The performance of a fasciotomy to circumvent reperfusion injury/compartment syndrome is an important consideration.

Complications Related to Treatment for Acute Limb Ischemia

Adverse events related to catheter-directed thrombolysis are primarily related to bleeding complications. The overall risk of hemorrhagic stroke from a thrombolysis procedure has been reported to be 1% to 2.3%, with 50% of hemorrhagic complications occurring during the thrombolytic procedure.[175] Hematoma at the vascular puncture site has been reported in 12% to 17% of cases. Gastrointestinal bleeding is reported in 5% to 10% of cases. Hematuria following thrombolysis is uncommon and should prompt a search for urinary tumors. Hemorrhage requiring transfusion can occur in approximately 25% of patients undergoing thrombolysis.[167,172] Lytic agents are absolutely contraindicated in patients with intracranial surgery, intracranial hemorrhage within the last 3 months, or any active bleeding. Most bleeding complications occur at the arterial puncture sites, but concealed retroperitoneal bleeding is possible. The most feared complication that patients can sustain is intracerebral hemorrhage. Older patients may be more susceptible to this complication, and thus many interventionalists are extremely reticent to use thrombolysis in patients older than 80 years of age.

Patients who are treated for acute ischemia are susceptible to two major complications following revascularization: reperfusion and compartment syndromes. Other procedure-related complications include arterial rethrombosis, recurrent embolization, and arterial injuries secondary to the balloon catheter manipulations.

Reperfusion of the ischemic limb is variable in its physiologic effects and directly relates to the severity and extent of the ischemia. Patients with a saddle embolus of the aortic bifurcation and severely ischemic limbs may develop the full-blown "reperfusion syndrome," whereas patients with minimal muscle ischemia who are reperfused in a timely fashion essentially develop no effects. Many patients with ALI have severe underlying cardiac disease and are unable to tolerate even short ischemic periods. Complications occurring after revascularization of the lower extremity and causes of recurrent thrombosis are listed in Table 23-22.

Compartment syndrome occurs after prolonged ischemia is followed by reperfusion. The capillaries leak fluid into the interstitial space in the muscles, which are enclosed within a nondistensible fascial envelope. When the pressure inside the compartment exceeds the capillary perfusion pressure, nutrient flow ceases and progressive ischemia occurs, even in the presence of peripheral pulses. Consequently, every patient who has sustained an ischemic event and is reperfused is monitored for compartment syndrome, which is characterized by excessive pain in the compartment, pain on passive stretching of the compartment, and sensory loss due to nerve compression of the nerves coursing though the compartment (Table 23-23 and Fig. 23-62). The most commonly affected compartment is the anterior compartment in the leg. Numbness in the web space between the first and second toes is diagnostic due to compression of the deep peroneal nerve. Compartment pressure is measured by inserting an arterial line into the compartment and recording the pressure. Although controversial, pressures greater than 20 mmHg are an indication for fasciotomy. Compartment pressures are relieved in the leg by medial and lateral incisions. Through

the medial incision, long openings are then made in the fascia of the superficial and deep posterior compartments. Through the lateral incision, the anterior and peroneal compartments are opened. Both skin and fascial incisions should be of adequate length to ensure full compartment decompression. Laboratory evidence of rhabdomyolysis is seen in 20% of cases. The myoglobin from damaged muscle precipitates in kidney tubules and causes acute tubular necrosis. Alkalinization of urine increases the solubility of myoglobin, thus preventing it from crystallizing in the tubules. In addition to alkalinization, therapy consists of forced saline diuresis and removal of the source of dead muscle that is releasing the myoglobin.

Clinical Manifestations of Chronic Limb Ischemia

The term CLI is reserved for patients with objectively proven arterial occlusive disease and symptoms lasting for more than 2 weeks. Symptoms include rest pain and tissue loss, such as ulceration or gangrene (Table 23-24). The diagnosis should be corroborated with noninvasive diagnostic tests, such as the ABI, toe pressures, and transcutaneous oxygen measurements. Ischemic rest pain most commonly occurs below an ankle pressure of 50 mmHg or a toe pressure less than 30 mmHg.[2] Ulcers are not always of an ischemic etiology (Table 23-25). In many instances, there are other etiologic factors (traumatic, venous, or neuropathic) that are contributory, but it is underlying peripheral arterial disease that may be responsible for delayed or absent healing (Fig. 23-63). Healing of ulcers requires an inflammatory response and greater perfusion than is required to support intact skin and underlying tissues. As a result, the ankle and toe pressure levels needed for healing are higher than the pressures seen with ischemic rest pain. For patients with ulcers or gangrene, the presence of CLI is suggested by an ankle pressure less than 70 mmHg or a toe systolic pressure less than 50 mmHg.[2] It is important to understand that there is no definite consensus regarding the vascular hemodynamic parameters required to make the diagnosis of CLI.

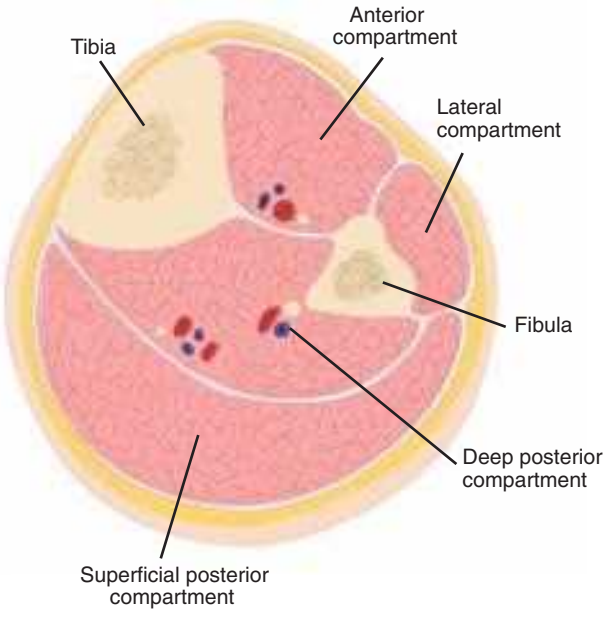

Figure 23-62. Schematic illustration of fascial compartments of the lower extremity.

One of the most common sites for occlusive disease is in the distal SFA as it passes deep through the adductor canal. It may be that the entrapment by the adductor hiatus prevents the compensatory dilation that occurs in atherosclerotic vessels. Stenoses, which develop here, progress to occlusion of the distal third of the SFA (Fig. 23-64). When distal SFA occlusion develops slowly, it may be totally asymptomatic because of development of collaterals from the proximal SFA, or the PFA can bypass the occlusion and reconstitute the popliteal artery. Symptom development is a function of the extent of occlusion, adequacy of collaterals, and the activity level of the patients.

Presenting symptoms of femoropopliteal occlusive disease are broadly classified into two types: limb-threatening and non–limb-threatening ischemia. Claudication is non–limb-threatening, while rest pain, ulceration, and gangrene are limb-threatening and warrant urgent intervention. Occlusive disease of the femoral artery may be isolated or occur in conjunction with multilevel disease that involves both the aortoiliac segment and the tibial vessels. Symptoms in patients with multilevel disease are more severe than in those with single-level disease. Pain from isolated SFA and popliteal occlusion typically manifests as calf claudication. Cramping pain develops in the calf on ambulation, occurs at a reproducible distance, and is relieved by rest. Activities such as climbing stairs or going uphill also exacerbate the pain. Many patients report worsening symptoms during cold

Table 23-24

Clinical categories of chronic limb ischemia

GRADE	CATEGORY	CLINICAL DESCRIPTION	OBJECTIVE CRITERIA
0	0	Asymptomatic—no hemodynamically significant occlusive disease	Normal treadmill or reactive hyperemia test
	1	Mild claudication	Able to complete treadmill exercise[a]; AP after exercise >50 mmHg but at least 20 mmHg lower than resting value
I	2	Moderate claudication	Between categories 1 and 3
	3	Severe claudication	Cannot complete standard treadmill exercise[a] *and* AP after exercise <50 mmHg
II[b]	4	Ischemic rest pain	Resting AP <40 mmHg, flat or barely pulsatile ankle or metatarsal PVR; TP <30 mmHg
III[b]	5	Minor tissue loss—nonhealing ulcer, focal gangrene with diffuse pedal ischemia	Resting AP <60 mmHg, ankle or metatarsal PVR flat or barely pulsatile; TP <40 mmHg
	6	Major tissue loss—extending above TM level, functional foot no longer salvageable	Same as category 5

[a]Five minutes at 2 miles per hour on a 12% incline of treadmill exercise.
[b]Grades II and III, categories 4, 5, and 6, are encompassed by the term chronic *critical* ischemia.
AP = ankle pressure; PVR = pulse volume recording; TM = transmetatarsal; TP = toe pressure.

weather. It is important to evaluate whether the symptoms are progressive or static. In greater than 70% of patients, the disease is stable, particularly with risk factor modification.

Progression of the underlying atherosclerotic process is more likely to occur in patients with diabetes, those who continue to smoke, and those who fail to modify their atherosclerotic risk factors. In comparison, rest pain is constant, and usually occurs in the forefoot across the metatarsophalangeal joint. It is worse at night and requires placing the foot in a dependent position to improve symptoms. Patients may report that they either sleep in a chair or hang the foot off the side of the bed. The pain is severe and relentless, even with narcotics. Ischemic ulceration most commonly involves the toes. Any toe can be affected. Occasionally ulcers develop on the dorsum of the foot. Ulceration can occur in atypical positions in an ischemic foot from trauma such as friction from poorly fitting shoes. Injury to a foot with borderline ischemia can convert an otherwise stable situation into one that is limb-threatening. The initial development of gangrene commonly involves the digits. As with all vascular patients, it is important to evaluate their risk factors, intercurrent cardiac diseases, and any prior vascular interventions.

Table 23-25

Symptoms and signs of neuropathic ulcer versus ischemic ulcer

NEUROPATHIC ULCER	ISCHEMIC ULCER
Painless	Painful
Normal pulses	Absent pulses
Regular margins, typically punched-out appearance	Irregular margin
Often located on plantar surface of foot	Commonly located on toes, glabrous margins
Presence of calluses	Calluses absent or infrequent
Loss of sensation, reflexes, and vibration	Variable sensory findings
Increased in blood flow (arteriovenous shunting)	Decreased in blood flow
Dilated veins	Collapsed veins
Dry, warm foot	Cold foot
Bony deformities	No bony deformities
Red or hyperemic in appearance	Pale and cyanotic in appearance

Treatment Considerations for Chronic Limb Ischemia

Patients with vascular diseases frequently have complicated medical comorbidities. Careful patient evaluation and selection should be performed for any peripheral arterial vascular procedure. The fundamental principle is to assess not only the surgical risk from the peripheral arterial system but also the global nature of the atherosclerotic process. Full cardiac evaluations are often necessary due to the high incidence of concomitant atherosclerotic coronary artery disease, resulting in a high risk for ischemic events. Hertzer and associates reviewed coronary angiographies on 1000 patients undergoing elective vascular procedure and identified 25% of concomitant correctable coronary artery disease including 21% in patients undergoing elective peripheral vascular intervention.[8] Conte and associates analyzed their 20-year experience in 1642 open lower extremity reconstructive surgeries and concluded that patients requiring lower extremity reconstruction presented an increasingly complex medical and surgical challenge compared with the previous decade in a tertiary practice setting.[176] With aging of the population, a growing number of vascular patients have prohibitive medical cormobidities and are deemed high-risk for open surgical repair. Endovascular intervention provides an attractive alternative.

A B

Figure 23-63. **A.** A neuropathic ulcer is characterized by a punched-out appearance with loss of sensation in the surrounding skin. The foot may be warm to touch, and pulses may be present in the distal pedal arteries. **B.** An ischemic ulcer is characterized by a gangrenous skin change in the foot or toes. The foot is usually cold to touch with absent pedal pulses. The foot is painful to touch with decreased distal capillary refills.

As for open surgical repair, the clinical indications for endovascular intervention of lower extremity peripheral arterial diseases include lifestyle-limiting claudication, ischemic rest pain, and tissue loss or gangrene. Importantly, endovascular procedures should be performed by a competent vascular interventionist who understands the vascular disease process and is familiar with a variety of endovascular techniques. In addition, certain lesions may not be amendable to endovascular treatment or may be associated with poor outcomes, such as long segment occlusion, heavily calcified lesion, orifice lesion, or lesions that cannot be traversed by a guidewire. Proper selection of patients and techniques is critical in achieving good long-term outcome.

Figure 23-64. Computed tomography angiogram of a patient with an occluded left superficial femoral artery (*single long arrow*) with reconstituted superficial femoral artery at the level of mid-thigh. Diffuse arterial calcifications (*double small arrows*) are noted in the mid and distal left superficial femoral arteries.

Endovascular intervention for lower extremity occlusive disease is continuously evolving. Success and patency rates of endovascular intervention are closely related to the anatomic and morphologic characteristics of the treated lesions. The TASC work group made recommendations on the intervention strategies of lower extremity arterial diseases based on the morphologic characteristics. Based on TASC guidelines, endovascular treatment is recommended for type A lesions, open surgery is recommended for type D lesions, and no recommendations were made for types B and C lesions. However, with rapid advancement in endovascular technologies, there are increased numbers of lesions amendable to endovascular interventions.

There is less literature support for infrapopliteal endovascular intervention due to higher complication and lower success rates. The treatment is restricted for patients with limb-threatening ischemia who lack surgical alternatives. However, with further advancement of endovascular technology and the development of new devices, endovascular intervention is becoming an integral part of treatment (Table 23-26). By itself or combined with open technique, percutaneous intervention plays an important role in therapeutic options for lower extremity occlusive disease. As described by TASC guidelines, four criteria should be measured to evaluate the clinical success of the treatment: improvement in walking distance, symptomatic improvement, quality of life, and overall graft patency. These criteria should all be carefully weighed and evaluated for each individual prior to endovascular therapy.

Endovascular Treatment

Technical Considerations. A sterile field is required in either an operating room or an angiography suite with image capability. The most common and safest access site is CFA via either a retrograde or an antegrade approach. For diagnostic angiography, arterial access should be contralateral to the symptomatic sides. For therapeutic procedures, location of the lesion and the anatomic structures of the arterial tree determine the puncture site. To avoid puncturing the iliac artery or SFA, the femoral head is located under the fluoroscopy and used as the guide for the level of needle entry. In addition, there are several useful techniques to help access a pulseless CFA including ultrasound-guided puncture, using a micropuncture kit, and targeting calcification in a calcified vessel. The antegrade approach may be challenging, particularly in obese patients. Meticulous technique is crucial in preventing

Table 23-26

Summary of endovascular treatment strategies using device-based infrapopliteal intervention

INTERVENTION	ADVANTAGES	DISADVANTAGES
Angioplasty	• Easy to use • Broad range of applications	• Failure in long lesions, calcified lesions, and disease at multiple levels
Balloon-expandable stent	• Overcomes arterial recoil from angioplasty • Useful in treatment of flow-limiting dissection	• Crushability can lead to restenosis • Poor distal runoff can result in stent thrombosis • Limited data
Self-expanding stent	• Vessel conformability and wall apposition prevent kinking and crushing of stent	• Limited sizes • Limited data; multicenter trials under way
Bioabsorbable stent	• Overcomes arterial recoil from angioplasty • Absorbed long term to prevent risk of stent thrombosis	• Limited data; multicenter trials under way
Cryoplasty	• Reduces the risk of flow-limiting dissection, therefore reducing the need for stent implantation	• Short-term results of a multicenter trial are promising; however, long-term data are limited
Cutting balloon	• Useful in anastomotic segments of bypass grafts and in-stent restenosis where "watermelon seeding" can prevent adequate expansion of plaque	• Limited data
Mechanical atherectomy	• Allows for debulking of plaque without the need for stent implantation in most cases • Allows for removal of plaque for histologic analysis	• Limited use in areas of heavy calcification • No large, randomized, prospective trial comparing this technique to angioplasty and stenting
Laser	• Useful in acute thrombotic and chronic total occlusions	• Minimal data in infrapopliteal arteries • Need adjunctive treatment with angioplasty, stenting, or atherectomy

complications, and a bony landmark can be used as guidance to ensure CFA puncture.

Traversing the lesion with a wire is the most critical part of the procedure. Typically, 0.035-inch guidewires are used for femoropopliteal lesions, and 0.014- or 0.018-inch guidewires are used for infrapopliteal access. Hydrophilic-coated wires, such as Glidewires, are useful in navigating through tight stenosis or occlusion. An angled-tip wire with a torque device may be helpful in crossing an eccentric lesion, and a shaped selective catheter is frequently used in helping manipulating the wire across the lesion. The soft and floppy end of the wire is carefully advanced crossing the lesion under fluoroscopy, and gentle force is applied while manipulating the wire. Once the lesion us traversed, one needs to pay particular attention on the tip of the wire to ensure a secure wire access and avoid vessel wall perforation or dissection.

Once the access to the diseased vessel is secured and the wire has successfully traversed the lesion, several treatment modalities can be used either alone or in conjunction with others, including angioplasty, stent or stent graft placement, and atherectomy. The available angioplasty techniques are balloon angioplasty, cryoplasty, subintimal angioplasty, and cutting balloon; the most commonly used atherectomy techniques include percutaneous atherectomy catheter and laser atherectomy device.

Systemic anticoagulation should be maintained routinely during lower extremity arterial interventions to minimize the risk of pericatheter thrombosis. Unfractionated heparin is the most commonly used agent, administered using a weight-based formula. We typically use 80 to 100 mg/kg initial bolus for therapeutic procedure to achieve an activated clotting time above 250 seconds upon catheter insertion and administer a subsequent 1000 units for each additional hour of the procedure. Newer agents, such as low molecular weight heparin, platelet IIb/IIIa inhibitors, direct thrombin inhibitors, or recombinant hirudin, have been available and can be used either alone or in conjunction with heparin particularly in patients sensitive to unfractionated heparin. After the procedure, all patients are placed on antiplatelet therapy, such as aspirin. Additional antiplatelet agents, such as clopidogrel (Plavix), are given to selected patients with stent placement for at least 6 weeks after lower extremity interventions unless otherwise contraindicated.

Percutaneous Transluminal Balloon Angioplasty. After the lesion is crossed with a wire, an appropriated balloon angioplasty catheter is selected and tracked along the wire to traverse the lesion. The length of the selected catheter should be slightly longer than the lesion, and the diameter should be equal to the adjacent normal vessel. The balloon tends to be approximately 10% to 20% oversized. The radiopaque markers of the balloon catheter are placed so that they will straddle the lesion. Then, the balloon is inflated with saline and contrast mixture to allow visualization of the insufflation process under the fluoroscopy (Fig. 23-65). The patient may experience mild pain, which is not uncommon. However, severe pain can be indicative of vessel rupture, dissection, or other complications. An angiography is crucial in confirming the intraluminal location of the catheter and absence of contrast extravasation. The inflation is continued until the waist of the atherosclerotic lesion is disappeared and the balloon is at the full profile. Frequently, several inflations are required to achieve a full profile of the balloon (Fig. 23-66). Occasionally, a lower profile balloon is needed to predilate the tight stenosis so that the selected balloon catheter can cross the lesion.

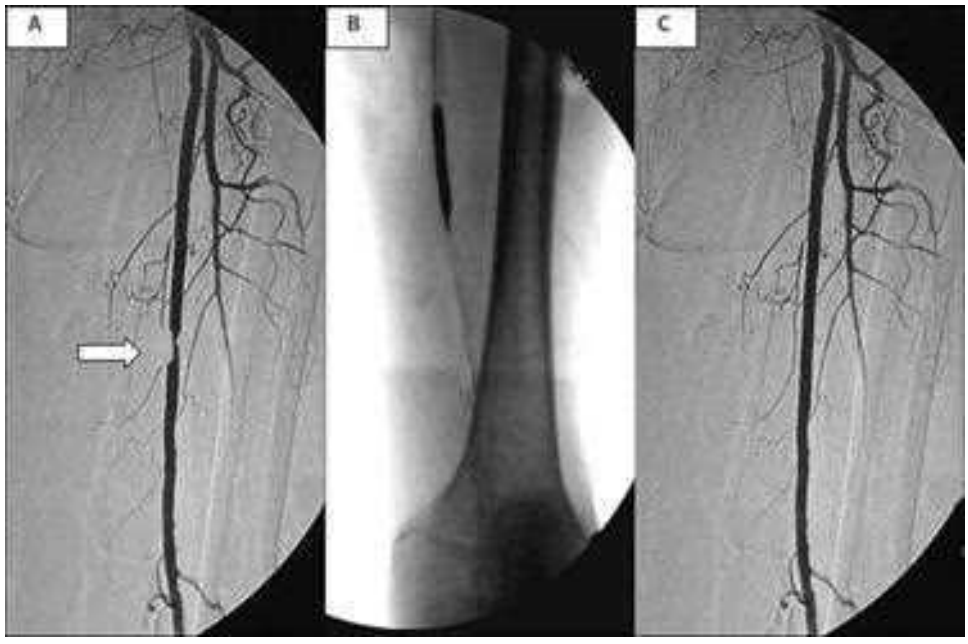

Figure 23-65. **A.** Angiogram demonstrating a focal stenosis in the superficial femoral artery (*arrow*). **B.** This lesion was treated with a balloon angioplasty catheter that inflated a dilating balloon and expanded the flow lumen. **C.** Completion angiogram demonstrating satisfactory radiographic result.

Besides length and diameter, the operators need to be familiar with several balloon characters. Noncompliant and low-compliant balloons tend to be inflated to their preset diameter and offer greater dilating force at the site of stenosis. Low-compliant balloons are the mainstay for peripheral intervention. A balloon with a low profile is used to minimize complications at the entry site and for crossing the tight lesions. Upon inflation, most balloons do not rewrap to their preinflation diameter and assume larger profiles. Furthermore, trackability, pushability, and crossability of the balloon should be considered when choosing a particular type of balloon. Lastly, shoulder length is an important characteristic when performing PTA to avoid injury to the adjacent arterial segments. After PTA, a completion angiogram is performed while the wire is still in place. Leaving the wire in place provides access for repeating the procedure if the result is unsatisfactory.

PTA is an established and effective therapy for select patients with lower extremity occlusive diseases. Studies have

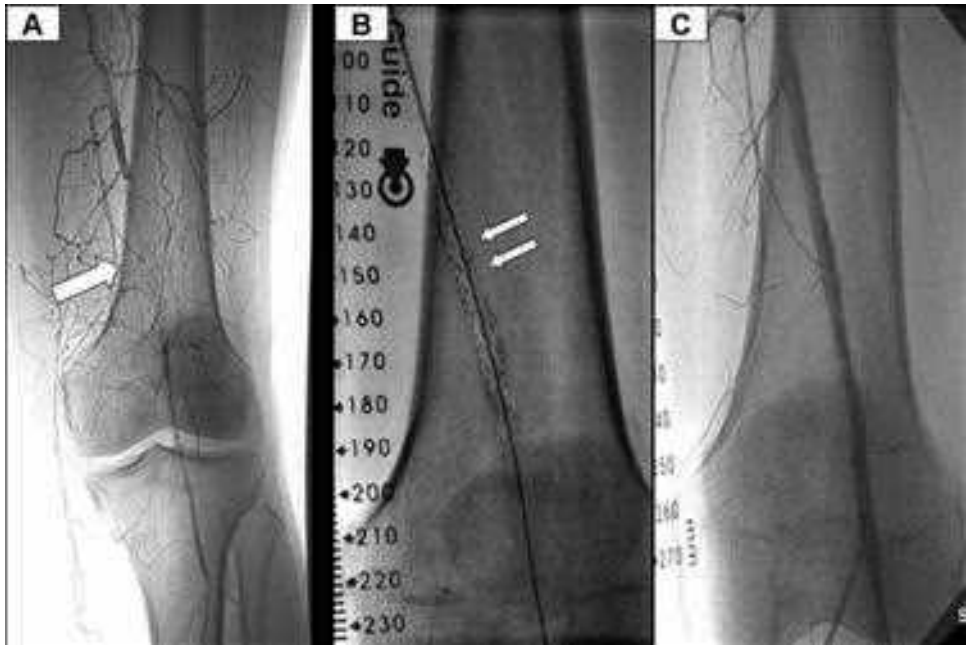

Figure 23-66. **A.** Angiogram demonstrating a segmental occlusion in the distal superficial femoral artery (*single arrow*). **B.** This lesion was treated with cryoplasty, which lowered the balloon catheter temperature to a temporary freezing state during the balloon angioplasty procedure (*double arrows*). **C.** Completion angiogram demonstrated satisfactory result with no evidence of vessel dissection.

shown that PTA of femoropopliteal segment achieved over 90% technical success rate and 38% to 58% 5-year primary patency rates.[177-179] However, efficacy of PTA is highly dependent on anatomic selection and patient condition.[134] PTA of lesions longer than 7 to 10 cm offers limited patency, whereas PTA of shorter lesions, such as those less than 3 cm, has fairly good results. Lofberg and associates performed 127 femoropopliteal PTA procedures and reported a primary 5-year success rate of 12% in limbs with occlusion longer than 5 cm versus 32% in limbs with occlusion less than 5 cm in length.[180] Occlusive lesions have much worse initial technical success rates than stenotic lesions. Concentric lesions respond better to PTA than eccentric lesions, and heavy calcifications have a negative impact on success rates. A meta-analysis by Hunink and associates showed that adjusted 5-year primary patencies after angioplasty of femoropopliteal lesions varied from 12% to 68%, with the best results being for patients with claudication and stenotic lesions.[179] Distal runoff is another powerful predictor of long-term success. Johnston analyzed 254 consecutive patients who underwent femoral and popliteal PTA and reported a 5-year patency rate of 53% for stenotic lesions and 36% for occlusive lesions in patients with good runoff versus a 5-year patency rate of 31% for stenotic lesions and 16% for occlusive lesions in patients with poor runoff.[178] Literature reviews showed that 5-year patency rates varied from 27% to 67% based on runoff status.[179]

Due to limited success with infrapopliteal PTA, the indication for infrapopliteal PTA is stringent and reserved for limb salvage. Current patency rates from infrapopliteal PTA can be improved further by proper patient selection, ensuring straight-line flow to the foot in at least one tibial vessel, and close patient surveillance for early reintervention. Possible future advances, including the use of drug-eluting stents, cutting balloons, and atherectomy devices, are being investigated to improve clinical outcomes following endovascular interventions on the tibial arteries. Varty and associates reported a 1-year limb salvage rate of 77% in patients with critical ischemia who underwent infrapopliteal PTA.[181] In patients with favorable anatomies, the 2-year limb salvage rate after infrapopliteal PTA is expected to exceed 80%.

Subintimal Angioplasty. The technique of subintimal angioplasty was first described in 1987 when successful establishment of flow was made by accidental creation of a subintimal channel during treatment of a long popliteal artery occlusion. Subintimal angioplasty is recommended for chronic occlusion, long segment of lesion, and heavily calcified lesions. In addition, this technique is applicable for vessels with diffuse disease and for vessels that had previously failed an intraluminal approach, when it is difficult to negotiate the wire across the entire diseased segment without dissection.

The principle of this technique is to bypass the occlusion by deliberately creating a subintimal dissection plan commencing proximal to the lesion and continuing in the subintimal space before break back into the true lumen distal to the lesion. The occluded lumen is recanalized through the subintimal plan. Subintimal angioplasty can be performed through either an ipsilateral antegrade or contralateral retrograde approach using the CFA approach. If selecting contralateral CFA puncture, a long guiding sheath is placed across the aortic bifurcation to provide access for the femoropopliteal and infrapopliteal vessels. The subintimal dissection is initiated at the origin of an occlusion by directing the tip of an angled guide wire, usually an angled hydrophilic wire, such as a Glidewire. A supporting catheter is used to guide the tip of the guidewire away from the important collaterals. When the wire is advanced, a loop is naturally formed at the tip of the guidewire. Once the subintimal plan is entered, the wire tends to move freely in dissection space. Subintimal location of the wire and the catheter can be confirmed by injecting a small amount of diluted contrast. At this point, the wire and the catheter are then advanced along the subintimal plan until the occlusion segment is passed. A loss of resistance is often encountered as the guidewire re-enters the true lumen distal to the occlusion. Recanalization is confirmed by advancing the catheter over the guidewire beyond the point of re-entry and obtaining an angiogram. This is followed by a balloon angioplasty. To confirm the patency following balloon dilatation, a completion angiogram is performed prior to withdrawing the catheter and wire. If flow is impaired, repeat balloon dilatation may be necessary. Frequently, a stent is required to maintain a patent lumen and treat residual stenosis if more than 30% luminal reduction is confirmed on completion angiogram.

Multiple studies have demonstrated the efficacy of subintimal angioplasty. Bolia and colleagues reported their extensive experiences on subintimal angioplasty for treating long-segment occlusions of infrainguinal vessels.[182,183] They achieved a technical success rate of over 80% for both femoropopliteal and tibial arteries. One-year patency rates varied from 53% for infrapopliteal vessels to 71% for femoropopliteal segments. Limb salvage rates reached over 80% at 12 months. They also reported that the factors influencing patency are smoking, number of runoff vessels, and occlusion length. Studies by other groups showed similar results.[184,185] Treiman and colleagues treated 25 patients with 6- to 18-cm femoropopliteal occlusion and achieved a technical success rate of 92% and a 13-month primary patency rate of 92%,[185] whereas Lipsitz and associates reported a technical success rate of 87% in 39 treated patients and a 12-month cumulative patency rate of 74%.[184] In addition, Ingle and associates reported a technical success rate of 87% in 67 patients with femoropopliteal lesions and a 36-month limb salvage rate of 94%.[186] As demonstrated herein, although technical success rates are similar in most series, the patency rates vary widely in different studies. Patient selection, anatomic character, and lesion locations may account for the wide range of outcomes.

Stent Placement. Although suggested by Dotter during the late 1960s, the use of an endoluminal stent was not pursued until the limitations of PTA were widely recognized. There are several situations where stent placement is appealing. The primary indication is the potential salvage of an unacceptable angioplasty result. Stent placement is typically used when residual stenosis after PTA is 30% or greater. An endoluminal stent is also used for dissection, perforation, and other PTA complications. Primary stent placement has become a viable alternative for treating ulcerative lesions that may potentially be the source for embolization. Primary stent is also used to treat occlusive lesions that have a tendency for reocclusion and distal embolization after PTA. In addition, an endoluminal stent is potentially beneficial for early restenosis after PTA. Drug-eluting stents are currently under investigation in the United States and may be promising in decreasing restenosis rates.

Although technical success rates are high, published series on femoropopliteal artery stents show that patency rates are comparable to PTA alone, with primary patency rates varying from 18% to 72% at 3 years.[134,187] Gray and associates stented 58 limbs after suboptimal PTA for long SFA lesions and

demonstrated a 1-year primary patency rate of 22%.[188] However, Mewissen treated 137 limbs using self-expanding SMART nitinol stents in patients with TASC A, B, and C femoropopliteal lesions and reported a 1-year primary patency of 76% and a 24-month primary patency rate of 60%.[189] Appropriate patient selection and the anatomic characteristics of the lesions are crucial in the success of treatment outcomes. Additionally, stent characteristics may contribute to the patency rate.

Several clinical studies have demonstrated the significant improvements of the new generation of nitinol stents for the SFA lesions: the German Multicenter Experience, the Mewissen trial, the BLASTER Trial, and the SIROCCO trial.[190] The German Multicenter Experience was a retrospective review of 111 SFA stenting procedures and predicted that the 6-month patency rate for SMART stents was 82% versus 37% for the Wallstent. The BLASTER (Bilateral Lower Arterial Stenting Employing Reopro) Trial evaluated the feasibility of using nitinol stents with and without intravenous abciximab for the treatment of femoral artery disease, and the preliminary results showed a 1-year clinical patency rate of 83%.[191]

Furthermore, the drug-eluting stent, which proved effective in decreasing restenosis in coronary intervention, may offer another promising alternative in lower extremity diseases. The drug released over a period of time interferes with smooth muscle cell proliferation, the main cellular element and source of extracellular matrix–producing restenosis. The first drug-eluting stent clinical trial used Cordis Cypher SMART stents coated with sirolimus (SIROCCO trial).[192] The SIROCCO results showed binary in-lesion restenosis rates of 0% in the sirolimus-eluting group versus 23.5% in the noneluting group at 6-month follow-up angiography. The PaRADISE (Preventing Amputations Using Drug-Eluting Stents) Trial investigated the efficacy and safety of using balloon-expandable drug-eluting stents to prevent amputations in patients with below-the-knee critical limb ischemia.[13] One hundred six patients (118 limbs) were treated with drug-eluting stents in this prospective, nonrandomized trial. There were 228 drug-eluting stents implanted (83% Cypher [Cordis, Johnson & Johnson, Warren, NJ], 17% Taxus [Boston Scientific, Maple Grove, MN]). The average length treated was 60 mm. The 3-year cumulative incidence of amputation was 6%, the survival rate was 71%, and the amputation-free survival rate was 68%. Only 12% of patients who died had a preceding major amputation. Rutherford category, age, creatinine level, and dialysis were predictors of death but not amputation. Target limb revascularization occurred in 15% of patients.

Stent Graft. The concept of endobypass using stent graft in treating atherosclerotic SFA disease has been entertained. A stent graft is placed percutaneously across a long segment or multiple segments of lesions and is used to create a femoropopliteal bypass. Theoretically, endobypass has the potential of being as successful as surgical bypass graft by relining the vessel wall in its anatomic position without the negative impact of anastomosis. Stent grafts can be divided into two categories: unsupported and fully supported. The unsupported grafts consist of segments of bypass graft, such as PTFE, with an expandable stent at one or both ends. The unsupported grafts are flexible with a low profile, but prone to external compression. The supported stent grafts consist of a metallic skeleton covered with graft fabric. The presence of a dense metal skeleton promotes an extensive inflammatory response and increases the risk of thrombosis. There is no FDA-approved stent graft for peripheral intervention. However, Viabahn (WL Gore & Associates, Flagstaff, AZ) is the most commonly used device in the United States and is composed of an ultra-thin PTFE graft externally supported by self-expanding nitinol meshwork. The Viabahn device has a specific delivery mechanism by pulling back the attached string, which results in proximal-to-distal delivery of the endoprosthesis.

Although it is an intriguing concept, data on endobypass results are limited, and the graft thrombosis rate is high. Additionally, covering major collateral vessels can potentially jeopardize the viability of the limb if stent graft occlusion occurs. Bauermeister treated 35 patients with Hemobahn and reported a 28.6% occlusion rate at an average 7-month follow-up.[193] Kedora and colleagues recently conducted a prospective, randomized study comparing covered PTFE/nitinol self-expanding stent grafts with prosthetic above-the-knee femoropopliteal bypass. Fifty limbs were randomized into each group. Primary patency at 1 year was approximately 74% for both cohorts, with a mean follow-up of 18 months. The covered nitinol/PTFE stent graft in the SFA had a 1-year patency comparable to surgical bypass, with a significantly shorter hospital stay (0.9 vs. 3.1 days).[194] A recent randomized prospective study comparing the treatment of SFA occlusive disease percutaneously with an expanded PTFE (ePTFE)/nitinol self-expanding stent graft (stent graft) versus surgical femoral to above-knee popliteal artery bypass with synthetic graft material showed no difference between the two groups with respect to primary or secondary patency rates at 48 months.[195] Mean total lesion length of the treated arterial segment in the stent graft group was 25.6 cm. The stent graft group demonstrated a primary patency of 72%, 63%, 63%, and 59% with a secondary patency of 83%, 74%, 74%, and 74% at 12, 24, 36, and 48 months, respectively. The surgical femoral-popliteal group demonstrated a primary patency of 76%, 63%, 63%, and 58% with a secondary patency of 86%, 76%, 76%, and 71% at 12, 24, 36, and 48 months, respectively. The authors concluded that ePTFE/nitinol self-expanding stent graft placement can be offered as an alternative to treatment of the SFA segment for revascularization when prosthetic bypass is being considered or when autologous conduit is unavailable.

Atherectomy. The basic principle of atherectomy is to remove the atheroma from obstructed arterial vessels. The currently available atherectomy devices can be generally categorized into directional, nondirectional, orbital, and rotational types based on their mecahnism. A few examples of FDA-approved atherectomy devices are Simpson AtheroCath (DVI, Redwood City, CA), Transluminal Extraction Catheter (Interventional Technologies, San Diego, CA), Thoratec recanalization arterial catheter (Thoratec, Pleasanton, CA), Auth Rotablator (Heart Technologies, Redmond, WA), SilverHawk system (FoxHollow Technologies, Redwood City, CA), Jetstream atherectomy system (Bayer, Indianola, PA), Diamondback 360° orbital atherectomy device (Cardiovascular Systems, Inc., St. Paul, MN), and Rotablator system (Boston Scientific Corporation, Natick, MA). These devices either cut and remove or pulverize the atheroma plaques.

The Simpson AtheroCath has a directional cutting element that is exposed to one third of the circumference of the arterial wall. The atheroma protruding into the window is excised and pushed into the collection chamber. The Transluminal Extraction Catheter has an over-the-wire nondirectional cutter mounted on the distal end of a torque tube. The excised atheroma is simultaneously removed by aspiration through the

torque tube. The Thoratec recanalization arterial catheter is a nondirectional, noncoaxial, atheroablative device. The rotating cam tip pulverizes the atheromatous lesion into minute particles. The Auth Rotablator is a nondirectional, coaxial, atheroablative device with a metal burr embedded with fine diamond chips. SilverHawk device is a monorail catheter designed to overcome the drawbacks of a directional atherectomy catheter. The working end consists of a hinged housing unit containing a carbide cutting blade. The blade is activated from the motor drive unit, and the catheter is then advanced through the length of the lesion. Once each pass is completed, the cutter then packs the tissue into the distal end of the nosecone to maximize collection capacity. The SilverHawk can then either be removed or torqued to treat a different quadrant in the same lesion or other lesions. Jetstream atherectomy system is a rotating, aspirating catheter with tip sizes of 1.6 and 1.8 mm for tibial arteries, and an expandable catheter with a tip size ranging from 2.1 to 3.4 mm for active removal of atherosclerotic debris and thrombus. The Diamondback 360° orbital atherectomy device uses a drive shaft with an eccentrically mounted, diamond-coated crown to create an orbital spin. As the speed of the crown increases from centrifugal force, it sands wider spaces, thereby providing variability in its working range. It can create a lumen that is >1.75 times the crossing profile depending on the size of the grit and the eccentricity of the offset. The greater the speed of the crown, the larger is the arc of debulking and, ultimately, the resultant lumen size. A constant flow of saline solution is delivered by a roller pump that lubricates the device and helps to flush the debris. The Rotablator system high-speed rotational device uses calcium ablation to achieve larger lumens. It has been used for more than 20 years to treat challenging, calcified coronary artery disease. The diamond-coated burr is designed to preferentially engage calcium and modify lesion compliance.

Despite the promising early technical and clinical success, the mid- and long-term results have been disappointing due to high incidence of restenosis. A multicenter clinical registry of plaque atherectomy in patients with femoropopliteal occlusive disease showed potential clinical efficacy of this technology, as the 6- and 12-month rates of survival free of target lesion revascularization were 90% and 80%, respectively.[196] Importantly, nearly three quarters (73%) of patients treated with plaque excision modality did not require adjunctive endovascular therapy as infrainguinal stenting was necessary in only 6.3% of lesions. Results from the TALON registry support the role of plaque excision in selected patients with lower extremity arterial disease.[196]

Recent technologic advances have made it possible to increase the spectrum of treatable peripheral arterial lesions with high acute procedure success rates. Recently presented data from multiple registries have shown some promising results in terms of short-term primary patency rates and freedom from unplanned major amputation.[197,198] Randomized clinical trials are expected and can hopefully provide conclusions on the effectiveness of these procedures.

Laser Atherectomy. Since laser atherectomy was reported in the 1960s, a variety of innovative approaches have been developed trying to overcome the limitation of laser angioplasty. Recent developments in Excimer laser technology have led to increased optimism regarding the ability to safely deliver laser energy. Excimer laser atherectomy approved by the FDA for peripheral artery intervention employs precision laser energy control (shallow tissue penetration) and safer wavelengths (ultraviolet as opposed to the infrared spectra in older laser technology), which decrease perforation and thermal injury to the treated vessels.

A laser atherectomy catheter, with diameters varying from 0.9 to 2.5 mm, is tracked over the guidewire to the desired target. Once activated, the Excimer laser uses ultraviolet energy to ablate the lesion and create a nonthrombogenic arterial lumen. This lumen is further dilated by an angioplasty balloon. Because the Excimer laser can potentially reduce the rate of distal embolization by evaporating the lesion, it may be used as an adjunct tool for ostial lesions and lesions that can be traversed by a wire but not an angioplasty balloon catheter.

Several studies regarding the use of Excimer laser atherectomy combined with balloon angioplasty on lower extremity occlusive disease have shown promising clinical outcomes.[199,200] The Peripheral Excimer Laser Angioplasty (PELA) trial involved 318 patients with chronic SFA occlusion and achieved a technical success rate of 83.2%, a 1-year primary patency rate of 33.6%, and an assisted-primary patency rate of 65%.[200] Steinkamp and his colleagues treated 127 patients with long-segment popliteal artery occlusion using laser atherectomy followed by balloon angioplasty and reported a 3-year primary patency rate of 22%.[201] A multicenter clinical trial, the Laser Angioplasty for Critical Limb Ischemia (LACI) trial, supports the efficacy of this treatment modality in selected patients, with 6-month primary patency and clinical improvement rates of 33% and 89%, respectively.[199] The technology and devices continue to evolve. With the Turbo- Booster and Turbo-Tandem technologies (Spectranetics Corporation, Colorado Springs, CO), the efficacy of plaque reduction was reported to be significantly improved in the CliRpath Excimer Laser System to Enlarge Lumen Openings (CELLO) study.[202] The CELLO study was a single-arm, prospective registry trial conducted at 17 investigational sites in the United States to evaluate the safety and efficacy of a modified laser catheter designed for the endovascular treatment of peripheral artery disease affecting the SFA and proximal popliteal artery. Laser ablation reduced percent diameter stenosis from 77% to 21% after adjunctive therapy with balloon angioplasty or balloon angioplasty with stenting; 12.3% patients did not receive postlaser adjunctive therapy. Patency rates were 59% and 54% at 6 and 12 months, respectively. Target lesion revascularization was not required in 76.9% of CELLO participants within the 1-year follow-up.

Complications of Endovascular Interventions

Angioplasty-Related Complications. Complications related to PTA vary widely and include dissection, rupture, embolization, pseudoaneurysms, restenosis, hematoma, and acute occlusion secondary to thrombosis, vasospasm, or intimal injury. Clark and associates analyzed the data from 205 patients in the SCVIR Transluminal Angioplasty and Revascularization (STAR) registry and reported a complication rate of 7.3% for patients undergoing femoropopliteal angioplasty.[203] Minor complications accounted for 75% of the cases, including distal emboli (41.7%), puncture site hematomas (41.7%), contained vessel rupture (8.3%), and vagal reactions (8.3%). In another study, Axisa and colleagues reported an overall rate of significant complications for patients undergoing PTA of the lower extremities of 4.2%, including retroperitoneal bleeding (0.2%), false aneurysm (0.2%), ALI (1.5%), and vessel perforation (1.7%).[204]

Complications limiting the application of subintimal angioplasty are parallel to those of PTA. A study investigating the use of subintimal angioplasty in 65 patients with

SFA occlusion found that complications developed in 15% of patients.[205] These complications included significant stenosis (44%), SFA rupture (6%), distal embolization (3%), retroperitoneal hemorrhage (1.5%), and pseudoaneurysm (1.5%). Additional complications reported included perforation, thrombosis, dissection, and extensions beyond the planned re-entry site.[206] Importantly, damage to significant collateral vessels may occur in 1% to 1.5% of patient who undergo subintimal angioplasty. If a successful channel is not achieved in this situation, the patient may have a compromised distal circulation that necessitates distal bypass. Cryoplasty is a modified form of angioplasty, and long-term results on lower extremity intervention are not yet available. Fava and associates treated 15 patients with femoropopliteal disease and had a 13% complication rate involving guidewire dissection and PTA-induced dissection of a tandem lesion remote to the cryoplasty zone.[207]

Endoluminal Stent– and Stent Graft–Related Complications. In addition to the aforementioned complications with angioplasty, endoluminal stent is associated with the risk of stent fraction and deformity. The adductor canal has nonlaminar flow dynamics, especially with walking. The forces exerted on the SFA include torsion, compression, extension, and flexion. These forces exert significant stress on the SFA and stents. In addition, the lower extremity is subject to external trauma, which further increases the risk of stent deformity and fracture (Fig. 23-67). The SIROCCO study showed that stent fracture, although not associated with clinical symptoms, occurs in 18.2% of the procedures involving both drug-eluting stents and control stents.[192]

Stent grafts may present additional complication of covering important collaterals, which results in compromised distal circulation. A prospective study evaluating Hemobahn stent grafts in the treatment of femoropopliteal arterial occlusions demonstrated a 23% immediate complication rate including distal embolization (7.7%), groin hematoma (13.5%), and arteriovenous fistula (1.9%).[208]

Atherectomy-Related Complications. Overall complication rates associated with atherectomy range from 15.4% to 42.8%, including spasm, thrombosis, dissection, perforation, distal emboli, no reflow, and hematoma.[209,210] Jahnke and associates conducted a prospective study evaluating high-speed rotational atherectomy in 15 patients with infrapopliteal occlusive disease. They yielded a 94% technical success rate, but success was complicated by vessel rupture (5%), distal embolization (5%), and arterial spasm (5%).[208] Although Excimer laser atherectomy reduces embolic events by evaporating the lesion, embolization still remain a problematic complication. Studies show that distal embolic events occur in 3% to 4% of procedures, and perforation occurs in 2.2% to 4.3% of cases.[200,201] Other complications compromising laser atherectomy therapy include acute reocclusion, vasospasm, direct vessel injury, and dissection.

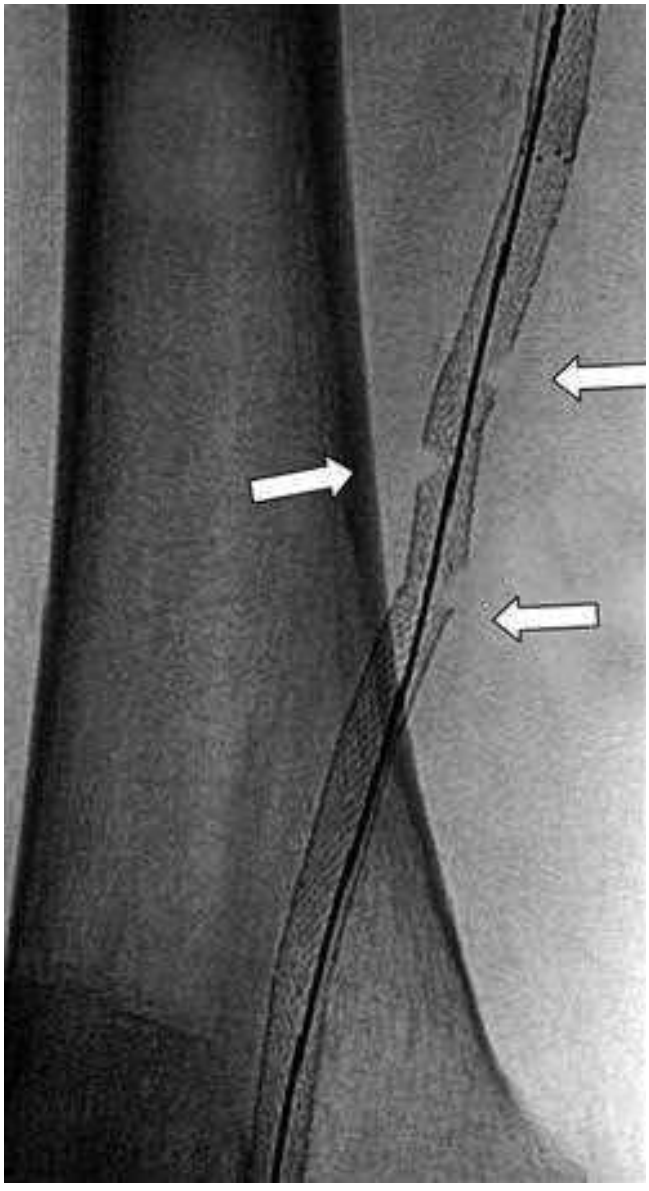

Figure 23-67. Due to various geometric forces, including torsion, compression, extension, and flexion, exerted on the superficial femoral artery (SFA), stent fracture (*arrows*) is a known complication following SFA stent placement.

Surgical Treatment for Chronic Limb Ischemia due to Femoropopliteal Disease

Endarterectomy. Endarterectomy has a limited, albeit important role in lower extremity occlusive disease. It is most frequently used when there is disease in the CFA or involving the PFA. In this procedure, the surgeon opens the diseased segment longitudinally and develops a cleavage plane within the media that is developed proximally and distally. This permits the inner layer containing the atheroma to be excised. Great care must be taken at the distal end of the endarterectomy to either ensure a smooth transition or tack down the distal endpoint to prevent the flow from elevating a potentially occlusive atheromatous flap. Currently, there is essentially no role for long open endarterectomy in the treatment of SFA stenoses or occlusions. The high incidence of restenosis is what limits utility of endarterectomy in this location. Short-segment stenoses are more appropriately treated with balloon angioplasty. Endarterectomy using a catheter-based approach (e.g., Moll endarterectomy device) supplemented with stent grafting or stenting across the endpoint of the endarterectomy is currently being re-evaluated; however, no long-term data are available.

Bypass Grafting. Bypass grafting remains the primary intervention for lower extremity occlusive disease. The type of bypass and the type of conduit are important variables to consider. Patients with occlusive disease limited to the SFA, who have at least 4 cm

(ideally 10 cm) of normal popliteal artery reconstituted above the knee joint, and with at least one continuous vessel to the foot can be treated with an above-knee femoropopliteal bypass graft. Despite the fact that in this above-knee location, the differential patencies between prosthetic (PTFE) and vein graft are comparable, undoubtedly, it remains ideal to use a saphenous vein as the bypass conduit if possible. Saving the vein for future coronary artery bypass or distal leg bypass grafting has been shown to be a flawed argument. One must also consider that the consequences to the vascular outflow after a thrombosed prosthetic are worse than after a thrombosed vein graft.

When the disease extends to involve the popliteal artery or the tibial vessels, the surgeon must select an appropriate outflow vessel to perform a bypass. Suitable outflow vessels are defined as uninterrupted flow channels beyond the anastomosis into the foot. Listed in order of descending preference, they are as follows: above-knee popliteal artery, below-knee popliteal artery, posterior tibial artery, anterior tibial artery, and peroneal artery. In patients with diabetes, it is frequently the peroneal artery that is spared. Although it has no direct flow into the foot, collateralization to the posterior tibial and anterior tibial arteries makes it an appropriate outflow vessel. There is no objective evidence to preferentially select tibial over peroneal arteries if they are vessels of equal caliber and quality. The dorsalis pedis, which is the continuation of the anterior tibial in the foot, is frequently spared from atherosclerotic disease and can be used as a target for distal bypasses. Patency is affected by the length of the bypass (longer bypasses have reduced patency), quality of the recipient artery, extent of runoff to the foot, and quality of the conduit (saphenous vein/graft). Five-year assisted patency rate for infrapopliteal venous bypasses is 60%. Venous conduits have also been shown to be suitable for bypasses to plantar arteries. In this location, venous conduits have a 3-year limb salvage rate of 84% and a 3-year secondary patency rate of 74%.[2] A meta-analysis suggests unsatisfactory results when PTFE-coated grafts are used to bypass to infrapopliteal arteries. In this location, prosthetic grafts have a 5-year primary patency rate of 30.5%.[211] Additionally, due to distal embolization and compromise of outflow vessels, prosthetic graft occlusion may have more severe consequences than vein graft occlusion.[211]

Two techniques are used for distal bypass grafting: reversed saphenous vein grafting and in situ saphenous vein grafting. There is no difference in outcomes (patency or limb salvage) between these techniques.[2] In the former, the vein is excised in its entirety from the leg using open or endoscopic vein harvest, reversed to render the valves nonfunctional, and tunneled from the CFA inflow to the distal target vessels. End-to-side anastomoses are then created.

Several adjunctive techniques have been used to try and improve the patency of bypass grafts to tibial arteries. Creation of an arteriovenous fistula at the distal anastomosis is one option, but it has not been shown to improve patency.[212] Another method involves creating varying configurations of vein cuffs or patches at the distal anastomosis in an attempt to streamline the flow and to reduce the likelihood of neointimal hyperplasia. Results with this approach are more promising, especially when done to improve patency of a below-the-knee prosthetic; however, there are no definitive comparative trials that support the superiority of one configuration over another.

Amputation. Primary amputation is defined as an amputation that is performed without a prior attempt at surgical or endovascular revascularization. It is rarely necessary in patients who, as a result of neglect, present with class III ALI. Primary amputation may play a role in patients with critical limb ischemia who are deemed nonambulatory because of knee contractures, debilitating strokes, or dementia.

Complications of Surgical Reconstruction

Vein Graft Stenoses. Fifteen percent of vein grafts will develop intrinsic stenoses within the first 18 months following implantation. Consequently, patients with vein grafts were entered into duplex surveillance protocols (scans every 3 months) to detect elevated (>300 cm/s) or abnormally low (<45 cm/s) graft velocities early. Stenoses greater than 50%, especially if associated with changes in ABI, should be repaired to prevent graft thrombosis. Repair usually entails patch angioplasty or short-segment venous interposition, but PTA/stenting is an option for short, focal lesions. Grafts with stenoses that are identified and repaired prior to thrombosis have assisted-primary patency identical to primary patency, whereas a thrombosed autogenous bypass has limited longevity resulting from ischemic injury to the vein wall. Secondary patency is markedly inferior to primary assisted patency. The recommendation for routine duplex ultrasound surveillance of autogenous infrainguinal bypasses was recently brought into question by a randomized controlled trial that demonstrated no cost benefit or quality-of-life improvement in patients with femoropopliteal venous bypasses after 18 months.[213] Many surgeons continue with programs of vein graft surveillance, as has been suggested in older trials, awaiting further confirmation of the findings from the more recent study. When intervening in a failing infrainguinal bypass, the original indication for surgery is an important consideration. Limb salvage rates for occluded grafts are better if the indication for the original bypass was claudication rather than rest pain or tissue loss. An acutely occluded infrainguinal graft (≤30 postoperative days) has a 25% limb salvage rate.[214]

Limb Swelling. Limb swelling is common following revascularization and usually returns to baseline within 2 to 3 months. The etiology is multifactorial with lymphatic interruption, interstitial edema, and disruption of venous drainage all contributing. Limb swelling tends to worsen with repeat revascularization (see Table 23-22).

Wound Infection. Since the most common inflow vessel for distal bypass is the CFA, groin infection is common and occurs in 7% of cases.[215] When an autogenous conduit such as the saphenous vein is used, most infections can be managed with local wound care because the infection involves the subcutaneous tissue or skin rather than infection of the actual vein. When a prosthetic graft has been used, management of graft infection is a major undertaking. Infection of a lower extremity prosthetic bypass graft is associated with a significant amputation rate because of the tendency for graft thrombosis and anastomotic disruption. Prosthetic graft infections cannot be eradicated with antibiotics and mandate graft excision and complex revascularization using a vein if available.

Choice of Conduit for Infrainguinal Bypass Grafting

Autogenous Vein. The autogenous vein is superior to prosthetic conduits for all infrainguinal bypasses, even in the above-knee position. This preference is applicable not only for the initial bypass but also for reoperative cases. For long bypasses, the ipsilateral great saphenous vein, contralateral great

saphenous vein, small saphenous vein, arm vein, and spliced vein are used in decreasing order of preference. If only a short segment of vein is missing, the SFA can be endarterectomized and the proximal anastomosis performed distally to decrease the length of the conduit and to avoid harvesting and splicing additional vein. When the great saphenous vein is not available and a relatively short bypass is necessary, the arm vein or small saphenous vein is effective. The small saphenous vein is of particular utility when a posterior approach is used. If a longer bypass with vein is necessary, the arm vein is preferable because it is less awkward to harvest. Another conduit alternative is to harvest the upper arm basilic, median cubital, and cephalic veins in continuity, while incising valves in the basilic segment and using the cephalic segment in reversed configuration to provide a relatively long, unspliced autogenous conduit.[216]

Cryopreserved Grafts. Cryopreserved grafts are usually cadaveric arteries or veins that have been subjected to rate-controlled freezing with dimethyl sulfoxide (DMSO) and other cryopreservants. Cryopreserved vein grafts are more expensive than prosthetic grafts and are more prone to failure. The endothelial lining is lost as part of the freezing process, making these grafts prone to early thrombosis. Cryopreserved grafts are also prone to aneurysmal degeneration. Despite the fact that these grafts have not performed as well as prosthetic bypasses and autogenous vein bypasses in clinical practice, they can still play a role when revascularization is required following removal of infected prosthetic bypass grafts, especially when the autogenous vein is unavailable to create a new bypass through clean tissue planes.[217]

Human Umbilical Vein. Human umbilical vein (HUV) is less commonly used than PTFE because it is thicker and more cumbersome to handle and because of concerns about aneurysmal degeneration. HUV allografts are stabilized with glutaraldehyde and do not have viable cells or antigenic reactivity. These grafts have poor handling characteristics and require extra care when suturing because of an outer Dacron mesh wrapping that is used to decrease aneurysmal degeneration. Dardik and colleagues have reported favorable results after using HUV and an adjunctive distal arteriovenous fistula.[218] One trial comparing HUV with PTFE and saphenous vein showed that HUV was better than PTFE but worse than saphenous vein in terms of 5-year patency in the above-knee location.[219] In a systematic review, HUV appears to perform better than cryopreserved veins.[220]

Prosthetic Conduits and Adjunctive Modifications. If a vein is truly unavailable, PTFE or Dacron is the best option for above-knee bypass. The addition of rings to PTFE did not confer benefit in a single prospective, randomized clinical trial.[221] For infrageniculate prosthetic bypasses, use of a vein patch, cuff, or other venous anastomotic modification can improve patency (52% patency at 2 years for PTFE with vein cuff vs. 29% for PTFE with no cuff) and also improve limb salvage (84% vs. 62%).[222]

Although prosthetic grafts are quickly available, easy to handle, and do not require extensive dissection to harvest, their propensity to undergo thrombosis and develop neointimal hyperplasia makes them a less favorable alternative when compared to vein. In a recent review of vein and prosthetic above-knee femoropopliteal bypasses, the 5-year primary patency rates were reported to be 74% and 39%, respectively.[223] Outcomes were even worse for below-knee prosthetic bypasses. Unfortunately, the use of autologous venous conduits is not possible in as many as 30% of patients. The great saphenous vein may be unsuitable because of small size and poor quality or unavailable due to prior harvest.

Methods to improve prosthetic graft performance have consisted of altering the geometry at the distal anastomosis to get the benefit obtained with vein cuffs (Distaflo; Bard Peripheral Vascular, Tempe, AZ) and covalently bonding agents onto the luminal surface with anticoagulant, anti-inflammatory, and antiproliferative characteristics (Propaten; Gore, Flagstaff, AZ). One randomized trial that compared precuffed PTFE versus PTFE with a vein cuff enrolled 104 patients at 10 centers. Of 89 patients, 47 were randomized to precuffed PTFE bypasses and 44 were randomized to bypasses with a vein cuff. At 1 and 2 years, primary patency rates were 52% and 49% in the precuffed group and 62% and 44% in the vein cuffed group, respectively. At 1 and 2 years, the limb salvage rates were 72% and 65% in the precuffed group and 75% and 62% in the vein cuffed group, respectively. Although numbers are small and follow-up short, the midterm analysis revealed that Distaflo precuffed grafts and PTFE grafts with vein cuff had similar results. The authors concluded that a precuffed graft was a reasonable alternative for infragenicular reconstruction in the absence of saphenous vein.[224] Other authors have been less optimistic and question whether there is any benefit derived from geometrically altering prosthetic conduits.[225]

Another approach for improving outcomes when using prosthetic for bypass grafts involves bonding anticoagulants to the conduit. The Gore Propaten graft has heparin bonded onto the luminal surface of the PTFE graft using Carmeda BioActive Surface (CBAS) technology, which immobilizes the heparin molecule with a single covalent bond that does not alter its anticoagulant properties.[226] The heparin binding does not alter the microstructure and handling characteristics of the PTFE. A prospective, randomized trial by Devine and colleagues suggested that heparin-bonded Dacron or PTFE was superior to plain PTFE for above-knee popliteal bypasses. The 3-year primary patency rate for the heparin-bonded grafts was 55% compared with 42% for PTFE (P <0.044). Both of these patency rates are inferior to great saphenous vein grafts; however, if the improved results with heparin bonding continue to be substantiated, then heparin-bonded prosthetic grafts will become the preferred conduit for above-knee bypass in the absence of suitable vein.[227] A recent review of available studies with this graft showed an 80% 1-year patency rate for below-knee bypasses.[228] Randomized controlled clinical trials with more patients and longer follow-up are necessary to validate whether the Propaten vascular graft is superior to other prosthetics and whether it is comparable to autogenous vein for below-knee interventions.

Clinical Results of Surgical and Endovascular Interventions for Femoropopliteal Occlusive Disease

Balloon angioplasty of the femoropopliteal vessels has not enjoyed the degree of success seen with iliac angioplasty. Patency in this region is dependent on whether the patient presents with claudication versus limb-threatening ischemia, the status of the distal runoff vessels, and lesion morphology.[2] Initial technical success for femoropopliteal angioplasty is seen in 80% to 90% of cases, with failure to cross a lesion occurring in 7% of stenoses and 18% of occlusive lesions. Studies have shown that PTA of the femoropopliteal segment achieved a greater than 90% technical success rate and had a 38% to 58% 5-year primary

patency rate.[177,178] PTA of lesions longer than 7 to 10 cm results in compromised patency, whereas PTA of shorter lesions (<3 cm) gives fairly good results. Lofberg and colleagues performed 127 femoropopliteal PTA procedures and reported a primary patency rate at 5-year follow-up of 12% in limbs with occlusion longer than 5 cm versus 32% in limbs with occlusion less than 5 cm in length.[180] Occlusive lesions have much worse initial technical success rates than stenotic lesions. Concentric lesions respond better to PTA than eccentric lesions, and heavy calcifications have a negative impact on success rates. Distal runoff is another powerful predictor of long-term success.

Johnston analyzed 254 consecutive patients who underwent femoropopliteal PTA and reported a 5-year patency rate of 53% for stenotic lesions and 36% for occlusive lesions in patients with good runoff versus a 5-year patency rate of 31% for stenotic lesions and 16% for occlusive lesions in patients with poor runoff.[178] A meta-analysis by Hunink and colleagues showed that adjusted 5-year primary patencies after angioplasty of femoropopliteal lesions varied from 12% to 68%, with the best results occurring in patients with claudication and stenotic lesions.[179] Although the initial technical success is better for stenoses than occlusions, long-term patency rates for stenoses and short occlusions have been variable, and there have been conflicting results regarding the efficacy of stent use. Early published series that examined efficacy of femoropopliteal artery stents showed patency rates that were comparable to standalone PTA, with primary patency rates varying from 18% to 72% at 3 years.[187] Patient selection and the anatomic character of the lesions may play important roles in the outcomes. Additionally, stent characteristics may contribute to the patency rate. Several recent clinical studies have demonstrated significant improvements in patency when the newer generations of nitinol stents are used to treat SFA lesions.[189,229]

Mewissen treated 137 lower limbs in 122 patients with CLI, secondary to TASC A (n = 12) or TASC B or C (n = 125) lesions in the SFA. Patients were treated with Cordis SMART self-expanding nitinol stents. Binary restenosis (>50%) was measured by standard duplex velocity criteria at various postintervention intervals. Primary stent patency, defined as absence of binary restenosis in this study, was calculated by life-table methods from the time of intervention. The mean lesion length was 12.2 cm (range, 4–28 cm). The technical success was 98%. Mean follow-up was 302 days. The primary stent patency rates were 92%, 76%, 66%, and 60% at 6, 12, 18, and 24 months, respectively.[189] Ferreira and colleagues treated 59 patients who had 74 femoropopliteal lesions (60% TASC D) with Zilver nitinol self-expanding stents (Cook, Bloomington, IN). Mean recanalization length was 19 cm (range, 3–53 cm). Mean follow-up time was 2.4 years (range, 3 days–4.8 years). Kaplan-Meier estimates for primary patency rates were 90%, 78%, 74%, 69%, and 69% at 1, 2, 3, 4, and 4.8 years, respectively.[230]

There is general agreement that for suboptimal PTA of an SFA lesion, stent placement is indicated, but a recent randomized trial by Schillinger and associates suggests that primary stenting results in lower restenosis rates than PTA and selective stenting. Restenosis rates at 2 years were 45.7% versus 69.2% in favor of primary stenting compared with PTA and optional secondary stenting using an intent-to-treat analysis ($P = 0.031$). Consistently, stenting, both primary and selective, was superior to standalone PTA with respect to the occurrence of restenosis (49.2% vs. 74.3%; $P = 0.028$) by a treatment-received analysis.[231]

Nitinol bare metal stents that are designed specifically for below-knee interventions are showing very encouraging results. Bosiers and colleagues reported their 12-month results using the commercially available non–drug-eluting Xpert (Abbott Vascular, Santa Clara, CA) nitinol stent system in below-knee arterial interventions.[232] They had a 12-month primary patency rate of 76.3% and a limb salvage rate of 95.9%. They followed patients for 12 months and performed angiography with quantitative vessel analysis on the 73% of patients available. Angiography revealed a binary restenosis rate (>50%) of only 20.5%, which is comparable to well-accepted coronary drug-eluting stent study outcomes. The authors attributed this optimal performance to the maintenance of flow dynamics because the stent was specifically designed for use in small vessels.[232] Kickuth and colleagues also have obtained good results using the Xpert stent. After stent placement, the primary cumulative patency rate at 6 months for the study group of 35 patients was 82%. The sustained clinical improvement rate as evidenced by improved ABI was 80%, and freedom from major amputation was 100% at the 6-month follow-up. The rate of major complications was 17%.[233]

Wolf and colleagues published a multicenter, prospective randomized trial comparing PTA with bypass in 263 men who had iliac, femoral, or popliteal artery obstruction.[234] In 56 patients, cumulative 1-year primary patency rate was 43% after PTA and 82% after bypass surgery, demonstrating that for long SFA stenoses or occlusions, surgery is better than PTA. Another recent randomized study (BASIL trial) of 452 patients with CLI demonstrated no difference in amputation-free survival at 6 months between surgery and PTA/stenting. The authors commented that surgery was somewhat more expensive and recommended that endovascular intervention should be used as first-line therapy especially in medically unfit patients. They did conclude that at the 2-year follow-up, healthy patients without medical comorbidities derived greater benefit from surgery because it was associated with decreased need for reintervention and had a decreased hazard ratio in terms of all-cause mortality.[235] The recently published randomized prospective study comparing the treatment of SFA occlusive disease percutaneously with an ePTFE/nitinol self-expanding stent graft versus surgical femoral to above-knee popliteal artery bypass with synthetic graft material showed no difference between the two groups with respect to primary or secondary patency rate at 48 months.[195] This finding suggests that ePTFE/nitinol self-expanding stent graft placement can be offered as an alternative to treatment of the SFA segment for revascularization when prosthetic bypass is being considered or when autologous conduit is unavailable. Using the 2000 TASC definitions and a Markov state transition model decision analysis, Nolan and colleagues showed that PTA/stenting surpasses bypass efficacy for TASC C lesions if PTA/stenting primary patency is >32% at 5 years, patient age is >80 years, and/or greater saphenous vein bypass operative mortality is >6%.[134,236]

NONATHEROSCLEROTIC DISORDERS OF BLOOD VESSELS

The majority of cases of peripheral vascular disease that are seen by vascular surgeons are attributable to underlying atherosclerosis. Nonatherosclerotic disease states that result in arterial pathology are less commonly encountered, but are nonetheless important, as they are potentially treatable lesions that may

mimic atherosclerotic lesions and result in vascular insufficiency (see Table 23-18). A thorough knowledge of these rare disease states is important for the practicing vascular surgeon in order to both make medical recommendations and provide appropriate surgical treatment.

Giant Cell Arteritis (Temporal Arteritis)

Giant cell arteritis is also known as temporal arteritis, which is a systemic chronic inflammatory vascular disease with many characteristics similar to those of Takayasu's disease. The histologic and pathologic changes and laboratory findings are similar. Patients tend to be white women over the age of 50 years, with a high incidence in Scandinavia and women of Northern European descent. Genetic factors may play a role in disease pathogenesis, with a human leukocyte antigen (HLA) variant having been identified. Differences exist between Takayasu's and giant cell arteritis in terms of presentation, disease location, and therapeutic efficacy. The inflammatory process typically involves the aorta and its extracranial branches, of which the superficial temporal artery is specifically affected.

The clinical syndrome begins with a prodromal phase of constitutional symptoms, including headache, fever, malaise, and myalgias. The patients may be initially diagnosed with coexisting polymyalgia rheumatica; an HLA-related association may exist between the two diseases. As a result of vascular narrowing and end-organ ischemia, complications may occur such as visual alterations, including blindness and mural weakness, resulting in acute aortic dissection that may be devastating. Ischemic optic neuritis resulting in partial or complete blindness occurs in up to 40% of patients and is considered a medical emergency. Cerebral symptoms occur when the disease process extends to the carotid arteries. Jaw claudication and temporal artery tenderness may be experienced. Aortic lesions are usually asymptomatic until later stages and consist of thoracic aneurysms and aortic dissections.

The diagnostic gold standard is a temporal artery biopsy, which will show the classic histologic findings of multinucleated giant cells with a dense perivascular inflammatory infiltrate. Treatment regimens are centered on corticosteroids, and giant cell arteritis tends to rapidly respond. Remission rates are high, and treatment tends to have a beneficial and preventative effect on the development of subsequent vascular complications.

Takayasu's Arteritis

Takayasu's arteritis is a rare but well-recognized chronic inflammatory arteritis affecting large vessels, predominantly the aorta and its main branches (Table 23-27).[237] Chronic vessel inflammation leads to wall thickening, fibrosis, stenosis, and thrombus formation. Symptoms are related to end-organ ischemia. The acute inflammation can destroy the arterial media and lead to aneurysm formation. This rare autoimmune disease occurs predominantly in women between the ages of 10 and 40 years who are of Asian descent. Genetic studies have demonstrated a high frequency of HLA haplotypes in patients from Japan and Mexico, suggesting increased susceptibility to developing the disease in patients with certain alleles. However, these associations have not been seen in North America. Vascular inflammation leads to arterial wall thickening, stenosis, and eventually, fibrosis and thrombus formation. The pathologic changes produce stenosis, dilation, aneurysm formation, and/or occlusion.

The clinical course of Takayasu's arteritis begins with a "prepulseless" phase in which the patient demonstrates constitutional symptoms. These include fever, anorexia, weight loss, general malaise, arthralgias, and malnutrition. As the inflammation progresses and stenoses develop, more characteristic features of the disease become evident. During the chronic phase, the disease is inactive or "burned out." It is during this latter stage that patients most frequently present with bruits and vascular insufficiency according to the arterial bed involved. Laboratory data may show elevations in erythrocyte sedimentation rate, C-reactive protein, and white blood cell count, or conversely, anemia may predominate. Characteristic clinical features during the second phase vary according to the involved vascular bed and include hypertension reflecting renal artery stenosis, retinopathy, aortic regurgitation, cerebrovascular symptoms, angina and congestive heart failure, abdominal pain or gastrointestinal bleeding, pulmonary hypertension, or extremity claudication.

Table 23-27

Angiographic classification of Takayasu's arteritis

TYPE	VESSEL INVOLVEMENT
Type I	Branches from the aortic arch
Type IIa	Ascending aorta, aortic arch and its branches
Type IIb	Ascending aorta, aortic arch and its branches, thoracic descending aorta
Type III	Thoracic descending aorta, abdominal aorta, and/or renal arteries
Type IV	Abdominal aorta and/or renal arteries
Type V	Combined features of types IIb and IV

Involvement of the coronary or pulmonary arteries is designated as C (+) or P (+), respectively.

The gold standard for diagnosis remains angiography showing narrowing or occlusion of the entire aorta or its primary branches, or focal or segmental changes in large arteries in the upper or lower extremities. Six types of Takayasu's arteritis exist and are graded in terms of severity: type I, affecting the aorta and arch vessels; type IIa, affecting the ascending aorta, aortic arch, and branches; type IIb, affecting the ascending aorta, aortic arch and branches, and thoracic descending aorta; type III, affecting the thoracic descending aorta, abdominal aorta, and/or renal arteries; type IV, affecting the abdominal aorta and/or renal arteries; and type V, with combined features of types IIb and IV.[237]

Treatment consists of steroid therapy initially, with cytotoxic agents used in patients who do not achieve remission. Surgical treatment is performed only in advanced stages, and bypass needs to be delayed during active phases of inflammation. There is no role for endarterectomy, and synthetic or autogenous bypass grafts need to be placed onto disease-free segments of vessels. For focal lesions, there have been reports of success with angioplasty.[208-210]

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is one of the more significant inheritable disorders affecting the connective tissue, along with Marfan's syndrome. This syndrome represents a heterogenous group of connective tissue disorders (types I through IV) that were first described in 1682 by van Meekeren.[238] It is an autosomal

dominant disorder affecting approximately 1 in 5000 persons that is characterized by skin elasticity, joint hypermobility, tissue fragility, multiple ecchymoses, and subcutaneous pseudotumors. Ehlers-Danlos syndrome is a disorder of fibrillar collagen metabolism with identifiable, specific defects that have been found in the collagen biosynthetic pathway that produce clinically distinct forms of this disease. Ten different phenotypes have been described, each with variable modes of inheritance and biochemical defects. Of the four basic types of collagen found in the body, the predominant type in blood vessels is type III. Within the vessel wall, type III collagen contributes to structural integrity and tensile strength and plays a role in platelet aggregation and thrombus formation.

Of the three types of Ehlers-Danlos syndrome that have arterial complications, type IV represents 5% of cases and is the one most likely to be seen by a vascular surgeon. These patients synthesize abnormal type III collagen (mutation *COL3A1*) and represent 5% of all cases.[238] Affected individuals do not show the typical skin and joint manifestations, and thus typically present for diagnosis when a major vascular catastrophe occurs. In a review of 36 patients with this disorder, Cikrit and colleagues reported a 44% mortality rate from major hemorrhage prior to any surgical intervention.[239] In the 20 patients who underwent 29 vascular procedures, there was a 29% mortality rate. Arterial rupture, aneurysm formation, and acute aortic dissection may occur in any major artery, with the most frequent site of rupture being the abdominal cavity. Repair is problematic because the vessel wall is soft and sutures pull through the fragile tissue. Ligation may be the only option in many circumstances.

Marfan's Syndrome

Another heterogeneous heritable disorder of connective tissue, Marfan's syndrome is characterized by abnormal musculoskeletal, ocular, and cardiovascular features first described by Antoine Marfan in 1896.[240] The inborn error of metabolism in this syndrome has been localized to the long arm of chromosome 15 (15q21.3). Defects occur in fibrillin, a basic protein in the microfibrillar apparatus that serves as a backbone for elastin, which is one of the main extracellular structural proteins in blood vessels. This is an autosomal dominant gene with high penetrance; however, approximately 15% to 20% of cases are secondary to new spontaneous mutations.[240]

Classic recognizable features of Marfan's syndrome include tall stature, long limbs (dolichostenomelia), long fingers (arachnodactyly), joint hyperextensibility, chest wall deformities, and scoliosis. Ocular manifestations are flattened corneas, lens subluxation, and myopia. Ninety-five percent of patients have cardiovascular involvement, which may include ascending aortic dilatation, mitral valve prolapse, valvular regurgitation, and aortic dissection. Skin, central nervous system, and pulmonary features may be present as well. Aortic root dilatation will generally occur in all patients. This may not be evident on standard chest radiograph until dilatation has resulted in an ascending aortic aneurysm, aortic valve regurgitation, or dissection. Left untreated, the cardiovascular complications are devastating and reduce the life expectancy to about 40 years for men and slightly higher for women. Death is usually attributable to life-threatening complications of aortic regurgitation, dissection, and rupture after the ascending aorta has dilated to 6 cm or more.

Aggressive medical management with β-adrenergic blocking agents and other blood pressure–lowering regimens is crucial to treatment. Surgical intervention entails replacement of the aortic root with a composite valve graft (e.g., Bentall procedure).[241] Prophylactic operative repair is indicated for an aneurysm greater than 5.5 cm, with an acceptable perioperative mortality of less than 5%.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is a rare inherited disorder of connective tissue that is characterized by an unbalanced elastic fiber metabolism and synthesis, resulting in fragmentation and calcification of the fibers. Clinical manifestations occur in the skin, ocular, gastrointestinal, and cardiovascular systems.[242] Characteristic skin lesions are seen in the axilla, antecubital and popliteal fossae, and groin. The yellow, xanthoma-like papules occur in redundant folds of skin and are said to resemble plucked chicken skin. The inheritance pattern includes both autosomal dominant and recessive types and has a prevalence of 1 in 160,000 individuals.[183] The ATP-binding cassette subfamily C member 6 (*ABCC6*) gene has been demonstrated to be responsible, and 43 mutations have been identified, all of which lead to calcification of the internal elastic laminae of medium-sized vessel walls.[242]

Cardiovascular features are common and include premature coronary artery disease, cerebrovascular disease, renovascular hypertension, diminished peripheral pulses, and restrictive cardiomyopathy. Symptom onset typically occurs in the second decade of life, with onset at an average age of 13 years. Patients should be counseled to reduce potential contributing factors for atherosclerosis such as tobacco use and high cholesterol levels. Calcium intake should be restricted in adolescents, as a positive correlation has been found between disease severity and calcium intake.[242] Surgical management involves standard vascular techniques, with the exception that arterial conduits should not be employed in cardiac bypass.

Kawasaki's Disease

Kawasaki's disease was first described in 1967, as a mucocutaneous lymph node syndrome occurring in young children. In most studies, more than half the patients are younger than 2 years of age, with a higher prevalence in boys.[243] Although originally described in Japan, the disease is found worldwide. An infectious agent may be causative; however, no specific agent has been identified. Immune activation with the contribution of cytokines, elastases, growth factors, and metalloproteinases is believed to be a mechanism for inflammation and aneurysm formation. Coronary artery aneurysms, the hallmark of the disease, histologically demonstrate a panarteritis with fibrinoid necrosis. Coronary arteriography may show occlusions, recanalization, and localized stenosis, in addition to multiple aneurysms. A variety of constitutional symptoms and signs resulting from systemic vasculitis are present in the acute phase of the illness.[243]

Medical therapy for Kawasaki's disease clearly decreases the manifestations of coronary artery involvement. Intravenous gamma globulin and aspirin therapy are most successful if begun within the first 10 days of illness. Up to 20% of untreated patients will develop coronary arterial lesions.[243] A long-term, low-dose aspirin therapy regimen is usually recommended.

Inflammatory Arteritis and Vasculitis

Chronic inflammatory arteritis and vasculitis (i.e., inflammatory changes within veins as well as arteries) include a spectrum of disease processes caused by immunologic mechanisms. These terms signify a necrotizing transmural inflammation of the

Table 23-28

Classification of vasculitis based on vessel involvement

Kawasaki's disease
Buerger's disease
Small-Vessel Vasculitis
Hypersensitivity angiitis

vessel wall associated with antigen-antibody immune complex deposition within the endothelium. These conditions show pronounced cellular infiltration in the adventitia, thickened intimal fibrosis, and organized thrombus.[204] These disease processes may clinically mimic atherosclerosis, and most are treated by corticosteroid therapy or chemotherapeutic agents. Even so, it is important to recognize distinguishing characteristics of each disease in order to establish the course of treatment and long-term prognosis. A classification system of systemic vasculitis by vessel size is shown in Table 23-28.

Behçet's Disease

Behçet's disease is a rare syndrome characterized by oral and genital ulcerations and ocular inflammation, affecting males in Japan and the Mediterranean. An HLA linkage has been found, indicating a genetic component to the etiology. Vascular involvement is seen in 7% to 38% of patients and is localized to the abdominal aorta, femoral artery, and pulmonary artery.[213] Vascular lesions may also include venous complications such as deep venous thrombosis or superficial thrombophlebitis. Arterial aneurysmal degeneration can occur; however, this is an uncommon, albeit potentially devastating, complication. Multiple true aneurysms and pseudoaneurysms may develop, and rupture of an aortic aneurysm is the major cause of death in patients with Behçet's disease.[244]

Histologically, degeneration of the vasa vasorum with surrounding perivascular lymphocyte infiltration is seen, along with thickening of the elastic laminae around the tunica media.[215] Aneurysm formation is believed to be associated with a loss of the nutrient flow and elastic component of the vessels, leading to progressive dilatation. Multiple aneurysms are relatively common, with a reported occurrence of 36% in affected Japanese patients.[244] Furthermore, pseudoaneurysm formation after surgical bypass is common at anastomotic suture lines due to the vascular wall fragility and medial destruction. Systemic therapy with corticosteroids and immunosuppressive agents may diminish symptoms related to the inflammatory process; however, they have no effect on the rate of disease progression and arterial degeneration.[244]

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is another systemic inflammatory disease process, which is characterized by a necrotizing inflammation of medium-sized or small arteries that spares the smallest blood vessels (i.e., arterioles and capillaries). This disease predominantly affects men over women by a 2:1 ratio. PAN develops subacutely, with constitutional symptoms that last for weeks to months. Intermittent, low-grade fevers, malaise, weight loss, and myalgias are common presenting symptoms. As medium-sized vessels lie within the deep dermis, cutaneous manifestations occur in the form of livedo reticularis, nodules, ulcerations, and digital ischemia.[218] Skin biopsies of these lesions may be sufficient for diagnosis. Inflammation may be seen histologically, with pleomorphic cellular infiltrates and segmental transmural necrosis leading to aneurysm formation.

Neuritis from nerve infarction occurs in 60% of patients, and gastrointestinal complications occur in up to 50%.[245] Additionally, renal involvement is found in 40% and manifests as microaneurysms within the kidney or segmental infarctions. Cardiac disease is a rare finding except at autopsy, where thickened, diseased coronary arteries may be seen, as well as patchy myocardial necrosis. Patients may succumb to renal failure, intestinal hemorrhage, or perforation. End-organ ischemia from vascular occlusion or aneurysm rupture can be disastrous complications with high mortality rates. The mainstay of treatment is steroid and cytotoxic agent therapy. Up to 50% of patients with active PAN will experience remission with high dosing.[245]

Radiation-Induced Arteritis

Radiation-induced arteritis results from progressive stenosis due to endothelial damage that leads to cellular proliferation and fibrosis. These are well-described complications of combined irradiation and chemotherapy for the treatment of head and neck malignancy. Arterial lesions are known complications of radiation and are similar to those found in atherosclerotic occlusive disease. A history of therapeutic irradiation to the neck can complicate the management of carotid artery occlusive disease. Radiation-induced damage to blood vessels has been well studied. The small capillaries and sinusoids are most susceptible to radiation effects, as endothelial cells are the most radiosensitive cells. The radiation effects on the medium- and large-sized arteries include myointimal proliferation, with or without lipid deposits, and thrombosis. Characteristically, irregular spindle-shaped cells are seen replacing the normal endothelial cells in the healing phase. Occlusive lesions develop in the irradiated carotid arteries and are either the result of vessel wall fibrosis or, more commonly, due to accelerated atherosclerosis. Neurologic complications related to radiation-induced carotid artery disease are similar to those due to nonirradiated atherosclerotic occlusive disease.

Rupture of the carotid artery has been reported following neck irradiation and is likely related to local wound complication and superimposed infection. The diagnosis of radiation arteritis is based on the clinical history and confirmation of the occlusive lesion by duplex ultrasound, MRA, CTA, or subtraction angiography. Irradiated lesions can be confined to the irradiated segment of the internal carotid artery with the remaining part of the vessel spared of disease. Characteristically, the radiation-induced atherosclerotic lesion does not involve the carotid bulb, unlike the nonradiated atherosclerotic lesions. The indications for intervention in radiation-induced carotid lesions are the same as previously discussed for atherosclerotic carotid occlusive lesions. However, asymptomatic irradiated carotid artery lesions should be considered for intervention because they can be more prone to progression and development of neurologic complications. Endovascular treatment with carotid angioplasty/stenting has become the treatment of choice for radiation-induced lesions, although surgical endarterectomy

and bypass have been shown to be safe. The rate of recurrent stenosis is higher in radiation-induced carotid lesions, whether stented or surgically treated.

Raynaud's Syndrome

First described in 1862 by Maurice Reynaud, the term *Raynaud's syndrome* applies to a heterogeneous symptom array associated with peripheral vasospasm, more commonly occurring in the upper extremities. The characteristically intermittent vasospasm classically follows exposure to various stimuli, including cold temperatures, tobacco, or emotional stress. Formerly, a distinction was made between Raynaud's "disease" and Raynaud's "phenomenon" for describing a benign disease occurring in isolation or a more severe disease secondary to another underlying disorder, respectively. However, many patients develop collagen vascular disorders at some point after the onset of vasospastic symptoms; progression to a connective tissue disorder ranges from 11% to 65% in reported series.[246, 247] Therefore, the term Raynaud's syndrome is now used to encompass both the primary and secondary conditions.

Characteristic color changes occur in response to the arteriolar vasospasm, ranging from intense pallor to cyanosis to redness as the vasospasm occurs. The digital vessels then relax, eventually leading to reactive hyperemia. The majority of patients are young women less than 40 years of age. Up to 70% to 90% of reported patients are women, although many patients with only mild symptoms may never present for treatment. Geographic regions with cooler, damp climates such as the Pacific Northwest and Scandinavian countries have a higher reported prevalence of the syndrome. Certain occupational groups, such as those who use vibrating tools, may be more predisposed to Raynaud's syndrome or digital ischemia. The exact pathophysiologic mechanism behind the development of such severe vasospasm remains elusive, and much attention has focused on increased levels of α_2-adrenergic receptors and their hypersensitivity in patients with Raynaud's syndrome, as well as abnormalities in the thermoregulatory response, which is governed by the sympathetic nervous system.[246]

The diagnosis of severe vasospasm may be made using noninvasive measurements in the vascular laboratory. Angiography is usually reserved for those who have digital ulceration and in whom an embolic or obstructive cause is believed to be present and potentially surgically correctable. Different changes in digital blood pressure will occur in patients with Raynaud's syndrome. Normal individuals will show only a slight decrease in digital blood pressure in response to external cold stimuli, whereas those with Raynaud's syndrome will show a similar curve until a critical temperature is reached.[246] It is at this point that arterial closure acutely occurs.

There is no cure for Raynaud's syndrome; thus all treatments mainly palliate symptoms and decrease the severity and perhaps frequency of attacks. Conservative measures predominate, including the wearing of gloves, use of electric or chemically activated hand warmers, avoiding occupational exposure to vibratory tools, abstinence from tobacco, and relocating to a warmer, dryer climate. The majority (90%) of patients will respond to avoidance of cold and other stimuli. The remaining 10% of patients with more persistent or severe syndromes can be treated with a variety of vasodilatory drugs, albeit with only a 30% to 60% response rate. Calcium channel–blocking agents such as diltiazem and nifedipine are the drugs of choice. The selective serotonin reuptake inhibitor fluoxetine has been shown to reduce the frequency and duration of vasospastic episodes.[246] Intravenous infusions of prostaglandins have been reserved for nonresponders with severe symptoms.

Surgical therapy is limited to debridement of digital ulcerations and amputation of gangrenous digits, which are rare complications. Upper extremity sympathectomy may provide relief in 60% to 70% of patients; however, the results are short-lived with a gradual recurrence of symptoms in 60% of patients within 10 years.[246,247]

Fibromuscular Dysplasia

FMD is a vasculopathy of uncertain etiology that is characterized by segmental arterial involvement. Histologically, fibrous tissue proliferation, smooth muscle cell hyperplasia, and elastic fiber destruction alternate with mural thinning.[248] The characteristic beaded appearance of FMD is due to areas of medial thinning alternating with areas of stenosis. The most commonly affected are medium-sized arteries, including the internal carotid, renal, vertebral, subclavian, mesenteric, and iliac arteries. The internal carotid artery is the second most common site of involvement after the renal arteries. FMD occurs most frequently in women (90%) and is recognized at approximately 55 years of age. Only 10% of patients with FMD will have complications attributable to the disease.[248] Pathologically, FMD is a heterogenous group of four distinct types of lesions that are subgrouped based on the predominant site of involvement within the vessel wall. Of the four types (medial fibroplasia, intimal fibroplasia, medial hyperplasia, and perimedial dysplasia), medial fibroplasia is the most common pathologic type, affecting the internal carotid artery (ICA) and the renal artery, and occurring in 85% of reported cases.[248]

The two main clinical syndromes associated with FMD are TIAs from disease in the internal carotid artery and hypertension from renal artery involvement. Symptoms produced by FMD are generally secondary to associated arterial stenosis and are clinically indistinguishable from those caused by atherosclerotic disease. Often, asymptomatic disease is found incidentally on conventional angiographic studies being performed for other reasons. Within the internal carotid artery, FMD lesions tend to be located higher in the extracranial segment than with atherosclerotic lesions and may not be readily demonstrated by duplex scan.

Clinically, symptoms are due to encroachment on the vessel lumen and a reduction in flow. Additionally, thrombi may form in areas of mural dilatation from a stagnation of flow, leading to distal embolization. Surgical treatment has been favored for symptomatic patients with angiographically proven disease. Due to the distal location of FMD lesions in the extracranial carotid artery, resection and repair are not usually feasible. Instead, graduated luminal dilatation under direct vision has been used successfully in patients, with antiplatelet therapy continued postoperatively. PTA has been used effectively in patients with FMD-induced hypertension. Several series have documented a high technical success rate, with recurrence rates of 8% to 23% at more than 1 year.[249] However, the therapeutic effect of blood pressure control may continue to be observed despite restenosis. Surgical reconstruction of the renal arteries for FMD has good long-term results and is recommended for recurrent lesions after angioplasty.[249] Open balloon angioplasty of the ICA has been described, which allows for precise fluoroscopic guidance, rather than blind dilatation with calibrated metal probes, and back-bleeding after dilatation to eliminate

cerebral embolization.[247] Distal neuroprotective devices may allow this procedure to be performed completely percutaneously, by lessening the threat of cerebral emboli.

Nonatherosclerotic Disease Affecting the Popliteal Artery Disease

There are three distinct nonatherosclerotic disease entities that may result in lower extremity claudication that predominantly occur in 40- to 50-year-old men. Adventitial cystic disease, popliteal artery entrapment syndrome, and Buerger's disease should be considered in any young patients presenting with intermittent claudication.

Adventitial Cystic Disease of the Popliteal Artery. The first successful operative repair of popliteal artery occlusion caused by a cyst arising from the adventitia was reported in 1954 by Ejrup and Hierton.[250] Adventitial cystic disease is a rare arterial condition occurring at an incidence of 0.1%, usually in the popliteal artery. This disease affects men in a ratio of approximately 5:1 and appears predominantly in the fourth and fifth decades. The incidence is approximately 1 in 1200 cases of claudication or 1 in 1000 peripheral arteriograms.[250] The predominance of reported cases is found in Japan and Europe. However, this disease may affect other vascular sites, such as the femoral, external iliac, radial, ulnar, and brachial arteries. Besides claudication as a symptom, this diagnosis should be considered in young patients who have a mass in a nonaxial vessel in proximity to a related joint. These synovial-like, mucin-filled cysts reside in the subadventitial layer of the vessel wall and have a similar macroscopic appearance to ganglion cysts. Despite this similarity and suggestion of a joint origin for these lesions, histochemical markers have failed to link the cystic lining to synovium.

Patients presenting at a young age with bilateral lower extremity claudication and minimal risk factors for atheroma formation should be evaluated for adventitial cystic disease, as well as the other two nonatherosclerotic vascular lesions described here. Because of luminal encroachment and compression, peripheral pulses may be present in the limb when extended, but then can disappear during knee joint flexion. Noninvasive studies may suggest arterial stenosis with elevated velocities. Color-flow duplex scanning followed by T2-weighted MRI now appears to be the best diagnostic choice. Angiography will demonstrate a smooth, well-defined, crescent-shaped filling defect, the classic "scimitar" sign.[250] There may be associated calcification in the cyst wall and no other evidence of atherosclerotic occlusive disease.

Various therapeutic methods have been described for the treatment of adventitial cystic disease. The recommended treatments are excision of the cyst with the cystic wall, enucleation, or simple aspiration when the artery is stenotic. Retention of the cystic lining leads to continued secretion of the cystic fluid and recurrent lesions. In 30% of patients who have an occluded artery, resection of the affected artery, followed by an interposition graft using autogenous saphenous vein, is recommended.

Popliteal Artery Entrapment Syndrome. Love and colleagues first coined the term *popliteal artery entrapment* in 1965 to describe a syndrome combining muscular involvement with arterial ischemia occurring behind the knee, with the successful surgical repair having taken place 6 years earlier.[251] This is a rare disorder with an estimated prevalence of 0.16% that occurs with a male-to-female ratio of 15:1. Five types of anatomic entrapment have been defined, according to the position of the medial head of the gastrocnemius muscle, abnormal muscle slips or tendinous bands, or the course of the popliteal artery itself (Table 23-29). Concomitant popliteal vein impingement occurs in up to 30% of cases. Twenty-five percent of cases are bilateral.

Table 23-29
Classification of popliteal entrapment syndrome

TYPE	DESCRIPTION
I	Popliteal artery is displaced medially around a normal medial head of the gastrocnemius
II	Medial head of gastrocnemius, which arises lateral to popliteal artery
III	Popliteal artery is compressed by an accessory slip of muscle from medial head of gastrocnemius
IV	Entrapment by a deeper popliteus muscle
V	Any of the above plus popliteal vein entrapment
VI	Functional entrapment

The typical patient presents with swelling and claudication of isolated calf muscle groups following vigorous physical activity. Various differential diagnoses must be considered when encountering patients with symptoms and signs suggestive of popliteal artery entrapment syndrome (Table 23-30). In a large series of 240 patients, the median age for surgical treatment was 28.5 years.[251] Noninvasive studies with ABIs should be performed with the knee extended and the foot in a neutral, forced plantar, and dorsiflexed position. A drop in pressure of 50% or greater or dampening of the plethysmographic waveforms in plantar or dorsiflexion is a classic finding.

Table 23-30
Differential diagnosis for popliteal entrapment syndrome

Vascular Etiologies
- Atherosclerosis
- Buerger's disease
- Trauma
- Popliteal aneurysm
- Adventitial cystic disease
- Extrinsic compression
- Cardiac embolism
- Deep vein thrombosis
- Venous entrapment

Musculoskeletal Etiologies
- Gastrocnemius or soleus strain
- Periostitis
- Compartment syndrome
- Stress fractures
- Tibialis posterior tendonitis
- Muscular anomalies

General Neurologic Etiologies
- Spinal stenosis

Contraction of the gastrocnemius should compress the entrapped popliteal artery. The sudden onset of signs and symptoms of acute ischemia with absent distal pulses is consistent with popliteal artery occlusion secondary to entrapment. Other conditions resulting from entrapment are thrombus formation with distal emboli or popliteal aneurysmal degeneration. Although CT and MRI have been employed, angiography remains the most widely used test. Angiography performed with the foot in a neutral position may demonstrate classical medial deviation of the popliteal artery or normal anatomic positioning. Coexisting abnormalities may include stenosis, luminal irregularity, delayed flow, aneurysm, or complete occlusion. Diagnostic accuracy is increased with the use of ankle stress view-active plantar flexion and passive dorsiflexion.

The treatment of popliteal artery entrapment consists of surgical decompression of the impinged artery with possible arterial reconstruction. Division of the anomalous musculotendinous insertion site with or without saphenous vein interposition grafting to bypass the damaged arterial segment has been described to be the procedure of choice. The natural history of entrapment is progressive arterial degeneration leading to complete arterial thrombosis. In such instances, thrombolytic therapy is needed with subsequent release of the functional arterial impairment. Lysis will improve distal runoff and may improve limb-salvage and bypass patency rates.

Buerger's Disease (Thromboangiitis Obliterans)

Buerger's disease, also known as thromboangiitis obliterans, is a progressive nonatherosclerotic segmental inflammatory disease that most often affects small- and medium-sized arteries, veins, and nerves of the upper and lower extremities.[252] The clinical and pathologic findings of this disease entity were published in 1908 by Leo Buerger in a description of 11 amputated limbs.[252] The typical age range for occurrence is 20 to 50 years, and the disorder is more frequently found in males who smoke. The upper extremities may be involved, and a migratory superficial phlebitis may be present in up to 16% of patients, thus indicating a systemic inflammatory response. In young adults presenting to the Mayo Clinic (1953–1981) with lower limb ischemia, Buerger's disease was diagnosed in 24%.[252] Conversely, the diagnosis was made in 9% of patients with ischemic finger ulcerations. The cause of thromboangiitis obliterans is unknown; however, use of or exposure to tobacco is essential to both the diagnosis and progression of the disease.

Pathologically, thrombosis occurs in small- to medium-sized arteries and veins with associated dense polymorphonuclear leukocyte aggregation, microabscesses, and multinucleated giant cells. The chronic phase of the disease shows a decrease in the hypercellularity and frequent recanalization of the vessel lumen. End-stage lesions demonstrate organized thrombus and blood vessel fibrosis. Although the disease is common in Asia, North American males do not appear to have any particular predisposition, as the diagnosis is made in less than 1% of patients with severe limb ischemia.

Buerger's disease typically presents in young male smokers, with symptoms beginning prior to age 40. Patients initially present with foot, leg, arm, or hand claudication, which may be mistaken for joint or neuromuscular problems. Progression of the disease leads to calf claudication and eventually ischemic rest pain and ulcerations on the toes, feet, or fingers. A complete history should exclude diabetes, hyperlipidemia, or autoimmune disease as possible etiologies for the occlusive lesions. Because it is likely that multiple limbs are involved, angiography should be performed of all four limbs. Even if symptoms are not yet present in a limb, angiographic findings may be demonstrated. Characteristic angiographic findings show disease confinement to the distal circulation, usually infrapopliteal and distal to the brachial artery. The occlusions are segmental and show "skip" lesions with extensive collateralization, the so-called "corkscrew collaterals."

The treatment of thromboangiitis obliterans revolves around strict smoking cessation. In patients who are able to abstain, disease remission is impressive and amputation avoidance is increased. In the experience reported from the Oregon Health Sciences Center, no disease progression with associated tissue loss occurred after discontinuation of tobacco. The role of surgical intervention is minimal in Buerger's disease, as there is often no acceptable target vessel for bypass. Furthermore, autogenous vein conduits are limited secondary to coexisting migratory thrombophlebitis. Mills and associates reported their results of 31% limb loss in 26 patients over 15 years, thus authenticating the virulence of Buerger's disease involving the lower extremities.[252] In addition, others have described a significant discrepancy in limb loss in patients who continued to smoke versus those who discontinued tobacco use (67% vs. 35%).

chapter 24

Venous and Lymphatic Disease

Jason P. Jundt, Timothy K. Liem, and Gregory L. Moneta

VENOUS ANATOMY

Veins are part of a dynamic and complex system that returns low-nutrient deoxygenated blood to the heart. Venous blood flow is dependent on multiple factors such as gravity, venous valves, the cardiac and respiratory cycles, blood volume, and the calf muscle pump. Alterations in the intricate balance of these factors can result in venous pathology.

Structure of Veins

Veins are thin-walled, highly distensible, and collapsible. Their structure specifically supports the primary functions of veins to transport blood toward the heart and serve as a reservoir to prevent intravascular volume overload.

The venous intima is composed of a nonthrombogenic endothelium with an underlying basement membrane and an elastic lamina. The endothelium produces endothelium-derived relaxing factors such as nitric oxide and prostacyclin, which help maintain a nonthrombogenic surface through inhibition of platelet aggregation and promotion of platelet disaggregation.[1] Circumferential rings of elastic tissue and smooth muscle located in the media of the vein allow for changes in vein caliber with minimal changes in venous pressure. The adventitia is most prominent in large veins and consists of collagen, elastic fibers, and fibroblasts. When a vein is maximally distended, its diameter may be several times greater than that in the supine position.

In the axial veins, unidirectional blood flow is achieved with multiple venous valves. The inferior vena cava (IVC), common iliac veins, portal venous system, and cranial sinuses are valveless. In the axial veins, valves are more numerous distally in the extremities than proximally. Each valve consists of two thin cusps of a fine connective tissue skeleton covered by endothelium. Venous valves close in response to cephalad-to-caudal blood flow at a velocity of at least 30 cm/s.[2]

Lower Extremity Veins

Lower extremity veins are divided into superficial, deep, and perforating veins. The superficial venous system lies above the uppermost fascial layer of the leg and thigh and consists of the great saphenous vein (GSV) and small saphenous vein (SSV) and their tributaries. The GSV originates from the dorsal pedal venous arch and courses cephalad, anterior to the medial malleolus, entering the common femoral vein approximately 4 cm inferior and lateral to the pubic tubercle. The saphenous nerve accompanies the GSV medially from the ankle to the level of the knee and supplies cutaneous sensation to the medial leg and ankle. The SSV originates laterally from the dorsal pedal venous arch and courses cephalad in the posterior calf. Most often, it penetrates the popliteal fossa, between the medial and lateral heads of the gastrocnemius muscle, to join the popliteal vein. The termination of the SSV may be quite variable, however, with a proximal extension of the SSV (the vein of Giacomini) frequently connecting with the deep femoral vein or GSV. The sural nerve accompanies the SSV laterally along its course and supplies cutaneous sensation to the lateral malleolar region.

The deep veins follow the course of major arteries in the extremities. In the lower leg, paired veins parallel the course of the anterior tibial, posterior tibial, and peroneal arteries, to join behind the knee forming the popliteal vein. Venous bridges connect the paired veins in the lower leg. The popliteal vein continues through the adductor hiatus to become the femoral vein. In the proximal thigh, the femoral vein joins with the deep femoral vein to form the common femoral vein, becoming the external iliac vein at the inguinal ligament.

Multiple perforator veins traverse the deep fascia to connect the superficial and deep venous systems. Potentially clinically important perforator veins are the Cockett and Boyd perforators. The Cockett perforator veins drain the medial

Key Points

1. Thrombolytic therapy, surgical thrombectomy, and placement of inferior vena cava filters are adjunctive treatments that may be indicated in patients with extensive and complicated venous thromboembolism.
2. Deep vein thrombosis (DVT) and pulmonary embolism are frequent complications after major abdominal and orthopedic procedures. The risk is further increased in patients with malignancy and a history of venous thromboembolism. Options for DVT prophylaxis include intermittent pneumatic compression, use of graduated compression stockings, and administration of low-dose unfractionated heparin, low molecular weight heparin, fondaparinux, and vitamin K antagonists. However, prophylaxis should be stratified based on the patient's level of risk.
3. In patients with established DVT, unfractionated heparin, low molecular weight heparin, and fondaparinux are options for *initial* antithrombotic therapy. The duration and type of *long-term* anticoagulation should be stratified based on the provoked or unprovoked nature of the DVT, the location of the DVT, previous occurrence of DVT, and presence of concomitant malignancy.
4. Saphenous vein stripping, endovenous laser treatment, and radiofrequency ablation are effective therapies for patients with saphenous vein valvular insufficiency. Concomitant varicose veins may be managed with compression therapy, sclerotherapy (for smaller varices), and phlebectomy.
5. The mainstay of treatment for chronic venous insufficiency is compression therapy. Sclerotherapy, perforator vein ligation, and venous reconstruction may be indicated in patients in whom conservative management fails.
6. Lymphedema is categorized as primary (with early or delayed onset) or secondary. The goals of treatment are to minimize edema and prevent infection. Lymphatic massage, sequential pneumatic compression, use of compression garments, and limb elevation are effective forms of therapy.

lower leg and are relatively constant. They connect the posterior arch vein (a tributary to the GSV) and the posterior tibial vein. They may become varicose or incompetent in venous insufficiency states. The Boyd perforator veins connect the GSV to the deep veins approximately 10 cm below the knee and 1 to 2 cm medial to the tibia.

Venous sinuses are thin-walled, large veins located within the substance of the soleus and gastrocnemius muscles. These sinuses are valveless and are linked by valved, small venous channels that prevent reflux. A large amount of blood can be stored in the venous sinuses. With each contraction of the calf muscle bed, blood is pumped out through the venous channels into the main conduit veins to return to the heart.

Upper Extremity Veins

As in the lower extremity, there are deep and superficial veins in the upper extremity. Deep veins of the upper extremity are paired and follow the named arteries in the arm. Superficial veins of the upper extremity are the cephalic and basilic veins and their tributaries. The cephalic vein originates at the lateral wrist and courses over the ventral surface of the forearm. In the upper arm, the cephalic vein terminates in the infraclavicular fossa, piercing the clavipectoral fascia to empty into the axillary vein. The basilic vein runs medially along the forearm and penetrates the deep fascia as it courses past the elbow in the upper arm. It then joins with the deep brachial veins to become the axillary vein. The median cubital vein joins the cephalic and the basilic veins on the ventral surface of the elbow.

The axillary vein becomes the subclavian vein at the lateral border of the first rib. At the medial border of the scalenus anterior muscle, the subclavian vein joins with the internal jugular vein to become the brachiocephalic vein, with the subclavian vein coursing anterior to the scalenus anterior muscle. The left and right brachiocephalic veins join to become the superior vena cava, which empties into the right atrium.

EVALUATION OF THE VENOUS SYSTEM

Clinical Evaluation

Evaluation of the venous system begins with a detailed history and physical examination. Risk factors for acute and chronic venous disease are identified. They include increased age, history of venous thromboembolism (VTE), malignancy, trauma and spinal cord injury, hospitalization and immobilization, obesity, nephrotic syndrome, pregnancy and the recently postpartum state, oral contraceptive use or hormone replacement therapy, varicose veins, and hypercoagulable states, as well as the postoperative state. Venous pathology is often, but not always, associated with visible or palpable signs that can be identified during the physical examination. There is variation among individuals in the prominence of superficial veins when the person is standing (Fig. 24-1). The superficial veins of a

lean athletic person, even when normal, will appear large and easily visualized, but these veins will be far less obvious in the obese individual. Possible signs of superficial venous abnormalities are listed in Table 24-1. The deep veins cannot be directly assessed clinically, and abnormalities within them can only be inferred indirectly from changes found on clinical examination.

Chronic venous insufficiency (CVI) may lead to characteristic changes in the skin and subcutaneous tissues in the affected limb. CVI results from incompetence of venous valves, venous obstruction, or both. Most CVI involves venous reflux, and severe CVI often reflects a combination of reflux and venous obstruction. It is important to remember that although CVI originates with abnormalities of the veins, the target organ of CVI is the skin, and the underlying physiologic and biochemical mechanisms leading to the cutaneous abnormalities associated with CVI are poorly understood. A typical leg affected by CVI will be edematous, with edema increasing over the course of the day. The leg may also be indurated and pigmented with eczema and dermatitis. These changes are associated with excessive proteinaceous capillary exudate and deposition of a pericapillary fibrin cuff that may limit nutritional exchange. In addition, an increase in white blood cell trapping within the skin microcirculation in CVI patients may lead to microvascular congestion and thrombosis. Subsequently, white blood cells may migrate into the interstitium and release necrotizing lysosomal enzymes, potentially leading to tissue destruction and eventual ulceration.

Fibrosis can eventually develop from impaired nutrition, chronic inflammation, and fat necrosis (lipodermatosclerosis). Hemosiderin deposition due to the extravasation of red cells and subsequent lysis in the skin contributes to the characteristic pigmentation of chronic venous disease (Fig. 24-2). Ulceration can develop with longstanding venous hypertension and is associated with alterations in microcirculatory and cutaneous lymphatic anatomy and function. The most common location of venous ulceration is approximately 3 cm proximal to the medial malleolus (Fig. 24-3).

Trendelenburg's test is a clinical test, historically important but now rarely used, that can help determine whether incompetent valves are present and in which of the three venous systems (superficial, deep, or perforator) the valves are abnormal. There are two components to this test. First, with the patient supine, the leg is elevated 45° to empty the veins, and the GSV is occluded with the examiner's hand or with a rubber tourniquet. With the GSV still occluded, the patient stands and the superficial veins are observed for blood filling. The compression on the GSV is released and the superficial veins are observed for filling with blood. A negative result, indicating no clinically relevant venous reflux, is the gradual filling of the veins from arterial inflow. A positive result is the sudden filling of veins with standing while the GSV remains occluded indicating incompetent perforator

Figure 24-2. Characteristic hyperpigmentation of chronic venous insufficiency.

Figure 24-3. Venous ulceration located proximal to the medial malleolus.

and deep veins. The GSV valves are incompetent if the second component of the test yields a positive result. Interpretation of the findings of Trendelenburg's test is subjective, and therefore, it has largely been supplanted by the more objective noninvasive vascular laboratory tests to localize sites of venous reflux.

Noninvasive Evaluation. Before the development of vascular ultrasound, noninvasive techniques to evaluate the venous system were based on plethysmographic techniques. Although a variety of plethysmographic techniques are used in the evaluation of both acute and chronic venous disease, they are all based on the detection of volume changes in the limb in response to blood flow.

Duplex ultrasonography (DUS) augmented by color flow imaging is now the most important noninvasive diagnostic method in the evaluation of the venous system. DUS has become standard for the detection of infrainguinal deep vein thrombosis (DVT), with near 100% sensitivity and specificity in symptomatic patients.[3] It is also the preferred method of evaluation for upper extremity venous thrombosis and is useful in the evaluation of CVI by documenting the presence of valvular reflux and venous obstruction. Overlying bowel gas and large body habitus make DUS less applicable to evaluation of intra-abdominal veins. Magnetic resonance venography (MRV) and computed tomography (CT) venography are noninvasive techniques for evaluation of pelvic and intra-abdominal veins.

Invasive Evaluation. Improved accuracy of noninvasive techniques for diagnostic purposes has made the use of invasive procedures more selective. Both venography and intravascular ultrasound (IVUS) are used as adjuncts to percutaneous or open surgical treatment of venous disorders. When planning endovascular or open surgical treatment, venography may be used to identify areas of obstruction in infrainguinal, intra-abdominal, and upper extremity veins as well as reflux in intra-abdominal and infrainguinal veins. IVUS, with access generally via the common femoral vein, is used primarily to assess for occlusive lesions of the iliac veins and appears more sensitive than venography in detecting iliac vein obstruction.

Complications of venography include pain, thrombosis, or hematoma at the puncture site. Pain is lower with nonionic low-osmolality contrast media than with conventional contrast agents (with 18% vs. 44% of patients experiencing discomfort, respectively).[4] Systemic effects of iodinated contrast media include allergic reaction and risk of renal failure. Postvenography venous thrombosis occurs distal to the venous puncture site in 1% to 9% of patients undergoing venography secondary to intimal damage from the intravenous (IV) contrast agent.[4] Complications of IVUS are primarily related to the access site.

VENOUS THROMBOEMBOLISM

Epidemiology

Despite increased awareness and use of prophylactic modalities, DVT and pulmonary embolism (PE), or VTE, remain important preventable sources of morbidity and mortality, especially in the surgical patient. The incidence of VTE is approximately 100 per 100,000 people per year in the general population, with 20% of the diagnoses made within 3 months of a surgical procedure. Of the symptomatic patients, one third will present with PE and two thirds with DVT.[5,6] The estimated number of cases of VTE may well be over 600,000 per year in the United States, making it a major U.S. health problem.[7] Furthermore, death occurs in 6% of DVT and 12% of PE cases within 1 month of diagnosis.[5] Not only does VTE pose a veritable threat to life, but it also places patients at higher risk for recurrence and post-VTE sequelae such as pulmonary hypertension and postthrombotic syndrome, with 4% and up to 30% incidence, respectively.[8-10]

Risk Factors

Three conditions, first described by Rudolf Virchow in 1862, contribute to VTE formation: stasis of blood flow, endothelial damage, and hypercoagulability. Of these risk factors, relative hypercoagulability appears most important in most cases of *spontaneous* VTE, or so-called idiopathic VTE, whereas stasis and endothelial damage likely play a greater role in *secondary* VTE, or so-called provoked VTE, occurring in association with transient risk factors such as immobilization, surgical procedures, and trauma. Identifiable risk factors for VTE generally relate to one of the conditions described by Virchow. Often more than one risk factor is present. Specific risk factors for VTE are listed in Table 24-2.

The more common acquired VTE risk factors include older age (>40 years), hospitalization and immobilization, hormone replacement and oral contraceptive therapy, pregnancy and the recently postpartum state, prior VTE, malignancy, major surgery, obesity, nephrotic syndrome, trauma and spinal cord injury, long-haul travel (>6 hours), varicose veins, antiphospholipid syndrome, myeloproliferative disorders, and polycythemia. Heritable risk factors include male sex, factor V Leiden

Table 24-2

Risk factors for venous thromboembolism

Hyperfibrinogenemia
Activated protein C resistance without factor V Leiden

mutation; prothrombin 20210A gene variant; antithrombin, protein C, and protein S deficiencies; and dysfibrinogenemias. In some patients, the cause of the thrombophilia may have both a heritable and an acquired component. These mixed causes include homocysteinemia; factor VII, VIII, IX, and XI elevation; hyperfibrinogenemia; and activated protein C resistance in the absence of factor V Leiden.[11] There may be a synergistic effect when particular multiple inherited and acquired risk factors are present in the same patient.

Other patient-specific factors associated with venous thrombosis include the traditional cardiovascular risk factors of obesity, hypertension, and diabetes. VTE is more common in whites and African Americans than Asians and Native Americans.[12,13] Certain gene variants (single nucleotide polymorphisms) are also associated with a mildly increased risk for VTE, and their presence may interact with other risk factors to increase the overall risk for venous thrombosis.[14]

Anatomic factors may also contribute to development of DVT. At the site where the right iliac artery crosses over the left iliac vein, the left iliac vein may become chronically narrowed predisposing to iliofemoral venous thrombosis, so-called May-Thurner syndrome. External compression of major veins by masses of various types can also lead to venous thrombosis.

Many cases of VTE are potentially preventable. Accordingly, in current clinical practice, preoperative VTE risk assessment is becoming increasingly common to identify patients at moderate and high risk. Scoring systems have been developed that take into account the number of VTE risk factors in an individual patient. These risk stratification scores, such as the Rogers score[15] and Caprini score,[16] provide individual patient risk stratification and recommendations for prophylactic anticoagulation. The ninth edition of the American College of Chest Physicians (ACCP) Guidelines for Prevention of VTE in Non-Orthopedic Surgical Patients acknowledges both the Rogers and Caprini scores and provides recommendations for VTE prophylaxis (Table 24-3). Orthopedic surgical patients are generally excluded from risk assessment scores because of the disproportionately increased risk of VTE in orthopedic surgery compared with the general and abdominopelvic surgery population.

Diagnosis

Clinical Evaluation. Early in the course of DVT development, venous thrombosis is thought to begin in an area of relative stasis, such as a soleal sinus vein or immediately downstream of the cusps of a venous valve in the axial calf veins. Isolated proximal DVT without tibial vein thrombosis is unusual. Early in the course of a DVT, there may be no or few clinical findings such as pain or swelling. Even extensive DVT may sometimes be present without signs or symptoms. History and physical examination are therefore unreliable in the diagnosis of DVT. In addition, symptoms and signs generally associated with DVT, such as extremity pain and/or swelling, are nonspecific. In large studies, DVT has been found by venography or DUS in ≤50% of patients in whom it was clinically suspected.[17,18] Objective studies are therefore required to confirm a diagnosis of VTE or to exclude the presence of VTE.

Clinical symptoms may worsen as DVT propagates and involves the major proximal deep veins. Extensive DVT of the major axial deep venous channels of the lower extremity with relative sparing of collateral veins causes a condition called *phlegmasia cerulea dolens* (Fig. 24-4). This condition is characterized by pain and pitting edema with associated cyanosis. When the thrombosis extends to the collateral veins, massive fluid sequestration and more significant edema ensue, resulting in a condition known as *phlegmasia alba dolens*.[19] The affected extremity in phlegmasia alba dolens is extremely painful and edematous and pale secondary to arterial insufficiency from dramatically elevated below lower knee compartment pressures. Both phlegmasia cerulean dolens and phlegmasia alba dolens can be complicated by venous gangrene and the need for amputation.

Table 24-3

Thromboembolism risk and recommended thromboprophylaxis in surgical patients

LEVEL OF RISK	APPROXIMATE DVT RISK WITHOUT THROMBOPROPHYLAXIS (%)	SUGGESTED THROMBOPROPHYLAXIS OPTIONS
Very low risk General or abdominopelvic surgery	<0.5% (Rogers score <7; Caprini score 0)	No specific thromboprophylaxis Early ambulation
Low risk General or abdominopelvic surgery	~1.5% (Rogers score 7–10; Caprini score 1–2)	Mechanical prophylaxis
Moderate risk General or abdominopelvic surgery	~3.0% (Rogers score >10; Caprini score 3–4)	LMWH (at recommended doses), LDUH, or mechanical prophylaxis
High bleeding risk		Mechanical prophylaxis
High risk General or abdominopelvic surgery	~6% (Caprini score ≥5)	LMWH (at recommended doses), fondaparinux and mechanical prophylaxis
High bleeding risk General or abdominopelvic surgery for cancer		Mechanical thromboprophylaxis Extended-duration LMWH (4 weeks)

DVT = deep vein thrombosis; INR = international normalized ratio; LDUH = low-dose unfractionated heparin; LMWH = low molecular weight heparin; VTE = venous thromboembolism.

Vascular Lab and Radiologic Evaluation

Duplex Ultrasound DUS is now the most commonly performed test for the detection of infrainguinal DVT, both above and below the knee, and has a sensitivity and specificity of >95% in symptomatic patients.[3] DUS refers to the combination of real-time B-mode ultrasound with pulsed Doppler capability. For VTE detection, color flow imaging is an extremely useful adjunct in the evaluation of possible calf vein DVT and evaluation of intra-abdominal veins. DUS provides the ability to noninvasively visualize venous anatomy, detect occluded and partially occluded venous segments, and demonstrate physiologic flow characteristics using a mobile self-contained device.

In the supine patient, normal lower extremity venous flow is phasic (Fig. 24-5), decreasing with inspiration in response to increased intra-abdominal pressure with the descent of the diaphragm and then increasing with expiration as the diaphragm rises and intra-abdominal pressure decreases. When the patient is upright, the decrease in intra-abdominal pressure with expiration cannot overcome the hydrostatic column of pressure existing between the right atrium and the calf. Muscular contractions of the calf, along with the one-way venous valves, are then required to promote venous return to the heart. Flow also can be increased by leg elevation or compression and decreased by sudden elevation of intra-abdominal pressure (Valsalva maneuver). In a venous DUS examination performed with the patient supine, spontaneous flow, variation of flow with respiration, and response of flow to Valsalva maneuver are all assessed.

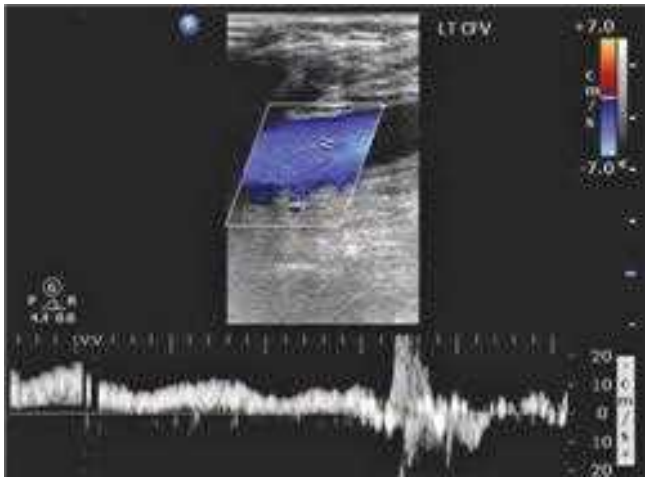

Figure 24-5. Duplex ultrasound scan of a normal femoral vein with phasic flow signals.

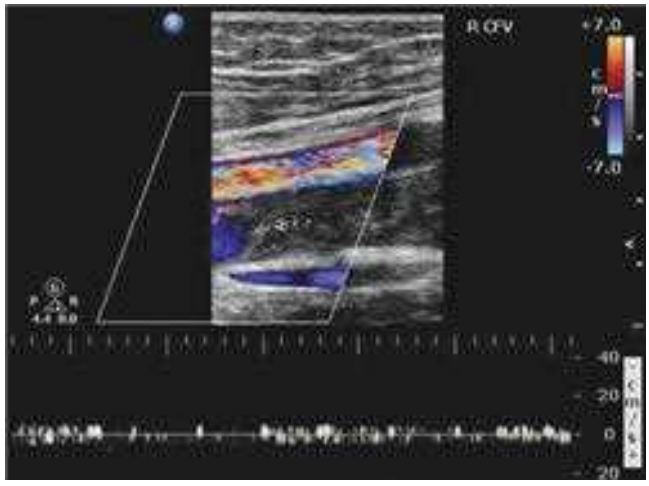

Figure 24-6. Duplex ultrasound of a femoral vein containing thrombus demonstrating no flow within the femoral vein.

From the common femoral through the popliteal vein, the primary method of detecting DVT with ultrasound is demonstration of the lack of compressibility of the vein with probe pressure on B-mode imaging. Normally, in transverse section, the vein walls should coapt with pressure. Lack of coaptation indicates thrombus. Calf vein thrombi are often best detected by abnormalities in color flow imaging.

The examination begins at the ankle and continues proximally to the groin. Each vein is visualized, and the flow signal is assessed with distal and proximal compression. Lower extremity DVT can be diagnosed by any of the following DUS findings: lack of spontaneous flow (Fig. 24-6), inability to compress the vein (Fig. 24-7), absence of color filling of the lumen by color flow DUS, loss of respiratory flow variation, and venous distention. Again, lack of venous compression on B-mode imaging is the primary diagnostic variable. Several studies comparing B-mode ultrasound to venography for the detection of femoropopliteal DVT in patients clinically suspected to have DVT report sensitivities of >91% and specificities of >97%.[20,21] The ability of DUS to assess isolated calf vein DVT varies greatly, with sensitivities ranging from 50% to 93% and specificities approaching 100%.[22,23]

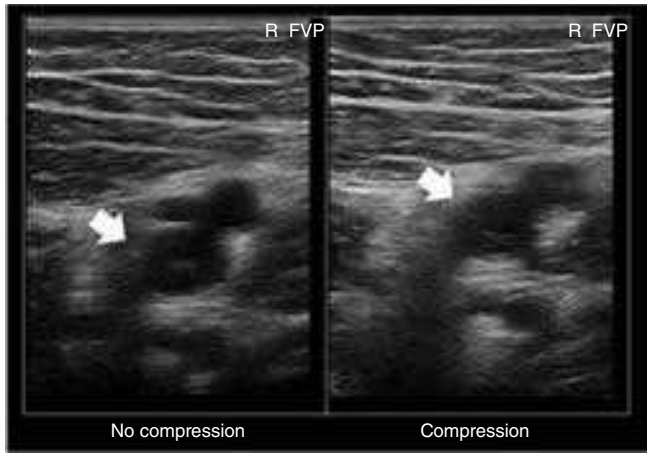

Figure 24-7. B-mode ultrasound of the femoral vein in cross-section. The femoral vein does not collapse with external compression (*arrows*).

Impedance Plethysmography Impedance plethysmography (IPG) was the primary noninvasive method of diagnosing DVT before the widespread use of DUS but is infrequently used today. Changes in electrical resistance resulting from lower extremity blood volume changes are quantified. IPG is less accurate than DUS for the detection of proximal DVT, with 83% sensitivity in symptomatic patients. It is a poor detector of calf vein DVT.[24]

Iodine-125 Fibrinogen Uptake Iodine-125 fibrinogen uptake (FUT) is a seldom used technique that involves IV administration of radioactive fibrinogen and monitoring for increased uptake in fibrin clots. An increase of 20% or more in one area of a limb indicates an area of thrombus. FUT can detect DVT in the calf, but high background radiation from the pelvis and the urinary tract limits its ability to detect proximal DVT. It also cannot be used in an extremity that has recently undergone surgery or has active inflammation. In a prospective study, FUT had a sensitivity of 73% and specificity of 71% for identification of DVT in a group of symptomatic and asymptomatic patients.[25] Currently, FUT is primarily a research tool of historic interest.

Venography Venography is the gold standard to which other diagnostic modalities are compared. A small catheter is placed in a dorsal foot vein with injection of a radiopaque contrast agent. Radiographs are obtained in at least two projections. A positive study result is failure to fill the deep system with passage of the contrast medium into the superficial system or demonstration of discrete filling defects (Fig. 24-8). A normal study result virtually excludes the presence of DVT. In a study of 160 patients with a normal venogram followed for 3 months, only two patients (1.3%) subsequently developed DVT and no patients experienced symptoms of PE.[26] Venography is not routinely used in clinical practice due to invasiveness and complication risk. It is still, however, frequently used in research studies evaluating DVT prophylaxis.

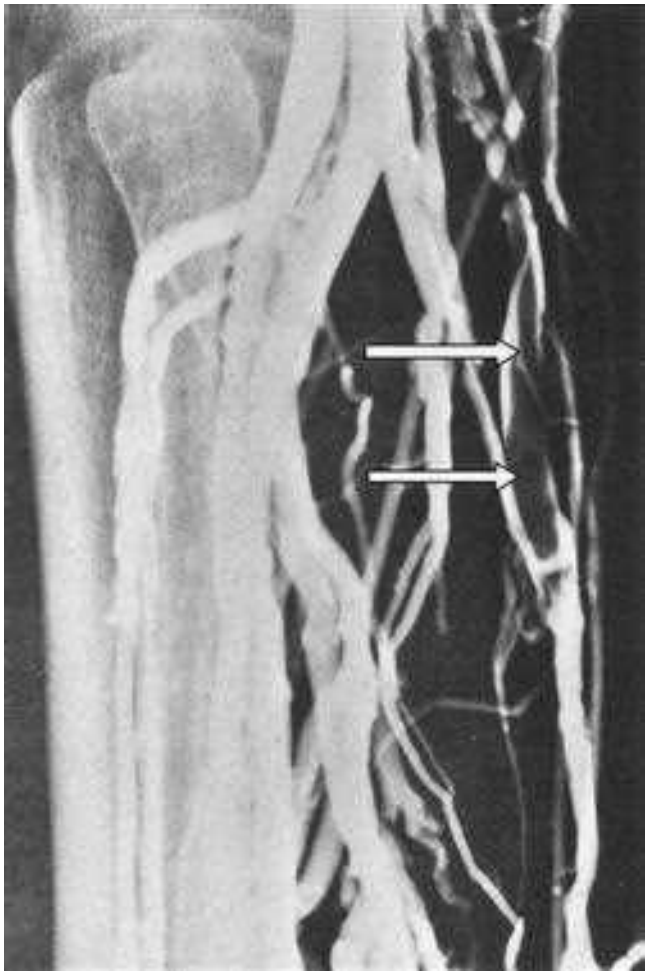

Figure 24-8. Venogram showing a filling defect in the popliteal vein (*arrows*).

Treatment

Once the diagnosis of VTE has been made, antithrombotic therapy should be initiated promptly. If clinical suspicion for VTE is high, it may be prudent to start treatment while the diagnosis is objectively confirmed. The goals of VTE treatment are the prevention of mortality and morbidity associated with PE and the prevention of the postthrombotic syndrome (PTS). Treatment regimens may include antithrombotic therapy, temporary or permanent vena cava filter placement, catheter-directed or systemic thrombolytic therapy, and operative thrombectomy.

1▶

Antithrombotic Therapy. Most often, antithrombotic therapy for VTE is initiated with IV or subcutaneous (SC) unfractionated heparin or SC low molecular weight heparin. Fondaparinux, a synthetic pentasaccharide, is sometimes also used as an alternative to heparin to initiate therapy. An oral vitamin K antagonist, usually sodium warfarin, is begun shortly after initiation of IV or SC therapy. Either SC or IV therapy is continued until effective oral anticoagulation with warfarin is achieved as indicated by an international normalized ratio (INR) ≥2 for 24 hours. A minimum of 5 days of heparin or fondaparinux therapy is recommended.[27] Recently, the U.S. Food and Drug Administration (FDA) has also approved alternative oral anticoagulants for both treatment and prophylaxis for VTE.

2▶

Unfractionated heparin (UFH) binds to antithrombin via a specific 18-saccharide sequence. This increases antithrombin activity over 1000-fold. The antithrombin-heparin complex primarily inhibits factor IIa (thrombin) and factor Xa and, to a lesser degree, factors IXa, XIa, and XIIa of the coagulation cascade. In addition, UFH also binds to tissue factor pathway inhibitor, which inhibits the conversion of factor X to Xa, and factor IX to IXa. Finally, UFH catalyzes the inhibition of thrombin by heparin cofactor II via a mechanism independent of antithrombin.

UFH therapy is most commonly administered with an initial IV bolus of 80 units/kg. Weight-based UFH dosages have been shown to be more effective than standard fixed boluses in rapidly achieving therapeutic levels.[28] The initial bolus is followed by a continuous IV drip at 18 units/kg per hour. The half-life of IV UFH ranges from 45 to 90 minutes and is dose dependent. The level of antithrombotic therapy should be monitored every 6 hours using the activated partial thromboplastin time (aPTT), with the goal range of 1.5 to 2.5 times control values. This should correspond with plasma heparin anti-Xa activity levels of 0.3 to 0.7 IU/mL.

Initial anticoagulation with UFH may also be administered SC, although this route is less commonly used. Adjusted-dose therapeutic SC UFH is initiated with 17,500 units, followed by 250 units/kg twice daily, and dosing is adjusted to an aPTT goal range similar to that for IV UFH. Fixed-dose unmonitored SC UFH is started with a bolus of 333 units/kg, followed by 250 units/kg twice daily.[29]

Hemorrhage is the primary complication of UFH therapy. The rate of major hemorrhage (fatal, intracranial, retroperitoneal, or requiring transfusion of >2 units of packed red

blood cells) is approximately 5% in hospitalized patients undergoing UFH therapy (1% in medical patients and 8% in surgical patients).[29] For patients with UFH-related bleeding complications, cessation of UFH is required, and anticoagulation may be reversed with protamine sulfate. Protamine sulfate binds to UFH and forms an inactive salt compound. Each milligram of protamine neutralizes 90 to 115 units of heparin, and the dosage should not exceed 50 mg IV over any 10-minute period. Side effects of protamine sulfate include hypotension, pulmonary edema, and anaphylaxis. Patients with prior exposure to protamine-containing insulin (NPH) and patients with allergy to fish may have an increased risk of hypersensitivity, although no direct relationship has been established. Protamine administration should be terminated if any side effects occur.

In addition to hemorrhage, heparin also has unique complications. Heparin-induced thrombocytopenia (HIT) results from heparin-associated antiplatelet antibodies (HAAbs) directed against platelet factor 4 complexed with heparin.[30] HIT occurs in 1% to 5% of patients being treated with heparin.[31,32] In patients with repeat heparin exposure (such as vascular surgery patients), the incidence of HAAbs may be as high as 21%.[33] HIT occurs most frequently in the second week of therapy and may lead to disastrous venous or arterial thrombotic complications. Therefore, platelet counts should be monitored periodically in patients receiving continuous heparin therapy.

HIT is diagnosed based on previous exposure to heparin, platelet count less than 100,000, and/or platelet count decline of 50% following exposure. All heparin must be stopped and alternative anticoagulation initiated immediately to avoid thrombotic complications, which may approach 50% over the subsequent 30 days in affected individuals.[34]

Another complication of prolonged high-dose heparin therapy is osteopenia. Heparin-induced osteopenia results from impairment of bone formation and enhancement of bone resorption by heparin.

Low molecular weight heparins (LMWHs) are derived from the depolymerization of porcine UFH. Like UFH, LMWHs bind to antithrombin via a specific pentasaccharide sequence to expose an active site for the neutralization of factor Xa. However, LMWHs have fewer additional saccharide units. This results in less inactivation of thrombin (factor IIa). In comparison to UFH, LMWHs have increased bioavailability (>90% after SC injection), longer half-lives (approximately 4 to 6 hours), and more predictable elimination rates.

Most patients treated with weight-based once- or twice-daily SC LMWH injections do not require laboratory monitoring for anticoagulant effect, a distinct advantage over continuous IV infusions of UFH. Patients who do require monitoring include those with significant renal insufficiency, pediatric patients, obese patients greater than 120 kg, and pregnant patients. Monitoring may be performed using anti-Xa activity assays. The therapeutic anti-Xa goal range depends on the type of LMWH and the frequency of dosing. There are numerous LMWHs available, and the various preparations differ in their anti-Xa and anti-IIa activities. Treatment dosing for one LMWH therefore cannot be extrapolated for use with another. The anticoagulant effect of LMWHs may be partially reversed (approximately 60%) with protamine sulfate.

Numerous well-designed trials comparing SC LMWH with IV and SC UFH for the treatment of DVT have been critically evaluated in several meta-analyses and demonstrate a decrease in thrombotic complications, bleeding, and mortality with LMWHs.[35-37] LMWHs also are associated with a decreased rate of HAAb formation and HIT (<2%) compared with UFH (at least in prophylactic doses).[29] However, patients with established HIT also should not receive LMWHs because there is cross-reactivity between the drugs.[38]

A major benefit of LMWHs is that it allows outpatient treatment of VTE.[39,40] In a randomized study comparing IV UFH and the LMWH nadroparin calcium,[39] there was no significant difference in recurrent thromboembolism (8.6% for UFH vs. 6.9% for LMWH) or major bleeding complications (2.0% for UFH vs. 0.5% for LMWH). There was, however, a 67% reduction in mean days in the hospital for the LMWH group.

Fondaparinux currently is a synthetic pentasaccharide that has been approved by the FDA for the initial treatment of DVT and PE. Its five-polysaccharide sequence binds and activates antithrombin, causing specific inhibition of factor Xa. In two large noninferiority trials, fondaparinux was compared with the LMWH enoxaparin for the initial treatment of DVT and with IV UFH for the initial treatment of PE.[41,42] The rates of recurrent VTE ranged from 3.8% to 5%, with rates of major bleeding of 2% to 2.6%, for all treatment arms. The drug is administered SC once daily with a weight-based dosing protocol: 5 mg, 7.5 mg, or 10 mg for patients weighing <50 kg, 50 to 100 kg, or >100 kg, respectively. The half-life of fondaparinux is approximately 17 hours in patients with normal renal function. There are rare case reports of fondaparinux-induced thrombocytopenia.[43]

Direct thrombin inhibitors (DTIs) include recombinant hirudin, argatroban, and bivalirudin. These antithrombotic agents bind to thrombin, inhibiting the conversion of fibrinogen to fibrin as well as thrombin-induced platelet activation. These actions are independent of antithrombin. The DTIs should be reserved for (a) patients in whom there is a high clinical suspicion or confirmation of HIT, and (b) patients who have a history of HIT or test positive for heparin-associated antibodies. In patients with established HIT, DTIs should be administered for at least 7 days, or until the platelet count normalizes. Warfarin may then be introduced slowly, overlapping therapy with a DTI for at least 5 days.[44]

Bivalirudin is approved primarily for patients with or without HIT who undergo percutaneous coronary intervention and is rarely used outside of that setting.

Commercially available hirudin is manufactured using recombinant DNA technology. It is indicated for the prophylaxis and treatment of patients with HIT. In patients with normal renal function, recombinant hirudin is administered as an IV bolus dose of 0.4 mg/kg, followed by a continuous IV infusion of 0.15 mg/kg per hour. The half-life ranges from 30 to 60 minutes. The aPTT is monitored, starting approximately 4 hours after initiation of therapy, and dosage is adjusted to maintain an aPTT of 1.5 to 2.5 times the laboratory normal value. The less commonly used ecarin clotting time is an alternative method of monitoring. Recombinant hirudin is eliminated via renal excretion, so dosage adjustments are required in patients with renal insufficiency.

Argatroban is indicated for the prophylaxis and treatment of thrombosis in HIT. It also is approved for patients with, or at risk for, HIT undergoing percutaneous coronary intervention. Antithrombotic prophylaxis and therapy are initiated with a continuous IV infusion of 2 μg/kg per minute, without the need for a bolus. The half-life ranges from 39 to 51 minutes, and the dosage is adjusted to maintain an aPTT of 1.5 to 3 times normal. Large initial boluses and higher rates of continuous infusion

are reserved for patients with coronary artery thrombosis and myocardial infarction. In these patients, therapy is monitored using the activated clotting time. Argatroban is metabolized and excreted by the liver; therefore, dosage adjustments are needed in patients with hepatic impairment. There is no reversal agent for argatroban.

Vitamin K antagonists, which include warfarin and other coumarin derivatives, are the mainstay of long-term antithrombotic therapy in patients with VTE. Warfarin inhibits the γ-carboxylation of vitamin K–dependent procoagulants (factors II, VII, IX, and X) and anticoagulants (proteins C and S), resulting in formation of less functional proteins. Warfarin usually requires several days to achieve full effect because normal circulating coagulation proteins must first undergo their normal degradation. Factors X and II have the longest half-lives, in the range of 36 and 72 hours, respectively. A steady-state concentration of warfarin is usually not reached for 4 to 5 days.

Warfarin therapy is monitored by measuring the INR, calculated using the following equation:

$$\text{INR} = (\text{patient prothrombin time/laboratory normal prothrombin time})^{\text{ISI}}$$

where *ISI* is the international sensitivity index. The ISI describes the strength of the thromboplastin that is added to activate the extrinsic coagulation pathway. The therapeutic target INR range is usually 2.0 to 3.0, but the response to warfarin is variable and depends on liver function, diet, age, and concomitant medications. In patients receiving anticoagulation therapy without concomitant thrombolysis or venous thrombectomy, the vitamin K antagonist may be started on the same day as the initial parenteral anticoagulant, usually at doses ranging from 5 to 10 mg. Smaller initial doses may be needed in older and malnourished patients, in those with liver disease or congestive heart failure, and in those who have recently undergone major surgery.[45]

The recommended duration of warfarin antithrombotic therapy is stratified based on whether the DVT was provoked or unprovoked, whether it was the first or a recurrent episode, where the DVT is located, and whether malignancy or thrombophilia is present. Current ACCP recommendations for duration of warfarin therapy are summarized in Table 24-4.

3▶

In patients with proximal DVT, several randomized clinical trials have demonstrated that shorter-term antithrombotic therapy (4 to 6 weeks) is associated with a higher rate of VTE recurrence than 3 to 6 months of anticoagulation.[46-48] In these trials, most of the patients with transient risk factors had a low rate of recurrent VTE, and most recurrences were in patients with continuing risk factors. The ACCP recommendation, therefore, is that 3 months of anticoagulation are sufficient to prevent recurrent VTE in patients with DVT occurring around the time of a transient risk factor (e.g., hospitalization, orthopedic or major general surgery).

In contrast to patients with thrombosis related to transient risk factors, patients with idiopathic VTE are much more likely to develop recurrence (rates as high as 40% at 10 years). In this latter group of patients, numerous clinical trials have compared 3 to 6 months of anticoagulation therapy with extended-duration warfarin therapy, both at low intensity (INR of 1.5 to 2.0) and at conventional intensity (INR of 2.0 to 3.0).[49-51] In patients with idiopathic DVT, extended-duration antithrombotic therapy is associated with a relative reduction in the rate of recurrent VTE by 75% to >90%. In addition, conventional-intensity warfarin reduces the risk even further compared with low-intensity warfarin (0.7 events per 100 person-years vs. 1.9 events per 100 person-years) without an increase in bleeding complications.[52]

Table 24-4

Summary of American College of Chest Physicians recommendations regarding duration of long-term antithrombotic therapy for deep vein thrombosis (DVT)

CLINICAL SUBGROUP	ANTITHROMBOTIC TREATMENT DURATION
First episode DVT/transient risk/surgery	VKA or LMWH for 3 months
First episode DVT/unprovoked	VKA or LMWH for 3 months Consider for long-term therapy if: • Proximal DVT • Minimal bleeding risk • Stable coagulation monitoring
Distal DVT/unprovoked • Symptomatic • Asymptomatic and no risk factors for progression	 VKA for 3 months Serial imaging in 2 weeks, if progression VKA for 3 months
Second episode DVT/unprovoked	VKA for extended therapy
DVT and cancer	LMWH for extended therapy over VKA

LMWH = low molecular weight heparin; VKA = vitamin K antagonist.
Source: Summary of recommendations from Kearon C, Akl EA, Comerota AJ, et al. Antithrombotic therapy for VTE disease: antithrombotic therapy and prevention of thrombosis: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, 9th ed. *Chest*. 2012;141:e495S. Reproduced with permission from the American College of Chest Physicians.

In patients with VTE in association with a hypercoagulable condition, the optimal duration of anticoagulation therapy is influenced more by the clinical circumstances at the time of the VTE (idiopathic vs. secondary) than by the actual presence or absence of the more common thrombophilic conditions. In patients with VTE related to malignancy, increasing evidence suggests that longer-term therapy with LMWH (up to 6 months) is associated with a lower VTE recurrence than treatment using conventional vitamin K antagonists.[53,54] The primary complication of warfarin therapy is hemorrhage, and the risk is related to the magnitude of INR prolongation. Depending on the INR and the presence of bleeding, warfarin anticoagulation may be reversed by (a) omitting or decreasing subsequent dosages, (b) administering oral or parenteral vitamin K, or (c) administering fresh-frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa.[45]

Warfarin therapy rarely may be associated with the development of skin necrosis and limb gangrene. These conditions occur more commonly in women (4:1), and the most commonly affected areas are the breast, buttocks, and thighs. This complication, which usually occurs in the first days of therapy, is occasionally, but not exclusively, associated with protein C or S deficiency and malignancy. Patients who require continued anticoagulation may restart low-dose warfarin (2 mg) while receiving

concomitant therapeutic heparin. The warfarin dosage is then gradually increased over a 1- to 2-week period.[45]

Systemic and Catheter-Directed Thrombolysis. Patients with extensive proximal, iliofemoral DVT may benefit from systemic thrombolysis or catheter-directed thrombolysis (CDT). CDT appears to be more effective (see later in chapter) and potentially reduces acute congestive lower extremity symptoms more rapidly than anticoagulation alone and decreases the development of PTS.

Several thrombolytic agents are available, including streptokinase, urokinase, alteplase (recombinant tissue plasminogen activator), reteplase, and tenecteplase. All share the ability to convert plasminogen to plasmin, which leads to the degradation of fibrin. They differ with regard to their half-lives, their potential for inducing fibrinogenolysis (generalized lytic state), their potential for antigenicity, and their FDA-approved indications for use.

Streptokinase is purified from β-hemolytic *Streptococcus* and is approved for the treatment of acute myocardial infarction, PE, DVT, arterial thromboembolism, and occluded central lines and arteriovenous shunts. It is not specific for fibrin-bound plasminogen, however, and its use is limited by its significant rates of antigenicity. Fevers and shivering occur in 1% to 4% of patients.

Urokinase is derived from human neonatal kidney cells grown in tissue culture. Currently, it is only approved for lysis of massive PE or PE associated with unstable hemodynamics.

Alteplase, reteplase, and tenecteplase all are recombinant variants of tissue plasminogen activator. Alteplase is indicated for the treatment of acute myocardial infarction, acute ischemic stroke, and acute massive PE. However, it often is used for CDT of DVT. Reteplase and tenecteplase are indicated only for the treatment of acute myocardial infarction.

Systemic thrombolysis was evaluated in numerous older prospective and randomized clinical trials, and its efficacy was summarized in a recent Cochrane Review.[55] In 12 studies involving over 700 patients, systemic thrombolysis was associated with significantly more clot lysis (relative risk [RR] 0.24 to 0.37) and significantly less PTS (RR 0.66). However, venous function was not significantly improved. In addition, more bleeding complications occurred (RR 1.73).

In an effort to minimize bleeding complications and increase efficacy, CDT techniques were developed for the treatment of symptomatic primarily iliofemoral DVT. With catheter-directed therapy, venous access may be achieved through percutaneous catheterization of the ipsilateral popliteal vein, retrograde catheterization through the contralateral femoral vein, or retrograde cannulation from the internal jugular vein. Multi-side-hole infusion catheters, with or without infusion wires, are used to deliver the lytic agent directly into the thrombus. Lytic agents may be administered alone or, now more commonly, in combination with catheter-based methods to physically break up the clot—so-called pharmacomechanical thrombolysis.

The efficacy of CDT for the treatment of symptomatic iliofemoral DVT has been reported in a large multicenter randomized control trial. Two-hundred and nine patients with proximal DVT were assigned to conventional anticoagulant therapy versus conventional anticoagulant therapy plus CDT. In the CDT group, placement of a venous stent was permitted for any identified iliac vein stenotic lesion. At 6 months, iliac vein patency was significantly improved in the thrombolysis group (65.9% vs. 47.4%). At 2 years, in the CDT group, there was an absolute risk reduction of nearly 15% for development of PTS, translating to a number needed to treat of seven patients to prevent one case of PTS.[56]

Inferior Vena Caval Filters. Since the introduction of the Kimray-Greenfield filter in the United States in 1973, numerous vena caval filters have been developed. Although the designs are variable, they all prevent pulmonary emboli, while allowing continuation of venous blood flow through the IVC. Early filters were placed surgically through the femoral vein. Currently, less invasive techniques allow percutaneous filter placement through a femoral vein, internal jugular vein, or small peripheral vein under fluoroscopic or ultrasound guidance.

Placement of an IVC filter is indicated for patients who have manifestations of lower extremity VTE and absolute contraindications to anticoagulation, those that have a bleeding complication from anticoagulation therapy of acute VTE, or those who develop recurrent DVT or PE despite adequate anticoagulation therapy and for patients with severe pulmonary hypertension.

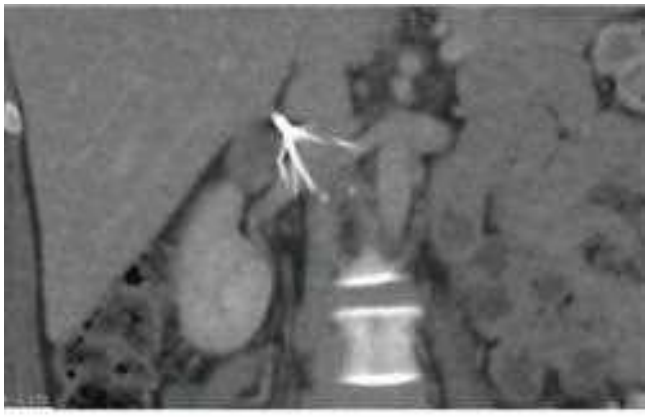
When possible, therapy should be continued in patients with vena cava filters. The duration of anticoagulation is determined by the underlying VTE and not by the presence of the IVC filter itself. Practically speaking, however, many patients who require an IVC filter for recurrent VTE are the same ones who would benefit most from indefinite anticoagulation. In patients who are not able to receive anticoagulants due to recent surgery or trauma, the clinician should continually reassess if anticoagulation may be started safely at a later date.

Placement of permanent IVC filters has been evaluated as an adjunct to routine anticoagulation in patients with proximal DVT.[57] Routine IVC filter placement has not been shown to prolong early or late survival in patients with proximal DVT but did decrease the rate of PE (hazard ratio, 0.22; 95% confidence interval, 0.05–0.90), however; an increased rate of recurrent DVT was seen in patients with IVC filters (hazard ratio, 1.87; 95% confidence interval, 1.10–3.20).

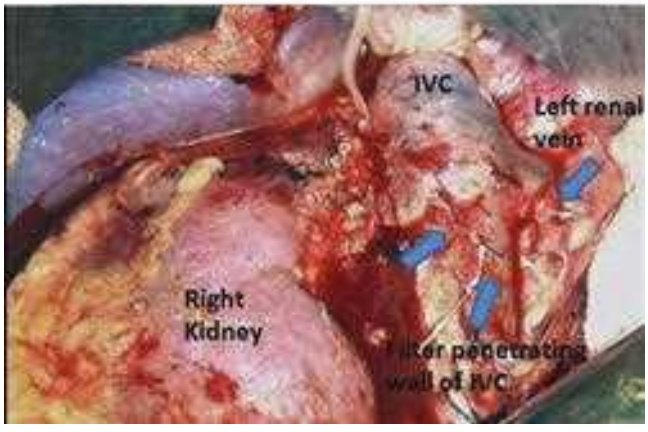
IVC filters are associated with acute and late complications. Acute complications include thrombosis or bleeding at the insertion site and misplacement of the filter. Late complications include thrombosis of the IVC, DVT, breaking, migration, or erosion of the filter through the IVC (Fig. 24-9). The rate of fatal complications is <0.12%.[58]

In some patients, the need for an IVC filter may be self-limited. Such patients can be treated with so-called removable IVC filters. Depending on the device, removable IVC filters are potentially removable by percutaneous endovascular techniques for up to several months after their initial implantation assuming the filter is no longer required and does not have large amounts of trapped thrombi. All temporary IVC filters are approved for permanent implantation, and many so-called temporary filters end up as permanent devices with all the potential complications of permanent IVC filters.

Operative Venous Thrombectomy. In patients with acute iliofemoral DVT, surgical therapy is generally reserved for patients who worsen with anticoagulation therapy and those with phlegmasia cerulea dolens and impending venous gangrene. If the patient has phlegmasia cerulea dolens, a fasciotomy of the calf compartments is first performed. In iliofemoral DVT, a longitudinal venotomy is made in the common femoral vein and a venous balloon embolectomy catheter is passed through



A



B

Figure 24-9. Preoperative computed tomography imaging and intraoperative photo demonstrating erosion of IVC filter through the IVC wall.

the thrombus into the IVC and pulled back several times until no further thrombus can be extracted. The distal thrombus in the leg is removed by manual pressure beginning in the foot. This is accomplished by application of a tight rubber elastic wrap beginning at the foot and extending to the thigh. If the thrombus in the femoral vein is old and cannot be extracted, the vein may be ligated. For a thrombus that extends into the IVC, the IVC is exposed transperitoneally and controlled below the renal veins. The IVC is opened and the thrombus is removed by gentle massage. An intraoperative completion venogram determines if any residual thrombus or stenosis is present. If a residual iliac vein stenosis is present, intraoperative angioplasty and stenting can be performed. In most cases, an arteriovenous fistula is then created by anastomosing the great saphenous vein (GSV) end to side with the superficial femoral artery in an effort to maintain patency of the thrombectomized iliofemoral venous segment. Heparin is administered postoperatively for several days. Warfarin anticoagulation is maintained for at least 6 months after thrombectomy. Complications of iliofemoral thrombectomy include PE in up to 20% of patients[59] and death in <1% of patients.[60]

One study followed 77 limbs for a mean of 8.5 years after thrombectomy for acute iliofemoral DVT. In limbs with successful thrombectomy, valvular competence in the thrombectomized

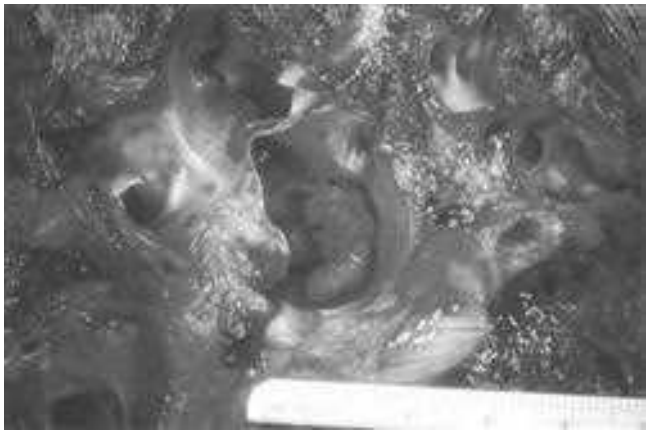


Figure 24-10. Autopsy specimen showing a massive pulmonary embolism.

venous segment was 80% at 5 years and 56% at 10 years. More than 90% of patients had minimal or no symptoms of PTS. There were 12 (16%) early thrombectomy failures. Patients were required to wear compression stockings for at least 1 year after thrombectomy.[61]

Survival rates for surgical pulmonary embolectomy have improved over the past 20 years with the addition of cardiopulmonary bypass. Emergency pulmonary embolectomy for acute PE is rarely indicated. Patients with preterminal massive PE (Fig. 24-10) for whom thrombolysis has failed or who have contraindications to thrombolytics may be candidates for this procedure. Open pulmonary artery embolectomy is performed through a posterolateral thoracotomy with direct visualization of the pulmonary arteries. Mortality rates range between 20% and 40%.[62-64]

Percutaneous catheter-based techniques for removal of a PE involve mechanical thrombus fragmentation or embolectomy using suction devices. Mechanical clot fragmentation is followed by CDT. Results of catheter-based fragmentation are based on small case series. In a study in which a fragmentation device was used in 10 patients with acute massive PE, fragmentation was successful in 7 patients with a mortality rate of 20%.[65] Transvenous catheter pulmonary suction embolectomy has also been performed for acute massive PE with a reported 76% successful extraction rate and a 30-day survival of 70%.[66]

Prophylaxis

Patients who undergo major general surgical, gynecologic, urologic, and neurosurgical procedures without thromboprophylaxis have a significant incidence of perioperative DVT. An estimated one third of the 150,000 to 200,000 VTE-related deaths per year in the United States occur following surgery.[67] The goal of prophylaxis is to reduce the mortality and morbidity associated with VTE. The first manifestation of VTE may be a life-threatening PE (Fig. 24-11), and as indicated earlier, clinical evaluation to detect DVT before PE is unreliable.

Effective methods of VTE prophylaxis involve the use of one or more pharmacologic or mechanical modalities. Currently available pharmacologic agents include low-dose UFH, LMWH, synthetic pentasaccharides, and vitamin K antagonists. Mechanical methods include intermittent pneumatic compression (IPC) and graduated compression stockings.

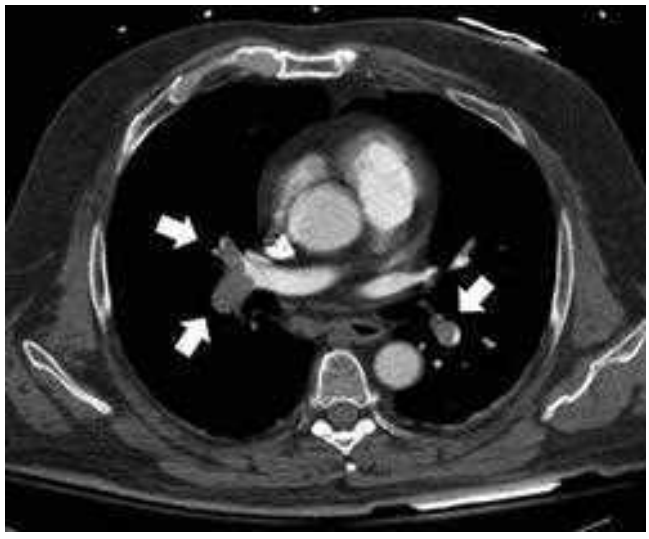

Figure 24-11. Computed tomography angiogram showing multiple pulmonary embolisms (*arrows*) (Used with permission from Dr. Scott Ambruster.)

There is insufficient evidence to consider aspirin alone as adequate DVT prophylaxis. Methods of prophylaxis vary with regard to efficacy, and the 2012 ACCP Clinical Practice Guidelines stratify their uses according to the patient's level of VTE risk, bleeding risk, and the values and preferences of individual patients (see Table 24-3).

Venous Thromboembolism Prophylaxis in Nonorthopedic Surgery. The risk for VTE associated with a surgical procedure depends on the type of operation, type of anesthesia, duration of surgery, and other risk factors, such as patient age, presence of cancer, prior VTE, obesity, presence of infection, and known thrombophilic disorders. VTE risk can be stratified according to the previously mentioned risk assessment models, the Caprini score and Rogers score. These risk assessment models are included in the prophylaxis guidelines for nonorthopedic surgery (Tables 24-5 and 24-6). A composite score is created using assigned values for each risk factor. The cumulative score for each patient is then used to predict thrombosis risk and provide recommendations regarding VTE prophylaxis.

Patients at very low risk (<0.5%; Rogers score <7; Caprini score 0) who undergo general or abdominopelvic procedures do not require pharmacologic or mechanical prophylaxis; however, early ambulation is required. Patients at low risk (<1.5%; Rogers score 7–10; Caprini score 1–2) should receive mechanical prophylaxis. Patients at moderate risk (3%; Rogers score >10; Caprini score 3–4) should receive LMWH at recommended doses, low-dose UFH, or mechanical prophylaxis. Patients at high risk (6%; Caprini score ≥5) should receive LMWH at recommended doses or low-dose UFH and mechanical prophylaxis. Thromboprophylaxis should continue until discharge, except in select high-risk patients with malignancy in whom extended-duration prophylaxis (up to 4–6 weeks) may be beneficial. Patients with significant risk for bleeding should receive mechanical prophylaxis until this risk subsides.[67]

Overall, low-dose UFH and LMWH reduce the risk for symptomatic and asymptomatic VTE by 60% to 70%. The risks for bleeding differ, depending on the dosage. Lower dosages of LMWH appear to be associated with less bleeding risk than low-dose UFH, but the latter produces less bleeding risk than higher prophylactic dosages of LMWH.[68] Other advantages of LMWH include once-daily dosing protocols and a lower rate of heparin-associated antibody formation.

Fondaparinux has been compared with the LMWH dalteparin in patients who undergo high-risk major abdominal surgery. It also has been compared with IPC alone in patients undergoing non–high-risk abdominal surgery.[69,70] Fondaparinux demonstrated rates of VTE prevention, bleeding complications, and mortality similar to those of LMWH. It was more beneficial than IPC alone in reducing VTE but with a higher rate of bleeding (1.6% vs. 0.2%).

Prophylactic insertion of IVC filters has been suggested for VTE prophylaxis in high-risk trauma patients, bariatric surgical patients, and some patients with malignancy who have contraindications for LMWH therapy.[71] A 5-year study of prophylactic IVC filter placement in 132 trauma patients at high risk of PE (head injury, spinal cord injury, pelvic or long bone fractures) reported a 0% incidence of symptomatic PE in patients with a correctly positioned IVC filter.[72] In 47 patients with a malpositioned IVC filter (strut malposition or filter tilt), there was a 6.3% incidence of symptomatic PE with three deaths. DVT occurred at the insertion site in 3.1% of the patients. IVC patency was 97.1% at 3 years.

Fatal and nonfatal PE can still occur in patients with vena cava interruption. As noted earlier, long-term complications associated with permanent IVC filters include IVC thrombosis and DVT. Currently, the ACCP recommends IVC filters be placed only if a proximal DVT is present and anticoagulation therapy is contraindicated. IVC filter insertion is not recommended for primary prophylaxis.[67]

Removable IVC filters may be placed in patients with a temporarily increased risk of PE.[73] The best patient groups for retrievable filter placement may include young trauma patients with transient immobility, patients undergoing surgical procedures associated with a high risk of PE, and patients with hypercoagulable states who cannot receive anticoagulation therapy for a short period of time. Careful follow-up is required to assure all potentially removable filters are in fact removed.

OTHER VENOUS THROMBOTIC DISORDERS

Superficial Vein Thrombophlebitis

Superficial vein thrombophlebitis (SVT) most commonly occurs in varicose veins but can occur in normal veins. When SVT recurs at variable sites in normal superficial veins, *thrombophlebitis migrans,* it may signify a hidden visceral malignancy or a systemic disorder such as a blood dyscrasia and/or a collagen vascular disease. SVT also frequently occurs as a complication of indwelling catheters, with or without associated extravasation of injected material. Upper extremity vein

Figure 24-12. Duplex ultrasound of a brachial vein containing thrombus and percutaneously inserted central catheter (PICC).

thrombosis has been reported to occur in 38% of patients with peripherally inserted central catheters; 57% of these developed in the cephalic vein (Fig. 24-12).[74] Suppurative SVT may occur in veins with indwelling catheters and may be associated with generalized sepsis.

Clinical signs of SVT include redness, warmth, and tenderness along the distribution of the affected veins, often associated with a palpable cord. Patients with suppurative SVT may have fever and leukocytosis. DUS should be performed in patients with signs and symptoms of acute SVT to confirm the diagnosis and to determine if any associated DVT is present. Concomitant lower extremity DVT may be present in 5% to 40% of patients with SVT; most occur in patients with greater saphenous vein SVT within 1 cm of the saphenofemoral junction. A follow-up DUS should be performed in 5 to 7 days in patients with SVT in the proximal GSV but without deep vein involvement. Approximately 10% to 20% of patients with SVT involving the proximal GSV experience progression to deep venous involvement within 1 week.[75,76]

Treatment of SVT is quite variable. A Cochrane Review reported that LMWHs and nonsteroidal anti-inflammatory drugs both reduce the rate of SVT extension or recurrence. Topical medications appear to improve local symptoms. Surgical treatment, combined with the use of graduated compression stockings, is associated with a lower rate of VTE and SVT progression.[77] The treatment is individualized and depends on the location of the thrombus and the severity of symptoms. In patients with SVT not within 1 cm of the saphenofemoral junction, treatment consists of compression and administration of an anti-inflammatory medication such as indomethacin. In patients with suppurative SVT, antibiotics and removal of any existing indwelling catheters are mandatory. Excision of the vein may be necessary but is usually reserved for patients with systemic symptoms or when excision of the involved vein is straightforward. If the SVT extends proximally to within 1 cm of the saphenofemoral junction, extension into the common femoral vein is more likely to occur. In these patients, anticoagulation therapy for 6 weeks and GSV ligation appear equally effective in preventing thrombus extension into the deep venous system.[78,79]

Upper Extremity Vein Thrombosis

Axillary-subclavian venous thrombosis (ASVT) is classified into two forms. Primary ASVT occurs in only a small minority of all patients with ASVT. In the primary form, no clear cause for the thrombosis is readily identifiable at initial evaluation. Patients with primary ASVT often give a history of performing prolonged, repetitive motion activities, which results in damage to the subclavian vein, usually where it passes between the head of the clavicle and the first rib in association with the subclavius muscle. This condition is also known as *venous thoracic outlet syndrome, effort thrombosis*, and *Paget-Schroetter syndrome.* Secondary ASVT is more common and is associated with an easily identified cause such as an indwelling catheter or a hypercoagulable state. Over 30% of patients with tunneled subclavian vein access devices develop ASVT.[80]

A patient with ASVT may be asymptomatic or may present with varying degrees of upper extremity edema, tenderness, and conspicuous superficial venous enlargement. DUS can be performed initially to confirm the diagnosis, but limitations to the exam by the clavicle and collateralization can lead to a false-negative study. Venography is recommended when there is nonconcordance between the duplex study and clinical suspicion. Anticoagulation therapy should be initiated once ASVT is diagnosed to prevent PE and decrease symptoms.

Treatment of patients with primary upper extremity venous thrombosis is controversial because the natural history of the disease may vary from minimal to no symptoms to significant symptoms with vigorous upper extremity activities. In recent years, patients presenting with acute symptomatic primary ASVT are often considered candidates for CDT therapy with the goal of minimizing long-term symptoms of venous congestion. Venography is performed through a catheter placed using an ultrasound-guided percutaneous basilic vein approach to document the extent of the thrombus (Fig. 24-13). A guidewire is traversed through the thrombus, and a catheter is placed within the thrombus. Typically, tissue plasminogen activator is administered through a multi–side-hole infusion catheter. Various catheter-based mechanical techniques may also be employed to speed thrombus removal. Heparin is administered concurrently with the thrombolytic infusion. After completion

Figure 24-13. Upper extremity venogram showing stenosis of the right subclavian vein (*arrow*).

of thrombolytic therapy, a follow-up venogram is obtained. Correctable anatomic abnormalities may then be considered for treatment. Adjuvant procedures after thrombolytic therapy may include cervical or first rib resection for thoracic outlet abnormalities, surgical venous reconstruction, and balloon angioplasty of residual venous stenosis.[81]

Mesenteric Vein Thrombosis

Five to 15% of cases of acute mesenteric ischemia occur as a result of mesenteric vein thrombosis (MVT). Mortality rates in patients with MVT may approach 50%.[82] The usual presenting symptom is nonspecific abdominal pain and distention, often accompanied by nausea, vomiting, and diarrhea.[83] Peritoneal signs, suggesting intestinal infarction, are present in fewer than half of MVT patients. MVT is more common in patients with a hypercoagulable states, malignancy, and cirrhosis. MVT occurs as a rare complication of laparoscopic surgery.[83,84]

Most cases of MVT are diagnosed with contrast-enhanced CT scanning or magnetic resonance imaging (MRI) in the course of an evaluation for abdominal pain. The sensitivity and specificity for CT and MRI approach 100% and 98%, respectively.[85] Ultrasound can also be used and has reported sensitivity and specificity of 93% and 99%, respectively.

Patients with MVT are treated with fluid resuscitation, heparin anticoagulation, and bowel rest. Once the patient's clinical status improves, oral intake can be carefully started. The patient is transitioned to oral anticoagulation over 3 to 4 days and, depending on the etiology of the MVT, continued for 3 to 6 months or indefinitely. Most patients with MVT can be treated nonoperatively, but urgent laparotomy is indicated in patients with peritoneal findings. Broad-spectrum antibiotics are administered perioperatively. Operative findings consist of edema and cyanotic discoloration of the mesentery and bowel wall. In more advanced cases, thrombus involves the distal mesenteric veins. The arterial supply to the involved bowel is usually intact. Nonviable bowel is resected, and primary anastomosis can be performed. If the viability of the remaining bowel is in question, a second-look operation is performed within 24 to 48 hours.

VARICOSE VEINS

Varicose veins are common and are present in at least 10% of the general population.[86] The findings of varicose veins may include dilated and tortuous veins, telangiectasias, and fine reticular varicosities. Risk factors for varicose veins include obesity, female sex, inactivity, and family history.[87] Varicose veins can be classified as primary or secondary. Primary varicose veins result from intrinsic abnormalities of the venous wall, whereas secondary varicose veins are associated with deep and/or superficial venous insufficiency.

Patients with varicose veins may complain of unsightly appearance, aching, heaviness, pruritus, and early fatigue of the affected leg. These symptoms worsen with prolonged standing and sitting and are relieved by elevation of the leg above the level of the heart. A mild amount of edema is often present. More severe signs include thrombophlebitis, hyperpigmentation, lipodermatosclerosis, ulceration, and bleeding from attenuated vein clusters.

An important component of treatment for patients with varicose veins is the use of elastic compression stockings. Patients may be prescribed elastic stockings with compression ranging from 20 to 30, 30 to 40, or even 40 to 50 mmHg. Stockings range in length from knee high to waist high, and they should cover the symptomatic varices. Elastic compression provides sufficient relief of symptoms in many symptomatic patients.

Cosmetic concerns may lead to intervention. Additionally, interventions are warranted in patients whose symptoms worsen or are unrelieved despite compression therapy or who have lipodermatosclerosis or venous ulcer. Randomized trials of symptomatic patients with varicose veins have demonstrated improved quality of life with interventional treatment. Interventional management includes injection sclerotherapy, surgical therapy, or a combination of both techniques. Injection sclerotherapy alone can be successful in varicose veins <3 mm in diameter and in telangiectatic vessels. Sclerotherapy acts by destroying the venous endothelium. Sclerosing agents include hypertonic saline, sodium tetradecyl sulfate, and polidocanol. Concentrations of 11.7% to 23.4% hypertonic saline, 0.125% to 0.250% sodium tetradecyl sulfate, and 0.5% polidocanol are used for telangiectasias. Larger varicose veins require higher concentrations: 23.4% hypertonic saline, 0.50% to 1% sodium tetradecyl sulfate, and 0.75% to 1.0% polidocanol.[83] Elastic bandages are wrapped around the leg after injection and worn continuously for 3 to 5 days to produce apposition of the inflamed vein walls and prevent thrombus formation. After the bandages are removed, elastic compression stockings should be worn for a minimum of 2 weeks. Complications from sclerotherapy include allergic reaction, local hyperpigmentation, thrombophlebitis, DVT, and possible skin necrosis.

Patients with symptomatic GSV or SSV reflux may be treated with endovenous ablation techniques or surgical removal of the affected vein. Endovenous laser and radiofrequency ablation (RFA) techniques have gained in popularity in the past several years. Such techniques are generally associated with more rapid postprocedure recovery than traditional open surgical stripping of the GSV.

4▶

With either endoluminal technique, the distal thigh or proximal calf GSV is punctured with a 21-gauge needle under ultrasound guidance. A sheath is placed over a guidewire, and the laser fiber or RFA catheter is advanced until it is near to, but not at, the saphenofemoral junction. Tumescent anesthetic is administered around the GSV, and the vein is treated as the catheter is withdrawn. Endovenous laser treatment and RFA result in durable ablation of the GSV, with rates of varicose vein recurrence and clinical severity scores comparable to those seen with open surgery.[88,89] Risks of endovenous ablation include DVT, ecchymosis, and saphenous nerve injury.

Saphenous vein ligation and stripping is still the more commonly performed procedure worldwide, and it may be the preferred therapy for patients with GSVs of very large diameter (>2 cm). Surgical removal of the GSV usually is performed via small incisions placed medially in the groin and just below the knee. The GSV is removed using a blunt tip catheter or an invagination pin stripper. Complications associated with GSV stripping include ecchymosis, lymphocele formation, DVT, infection, and saphenous nerve injury. GSV stripping is associated with a lower rate of recurrence of varicose veins and a better quality of life than saphenofemoral junction ligation alone.

Larger varicose veins are best treated by surgical excision using the "stab avulsion" technique. Stab avulsions are performed by making 2-mm incisions directly over branch varicosities, and the varicosity is dissected from the surrounding subcutaneous tissue as far proximally and distally as possible

Figure 24-14. Removal of varicose veins via stab avulsions.

through the small incisions (Fig. 24-14). In most cases the vein is simply avulsed with no attempt at ligation. Bleeding is easily controlled with leg elevation, manual compression, and preprocedure tumescent anesthesia.

CHRONIC VENOUS INSUFFICIENCY

Chronic venous insufficiency (CVI) affects an estimated 600,000 people in the United States.[90] Patients complain of leg fatigue, discomfort, and heaviness. Signs of CVI may include varicose veins, pigmentation, lipodermatosclerosis, and venous ulceration. Importantly, severe CVI is not necessarily associated with varicose veins. Chronic venous ulcers carry significant negative physical, financial, and psychological implications. A quality-of-life study reported that 65% of patients with chronic leg ulcers had severe pain, 81% had decreased mobility, and 100% experienced a negative impact of their disease on their work capacity.[91] The socioeconomic impact of chronic venous leg ulcers is staggering, with an estimated 2 million workdays lost per year.[92] The annual healthcare cost in the United States to treat CVI is estimated at $1 billion.[93]

CVI can be primary or secondary. Primary CVI results from intrinsic abnormalities of the vein wall, whereas secondary CVI, so-called postthrombotic syndrome (PTS), occurs as a result of DVT. The signs and symptoms of CVI can be therefore be attributed to venous reflux, venous obstruction, calf muscle pump dysfunction, or a combination of these factors, as well as loss of venous wall elasticity.[94] In the majority of patients with CVI, the most important factor appears to be venous reflux. Venous reflux results from abnormalities of the venous valve. Primary valvular reflux or incompetence is diagnosed when there is no known underlying cause of valvular dysfunction. Secondary valvular reflux is diagnosed when an identifiable cause is present. The most frequent secondary cause is DVT.

Evaluation of Venous Insufficiency

Early diagnostic studies to evaluate CVI required invasive measurements of ambulatory venous pressure (AVP) and venous recovery time (VRT). To measure AVP and VRT, a needle is inserted into a dorsal foot vein and connected to a pressure transducer. The patient is asked to perform 10 tiptoe exercises. Initially there is often a slight upward deflection of pressure with the onset of exercise followed by a decline in pressure with each subsequent tiptoe maneuver. After approximately 10 tiptoes, the measured pressure stabilizes and reflects a balance of venous inflow and outflow. The pressure at this point is the AVP, which is measured in millimeters of mercury. The patient is then asked to stop exercising to allow the vein to fill with return of the venous pressure to baseline. The time required for the venous pressure to return from the AVP level to 90% of baseline pressure is referred to as the *VRT*. Elevations of AVP indicate venous hypertension. The magnitude of AVP reflects the severity of CVI. There is an 80% incidence of venous ulceration in patients with an AVP of >80 mmHg.[95]

Plethysmography. Noninvasive plethysmography has been used to evaluate CVI. Venous photoplethysmography indirectly evaluates venous function through the use of infrared light. A light-emitting diode is placed just above the medial malleolus, and the patient then performs a series of tiptoe maneuvers. Photoplethysmography provides a measurement of VRT. In limbs with CVI, VRT is shortened compared with that in a normal limb. AVP and VRT are only measures of the overall venous function of a lower extremity venous system. They cannot localize the site of reflux or evaluate the function of the calf pump.

Air plethysmography is a theoretically attractive but not widely used method to assess calf pump function, venous reflux, and overall lower extremity venous function.[96] An air-filled plastic pressure bladder is placed on the calf to detect volume changes in the leg during a standard set of maneuvers. The patient is first supine and then the leg is elevated and the minimum volume of venous blood recorded. The patient is then asked to assume an upright position with the examined leg non-weight bearing. The venous volume of the examined leg is determined when the volume curve flattens. The venous filling index (VFI), a measure of reflux, is calculated by dividing the maximum venous volume by the time required to achieve maximum venous volume. Next, the patient performs a single tiptoe maneuver, and the ejection fraction (EF) is determined. The EF is the volume change between the recorded volume before and after the tiptoe maneuver and is a measure of calf pump function. At this point, the veins of the leg are allowed to refill. The patient then performs 10 tiptoe maneuvers, and the residual volume fraction is calculated by dividing the venous volume in the leg after 10 tiptoe exercises by the venous volume present before the exercises. The residual volume fraction is a reflection of overall venous function. Theoretically, patients with increased VFIs and normal EFs (indicating the presence of reflux with normal calf pump function) would benefit from antireflux surgery, whereas patients with normal VFIs and diminished EFs would not.

Venous Duplex Ultrasound. Venous DUS has become the gold standard for evaluation of venous function largely supplanting venographic and plethysmographic techniques. The principle advantage of DUS is that it can be used to evaluate reflux in individual venous segments targeting abnormal areas for treatment. The examination has been validated when performed with the patient in the standing position and the examined leg non-weight bearing. Pneumatic pressure cuffs of appropriate size are placed around the thigh, calf, and forefoot. The ultrasound transducer is positioned over the venous segment to be examined, just proximal to the pneumatic cuff (Fig. 24-15). The cuff is then inflated to a standard pressure for 3 seconds and then rapidly deflated. Ninety-five percent of normal venous valves close within 0.5 second.[97] The presence of reflux for >0.5 second is considered abnormal. Typically, the common femoral, femoral, popliteal, and posterior tibial veins, as well as the GSV and SSV, are evaluated in a complete examination.

Figure 24-15. Evaluation of a patient with chronic venous insufficiency with duplex ultrasonography.

Nonoperative Treatment of Chronic Venous Insufficiency

Compression Therapy. Compression therapy is the mainstay of CVI management. Compression can be achieved using a variety of techniques, including elastic compression stockings, paste gauze boots (Unna's boots), multilayer elastic wraps or dressings (Fig. 24-16), and pneumatic compression devices. Nonelastic compression bandages generally achieve higher and more prolonged degrees of compression than elastic compression bandages. The exact mechanism by which compression therapy can improve CVI remains uncertain. An improvement in skin and subcutaneous tissue microcirculatory hemodynamics as well as a direct effect on subcutaneous pressure have been hypothesized as the mechanisms of efficacy of compression therapy.[98] Additionally, compression therapy has demonstrated quantifiable differences in ulcer healing with decreases in matrix metalloproteins and inflammatory cytokines.[99,100] Clinically, routine use of elastic and nonelastic bandages reduces lower extremity edema in patients with CVI. In addition, supine perimalleolar subcutaneous pressure has been demonstrated to increase with elastic compression.[101] With edema reduction, cutaneous metabolism may improve due to enhanced diffusion of oxygen and other nutrients to the cellular elements of skin and subcutaneous tissues. Increases in subcutaneous tissue pressure with elastic compression bandages may counteract transcapillary Starling forces, which favor leakage of fluid out of the capillary.

5▶

Figure 24-16. Multilayered dressing for treatment of chronic venous insufficiency.

Before the initiation of therapy for CVI, patients must be educated about their chronic disease and the need to comply with their treatment plan to heal ulcers and prevent recurrence. A definitive diagnosis of venous ulceration must be made before treatment is initiated. A detailed history should be obtained from a patient presenting with lower extremity ulcerations, including medications used and associated medical conditions that may promote lower extremity ulceration. Arterial insufficiency is assessed by physical examination or noninvasive studies. In addition, systemic conditions that affect wound healing and leg edema, such as diabetes mellitus, immunosuppression, malnutrition, and congestive heart failure, should be improved as much as possible.

Compression therapy is most commonly achieved with graduated elastic compression stockings. Elastic compression stockings are available in various compositions, strengths, and lengths, and can be customized for a particular patient. The benefits of elastic compression stocking therapy for the treatment of CVI and healing of ulcerations have been well documented.[102-105] In a retrospective study involving 113 venous ulcer patients,[103] the use of below-knee, 30- to 40-mmHg elastic compression stockings, after edema and cellulitis were first resolved if present, resulted in 93% healing. Complete ulcer healing occurred in 99 of 102 patients (97%) who were compliant with stocking use vs. 6 of 11 patients (55%) who were noncompliant ($P < .0001$). The mean time to ulcer healing was 5 months. The rate of ulcer recurrence was lower in patients who were compliant with their compression therapy. By life table analysis, ulcer recurrence was 29% at 5 years for compliant patients and 100% at 3 years for noncompliant patients.

In addition to promoting ulcer healing, elastic compression therapy can also improve quality of life in patients with CVI. In one prospective study,[106] 112 patients with CVI documented by DUS were administered a questionnaire to quantify the symptoms of swelling, pain, skin discoloration, cosmesis, activity tolerance, depression, and sleep alterations. Patients were treated with 30- to 40-mmHg elastic compression stockings. There were overall improvements in symptom severity scores at 1 month after initiation of treatment. Further improvements were noted at 16 months after treatment.

Patient compliance with compression therapy is crucial in treating CVI and especially venous leg ulcers. Many patients are initially intolerant of compression in areas of hypersensitivity adjacent to an active ulcer or at sites of previously healed ulcers. They may also have difficulty applying elastic stockings. To improve compliance, patients should be instructed to wear their stockings initially only as long as it is easily tolerated and then gradually to increase the amount of time the stockings are worn. Alternatively, patients can be fitted with lower-strength stockings initially followed by introduction of higher-strength stockings over a period of several weeks. Many commercially available devices, such as silk inner toe liners, adjustable elastic compression with Velcro, stockings with zippered sides (Fig. 24-17), and metal fitting aids (Fig. 24-18), are available to assist patients in applying elastic stockings. However, despite all these available adjuncts, many patients remain noncompliant with elastic compression therapy.

Another method of compression was developed by the German dermatologist Paul Gerson Unna. Unna's boot has

Figure 24-17. Elastic compression device with Velcro to facilitate treatment of chronic venous insufficiency.

Figure 24-18. Metal fitting aid to assist in placement of elastic compression stockings.

been used for many years to treat venous ulcers and is available in many versions. A typical Unna's boot consists of a three-layer dressing and requires application by trained personnel. A rolled gauze bandage impregnated with calamine, zinc oxide, glycerin, sorbitol, gelatin, and magnesium aluminum silicate is first applied with graded compression from the forefoot to just below the knee. The next layer consists of a 4-in-wide continuous gauze dressing followed by an outer layer of elastic wrap, also applied with graded compression. The bandage becomes stiff after drying, and the rigidity may aid in preventing edema formation. Unna's boot is changed weekly or sooner if the patient experiences significant drainage and soiling of the dressing.

Once applied, Unna's boot requires minimal patient involvement and provides continuous compression and topical therapy. However, Unna's boot has several disadvantages. It is bulky and can be uncomfortable, which may affect patient compliance. In addition, the ulcer cannot be monitored after the boot is applied, the technique is labor intensive, and the degree of compression provided is operator dependent. Occasionally, patients may also develop contact dermatitis to the components of Unna's boot.

The efficacy of Unna's dressing has been studied. A retrospective 15-year survey encompassing 998 patients with one or more venous ulcers treated weekly with Unna's dressing[107] reported that 73% of ulcers healed in patients who returned for more than one treatment. The median time to healing for individual ulcers was 9 weeks. Unna's dressing has been compared to other forms of treatment. A randomized, prospective study[108] comparing Unna's boot to polyurethane foam dressing in 36 patients with venous ulcers demonstrated superior healing over 12 months in patients treated with Unna's boot (94.7% vs. 41.2%).[108] A recent Cochrane Review of 39 randomized controlled trials demonstrated that compression increases ulcer healing rates compared with no compression, multicomponent systems are more effective than single-component systems, and multicomponent systems that include an elastic bandage are more effective than those composed mainly of inelastic constituents.[109]

Other forms of compression dressing available to treat CVI include multilayered dressings and legging orthoses. The purported advantages of multilayered dressings include maintenance of compression for a longer period of time, more even distribution of compression, and better absorption of wound exudates. However, the efficacy of multilayered dressings depends on the wrapping technique of healthcare personnel. A commercially available legging orthosis consisting of multiple adjustable loop-and-hook closure compression bands provides compression similar to that of Unna's boot and can be applied daily by the patient.[110]

Skin Substitutes. Several types of skin substitutes are commercially available or under clinical study in the United States.[92] Bioengineered skin ranges in composition from acellular skin substitutes to partial living skin substitutes. Their mechanism of action in healing venous ulcers is uncertain; however, they may serve as delivery vehicles for various growth factors and cytokines important in wound healing.

Apligraf is a commercially available bilayered living skin construct that closely approximates human skin for use in the treatment of venous ulcers. It contains a protective stratum corneum and a keratinocyte-containing epidermis overlying a dermis consisting of dermal fibroblasts in a collagen matrix.[111]

Figure 24-19. Apligraf skin graft material supplied as a disk on an agarose gel nutrient medium.

Figure 24-20. Trocar placement for subfascial endoscopic perforator vein surgery. (Used with permission of Dr. Pankaj Patel.)

Apligraf is between 0.5 mm and 1.0 mm thick and is supplied as a disk of living tissue on an agarose gel nutrient medium. It must be used within 5 days of release from the manufacturer[111] (Fig. 24-19). The disk is easily handled and applied and conforms to irregularly contoured ulcer beds.

A prospective randomized study comparing multilayer compression therapy alone to treatment with Apligraf in addition to multilayered compression therapy has been performed to assess the efficacy of Apligraf in the treatment of venous ulcers.[105] More patients treated with Apligraf had ulcer healing at 6 months (63% vs. 49%, $P = .02$). The median time to complete ulcer closure was significantly shorter in patients treated with Apligraf (61 days vs. 181 days, $P = .003$). The ulcers that showed the greatest benefit with the living skin construct were ones that were large and deep (>1000 mm^2) or were longstanding (>6 months). No evidence of rejection or sensitization has been reported in response to Apligraf application.

Surgical/Interventional Treatment of Chronic Venous Insufficiency

Perforator Vein Ligation. Incompetence of the perforating veins connecting the superficial and deep venous systems of the lower extremities has been implicated in the development of venous ulcers. The classic open technique described by Linton in 1938 for perforator vein ligation has a high incidence of wound complications and has largely been abandoned.[112] A minimally invasive technique termed subfascial endoscopic perforator vein surgery (SEPS) evolved with improvement of endoscopic equipment.

DUS is performed preoperatively in patients undergoing SEPS to document deep venous competence and to identify perforating veins in the posterior compartment. The patient is positioned on the operating table with the affected leg elevated at 45° to 60°. An Esmarch bandage and a thigh tourniquet are used to exsanguinate the limb. The knee is then flexed, and two small incisions are made in the proximal medial leg away from areas of maximal induration at the ankle. Laparoscopic trocars are then positioned, and the subfascial dissection is performed with a combination of blunt and sharp dissection. Carbon dioxide is then used to insufflate the subfascial space. The thigh tourniquet is inflated to prevent air embolism. The perforators are then identified and doubly clipped and divided. After completion of the procedure, the leg is wrapped in a compression bandage for 5 days postoperatively.

The efficacy of SEPS as a stand-alone procedure in treatment of venous insufficiency is controversial and unproven. In a report from a large North American registry of 146 patients undergoing SEPS[113] (Fig. 24-20), healing was achieved in 88% of ulcers (75 of 85) at 1 year. Adjunctive procedures, primarily superficial vein stripping, were performed in 72% of patients. Ulcer recurrence was predicted to be 16% at 1 year and 28% at 2 years by life table analysis. These results are similar to those achieved in some studies with compression therapy alone. A review of several studies from 2003 to 2011 demonstrated, when taken in aggregate, that 2059 limbs with 896 ulcers underwent SEPS and concomitant saphenous vein ablation (70%) with a 0% to 16% complication rate and achieved ulcer healing in 90% of patients.[114] There has been a multicenter, prospective, European trial performed in patients with venous ulcers to evaluate the efficacy of SEPS. Post hoc analysis suggested possible benefit for SEPS in certain categories of patients with venous ulcer. Overall, however, primary analysis of the study's end points indicated no advantage to SEPS in addition to superficial venous surgery and compression in the healing of venous ulcers.[115] The technique appears to have fallen out of favor in most institutions.

Superficial Venous Surgery. Currently it is accepted that superficial venous surgery in addition to compression therapy has a role in the treatment of patients with venous ulcer. The ESCHAR trial was a randomized prospective trial performed in the United Kingdom to evaluate the combination of superficial venous surgery and compression vs. compression alone in the treatment of venous ulcer. Superficial venous surgery had no additive effect to compression alone in the healing of a venous ulcer but significantly reduced venous ulcer recurrence at 4 years. Based on the results of this trial, it is reasonable to offer ablation or removal of the GSV in addition to compression therapy in patients with abnormal saphenous veins and signs and/or symptoms of severe CVI.[116]

Deep Venous Valvular Reconstruction. In the absence of significant deep vein valvular incompetence, saphenous vein stripping and possibly perforator vein ligation can be effective in the treatment of CVI. However, in patients with a combination of superficial and deep vein valvular incompetence, the addition of deep vein valvular reconstruction theoretically may

improve ulcer healing.[117] Numerous techniques of deep vein valve correction have been reported. These techniques consist of repair of existing valves, transplant of venous segments from the arm, transposition of an incompetent vein onto an adjacent competent vein, and implantation of cryopreserved vein segments including competent valves.

Successful long-term outcomes of 60% to 80% have been reported for venous valve reconstructions by internal suture repair.[117,118] However, among patients who initially had ulceration, 40% to 50% still had persistence or recurrence of ulcers in the long term.[115,116]

Valve transplantation involves replacement of a segment of incompetent femoral vein or popliteal vein with a segment of axillary or brachial vein with competent valves. Early results are similar to those for venous valve reconstruction.[117,118] However, in the long term, the transplanted venous segments tend to develop incompetence, intimal hyperplasia, and cusp sinus thrombosis with long-term outcomes that are poorer than those for venous valve reconstructions. The outcomes for venous transposition are similar to those for valve transplantation.

Currently, reconstruction techniques for deep venous insufficiency and associated CVI are rarely performed.

Venous Stenting. Currently there is great interest in the role of venous stents in the treatment of CVI. Stenotic lesions of the iliac veins, primarily documented with IVUS, are being reported in a very high percentage of patients with edema, lipodermatosclerosis, or ulceration secondary to venous disease. It appears possible to place percutaneous stents in the iliac veins with near 100% technical success and excellent patency of the stent out to 4 years. Retrospective case series suggest favorable effects on ulcer healing, symptoms of CVI, and quality of life in patients with CVI. The role of venous stenting as a favorable independent procedure in the treatment of patients with CVI remains an area of active investigation.[119]

LYMPHEDEMA

Pathophysiology

Lymphedema is extremity swelling that results from a reduction in lymphatic transport and accumulation of lymph within the interstitial space. It is caused by anatomic and or physiologic abnormalities such as lymphatic hypoplasia, functional insufficiency, or absence of lymphatic valves.

The original classification system, described by Allen, is based on the cause of the lymphedema. Primary lymphedema is further subdivided into congenital lymphedema, lymphedema praecox, and lymphedema tarda. *Congenital lymphedema* may involve a single lower extremity, multiple limbs, the genitalia, or the face. The edema typically develops before 2 years of age and may be associated with specific hereditary syndromes (Turner syndrome, Milroy syndrome, Klippel-Trénaunay-Weber syndrome). *Lymphedema praecox* is the most common form of primary lymphedema, accounting for 94% of cases. Lymphedema praecox is far more common in women, with the gender ratio favoring women 10:1. The onset is during childhood or the teenage years, and the swelling involves the foot and calf. *Lymphedema tarda* is uncommon, accounting for <10% of cases of primary lymphedema. The onset of edema is after 35 years of age.

6▶

Secondary lymphedema is far more common than primary lymphedema. Secondary lymphedema develops as a result of lymphatic obstruction or disruption. Axillary node dissection leading to lymphedema of the arm is the most common cause of secondary lymphedema in the United States. Other causes of secondary lymphedema include radiation therapy, trauma, infection, and malignancy. Globally, filariasis (an infection caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*) and environmental exposure to minerals in volcanic soil resulting in podoconiosis in barefoot populations are the most common causes of secondary lymphedema.

Clinical Diagnosis

In most patients, the diagnosis of lymphedema can be made based on the history and physical examination alone. Patients commonly complain of heaviness and fatigue in the affected extremity. The limb size increases throughout the day and decreases to some extent over the course of the night when the patient is recumbent. The limb, however, never completely normalizes. In the lower extremity, the swelling classically involves the dorsum of the foot, and the toes have a squared-off appearance. In advanced cases, hyperkeratosis of the skin develops, and fluid weeps from lymph-filled vesicles (Fig. 24-21).

Recurrent cellulitis is a common complication of lymphedema. Repeated infection results in further lymphatic damage, worsening existing disease. The clinical presentation of cellulitis ranges from subtle erythema and worsening of edema to a rapidly progressive soft tissue infection with systemic toxicity.

Many medical conditions can cause edema. If the symptoms are mild, distinguishing lymphedema from other causes of leg swelling can be difficult. Venous insufficiency is often confused with lymphedema. However, patients with advanced venous insufficiency typically have lipodermatosclerosis in the gaiter region, skin ulceration, and/or varicose veins. Bilateral pitting edema is

Figure 24-21. Patient with severe longstanding lymphedema.

typically associated with congestive heart failure, renal failure, or a hypoproteinemic state.

Radiologic Diagnosis

Duplex Ultrasound. When a patient is evaluated for edema, it is often difficult to distinguish the early stages of lymphedema from venous insufficiency. DUS of the venous system can determine if there is concomitant venous thrombosis or venous reflux, perhaps contributing to extremity edema. The diagnostic modalities discussed in the following sections have limited use in clinical practice. They are invasive and tedious and rarely change the management of a patient with lymphedema. Most physicians rely on the patient's history and physical examination alone to make the diagnosis of lymphedema.

Lymphoscintigraphy. Lymphoscintigraphy has become the most commonly used diagnostic test to identify lymphatic abnormalities. It has largely replaced lymphangiography. A radiolabeled sulfur colloid (technetium 99m sulfur colloid) is injected into the subdermal, interdigital region of the affected limb. The lymphatic transport is monitored with a whole-body gamma camera, and major lymphatics and nodes can be visualized (Fig. 24-22). In normal individuals, tracer activity may be detected in the inguinal region within 15 to 60 minutes. Within 3 hours, uptake should be present in the pelvic and abdominal lymph nodes. In patients with lymphedema, various patterns may be seen on lymphoscintigraphy. There may be delayed or absent transport to the inguinal nodes. Increased cutaneous collaterals may be seen with obstruction of the primary axial channels. There may be localized regions of reduced uptake in patients with prior node dissection or radiation therapy.

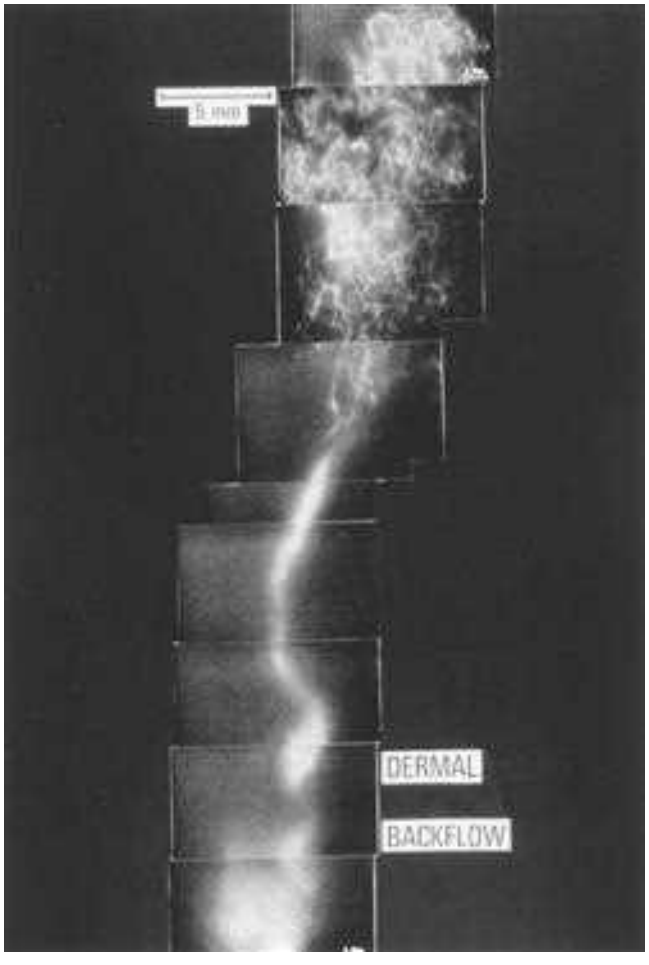

Figure 24-22. Lymphoscintigraphy of the lower extremity.

Figure 24-23. Normal lymphangiogram of the pelvis.

Lymphangiography. Radiologic lymphangiography is performed by first visualizing the lymphatics by injecting colored dye into the hand or foot. The visualized lymphatic segment is exposed through a small incision and cannulated with a 27- to 30-gauge needle. An oil-based dye is then injected slowly into the lymphatics over several hours. The lymphatic channels and nodes are then visualized with traditional radiographs (Figs. 24-23 and 24-24). Lymphangiography is reserved for patients with lymphangiectasia or lymphatic fistulas, and patients who are being considered for microvascular reconstruction.

Management

An important aspect of the management of lymphedema is patient understanding that there is no cure for lymphedema. The primary goals of treatment are to minimize swelling and to prevent recurrent infections. Controlling the chronic limb swelling can improve discomfort, heaviness, and tightness, and potentially reduce the progression of disease.[120]

Compression Garments. Graded compression stockings are widely used in the treatment of lymphedema. The stockings reduce the amount of swelling in the involved extremity by decreasing edema accumulation while the extremity is dependent. When worn daily, compression stockings have been associated with long-term maintenance of reduced limb circumference.[121] They may also protect the tissues against chronically elevated intrinsic pressures, which lead to thickening of the skin and subcutaneous tissue.[122] Compression stockings also offer a degree of protection against external trauma that may lead to cellulitis.

The amount of compression required for controlling lymphedema ranges from 20 to 60 mmHg and varies

Figure 24-24. Normal lymphangiogram of the thigh and lower leg.

among patients. The stockings can be custom made or prefabricated and are available in above- and below-knee lengths. The stockings should be worn during waking hours. The garments should be replaced approximately every 6 months when they lose elasticity.

Bedrest and Leg Elevation. Elevation is an important aspect of controlling lower extremity swelling and is often the first recommended intervention. However, continuous elevation throughout the day can interfere with quality of life more than lymphedema itself. Elevation is an adjunct to lymphedema therapy but is not the mainstay of treatment.

Intermittent Pneumatic Compression Therapy. The use of IPC with a single-chamber or multichamber pump temporarily reduces edema and provides another adjunct to the use of compression stockings. These devices have been shown to be effective in reducing limb volume; however, use of compression stockings is necessary to maintain the volume reduction when the patient is no longer supine because fluid transport is not associated with the transport of macromolecules (proteins) from the tissue. Typically, IPC is used for 4 to 6 hours per day at home when the patient is supine with pressure ranges between 30 and 60 mmHg demonstrated to be most effective.[123]

Lymphatic Massage. Manual lymphatic drainage is a form of massage developed by Vodder[124] that is directed at reducing edema. In combination with the use of compression stockings, manual lymphatic drainage is associated with a long-term reduction in edema and fewer infections per patient per year.[125]

Antibiotic Therapy. Patients with lymphedema are at increased risk of developing cellulitis in the affected extremity due to microscopic breakdown in the skin barrier either secondary to swelling or unrecognized and untreated tinea pedis. Recurrent infection can damage the lymphatics, aggravating the edema and increasing the risk for subsequent infection. Staphylococcus and β-hemolytic Streptococcus are the most common organisms causing soft tissue infection. Aggressive antibiotic therapy and elevation with compression are recommended at the earliest signs or symptoms of cellulitis. The drug of choice is penicillin or a cephalosporin active against Streptococcus for 5 days. In patients with recurrent lymphedema despite methods to reduced edema, treatment with monthly intramuscular injections of benzathine penicillin 1.2 MU, twice-daily erythromycin 250 mg, or penicillin V 1 g daily has proven effective at suppression.[126]

Surgery. A variety of surgical procedures have been devised for the treatment of lymphedema. Surgical treatment involves either excision of extra tissue[127] or anastomosis of a lymphatic vessel to another lymphatic or vein.[128] In excisional procedures, part or all of the edematous tissue is removed. This does not improve lymphatic drainage but debulks redundant tissue. The microsurgical procedures involve the creation of a lymphaticolymphatic or lymphaticovenous anastomosis, which theoretically improves lymphatic drainage. No long-term follow-up data are available for these interventions, and therefore operative therapy for lymphedema is not well accepted worldwide. Furthermore, operative intervention can further obliterate lymphatic channels, worsening the edema.[129]

SUMMARY

Lymphedema is a chronic condition caused by ineffective lymphatic transport, which results in edema and skin damage. Lymphedema is not curable, but the symptoms and long-term effects can be controlled with a combination of elastic compression stockings, limb elevation, pneumatic compression, and massage. Controlling the edema protects the skin and potentially prevents cellulitis.

chapter 25

Esophagus and Diaphragmatic Hernia

Blair A. Jobe, John G. Hunter, and David I. Watson

SURGICAL ANATOMY

The esophagus is a muscular tube that starts as the continuation of the pharynx and ends as the cardia of the stomach. When the head is in a normal anatomic position, the transition from pharynx to esophagus occurs at the lower border of the sixth cervical vertebra. Topographically this corresponds to the cricoid cartilage anteriorly and the palpable transverse process of the sixth cervical vertebra laterally (Fig. 25-1). The esophagus is firmly attached at its upper end to the cricoid cartilage and at its lower end to the diaphragm; during swallowing, the proximal points of fixation move craniad the distance of one cervical vertebral body.

The esophagus lies in the midline, with a deviation to the left in the lower portion of the neck and upper portion of the thorax, and returns to the midline in the midportion of the thorax near the bifurcation of the trachea (Fig. 25-2). In the lower portion of the thorax, the esophagus again deviates to the left and anteriorly to pass through the diaphragmatic hiatus.

Key Point

1. Benign esophageal disease is common and is best evaluated with thorough physiologic testing (high resolution esophageal motility, 24 hour ambulatory pH measurement, and/or esophageal impedance testing) and anatomic testing (esophagoscopy, video esophagography, and/or CT scanning).
2. GERD is the most common disease of the gastrointestinal tract for which patients seek medical therapy. When GERD symptoms (heartburn, regurgitation, chest pain, and/or supraesophageal symptoms) are troublesome despite adequately dosed PPI, surgical correction may be indicated.
3. Barrett's esophagus is the transformation of the distal esophageal epithelium from squamous to a specialized columnar epithelium capable of further neoplastic progression. The detection of Barrett's esophagus on endoscopy and biopsy increases the future risk of cancer by >40x compared to individuals without Barrett's esophagus.
4. Giant hiatal hernia, otherwise known as paraesophageal hernia, should be repaired when symptomatic or associated with iron deficiency anemia. Laparoscopic hiatal hernia repair with fundoplication is the most common approach to repair.
5. Achalasia is the most common primary esophageal motor disorder. It is characterized by an absence of peristalsis and a hypertensive nonrelaxing lower esophageal sphincter. It is best treated with laparoscopic Heller myotomy and partial fundoplication.
6. Most esophageal cancer presents with dysphagia, at which time it has invaded the muscularis of the esophagus and is often associated with lymph node metastases. The preferred treatment at this stage is multimodality therapy with chemoradiation therapy followed by open or minimally invasive esophagectomy.

Three normal areas of esophageal narrowing are evident on the barium esophagogram or during esophagoscopy. The uppermost narrowing is located at the entrance into the esophagus and is caused by the cricopharyngeal muscle. Its luminal diameter is 1.5 cm, and it is the narrowest point of the esophagus. The middle narrowing is due to an indentation of the anterior and left lateral esophageal wall caused by the crossing of the left main stem bronchus and aortic arch. The luminal diameter at this point is 1.6 cm. The lowermost narrowing is at the hiatus of the diaphragm and is caused by the gastroesophageal sphincter mechanism. The luminal diameter at this point varies somewhat, depending on the distention of the esophagus by the passage of food, but has been measured at 1.6 to 1.9 cm. These normal constrictions tend to hold up swallowed foreign objects, and the overlying mucosa is subject to injury by swallowed corrosive liquids due to their slow passage through these areas.

Figure 25-3 shows the average distance in centimeters measured during endoscopic examination between the incisor teeth and the cricopharyngeus, aortic arch, and cardia of the stomach. Manometrically, the length of the esophagus between

the lower border of the cricopharyngeus and upper border of the lower sphincter varies according to the height of the individual.

The pharyngeal musculature consists of three broad, flat, overlapping fan-shaped constrictors (Fig. 25-4). The opening of the esophagus is collared by the cricopharyngeal muscle, which

arises from both sides of the cricoid cartilage of the larynx and forms a continuous transverse muscle band without an interruption by a median raphe. The fibers of this muscle blend inseparably with those of the inferior pharyngeal constrictor above and the inner circular muscle fibers of the esophagus below. Some investigators believe that the cricopharyngeus is part of the inferior constrictor; that is, that the inferior constrictor has two parts, an upper or retrothyroid portion having diagonal fibers, and a lower or retrocricoid portion having transverse fibers. Keith in 1910 showed that these two parts of the same muscle serve totally different functions. The retrocricoid portion serves as the upper sphincter of the esophagus and relaxes when the retrothyroid portion contracts, to force the swallowed bolus from the pharynx into the esophagus.

The cervical portion of the esophagus is approximately 5 cm long and descends between the trachea and the vertebral column, from the level of the sixth cervical vertebra to the level of the interspace between the first and second thoracic vertebrae posteriorly, or the level of the suprasternal notch anteriorly. The recurrent laryngeal nerves lie in the right and left grooves between the trachea and the esophagus. The left recurrent nerve lies somewhat closer to the esophagus than the right, owing to the slight deviation of the esophagus to the left, and the more lateral course of the right recurrent nerve around the right subclavian artery. Laterally, on the left and right sides of the cervical esophagus are the carotid sheaths and the lobes of the thyroid gland.

The thoracic portion of the esophagus is approximately 20 cm long. It starts at the thoracic inlet. In the upper portion of the thorax, it is in intimate relationship with the posterior wall of the trachea and the prevertebral fascia. Just above the tracheal bifurcation, the esophagus passes to the right of the aorta. This anatomic positioning can cause a notch indentation in its left lateral wall on a barium swallow radiogram. Immediately below this notch, the esophagus crosses both the bifurcation of the trachea and the left main stem bronchus, owing to the slight deviation of the terminal portion of the trachea to the right by the aorta (Fig. 25-5). From there down, the esophagus passes over the posterior surface of the subcarinal lymph nodes (LNs), and then descends over the pericardium of the left atrium to reach the diaphragmatic hiatus (Fig. 25-6). From the bifurcation of the trachea downward, both the vagal nerves and the esophageal nerve plexus lie on the muscular wall of the esophagus.

Dorsally, the thoracic esophagus follows the curvature of the spine and remains in close contact with the vertebral bodies. From the eighth thoracic vertebra downward, the esophagus moves vertically away from the spine to pass through the hiatus of the diaphragm. The thoracic duct passes through the hiatus of the diaphragm on the anterior surface of the vertebral column behind the aorta and under the right crus. In the thorax, the thoracic duct lies dorsal to the esophagus between the azygos vein on the right and the descending thoracic aorta on the left.

The abdominal portion of the esophagus is approximately 2 cm long and includes a portion of the lower esophageal sphincter (LES). It starts as the esophagus passes through the diaphragmatic hiatus and is surrounded by the phrenoesophageal membrane, a fibroelastic ligament arising from the subdiaphragmatic fascia as a continuation of the transversalis fascia lining the abdomen (Fig. 25-7). The upper leaf of the membrane attaches itself in a circumferential fashion around the esophagus, about 1 to 2 cm above the level of the hiatus. These fibers blend in with the elastic-containing adventitia of the abdominal esophagus and the cardia of the stomach. This portion of the esophagus is subjected to the positive-pressure environment of the abdomen.

The musculature of the esophagus can be divided into an outer longitudinal and an inner circular layer. The upper 2 to 6 cm of the esophagus contains only striated muscle fibers. From then on, smooth muscle fibers gradually become more abundant. Most clinically significant esophageal motility disorders involve only the smooth muscle in the lower two- thirds of the esophagus. When a surgical esophageal myotomy is indicated, the incision needs to extend only this distance.

The longitudinal muscle fibers originate from a cricoesophageal tendon arising from the dorsal upper edge of the anteriorly located cricoid cartilage. The two bundles of muscle diverge and meet in the midline on the posterior wall of the esophagus about 3 cm below the cricoid (see Fig. 25-4).

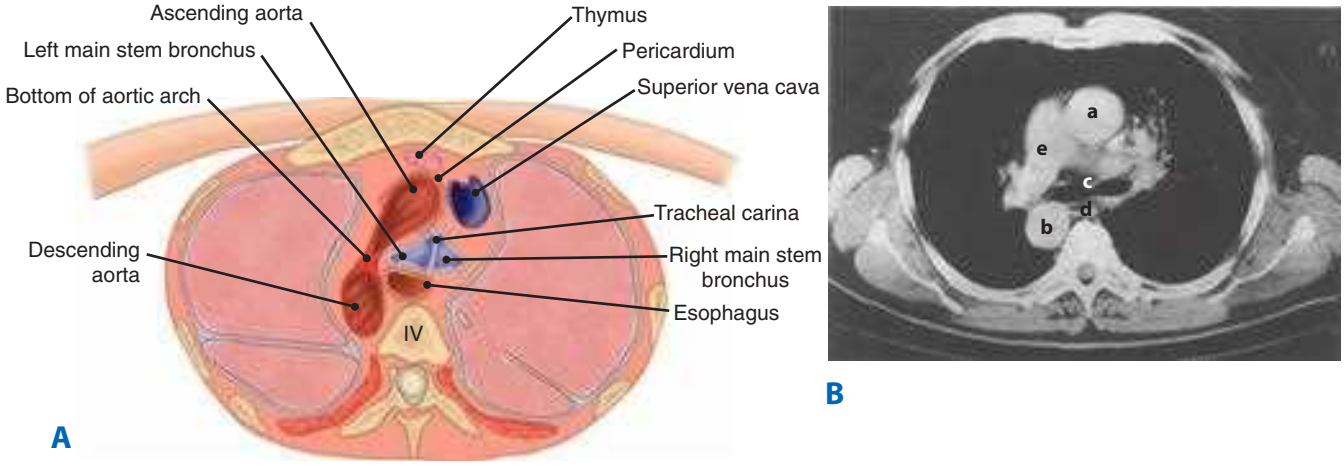

Figure 25-5. **A.** Cross-section of the thorax at the level of the tracheal bifurcation. **B.** Computed tomographic scan at same level viewed from above: (a) ascending aorta, (b) descending aorta, (c) tracheal carina, (d) esophagus, (e) pulmonary artery. *(Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed):* General Thoracic Surgery, *3rd ed. Philadelphia: Lea & Febiger, 1989, p 81.)*

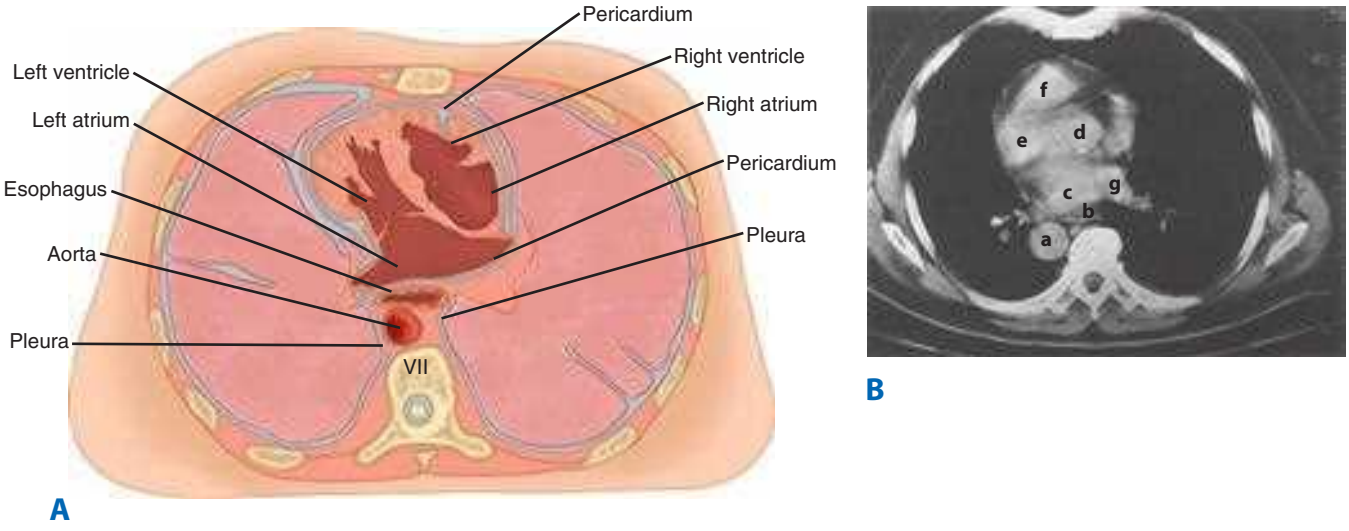

Figure 25-6. **A.** Cross-section of the thorax at the midleft atrial level. **B.** Computed tomographic scan at same level viewed from above: (a) aorta, (b) esophagus, (c) left atrium, (d) right atrium, (e) left ventricle, (f) right ventricle, (g) pulmonary vein. *(Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed):* General Thoracic Surgery, *3rd ed. Philadelphia: Lea & Febiger, 1989, p 82.)*

From this point on, the entire circumference of the esophagus is covered by a layer of longitudinal muscle fibers. This configuration of the longitudinal muscle fibers around the most proximal part of the esophagus leaves a V-shaped area in the posterior wall covered only with circular muscle fibers. Contraction of the longitudinal muscle fibers shortens the esophagus. The circular muscle layer of the esophagus is thicker than the outer longitudinal layer. In situ, the geometry of the circular muscle is helical and makes the peristalsis of the esophagus assume a worm-like drive, as opposed to segmental and sequential squeezing. As a consequence, severe motor abnormalities of the esophagus assume a corkscrew-like pattern on the barium swallow radiogram.

The cervical portion of the esophagus receives its main blood supply from the inferior thyroid artery. The thoracic portion receives its blood supply from the bronchial arteries, with 75% of individuals having one right-sided and two left-sided branches. Two esophageal branches arise directly from the aorta.

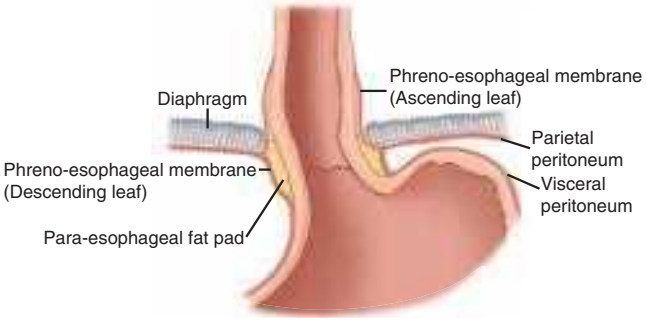

Figure 25-7. Attachments and structure of the phrenoesophageal membrane. Transversalis fascia lies just above the parietal peritoneum. *(Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed):* General Thoracic Surgery, *3rd ed. Philadelphia: Lea & Febiger, 1989, p 83.)*

The abdominal portion of the esophagus receives its blood supply from the ascending branch of the left gastric artery and from inferior phrenic arteries (Fig. 25-8). On entering the wall of the esophagus, the arteries assume a T-shaped division to form a longitudinal plexus, giving rise to an intramural vascular network in the muscular and submucosal layers. As a consequence, the esophagus can be mobilized from the stomach to the level of the aortic arch without fear of devascularization and ischemic necrosis. Caution should be exercised as to the extent

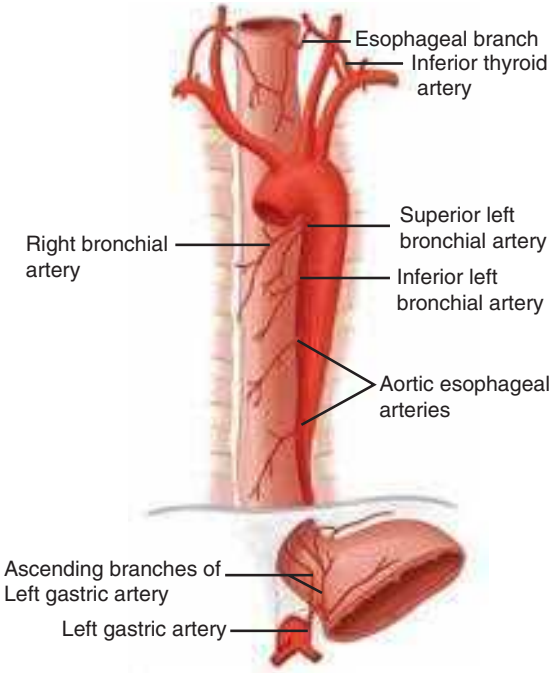

Figure 25-8. Arterial blood supply of the esophagus. *(Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed):* General Thoracic Surgery, *3rd ed. Philadelphia: Lea & Febiger, 1989, p 84.)*

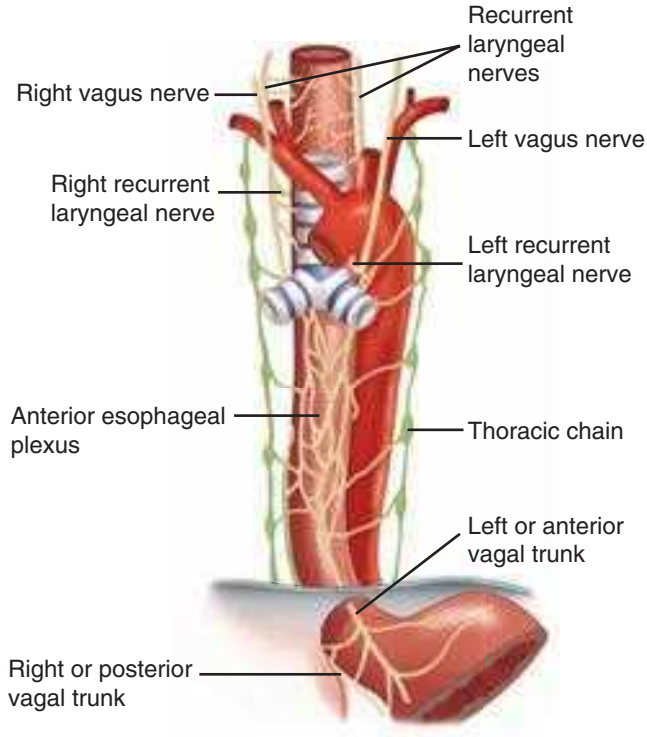

Figure 25-10. Innervation of the esophagus. *(Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed):* General Thoracic Surgery, *3rd ed. Philadelphia: Lea & Febiger, 1989, p 85.)*

of esophageal mobilization in patients who have had a previous thyroidectomy with ligation of the inferior thyroid arteries proximal to the origin of the esophageal branches.

Blood from the capillaries of the esophagus flows into a submucosal venous plexus, and then into a periesophageal venous plexus from which the esophageal veins originate. In the cervical region, the esophageal veins empty into the inferior thyroid vein; in the thoracic region, they empty into the bronchial, azygos, or hemiazygos veins; and in the abdominal region, they empty into the coronary vein (Fig. 25-9). The submucosal venous networks of the esophagus and stomach are in continuity with each other, and, in patients with portal venous obstruction, this communication functions as a collateral pathway for portal blood to enter the superior vena cava via the azygos vein.

The parasympathetic innervation of the pharynx and esophagus is provided mainly by the vagus nerves. The constrictor muscles of the pharynx receive branches from the pharyngeal plexus, which is on the posterior lateral surface of the middle constrictor muscle, and is formed by pharyngeal branches of the vagus nerves with a small contribution from cranial nerves IX and XI (Fig. 25-10). The cricopharyngeal sphincter and the cervical portion of the esophagus receive branches from both recurrent laryngeal nerves, which originate from the vagus nerves—the right recurrent nerve at the lower margin of the subclavian artery and the left at the lower margin of the aortic arch. They are slung dorsally around these vessels and ascend in the groove between the esophagus and trachea, giving branches to each. Damage to these nerves interferes not only with the function of the vocal cords, but also with the function of the cricopharyngeal sphincter and the motility of the cervical esophagus, predisposing the individual to pulmonary aspiration on swallowing.

Afferent visceral sensory pain fibers from the esophagus end without synapse in the first four segments of the thoracic spinal cord, using a combination of sympathetic and vagal pathways. These pathways are also occupied by afferent visceral sensory fibers from the heart; hence, both organs have similar symptomatology.

The lymphatics located in the submucosa of the esophagus are so dense and interconnected that they constitute a single plexus (Fig. 25-11). There are more lymph vessels than blood

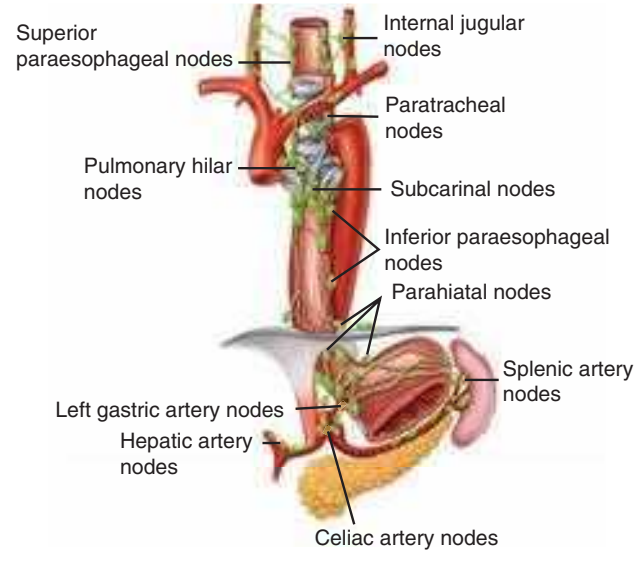

Figure 25-11. Lymphatic drainage of the esophagus. *(Reproduced with permission from DeMeester TR, Barlow AP: Surgery and current management for cancer of the esophagus and cardia: Part I.* Curr Probl Surg *25:498, 1988. Copyright Elsevier.)*

capillaries in the submucosa. Lymph flow in the submucosal plexus runs in a longitudinal direction, and, on injection of a contrast medium, the longitudinal spread is seen to be about six times that of the transverse spread. In the upper two-thirds of the esophagus, the lymphatic flow is mostly cephalad, and, in the lower third, caudad. In the thoracic portion of the esophagus, the submucosal lymph plexus extends over a long distance in a longitudinal direction before penetrating the muscle layer to enter lymph vessels in the adventitia. As a consequence of this nonsegmental lymph drainage, a primary tumor can extend for a considerable length superiorly or inferiorly in the submucosal plexus. Consequently, free tumor cells can follow the submucosal lymphatic plexus in either direction for a long distance before they pass through the muscularis and on into the regional LNs. The cervical esophagus has more direct segmental lymph drainage into the regional nodes, and, as a result, lesions in this portion of the esophagus have less submucosal extension and a more regionalized lymphatic spread.

The efferent lymphatics from the cervical esophagus drain into the paratracheal and deep cervical LNs, and those from the upper thoracic esophagus empty mainly into the paratracheal LNs. Efferent lymphatics from the lower thoracic esophagus drain into the subcarinal nodes and nodes in the inferior pulmonary ligaments. The superior gastric nodes receive lymph not only from the abdominal portion of the esophagus, but also from the adjacent lower thoracic segment.

PHYSIOLOGY

Swallowing Mechanism

The act of alimentation requires the passage of food and drink from the mouth into the stomach. One-third of this distance consists of the mouth and hypopharynx, and two-thirds is made up by the esophagus. To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a mechanical model in which the tongue and pharynx function as a piston pump with three valves, and the body of the esophagus and cardia function as a worm-drive pump with a single valve. The three valves in the pharyngeal cylinder are the soft palate, epiglottis, and cricopharyngeus. The valve of the esophageal pump is the LES. Failure of the valves or the pumps leads to abnormalities in swallowing—that is, difficulty in food propulsion from mouth to stomach—or regurgitation of gastric contents into the esophagus or pharynx.

Food is taken into the mouth in a variety of bite sizes, where it is broken up, mixed with saliva, and lubricated. Once initiated, swallowing is entirely a reflex act. When food is ready for swallowing, the tongue, acting like a piston, moves the bolus into the posterior oropharynx and forces it into the hypopharynx (Fig. 25-12). Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. This partitioning prevents pressure generated in the oropharynx from being dissipated through the nose. When the soft palate is paralyzed, for example, after a cerebrovascular accident, food is commonly regurgitated into the nasopharynx. During swallowing, the hyoid bone moves upward and anteriorly, elevating the larynx and opening the retrolaryngeal space, bringing the epiglottis under the tongue (see Fig. 25-12). The backward tilt of the epiglottis covers the opening of the larynx to prevent aspiration. The entire pharyngeal part of swallowing occurs within 1.5 seconds.

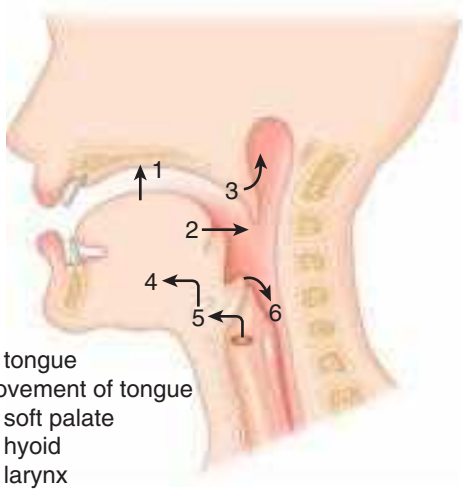

Figure 25-12. Sequence of events during the oropharyngeal phase of swallowing. (Reproduced with permission from DeMeester TR, Stein HJ, Fuchs KH: Physiologic diagnostic studies, in Zuidema GD, Orringer MB (eds): Shackelford's Surgery of the Alimentary Tract, 3rd ed., Vol. I. Philadelphia: W.B. Saunders, 1991, p 95. Copyright Elsevier.)

During swallowing, the pressure in the hypopharynx rises abruptly, to at least 60 mmHg, due to the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the less-than-atmospheric midesophageal or intrathoracic pressure (Fig. 25-13). This pressure gradient speeds the movement of food from the hypopharynx

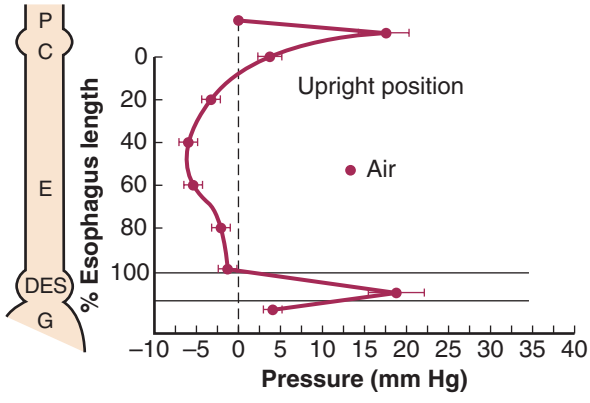

Figure 25-13. Resting pressure profile of the foregut showing the pressure differential between the atmospheric pharyngeal pressure (P) and the less-than-atmospheric midesophageal pressure (E) and greater-than-atmospheric intragastric pressure (G), with the interposed high pressure zones of the cricopharyngeus (C) and distal esophageal sphincter (DES). The necessity for relaxation of the cricopharyngeus and DES pressure to move a bolus into the stomach is apparent. Esophageal work occurs when a bolus is pushed from the midesophageal area (E), with a pressure less than atmospheric, into the stomach, which has a pressure greater than atmospheric (G). *(Reproduced with permission from Waters PF, DeMeester TR: Foregut motor disorders and their surgical management.* Med Clin North Am *65:1237, 1981. Copyright Elsevier.)*

into the esophagus when the cricopharyngeus or upper esophageal sphincter relaxes. The bolus is both propelled by peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus. Critical to receiving the bolus is the compliance of the cervical esophagus; when compliance is lost due to muscle pathology, dysphagia can result. The upper esophageal sphincter closes within 0.5 second of the initiation of the swallow, with the immediate closing pressure reaching approximately twice the resting level of 30 mmHg. The postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 25-14). The high closing pressure and the initiation of the peristaltic wave prevents reflux of the bolus from the esophagus back into the pharynx. After the peristaltic wave has passed farther down the esophagus, the pressure in the upper esophageal sphincter returns to its resting level.

Swallowing can be started at will, or it can be reflexively elicited by the stimulation of areas in the mouth and pharynx, among them the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. The afferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagus nerves. Once aroused by stimuli entering via these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through cranial nerves V, VII, X, XI, and XII, as well as the motor neurons of C1 to C3. Discharges through these nerves occur in a rather specific pattern and last for approximately 0.5 second. Little is known about the organization of the swallowing center, except that it can trigger swallowing after a variety of different inputs, but the response is always a rigidly ordered pattern of outflow. Following a cerebrovascular accident, this coordinated outflow may be altered, causing mild to severe abnormalities of swallowing. In more severe injury, swallowing can be grossly disrupted, leading to repetitive aspiration.

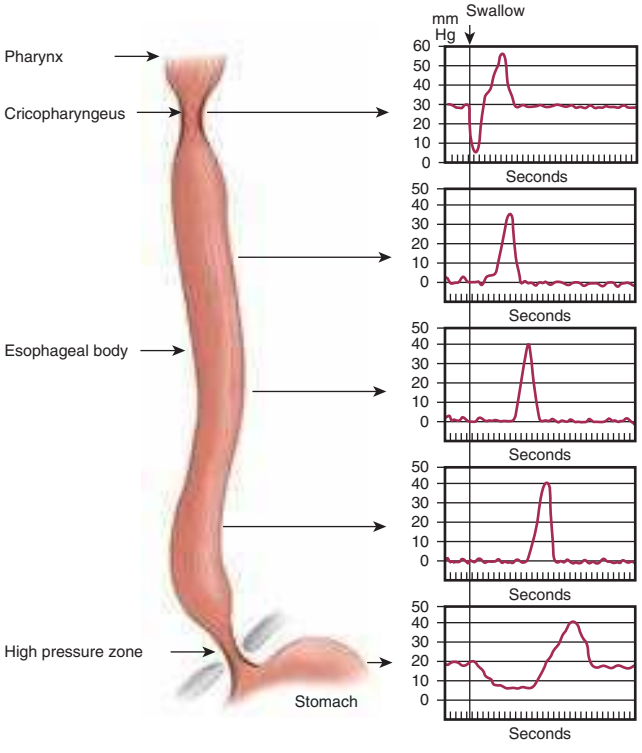

Figure 25-14. Intraluminal esophageal pressures in response to swallowing. *(Reproduced with permission from Waters PF, DeMeester TR: Foregut motor disorders and their surgical management*. Med Clin North Am *65:1238, 1981. Copyright Elsevier.)*

The striated muscles of the cricopharyngeus and the upper one-third of the esophagus are activated by efferent motor fibers distributed through the vagus nerve and its recurrent laryngeal branches. The integrity of innervation is required for the cricopharyngeus to relax in coordination with the pharyngeal contraction, and resume its resting tone once a bolus has entered the upper esophagus. Operative damage to the innervation can interfere with laryngeal, cricopharyngeal, and upper esophageal function, and predispose the patient to aspiration.

The pharyngeal activity in swallowing initiates the esophageal phase. The body of the esophagus functions as a worm-drive propulsive pump due to the helical arrangement of its circular muscles, and is responsible for transferring a bolus of food into the stomach. The esophageal phases of swallowing represents esophageal work done during alimentation, in that food is moved into the stomach from a negative-pressure environment of –6 mm Hg intrathoracic pressure, to a positive-pressure environment of 6 mm Hg intra-abdominal pressure, or over a gradient of 12 mm Hg (see Fig. 25-13). Effective and coordinated smooth muscle function in the lower one- third of the esophagus is therefore important in pumping the food across this gradient.

The peristaltic wave generates an occlusive pressure varying from 30 to 120 mmHg (see Fig. 25-14). The wave rises to a peak in 1 second, lasts at the peak for about 0.5 second, and then subsides in about 1.5 seconds. The whole course of the rise and fall of occlusive pressure may occupy one point in the esophagus for 3 to 5 seconds. The peak of a primary peristaltic contraction initiated by a swallow (primary peristalsis) moves down the esophagus at 2 to 4 cm/s and reaches the distal esophagus about 9 seconds after swallowing starts. Consecutive swallows produce similar primary peristaltic waves, but when the act of swallowing is rapidly repeated, the esophagus remains relaxed and the peristaltic wave occurs only after the last movement of the pharynx. Progress of the wave in the esophagus is caused by sequential activation of its muscles, initiated by efferent vagal nerve fibers arising in the swallowing center.

Continuity of the esophageal muscle is not necessary for sequential activation if the nerves are intact. If the muscles, but not the nerves, are cut across, the pressure wave begins distally below the cut as it dies out at the proximal end above the cut. This allows a sleeve resection of the esophagus to be done without destroying its normal function. Afferent impulses from receptors within the esophageal wall are not essential for progress of the coordinated wave. Afferent nerves, however, do go to the swallowing center from the esophagus, because, if the esophagus is distended at any point, a contractual wave begins with a forceful closure of the upper esophageal sphincter and sweeps down the esophagus. This secondary contraction occurs without any movements of the mouth or pharynx. Secondary peristalsis can occur as an independent local reflex to clear the esophagus of ingested material left behind after the passage of the primary wave. Current studies suggest that secondary peristalsis is not as common as once thought.

Despite the powerful occlusive pressure, the propulsive force of the esophagus is relatively feeble. If a subject attempts to swallow a bolus attached by a string to a counterweight, the maximum weight that can be overcome is 5 to 10 g.

Orderly contractions of the muscular wall and anchoring of the esophagus at its inferior end are necessary for efficient aboral propulsion to occur. Loss of the inferior anchor, as occurs with a large hiatal hernia, can lead to inefficient propulsion.

The LES provides a pressure barrier between the esophagus and stomach and acts as the valve on the worm-drive pump of the esophageal body. Although an anatomically distinct LES has been difficult to identify, microdissection studies show that, in humans, the sphincter-like function is related to the architecture of the muscle fibers at the junction of the esophageal tube with the gastric pouch (Fig. 25-15). The sphincter actively remains closed to prevent reflux of gastric contents into the esophagus and opens by a relaxation that coincides with a pharyngeal swallow (see Fig. 25-14). The LES pressure returns to its resting level after the peristaltic wave has passed through the esophagus. Consequently, reflux of gastric juice that may occur through the open valve during a swallow is cleared back into the stomach.

If the pharyngeal swallow does not initiate a peristaltic contraction, then the coincident relaxation of the LES is unguarded and reflux of gastric juice can occur. This may be an explanation for the observation of spontaneous lower esophageal relaxation, thought by some to be a causative factor in gastroesophageal reflux disease (GERD). The power of the worm-drive pump of the esophageal body is insufficient to force open a valve that does not relax. In dogs, a bilateral cervical parasympathetic blockade abolishes the relaxation of the LES that occurs with pharyngeal swallowing or distention of the esophagus. Consequently, vagal function appears to be important in coordinating the relaxation of the LES with esophageal contraction.

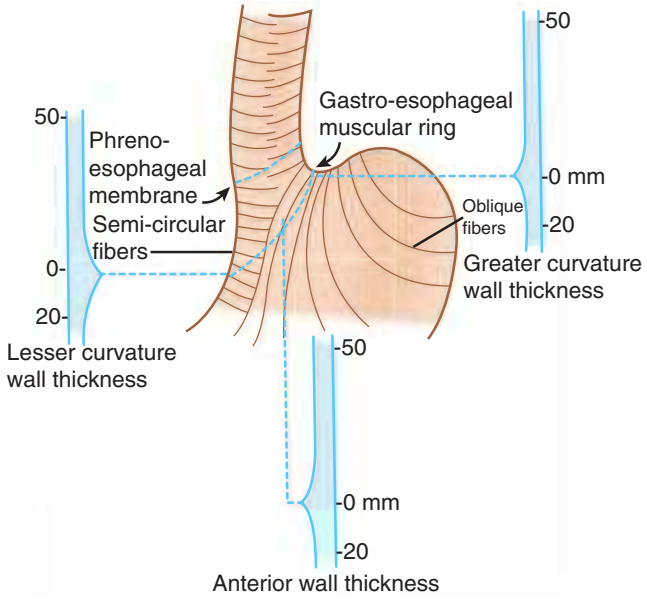

Figure 25-15. Wall thickness and orientation of fibers on microdissection of the cardia. At the junction of the esophageal tube and gastric pouch, there is an oblique muscular ring composed of an increased muscle mass inside the inner muscular layer. On the lesser curve side of the cardia, the muscle fibers of the inner layer are oriented transversely and form semicircular muscle clasps. On the greater curve side of the cardia, these muscle fibers form oblique loops that encircle the distal end of the cardia and gastric fundus. Both the semicircular muscle clasps and the oblique fibers of the fundus contract in a circular manner to close the cardia. (Reproduced with permission from DeMeester TR, Skinner DB: Evaluation of esophageal function and disease, in Glenn WWL (ed): Thoracic and Cardiovascular Surgery, 4th ed. Norwalk, CT: Appleton-Century-Crofts, 1983, p 461.)

The antireflux mechanism in human beings is composed of three components: a mechanically effective LES, efficient esophageal clearance, and an adequately functioning gastric reservoir. A defect of any one of these three components can lead to increased esophageal exposure to gastric juice and the development of mucosal injury.

Physiologic Reflux

On 24-hour esophageal pH monitoring, healthy individuals have occasional episodes of gastroesophageal reflux. This physiologic reflux is more common when awake and in the upright position than during sleep in the supine position. When reflux of gastric juice occurs, normal subjects rapidly clear the acid gastric juice from the esophagus regardless of their position.

There are several explanations for the observation that physiologic reflux in normal subjects is more common when they are awake and in the upright position than during sleep in the supine position. First, reflux episodes occur in healthy volunteers primarily during transient losses of the gastroesophageal barrier, which may be due to a relaxation of the LES or intragastric pressure overcoming sphincter pressure. Gastric juice can also reflux when a swallow-induced relaxation of the LES is not protected by an oncoming peristaltic wave. The average frequency of these "unguarded moments" or of transient losses of the gastroesophageal barrier is far less while asleep and in the supine position than while awake and in the upright position. Consequently, there are fewer opportunities for reflux to occur in the supine position. Second, in the upright position, there is a 12-mmHg pressure gradient between the resting, positive intra-abdominal pressure measured in the stomach and the most negative intrathoracic pressure measured in the esophagus at midthoracic level. This gradient favors the flow of gastric juice up into the thoracic esophagus when upright. The gradient diminishes in the supine position. Third, the LES pressure in normal subjects is significantly higher in the supine position than in the upright position. This is due to the apposition of the hydrostatic pressure of the abdomen to the abdominal portion of the sphincter when supine. In the upright position, the abdominal pressure surrounding the sphincter is negative compared with atmospheric pressure, and, as expected, the abdominal pressure gradually increases the more caudally it is measured. This pressure gradient tends to move the gastric contents toward the cardia and encourages the occurrence of reflux into the esophagus when the individual is upright. In contrast, in the supine position, the gastroesophageal pressure gradient diminishes, and the abdominal hydrostatic pressure under the diaphragm increases, causing an increase in sphincter pressure and a more competent cardia.

The LES has intrinsic myogenic tone, which is modulated by neural and hormonal mechanisms. Alpha-adrenergic neurotransmitters or beta blockers stimulate the LES, and alpha blockers and beta stimulants decrease its pressure. It is not clear to what extent cholinergic nerve activity controls LES pressure. The vagus nerve carries both excitatory and inhibitory fibers to the esophagus and sphincter. The hormones gastrin and motilin have been shown to increase LES pressure; and cholecystokinin, estrogen, glucagon, progesterone, somatostatin, and secretin decrease LES pressure. The peptides bombesin, l-enkephalin,

and substance P increase LES pressure; and calcitonin gene-related peptide, gastric inhibitory peptide, neuropeptide Y, and vasoactive intestinal polypeptide decrease LES pressure. Some pharmacologic agents such as antacids, cholinergics, agonists, domperidone, metoclopramide, and prostaglandin F_2 are known to increase LES pressure; and anticholinergics, barbiturates, calcium channel blockers, caffeine, diazepam, dopamine, meperidine, prostaglandin E_1 and E_2, and theophylline decrease LES pressure. Peppermint, chocolate, coffee, ethanol, and fat are all associated with decreased LES pressure and may be responsible for esophageal symptoms after a sumptuous meal.

ASSESSMENT OF ESOPHAGEAL FUNCTION

A thorough understanding of the patient's underlying anatomic and functional deficits before making therapeutic decisions is fundamental to the successful treatment of esophageal disease. The diagnostic tests, as presently used, may be divided into four broad groups: (a) tests to detect structural abnormalities of the esophagus; (b) tests to detect functional abnormalities of the esophagus; (c) tests to detect increased esophageal exposure to gastric juice; and (d) tests of duodenogastric function as they relate to esophageal disease.

1▶

Tests to Detect Structural Abnormalities

Endoscopic Evaluation. The first diagnostic test in patients with suspected esophageal disease is usually upper gastrointestinal endoscopy. This allows assessment and biopsy of the mucosa of the stomach and the esophagus, as well as the diagnosis and assessment of obstructing lesions in the upper gastrointestinal tract. In any patient complaining of dysphagia, esophagoscopy is indicated, even in the face of a normal radiographic study.

For the initial endoscopic assessment, the flexible fiberoptic esophagoscope is the instrument of choice because of its technical ease, patient acceptance, and the ability to simultaneously assess the stomach and duodenum. Rigid endoscopy is now only rarely required, mainly for the disimpaction of difficult foreign bodies impacted in the esophagus.

When GERD is the suspected diagnosis, particular attention should be paid to detecting the presence of esophagitis and Barrett's columnar-lined esophagus (CLE). When endoscopic esophagitis is seen, severity and the length of esophagitis involved are recorded. Many different grading systems have been proposed. In a commonly used system, Grade I esophagitis is defined as small, circular, nonconfluent erosions (Fig. 25-16). Grade II esophagitis is defined by the presence of linear erosions lined with granulation tissue that bleeds easily when touched. Grade III esophagitis represents a more advanced stage, in which the linear erosions coalesce into circumferential loss of the epithelium and the mucosa may take a "cobblestone" appearance. Grade IV esophagitis is the presence of a stricture. Its severity can be assessed by the ease of passing a 36F endoscope. When a stricture is observed, the severity of the esophagitis above it should be recorded. The absence of esophagitis above a stricture suggests a chemical-induced injury or a neoplasm as a cause. The latter should always be considered and is ruled out only by evaluation of a tissue biopsy of adequate size. It should be remembered that gastroesophageal reflux is not always associated with visible mucosal abnormalities, and patients can experience significant reflux symptoms, despite an apparently normal endoscopy examination.

Barrett's esophagus (BE) is a condition in which the tubular esophagus is lined with columnar epithelium, as opposed to the normal squamous epithelium (Fig. 25-16). Histologically, it appears as intestinal metaplasia (IM). It is suspected at endoscopy when there is difficulty in visualizing the squamocolumnar junction at its normal location, and by the appearance of a redder, more luxuriant mucosa than is normally seen in the lower esophagus. Its presence is confirmed by biopsy. Multiple biopsy specimens should be taken in a cephalad direction to determine the level at which the junction of Barrett's epithelium with normal squamous mucosa occurs. BE is susceptible to ulceration, bleeding, stricture formation, and, most important, malignant degeneration. The earliest sign of the latter is high grade dysplasia or intramucosal adenocarcinoma (Fig. 25-16). These dysplastic changes have a patchy distribution, so a minimum of four biopsy samples spaced 2 cm apart should be taken from the Barrett's-lined portion of the esophagus. Changes seen in one biopsy are significant. Nishimaki has determined that the tumors occur in an area of specialized columnar epithelium near the squamocolumnar junction in 85% of patients, and within 2 cm of the squamocolumnar junction in virtually all patients. Particular attention should be focused on this area in patients suspected of harboring a carcinoma.

Abnormalities of the gastroesophageal flap valve can be visualized by retroflexion of the endoscope. Hill has graded the appearance of the gastroesophageal valve from I to IV according to the degree of unfolding or deterioration of the normal valve architecture (Fig. 25-17). The appearance of the valve correlates with the presence of increased esophageal acid exposure, occurring predominantly in patients with Grade III and IV valves.

A hiatal hernia is endoscopically confirmed by finding a pouch lined with gastric rugal folds lying 2 cm or more above the margins of the diaphragmatic crura, identified by having the patient sniff. A hernia is best demonstrated with the stomach fully insufflated and the gastroesophageal junction observed with a retroflexed endoscope. A prominent sliding hiatal hernia frequently is associated with increased esophageal exposure to gastric juice. When a paraesophageal hernia (PEH) is observed, particular attention is taken to exclude a gastric (Cameron's) ulcer or gastritis within the pouch. The intragastric retroflex or J maneuver is important in evaluating the full circumference of the mucosal lining of the herniated stomach.

When an esophageal diverticulum is seen, it should be carefully explored with the flexible endoscope to exclude ulceration or neoplasia. When a submucosal mass is identified, biopsy specimens are usually not performed. At the time of surgical resection, a submucosal leiomyoma or reduplication cyst can generally be dissected away from the intact mucosa, but if a biopsy sample is taken, the mucosa may become fixed to the underlying abnormality. This complicates the surgical dissection by increasing the risk of mucosal perforation. Endoscopic ultrasound provides a better method for evaluating these lesions.

Radiographic Evaluation. Barium swallow evaluation is undertaken selectively to assess anatomy and motility. The anatomy of large hiatal hernias are more clearly demonstated by contrast radiology than endoscopy, and the presence of coordinated esophageal peristalsis can be determined by observing several individual swallows of barium traversing the entire length of the organ, with the patient in the horizontal position. Hiatal hernias are best demonstrated with the patient prone because the increased intra-abdominal pressure produced in this

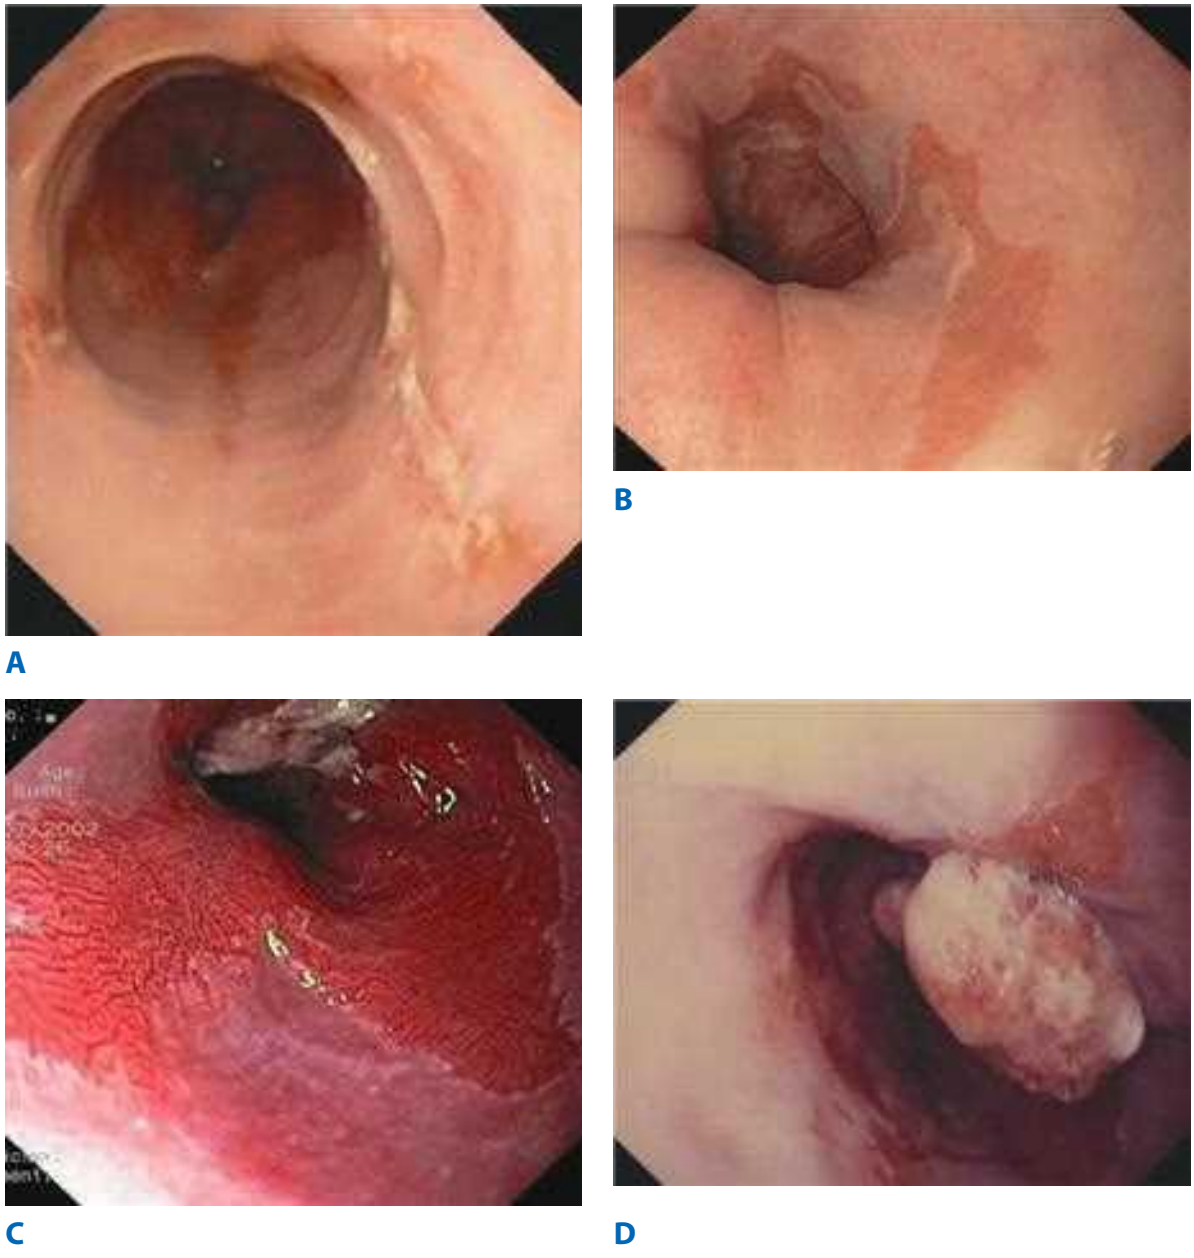

Figure 25-16. Complications of reflux disease as seen on endoscopy. **A.** Linear erosions of grade II esophagitis. **B.** Uncomplicated Barrett's mucosa. **C.** High Grade dysplasia in Barrett's mucosa, **D.** Early adenocarcinoma arising in Barrett's mucosa.

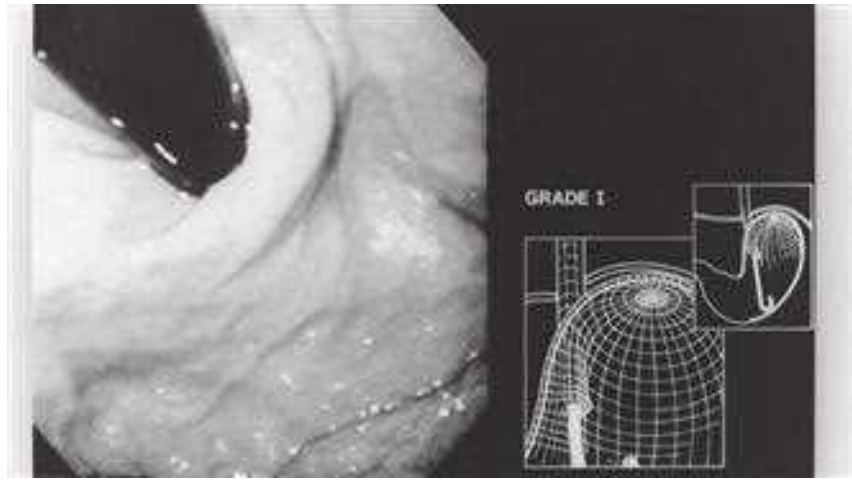
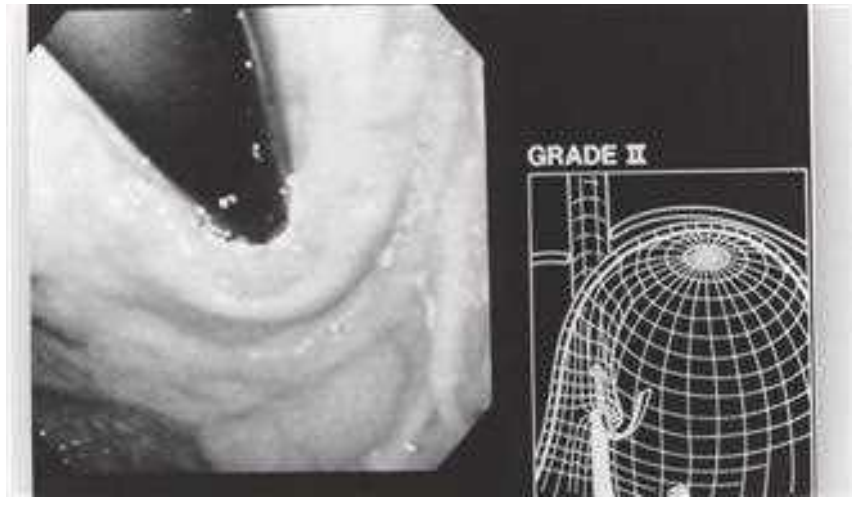
position promotes displacement of the esophagogastric junction above the diaphragm. To detect lower esophageal narrowing, such as rings and strictures, fully distended views of the esophagogastric region are crucial. The density of the barium used to study the esophagus can potentially affect the accuracy of the examination. Esophageal disorders shown clearly by a full-column technique include circumferential carcinomas, peptic strictures, large esophageal ulcers, and hiatal hernias. A small hiatal hernia is usually not associated with significant symptoms or illness, and its presence is an irrelevant finding unless the hiatal hernia is large (Fig. 25-18), or the hernia is of the paraesophageal variety. Lesions extrinsic but adjacent to the esophagus can be reliably detected by the full-column technique if they contact the distended esophageal wall. Conversely, a number of important disorders may go undetected if this is the sole technique used to examine the esophagus. These include small esophageal neoplasms, mild esophagitis, and esophageal varices. Thus, the full-column technique should be supplemented with mucosal relief or double-contrast films to enhance detection of these smaller or more subtle lesions.

Motion-recording techniques greatly aid in evaluating functional disorders of the pharyngoesophageal and esophageal phases of swallowing. The technique and indications for cine- and videoradiography will be discussed in the section entitled *Video- and Cineradiography*, as they are more useful to evaluate function and seldom used to detect structural abnormalities.

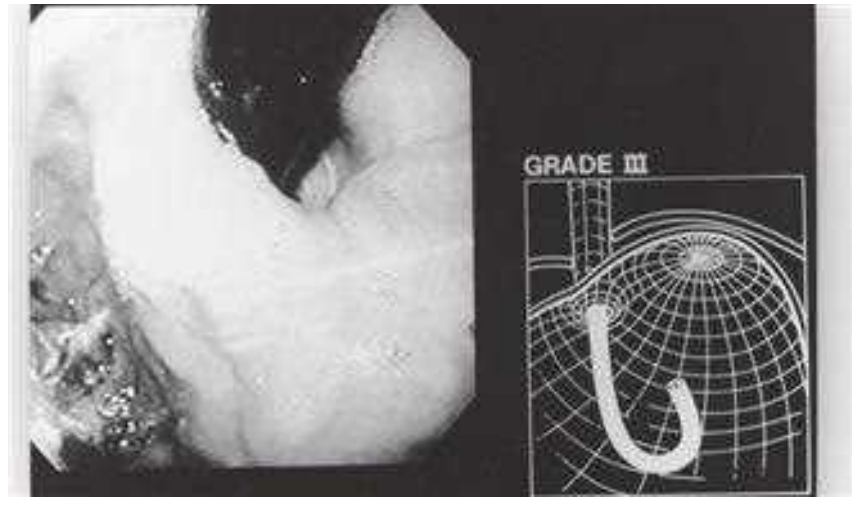
The radiographic assessment of the esophagus is not complete unless the entire stomach and duodenum have been examined. A gastric or duodenal ulcer, partially obstructing gastric neoplasm, or scarred duodenum and pylorus may contribute significantly to symptoms otherwise attributable to an esophageal abnormality.



A



B



C

Figure 25-17. **A.** Grade I flap valve appearance. Note the ridge of tissue that is closely approximated to the shaft of the retroflexed endoscope. It extends 3–4 cm along the lesser curve. **B.** Grade II flap valve appearance. The ridge is slightly less well defined than in grade I and it opens rarely with respiration and closes promptly. **C.** Grade III flap valve appearance. The ridge is barely present, and there is often failure to close around the endoscope. It is nearly always accompanied by a hiatal hernia. **D.** Grade IV flap valve appearance. There is no muscular ridge at all. The gastroesophageal valve stays open all the time, and squamous epithelium can often be seen from the retroflexed position. A hiatal hernia is always present. *(Reproduced with permission from Hill LD, Kozarek RA, et al.: The gastroesophageal flap valve. In vitro and in vivo observations.* Gastrointest Endosc. *44:541, 1996. Copyright Elsevier.)*

Figure 25-17. (*Continued*)

When a patient's complaints include dysphagia and no obstructing lesion is seen on the barium swallow, it is useful to have the patient swallow a barium-impregnated marshmallow, a barium-soaked piece of bread, or a hamburger mixed with barium. This test may bring out a functional disturbance in esophageal transport that can be missed when liquid barium is used.

Tests to Detect Functional Abnormalities

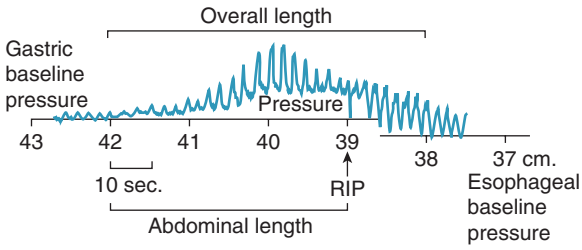
In many patients with symptoms of an esophageal disorder, standard radiographic and endoscopic evaluation fails to demonstrate a structural abnormality. In these situations, esophageal function tests are necessary to identify a functional disorder.

Stationary Manometry. Esophageal manometry is a widely used technique to examine the motor function of the esophagus and its sphincters. Manometry is indicated whenever a motor abnormality of the esophagus is suspected on the basis of complaints of dysphagia, odynophagia, or noncardiac chest pain, and the barium swallow or endoscopy does not show a clear structural abnormality. Esophageal manometry is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders (i.e., achalasia, diffuse esophageal spasm [DES], nutcracker esophagus, and hypertensive LES). It also identifies nonspecific esophageal motility abnormalities and motility disorders secondary to systemic disease such as scleroderma, dermatomyositis, polymyositis, or mixed connective tissue disease. In patients with symptomatic GERD, manometry of the esophageal body can identify a mechanically defective LES, and evaluate the adequacy of esophageal peristalsis and contraction amplitude. Manometry has become an essential tool in the preoperative evaluation of patients before antireflux surgery, guiding selection of the appropriate procedure based upon the patient's underlying esophageal function, and excluding patients with achalasia who can be misdiagnosed with gastroesophageal reflux when clinical and endoscopic parameters alone are used for diagnosis.

Figure 25-18. Radiogram of an intrathoracic stomach. This is the end stage of a large hiatal hernia, regardless of its initial classification.

Esophageal manometry is performed using electronic, pressure-sensitive transducers located within the catheter, or water-perfused catheters with lateral side holes attached to transducers outside the body. The traditional catheter consists of a train of five pressure transducers or five or more water-perfused tubes bound together. The transducers or lateral openings are placed at 5-cm intervals from the tip and oriented radially at 72° from each other around the circumference of the catheter. A special catheter assembly consisting of four lateral openings at the same level, oriented at 90° to each other, is of special use in measuring the three-dimensional vector volume of the LES. Other specially designed catheters can be used to assess the upper sphincter.

As the pressure-sensitive station is brought across the gastroesophageal junction (GEJ), a rise in pressure above the gastric baseline signals the beginning of the LES. The respiratory inversion point is identified when the positive excursions that occur in the abdominal cavity with breathing change to negative deflections in the thorax. The respiratory inversion point serves as a reference point at which the amplitude of LES pressure and the length of the sphincter exposed to abdominal pressure



RIP = Respiratory inversion point

are measured. As the pressure-sensitive station is withdrawn into the body of the esophagus, the upper border of the LES is identified by the drop in pressure to the esophageal baseline. From these measurements, the pressure, abdominal length, and overall length of the sphincter are determined (Fig. 25-19). To account for the asymmetry of the sphincter (Fig. 25-20), the pressure profile is repeated with each of the five radially oriented transducers, and the average values for sphincter pressure above gastric baseline, overall sphincter length, and abdominal length of the sphincter are calculated.

Table 25-1 shows the values for these parameters in 50 normal volunteers without subjective or objective evidence of a foregut disorder. The level at which a deficiency in the mechanics of the LES occurs was defined by comparing the frequency

Table 25-1

distribution of these values in the 50 healthy volunteers with a population of similarly studied patients with symptoms of GERD. The presence of increased esophageal exposure to gastric juice was documented by 24-hour esophageal pH monitoring. Based on these studies, a mechanically defective sphincter is identified by having one or more of the following characteristics: an average LES pressure of <6 mmHg, an average length exposed to the positive-pressure environment in the abdomen of 1 cm or less, and/or an average overall sphincter length of 2 cm or less. Compared with the normal volunteers, these values are below the 2.5 percentile for sphincter pressure and overall length and for abdominal length.

To assess the relaxation and postrelaxation contraction of the LES, a pressure transducer is positioned within the high-pressure zone, with the distal transducer located in the stomach and the proximal transducer within the esophageal body. Ten wet swallows (5 mL water each) are performed. The normal pressure of the LES should drop to the level of gastric pressure during each wet swallow.

The function of the esophageal body is assessed with the five pressure transducers located in the esophagus. The standard procedure is to locate the most proximal pressure transducer 1 cm below the well-defined cricopharyngeal sphincter, allowing a pressure response throughout the whole esophagus to be obtained on one swallow. Ten wet swallows are recorded. Amplitude, duration, and morphology of contractions following each swallow are calculated at all recorded levels of the esophageal body. The delay between the onset and peak of esophageal contractions at the various levels of the esophagus is used to calculate the speed of wave propagation. The relationship of the esophageal contractions following a swallow is classified as peristaltic or simultaneous. The data are used to identify motor disorders of the esophagus.

The position, length, and pressure of the cricopharyngeal sphincter are assessed with a stationary pull-through technique similar to that used for the LES. The manometric catheter is withdrawn in 0.5-cm intervals from the upper esophagus through the upper esophageal sphincter region into the pharynx. The relaxation of the upper esophageal sphincter is studied by straddling the eight pressure transducers across the sphincter so that some are in the pharynx and some are in the upper esophagus. High-speed graphic recordings (50 mm/s) are necessary to obtain an assessment of the coordination of cricopharyngeal relaxation with hypopharyngeal contraction. It has been difficult to consistently demonstrate a motility abnormality in patients with pharyngoesophageal disorders.

High-Resolution Manometry. Esophageal manometry was introduced into clinical practice in the 1970s and, until recently, has changed little. In 1991, Ray Clouse introduced the concept of improving conventional manometry by increasing the number of recording sites and adding a three-dimensional assessment. This "high-resolution manometry" is a variant of the conventional manometry in which multiple, circumferential recording sites are used, in essence creating a "map" of the esophagus and its sphincters. High-resolution catheters contain 36 miniaturized pressure sensors positioned every centimeter along the length of the catheter. The vast amount of data generated by these sensors is then processed and presented in traditional linear plots or as a visually enhanced spatiotemporal video tracing that is readily interpreted (Fig. 25-21).

Simultaneous acquisition of data for the upper esophageal sphincter, esophageal body, LES, and gastric pressure minimizes the movement artifacts and study time associated with conventional esophageal manometry. Powerful, computer-based, and easy-to-use tools give unprecedented data analysis capability. This technology significantly enhances esophageal diagnostics, bringing it into the realm of "image" based studies. High-resolution manometry may allow the identification of focal motor abnormalities previously overlooked. It has enhanced the ability to predict bolus propagation and increased sensitivity in the measurement of pressure gradients.

Esophageal Impedance. New technology recently introduced into the clinical realm allows measurement of esophageal function and gastroesophageal reflux in a way that has heretofore not been possible. An intraluminal electrical impedance catheter has recently been developed for the measurement of GI function. Impedance is the ratio of voltage to current, and is a measure of the electrical conductivity of a hollow organ and its contents. Intraluminal electrical impedance is inversely proportional to the electrical conductivity of the luminal contents and the cross-sectional area of the lumen. Air has a very low electrical conductivity and, therefore, high impedance. Saliva and food cause an impedance decrease because of their increased conductivity. Luminal dilatation results in a decrease in impedance, whereas luminal contraction yields an impedance increase. Investigators have established the impedance waveform characteristics that define esophageal bolus transport. This allows for the characterization of both esophageal function, via quantification of bolus transport, and gastroesophageal reflux (Fig. 25-22). The probe measures impedance between adjacent electrodes, with measuring segments located at 2, 4, 6, 8, 14, and 16 cm from the distal tip. An extremely low electric current of 0.00025 μW is transmitted across the electrodes at a frequency of 1 to 2 kHz and is limited to 8 μA. This is below the stimulation threshold for nerves and muscles, and is three orders of magnitude below the threshold of cardiac stimulation. A standard pH electrode is located 5 cm from the distal tip, so that the acidic or nonacidic nature of refluxate can be correlated with the number of reflux events.

Esophageal impedance has been validated as an appropriate method for the evaluation of GI function and is becoming increasingly used for the diagnosis of gastroesophageal reflux. It has been compared to cineradiography showing that impedance waves correspond well with actual bolus transport illustrated by radiography. Bolus entry, transit, and exit can be clearly identified by impedance changes in the corresponding measuring segments. Preliminary studies comparing standard esophageal manometry with impedance measurements in healthy volunteers have been performed, and have validated the ability of esophageal impedance to correlate with peristaltic wave progression and bolus length. Clinical investigators are beginning to examine and validate impedance measurement in the evaluation of esophageal and small intestinal pathophysiology.

It is increasingly recognized that 24-hour pH monitoring as the historical gold standard for diagnosing and quantifying gastroesophageal reflux has significant limitations. With 24-hour ambulatory pH testing, reflux is defined as a drop in the pH below 4, which effectively "blinds" the test to reflux occurring at higher pH values. Furthermore, in patients with persistent symptoms on proton pump inhibitor (PPI) therapy, pH monitoring has limited use as it can only detect abnormal acid reflux (pH <4), the occurrence of which has been altered by the antisecretory medication. Given that PPI antisecretory therapy is highly effective in neutralizing gastric acid, the question of whether persistent symptoms are a result of persistent acid reflux, nonacid reflux, or are not reflux related becomes a key issue in surgical decision making. Until recently, this differentiation could not be made. A reliable method for detecting both acid and nonacid reflux has potential to define these populations of patients and thus improve patient selection for antireflux surgery. The recent introduction of multichannel intraluminal impedance technology allows the measurement of both acid and nonacid reflux, with potential to significantly enhance diagnostic accuracy.

Using this technology, Balaji and colleagues showed that most gastroesophageal reflux remains despite acid suppression. Impedance pH may be particularly useful in evaluating patients with persistent symptoms despite PPI treatment, patients with respiratory symptoms, and postoperative patients who are having symptoms that are elusive to diagnosis.

Esophageal Transit Scintigraphy. The esophageal transit of a 10-mL water bolus containing technetium-99m (^{99m}Tc) sulfur colloid can be recorded with a gamma camera. Using this technique, delayed bolus transit has been shown in patients with a variety of esophageal motor disorders, including achalasia, scleroderma, DES, and nutcracker esophagus.

Video- and Cineradiography

High-speed cinematic or video recording of radiographic studies allows re-evaluation by reviewing the studies at various speeds. This technique is more useful than manometry in the evaluation of the pharyngeal phase of swallowing. Observations suggesting oropharyngeal or cricopharyngeal dysfunction include misdirection of barium into the trachea or nasopharynx, prominence of the cricopharyngeal muscle, a Zenker's diverticulum, a narrow pharyngoesophageal segment, and stasis of the

contrast medium in the valleculae or hypopharyngeal recesses (Fig. 25-23). These findings are usually not specific, but rather common manifestations of neuromuscular disorders affecting the pharyngoesophageal area. Studies using liquid barium, barium-impregnated solids, or radiopaque pills aid the evaluation of normal and abnormal motility in the esophageal body. Loss of the normal stripping wave or segmentation of the barium column with the patient in the recumbent position correlates with abnormal motility of the esophageal body. In addition, structural abnormalities such as small diverticula, webs, and minimal extrinsic impressions of the esophagus may be recognized only with motion-recording techniques. The simultaneous computerized capture of videofluoroscopic images and manometric tracings is now available, and is referred to as manofluorography. Manofluorographic studies allow precise correlation of the anatomic events, such as opening of the upper esophageal sphincter, with manometric observations, such as sphincter relaxation. Manofluorography, although not widely available, is presently the best means available to evaluate complex functional abnormalities.

Tests to Detect Increased Exposure to Gastric Juice

24-Hour Ambulatory pH Monitoring. The most direct method of measuring increased esophageal exposure to gastric juice is by an indwelling pH electrode, or, more recently, via a radiotelemetric pH monitoring capsule that can be clipped to the esophageal mucosa. The latter consists of an antimony pH electrode fitted inside a small, capsule-shaped device accompanied by a battery and electronics that allow 48-hour monitoring and transmission of the pH data via transcutaneous radio telemetry to a waist-mounted data logger. The device can be introduced either transorally or transnasally, and clipped to the esophageal mucosa using endoscopic fastening techniques. It passes spontaneously within 1 to 2 weeks. Prolonged monitoring of esophageal pH is performed by placing the pH probe or telemetry capsule 5 cm above the manometrically measured upper border of the distal sphincter for 24 hours. It measures the actual time the esophageal mucosa is exposed to gastric juice, measures the

ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure with the patient's symptoms. A 24- to 48-hour period is necessary so that measurements can be made over one or two complete circadian cycles. This allows measuring the effect of physiologic activity, such as eating or sleeping, on the reflux of gastric juice into the esophagus (Fig. 25-24).

The 24-hour esophageal pH monitoring should not be considered a test for reflux, but rather a measurement of the esophageal exposure to gastric juice. The measurement is expressed by the time the esophageal pH was below a given threshold during the 24-hour period. This single assessment, although concise, does not reflect how the exposure has occurred; that is, did it occur in a few long episodes or several short episodes? Consequently, two other assessments are necessary: the frequency of the reflux episodes and their duration.

The units used to express esophageal exposure to gastric juice are: (a) cumulative time the esophageal pH is below a chosen threshold, expressed as the percentage of the total, upright, and supine monitored time; (b) frequency of reflux episodes below a chosen threshold, expressed as number of episodes per 24 hours; and (c) duration of the episodes, expressed as the number of episodes >5 minutes per 24 hours, and the time in minutes of the longest episode recorded. Table 25-2 shows the normal values for these components of the 24-hour record at the whole-number pH threshold derived from 50 normal asymptomatic subjects. The upper limits of normal were established at the ninety-fifth percentile. Most centers use pH 4 as the threshold.

The components' 24-hour pH record are then combined into one expression of the overall esophageal acid exposure below a pH threshold; the pH score is calculated by using the

Table 25-2

Normal values for esophageal exposure to pH <4 (n = 50)

standard deviation (SD) of the mean of each of the six components measured in the 50 normal subjects as a weighting factor. By accepting an abstract zero level two SDs below the mean, the data measured in normal subjects could be treated as though they had a normal distribution. Thus, any measured patient value could be referenced to this zero point, and, in turn, be awarded points based on whether it was below or above the normal mean value for that component, according to this formula:

$$\text{Component score} = \frac{\text{Point value} - \text{mean}}{\text{SD} + 1}$$

The upper limits of normal for the composite score for each whole-number pH threshold are shown in Table 25-3.

The detection of increased esophageal exposure to acid gastric juice is more dependable than the detection of increased exposure to alkaline gastric juice. The latter is suggested by an increased alkaline exposure time above pH 7 or 8. Increased

Table 25-3

Normal composite score for various pH thresholds: upper level of normal value

pH THRESHOLD	95TH PERCENTILE
<1	14.2
<2	17.37
<3	14.10
<4	14.72
<5	15.76
<6	12.76

exposure in this pH range can be caused by abnormal calibration of the pH recorder; dental infection, which increases salivary pH; esophageal obstruction, which results in static pools of saliva with an increase in pH secondary to bacterial overgrowth; or regurgitation of alkaline gastric juice into the esophagus. Using a properly calibrated probe, in the absence of dental infections or esophageal obstruction, the percentage of time the pH is measured above 7 correlates with the concentration of bile acids continuously aspirated over a 24-hour period.

When done in a test population with an equal distribution of normal healthy subjects and patients with the classic reflux symptoms and a defective sphincter, 24-hour esophageal pH monitoring had a sensitivity and specificity of 96%. (Sensitivity is the ability to detect a disease when known to be present; specificity is the ability to exclude the disease when known to be absent.) This gave a predictive value of a positive and negative test of 96%, and an overall accuracy of 96%. Based on these studies and extensive clinical experience, 24-hour esophageal pH monitoring has emerged as the gold standard for the diagnosis of GERD.

Catheter-based, 24-hour, ambulatory, esophageal pH monitoring does have a significant drawback of the physical presence of a transnasal catheter that must be worn for 24 hours. Although most doctors ask patients to go about their normal activities of daily living, many do not comply due to embarrassment about the catheter or from discomfort. The recent development of a wireless capsule, which can be implanted in the esophagus and record pH data for 48 hours, has significantly changed patient satisfaction with the procedure.

The Bravo pH Capsule (Medtronics, Minneapolis, MN) measures pH levels in the esophagus and transmits continuous esophageal pH readings to a receiver worn on the patient's belt or waistband (Fig. 25-27). Symptoms that the patient experience are recorded in a diary and/or by pressing buttons on the receiver unit. Generally, 48 hours of pH data are measured with this probe. A recent study has shown that the addition of a second day of pH monitoring increased the sensitivity of pH measurement by 22%. The capsule eventually detaches and passes through the digestive tract in 5 to 7 days.

Radiographic Detection of Gastroesophageal Reflux. The definition of radiographic gastroesophageal reflux varies depending on whether reflux is spontaneous or induced by various maneuvers. In only about 40% of patients with classic symptoms of GERD is spontaneous reflux (i.e., reflux of barium from the stomach into the esophagus with the patient in the upright position) observed by the radiologist. In most patients who show spontaneous reflux on radiography, the diagnosis of increased esophageal acid exposure is confirmed by 24-hour esophageal pH monitoring. Therefore, the radiographic demonstration of spontaneous regurgitation of barium into the esophagus in the upright position is a reliable indicator that reflux is present. However, failure to see this does not indicate the absence of disease, and for this reason this test is rarely relied on for clinical diagnosis.

2▶

Tests of Duodenogastric Function

Esophageal disorders are frequently associated with abnormalities of duodenogastric function. Abnormalities of the gastric reservoir or increased gastric acid secretion can be responsible for increased esophageal exposure to gastric juice. Reflux of alkaline duodenal juice, including bile salts, pancreatic enzymes, and bicarbonate, is thought to have a role in the pathogenesis of esophagitis and complicated Barrett's esophagus. Furthermore, functional disorders of the esophagus are often not confined to the esophagus alone, but are associated with functional disorders of the rest of the foregut (i.e., stomach and duodenum). Tests of duodenogastric function that are helpful to investigate esophageal symptoms include gastric emptying studies, gastric acid analysis, and cholescintigraphy (for the diagnosis of pathologic duodenogastric reflux). The single test of 24-hour gastric pH monitoring can be used to identify gastric hypersecretion and imply the presence of duodenogastric reflux and delayed gastric emptying.

Gastric Emptying. Gastric emptying studies are performed with radionuclide-labeled meals. Emptying of solids and liquids can be assessed simultaneously when both phases are marked with different tracers. After ingestion of a labeled standard meal, gamma camera images of the stomach are obtained at 5- to 15-minute intervals for 1.5 to 2 hours. After correction for decay, the counts in the gastric area are plotted as the percentage of total counts at the start of the imaging. The resulting emptying curve can be compared with data obtained in normal volunteers. In general, normal subjects will empty 59% of a meal within 90 minutes. Although delayed gastric emptying is often associated with gastroesophageal reflux, in general delayed emptying does not correlate with a poorer clinical outcome after antireflux surgery, and it should not be considered a contraindication to surgical treatment.

24-Hour Gastric pH Monitoring. Monitoring is performed over a complete circadian cycle with a pH electrode placed 5 cm below the manometrically located LES. The patient is fully ambulatory during the test and is encouraged to perform normal daily activity. The gastric pH profile is assessed separately for the meal, postprandial period, and fasting period. The latter is divided into the time spent upright and supine.

The interpretation of continuous gastric pH recordings is more difficult than that of esophageal pH recordings. This is because the gastric pH environment is determined by a complex interplay of acid secretion; mucus secretion; ingested food; swallowed saliva; regurgitated duodenal, pancreatic, and biliary secretions; and the effectiveness of the mixing and evacuation of the chyme. Using 24-hour gastric pH monitoring to evaluate the gastric secretory state is based on studies that have shown that a good correlation exists between increased basal acid output on standard gastric acid analysis, and a left shift on the frequency distribution graph of gastric pH recordings during the supine fasting period. The evaluation of gastric emptying by 24-hour gastric pH monitoring is based on studies demonstrating a good correlation between the emptying of a solid meal and the duration of the postprandial plateau and decline phase of the gastric pH record.

Using 24-hour gastric pH monitoring to evaluate duodenogastric reflux is based on the observation that reflux of alkaline duodenal juice into the stomach can alkalinize the gastric pH environment. The measurement is not straightforward because of the effect of meals, and reduction in acid secretion can result in changes in gastric pH that mimic alkaline reflux episodes. To overcome this problem, computerized measurements of the number and height of alkalinizing peaks, the baseline pH, the postprandial pH plateau, and the pattern of pH decline from the plateau can be used to identify the probability of duodenogastric reflux. The results are presented as an overall score that indicates the likelihood of pathologic duodenogastric reflux.

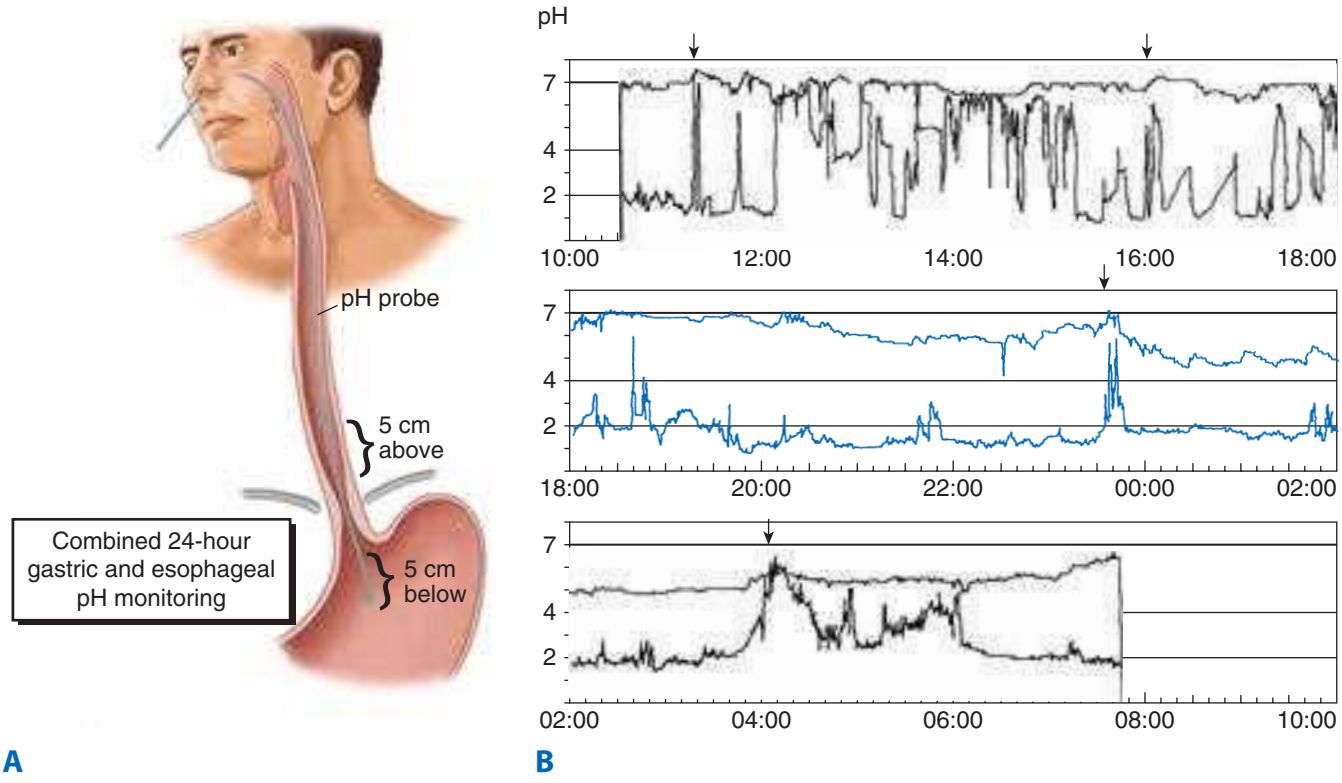

Figure 25-25. **A.** Combined esophageal and gastric pH monitoring showing position of probes in relation to the lower esophageal sphincter. **B.** Combined ambulatory esophageal (upper tracing) and gastric (lower tracing) pH monitoring showing duodenogastric reflux (arrows) with propagation of the alkaline juice into the esophagus of a patient with complicated Barrett's esophagus. The gastric tracing (lower) is taken from a probe lying 5 cm below the upper esophageal sphincter. The esophageal tracing (upper) is taken from a probe lying 5 cm above the lower esophageal sphincter. Note that in only a small proportion of time does duodenogastric reflux move the pH of the esophagus above the threshold of 7, causing the iceberg effect. (Reproduced with permission from DeMeester TR, Stein HJ, Fuchs KH: Physiologic diagnostic studies, in Zuidema GD, Orringer MB (eds): Shackelford's Surgery of the Alimentary Tract, 3rd ed., Vol. I. Philadelphia: W.B. Saunders, 1991, p 123. Copyright Elsevier.)

Initial data indicate that this approach has a higher sensitivity and specificity for the diagnosis of pathologic duodenogastric reflux than scintigraphic methods do.

Combined 24-hour esophageal and gastric pH monitoring can identify excessive alkaline duodenogastric and alkaline gastroesophageal reflux in symptomatic patients. The combined tracings can often identify simultaneous gastric and esophageal alkalinization, suggesting a duodenal origin for the esophageal alkaline exposure (Fig. 25-25).

GASTROESOPHAGEAL REFLUX DISEASE

GERD was not recognized as a significant clinical problem until the mid-1930s and was not identified as a precipitating cause for esophagitis until after World War II. In the early twenty-first century, it has grown to be a very common problem and now accounts for a majority of esophageal pathology. It is recognized as a chronic disease, and when medical therapy is required, it is often lifelong treatment. Recent efforts at the development of various endoscopic antireflux interventions, although innovative, have not been successful in consistently controlling gastroesophageal reflux. Antireflux surgery is an effective and long-term therapy and is the only treatment that is able to restore the gastroesophageal barrier. Despite the common prevalence of GERD, it can be one of the most challenging diagnostic and therapeutic problems in clinical medicine. A contributing factor to this is the lack of a universally accepted definition of the disease.

The most simplistic approach is to define the disease by its symptoms. However, symptoms thought to be indicative of GERD, such as heartburn or acid regurgitation, are very common in the general population and many individuals consider them to be normal and do not seek medical attention. Even when excessive, these symptoms are not specific for gastroesophageal reflux. They can be caused by other diseases such as achalasia, DES, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease.

A thorough, structured evaluation of the patient's symptoms is essential before any therapy, particularly any form of esophageal surgery. The presence and severity of both typical symptoms of heartburn, regurgitation, and dysphagia, and atypical symptoms of cough, hoarseness, chest pain, asthma, and aspiration should be discussed with the patient in detail. Many of these atypical symptoms may not be esophageal related and hence will not improve and may even worsen with antireflux surgery.

Heartburn is generally defined as a *substernal burning-type discomfort*, beginning in the epigastrium and radiating upward. It is often aggravated by meals, spicy or fatty foods, chocolate, alcohol, and coffee and can be worse in the supine position. It is commonly, although not universally, relieved by antacid or antisecretory medications. Epidemiologic studies

Table 25-4

American Gastroenterologic Association Gallup poll on nighttime gastroesophageal reflux disease symptoms

- 50 million Americans have nighttime heartburn at least 1/wk
- 80% of heartburn sufferers had nocturnal symptoms—65% both day & night
- 63% report that it affects their ability to sleep and impacts their work the next day
- 72% are on prescription medications
- Nearly half (45%) report that current remedies do not relieve all symptoms

have shown that heartburn occurs monthly in as many as 40% to 50% of the Western population. The occurrence of heartburn at night and its effect on quality of life have recently been highlighted by a Gallup poll conducted by the American Gastroenterologic Society (Table 25-4).

Regurgitation, the effortless return of acid or bitter gastric contents into the chest, pharynx, or mouth, is highly suggestive of foregut pathology. It is often particularly severe at night when supine or when bending over and can be secondary to either an incompetent or obstructed GEJ. With the later, as in achalasia, the regurgitant is often bland, as if food was put into a blender. When questioned, most patients can distinguish the two. It is the regurgitation of gastric contents that may result in associated pulmonary symptoms, including cough, hoarseness, asthma, and recurrent pneumonia. Bronchospasm can be precipitated by esophageal acidification and cough by either acid stimulation or distention of the esophagus.

Dysphagia, or difficulty swallowing, is a relatively nonspecific term but arguably the most specific symptom of foregut disease. It can be a sign of underlying malignancy and should be aggressively investigated until a diagnosis is established. Dysphagia refers to the sensation of difficulty in the passage of food from the mouth to the stomach and can be divided into oropharyngeal and esophageal etiologies. Oropharyngeal dysphagia is characterized by difficulty transferring food out of the mouth into the esophagus, nasal regurgitation, and/or aspiration. Esophageal dysphagia refers to the sensation of food sticking in the lower chest or epigastrium. This may or may not be accompanied by pain (odynophagia) that will be relieved by the passage of the bolus.

Chest pain, although commonly and appropriately attributed to cardiac disease, is frequently secondary to esophageal pathology as well. As early as 1982, DeMeester and associates showed that nearly 50% of patients with severe chest pain, normal cardiac function, and normal coronary arteriograms had positive 24-hour pH studies, implicating gastroesophageal reflux as the underlying etiology. Exercise-induced gastroesophageal reflux is well known to occur, and may result in exertional chest pain similar to angina. It can be quite difficult, if not impossible, to distinguish between the two etiologies, particularly on clinical grounds alone. Nevens and colleagues evaluated the ability of experienced cardiologists to differentiate pain of cardiac vs. esophageal origin. Of 248 patients initially seen by cardiologists, 185 were thought to have typical angina and 63 atypical chest pain. Forty eight (26%) of those thought to have classic angina had normal coronary angiograms and 16 of the 63 with atypical pain had abnormal angiogram. Thus, the cardiologists' clinical impression was wrong 25% of the time. Finally, Pope and associates investigated the ultimate diagnosis in 10,689 patients presenting to an emergency room with acute chest pain. Approximately 17% were found to have acute ischemia, 6% stable angina, 21% other cardiac causes, and 55% had noncardiac causes. They concluded that the majority of people presenting to the emergency room with chest pain do not have an underlying cardiac etiology for their symptoms. Chest pain precipitated by meals, occurring at night while supine, nonradiating, responsive to antacid medication, or accompanied by other symptoms suggesting esophageal disease such as dysphagia or regurgitation should trigger the thought of possible esophageal origin. Further, the distinction between heartburn and chest pain is also difficult and largely dependent upon the individual patient. One person's heartburn is another's chest pain.

The precise mechanisms accounting for the generation of symptoms secondary to esophageal pathology remain unclear. Considerable insight has been acquired, however. Investigations into the effect of luminal content, esophageal distention and muscular function, neural pathways, and brain localization have provided a basic understanding of the stimuli responsible for symptom generation. It is also clear that the visceroneural pathways of the foregut are complexly intertwined with that of the tracheobronchial tree and heart. This fact accounts for the common overlap of clinical presentations with diverse disease processes in upper GI, cardiac, and pulmonary systems.

The Human Antireflux Mechanism and the Pathophysiology of Gastroesophageal Reflux Disease

There is a high-pressure zone located at the esophagogastric junction in humans. Although this is typically referred to as the lower esophageal "sphincter," there are no distinct anatomical landmarks which define its beginning and end. Architecturally speaking, there is a specialized thickening in this region that is made up of the collar sling musculature and the clasp fibers. The collar sling is located on the greater curvature side of the junction, and the clasp fibers are located on the lesser curvature side. These muscles remain in tonic opposition until the act of swallowing, whereupon receptive relaxation occurs allowing passage of a food bolus into the stomach. In addition, the LES will also open when the gastric fundus is distended with gas and liquid, thus resulting in an unfolding of the valve and enabling venting of gas (a belch). Whether physiologic or pathologic, the common denominator for most episodes of gastroesophageal reflux is the loss of the high-pressure zone and thus, a decrease in the resistance it imparts to the retrograde flow of gastric juice into the esophageal body. The primary cause of GERD is secondary to the permanent attenuation of the collar sling musculature, with a resultant opening of the gastric cardia and loss of the high-pressure zone as measured with esophageal manometry.

The Lower Esophageal Sphincter. As defined by esophageal manometry, there are three characteristics of the LES that work in unison to maintain its barrier function. These characteristics include the resting LES pressure, its overall length, and the intra-abdominal length that is exposed to the positive pressure environment of the abdomen (Table 25-5). The resistance to gastroesophageal reflux is a function of both the resting LES pressure and length over which this pressure is exerted. Thus, as the sphincter becomes shorter, a higher pressure will be required in order to prevent a given amount of reflux (Fig. 25-26).

Table 25-5

Normal manometric values of the distal esophageal sphincter, n = 50

PARAMETER	MEDIAN VALUE	2.5TH PERCENTILE	97.5TH PERCENTILE
Pressure (mmHg)	13	5.8	27.7
Overall length (cm)	3.6	2.1	5.6
Abdominal length (cm)	2	0.9	4.7

Much like the neck of a balloon as it is inflated, as the stomach fills and distends, sphincter length decreases. Therefore, if the overall length of the sphincter is permanently short from repeated distention of the fundus secondary to large volume meals, then with minimal episodes of gastric distention and pressure, there will be insufficient sphincter length for the barrier to remain competent, and reflux will occur.

A third characteristic of the LES that impacts its ability to prevent reflux is its position about the diaphragm. It is important that a portion of the total length of the LES be exposed to the effects of an intra-abdominal pressure. That is, during periods of elevated intra-abdominal pressure, the resistance of the barrier would be overcome if pressure were not applied equally to both the LES and stomach simultaneously. Thus, in the presence of a hiatal hernia, the sphincter resides entirely within the chest cavity and cannot respond to an increase in intra-abdominal pressure because the pinch valve mechanism is lost and gastroesophageal reflux is more liable to occur.

Therefore, a permanently defective sphincter is defined by one or more of the following characteristics: An LES with a mean resting pressure of less than 6 mmHg, an overall sphincter length of <2 cm, and intra-abdominal sphincter length of <1 cm. Compared to normal subjects without GERD these values are below the 2.5 percentile for each parameter. The most common cause of a defective sphincter is an inadequate abdominal length.

Once the sphincter is permanently defective, this condition is irreversible, and although esophageal mucosal injury may be healed with antisecretory medication, reflux will continue to occur. Additionally, the presence of a defective LES may be associated with reduced esophageal body function and thus decrease clearance times of refluxed material. In addition, with the progressive loss of effective esophageal clearance the patient may be predisposed to severe mucosal injury, volume regurgitation, aspiration, and pulmonary failure. Reflux may occur in the face of a normal LES resting pressure. This condition is usually due to a functional problem of gastric emptying or excessive air swallowing. These conditions may lead to gastric distention, increased intra-gastric pressure, a resultant shortening or unfolding of the LES, and subsequent reflux. The mechanism by which gastric distention contributes to LES unfolding provides a mechanical explanation for "transient LES relaxation." It is thought that with repeated gastric distention secondary to large meal volume or chronic air swallowing, there is repeated unfolding of the LES and subsequent attenuation of the collar sling musculature. It is at this point that the physiologic and normal mechanism of gastric venting is replaced with pathologic and severe postprandial reflux disease. In addition, patients with GERD will increase the frequency of swallowing in an effort to neutralize the refluxed acid with their saliva (pH 7.0). This phenomenon leads to increased air swallowing and further gastric distention thus, compounding the problem. Therefore GERD may have its origins in the stomach secondary to gastric distention due to overeating, and this may be further compounded by the ingestion of fatty meals, which result in delayed gastric emptying.

Relationship Between Hiatal Hernia and Gastroesophageal Reflux Disease. As the collar sling musculature and clasp fibers become attenuated with repeated gastric distention, the esophagogastric junction begins to assume an "upside down funnel" appearance, with progressive opening of the acute angle of His. This in turn may result in attenuation and stretching of the phrenoesophageal ligament, with subsequent enlargement of the hiatal opening and axial herniation. There is a high degree of correlation between reflux threshold and the degree of hiatal herniation (Fig. 25-27).

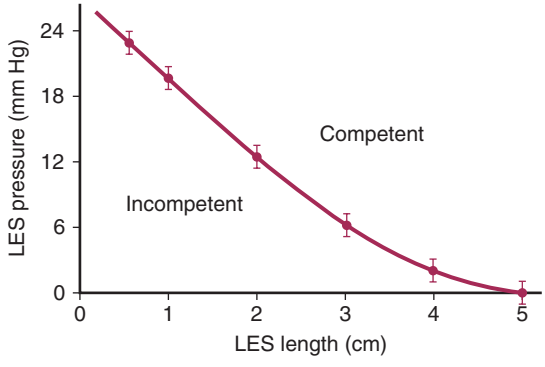

Figure 25-26. As the esophageal sphincter becomes shorter, increased pressure is necessary to maintain competence. LES = lower esophageal sphincter.

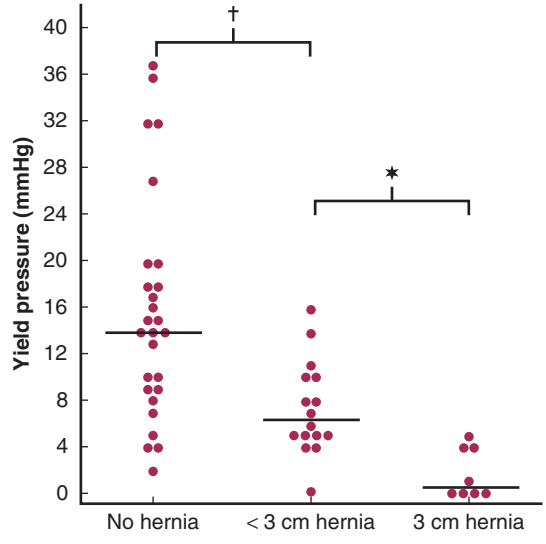

Figure 25-27. Yield pressure of the lower esophageal sphincter decreases as hiatal hernia size increases.

It is believed that the source of postprandial esophageal acid exposure results from a "pocket of acid" at the esophageal gastric junction that is unaffected by the buffering action of the meal. This same process is thought to occur in patients with endoscopy-negative dyspepsia and normal conventional esophageal pH monitoring at a location of 5 cm proximal to the upper boarder of the LES.

Summary. It is believed that GERD has its origins within the stomach. Distention of the fundus occurs because of overeating and delayed gastric emptying secondary to a high-fat diet. The resultant distention causes "unrolling" of the sphincter by the expanding fundus, and this subsequently exposes the squamous epithelium in the region of the distal LES to gastric juice. Repeated exposure results in inflammation and the development of columnar epithelium at the cardia. This is the initial step of the development of carditis and explains why in early disease esophagitis is mild and commonly limited to the very distal aspect of the esophagus. The patient attempts to compensate for this by increased swallowing, allowing the saliva to neutralize the refluxed gastric juice and thus, alleviate the discomfort induced by the reflux event. The increased swallowing results in aerophagia, bloating, and belching. This in turn creates a viscous cycle of increased gastric distention and thus further exposure and repetitive injury to the distal esophagus. The development of carditis explains the complaint of epigastric pain often experienced by patients with early reflux disease. Additionally this process can lead to a fibrotic mucosal ring located at the squamocolumnar junction, which is termed a "Schatzki ring," and may result in dysphagia. This inflammatory process may extend into muscularis propria and thus result in a progressive loss in the length and pressure of the LES. This explanation for the pathophysiology of GERD is supported by the observation that severe esophagitis is almost always associated with a defective LES.

Complications Associated with Gastroesophageal Reflux Disease

The complications of gastroesophageal reflux disease may result from the direct injurious effects of gastric fluid on the mucosa, larynx, or respiratory epithelium. Complications due to repetitive reflux are esophagitis, stricture, and BE; repetitive aspiration may lead to progressive pulmonary fibrosis. The severity of the complications is directly related to the prevalence of a structurally defective sphincter (Table 25-6). The observation that a structurally defective sphincter occurs in 42% of patients without complications (most of whom have one or two components failed) suggests that disease may be confined to the sphincter due to compensation by a vigorously contracting esophageal body. Eventually, all three components of the sphincter fail, allowing unrestricted reflux of gastric juice into the esophagus and overwhelming its normal clearance mechanisms. This leads to esophageal mucosal injury with progressive deterioration of esophageal contractility, as is commonly seen in patients with strictures and BE. The loss of esophageal clearance increases the potential for regurgitation into the pharynx with aspiration.

The potential injurious components that reflux into the esophagus include gastric secretions such as acid and pepsin, as well as biliary and pancreatic secretions that regurgitate from the duodenum into the stomach. There is a considerable body of experimental evidence to indicate that maximal epithelial injury occurs during exposure to bile salts combined with acid and pepsin. These studies have shown that acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, although the combination of duodenal juice and gastric acid is particularly noxious.

Table 25-6

Complications of gastroesophageal reflux disease: 150 consecutive cases with proven gastroesophageal reflux disease (24-hour esophageal pH monitoring endoscopy, and motility)

COMPLICATION	NO.	STRUCTURALLY NORMAL SPHINCTER (%)	STRUCTURALLY DEFECTIVE SPHINCTER (%)
None	59	58	42
Erosive esophagitis	47	23	77[a]
Stricture	19	11	89
Barrett's esophagus	25	0	100
Total	150		

[a]Grade more severe with defective cardia.

Experimental animal studies have shown that the reflux of duodenal contents into the esophagus enhances inflammation, increases the prevalence of Barrett's esophagus, and results in the development of esophageal adenocarcinoma. The component of duodenal juice thought to be most damaging is bile acids. For bile acids to injure mucosal cells, it is necessary that they be both soluble and un-ionized, so that the un-ionized, nonpolar form may enter mucosal cells. Before the entry of bile into the GI tract, 98% of bile acids are conjugated with either taurine or glycine in a ratio of about 3:1. Conjugation increases the solubility and ionization of bile acids by lowering their pK_a. At the normal duodenal pH of approximately 7, over 90% of bile salts are in solution and completely ionized. At pH ranges from 2 to 7, there is a mixture of the ionized salt and the lipophilic, nonionized acid. Acidification of bile to below pH 2 results in an irreversible bile acid precipitation. Consequently, under normal physiologic conditions, bile acids precipitate and are of minimal consequence when an acid gastric environment exists. On the other hand, in a more alkaline gastric environment, such as occurs with excessive duodenogastric reflux and after acid suppression therapy or vagotomy and partial or total gastrectomy, bile salts remain in solution, are partially dissociated, and when refluxed into the esophagus can cause severe mucosal injury by crossing the cell membrane and damaging the mitochondria.

Complications of gastroesophageal reflux such as esophagitis, stricture, and Barrett's metaplasia occur in the presence of two predisposing factors: a mechanically defective LES and an increased esophageal exposure to fluid containing duodenal content which includes bile and pancreatic juice. The duodenal origin of esophageal contents in patients with an increased exposure to a pH >7 has previously been confirmed by esophageal

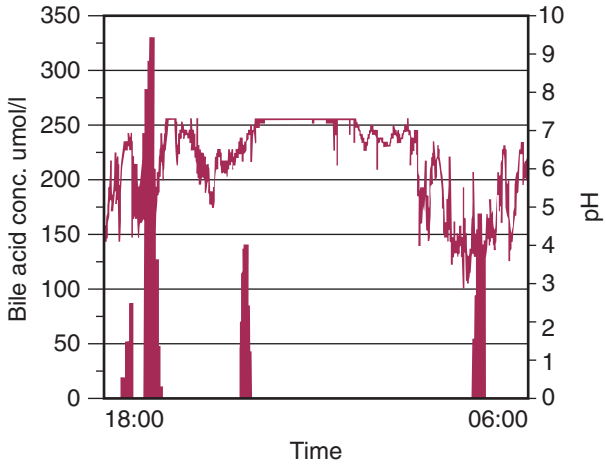

Figure 25-28. Sample bile acid concentration and esophageal pH plotted against time to obtain detailed profiles; in this case showing both significant bile acid (vertical bars) and acid (linear plot) reflux. (Reproduced with permission from Nehra D, Watt P, Pye JK, et al.: Automated oesophageal reflux sampler: A new device used to monitor bile acid reflux in patients with gastroesophageal reflux disease. J Med Engr Tech 21:1, 1997.)

aspiration studies (Fig. 25-28). Studies have clarified and expanded these observations by measuring esophageal bilirubin exposure over a 24-hour period as a marker for the presence of duodenal juice. Direct measurement of esophageal bilirubin exposure as a marker for duodenal juice has shown that 58% of patients with GERD have increased esophageal exposure to duodenal juice, and that this exposure occurs most commonly when the esophageal pH is between 4 and 7 (Fig. 25-29). These earlier studies have been confirmed by other studies which measure volume reflux using impedance technology.

The fact that the combination of refluxed gastric and duodenal juice is more noxious to the esophageal mucosa than gastric juice alone may explain the repeated observation that 25% of patients with reflux esophagitis develop recurrent and/or progressive mucosal damage, often despite medical therapy (Fig. 25-30). A potential reason is that acid suppression therapy is unable to consistently maintain the pH of refluxed gastric and duodenal juice above the range of 6. Lapses into pH ranges from 2 to 6 encourage the formation of undissociated, nonpolarized, soluble bile acids, which are capable of penetrating the cell wall and injuring mucosal cells. To ensure that bile acids remain completely ionized in their polarized form, and thus unable to penetrate the cell, requires that the pH of the refluxed material be maintained above 7, 24 hours a day, 7 days a week, for the patient's lifetime. In practice, this would not only be impractical but likely impossible, unless very high doses of medications were used. The use of lesser doses would allow esophageal mucosal damage to occur while the patient was relatively asymptomatic. Antireflux operative procedures re-establish the barrier between stomach and esophagus, protecting the esophagus from damage in patients with mixed gastroesophageal reflux.

If reflux of gastric juice is allowed to persist and sustained or repetitive esophageal injury occurs, two sequelae can result. First, a luminal stricture can develop from submucosal and

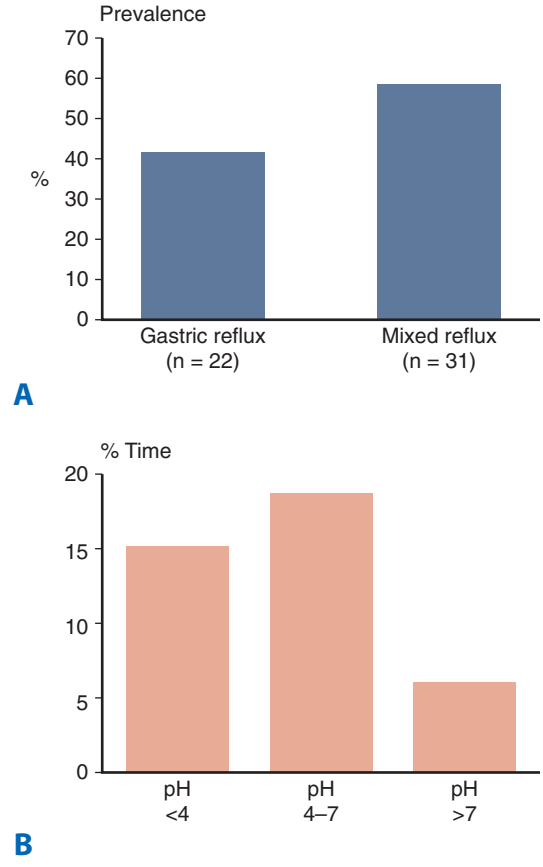

Figure 25-29. **A.** Prevalence of reflux types in 53 patients with gastroesophageal reflux disease. **B.** Esophageal luminal pH during bilirubin exposure. *(Reproduced with permission from Kauer WK, Peters JH, DeMeester TR, et al.: Mixed reflux of gastric juice is more harmful to the esophagus than gastric juice alone: The need for surgical therapy reemphasized.* Ann Surg. *222:525, 1995.)*

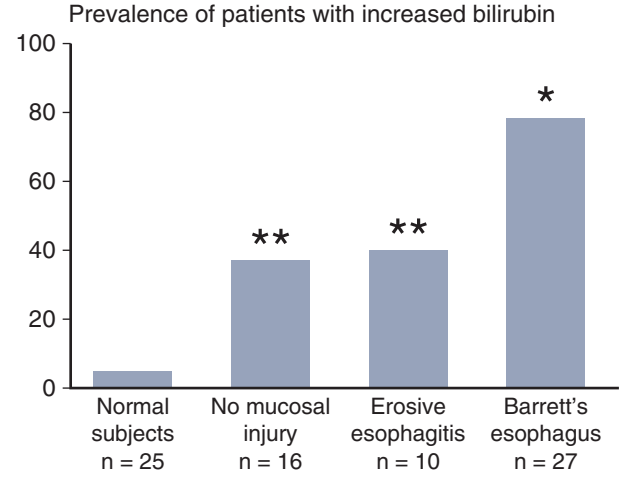

Figure 25-30. Prevalence of abnormal esophageal bilirubin exposure in healthy subjects and in patients with gastroesophageal reflux disease with varied degrees of mucosal injury. (*P<.03 vs all other groups, **P <.03 vs. healthy subjects.) *(Reproduced with permission from Kauer WK, Peters JH, DeMeester TR, et al.: Mixed reflux of gastric juice is more harmful to the esophagus than gastric juice alone: The need for surgical therapy reemphasized.* Ann Surg. *222:525, 1995.)*

eventually intramural fibrosis. Second, the tubular esophagus may become replaced with columnar epithelium. The columnar epithelium is resistant to acid and is associated with the alleviation of the complaint of heartburn. This columnar epithelium often becomes intestinalized, identified histologically by the presence of goblet cells. This specialized IM is currently required for the diagnosis of BE. Endoscopically, BE can be quiescent or associated with complications of esophagitis, stricture, Barrett's ulceration, and dysplasia. The complications associated with BE may be due to the continuous irritation from refluxed duodenogastric juice. This continued injury is pH dependent and may be modified by medical therapy. The incidence of metaplastic Barrett's epithelium becoming dysplastic and progressing to adenocarcinoma is approximately 0.2% to 0.5% per year.

An esophageal stricture can be associated with severe esophagitis or BE. In the latter situation, it occurs at the site of maximal inflammatory injury (i.e., the columnar-squamous epithelial interface). As the columnar epithelium advances into the area of inflammation, the inflammation extends higher into the proximal esophagus, and the site of the stricture moves progressively up the esophagus. Patients who have a stricture in the absence of Barrett's esophagus should have the presence of gastroesophageal reflux documented before the presence of the stricture is ascribed to reflux esophagitis. In patients with normal acid exposure, the stricture may be due to cancer or a drug-induced chemical injury, the latter resulting from the lodgment of a capsule or tablet in the distal esophagus. In such patients, dilation usually corrects the problem of dysphagia. Heartburn, which may have occurred only because of the chemical injury, need not be treated. It is also possible for drug-induced injuries to occur in patients who have underlying esophagitis and a distal esophageal stricture secondary to gastroesophageal reflux. In this situation, a long, string-like stricture progressively develops as a result of repetitive caustic injury from capsule or tablet lodgment on top of an initial reflux stricture. These strictures are often resistant to dilation. The incidence of this problem has lessened since the introduction of proton pump inhibitor medication.

Metaplastic (Barrett's Esophagus) and Neoplastic (Adenocarcinoma) Complications

The condition whereby the tubular esophagus is lined with columnar epithelium rather than squamous epithelium was first described by Norman Barrett in 1950. He incorrectly believed it to be congenital in origin. It is now realized that it is an acquired abnormality, occurs in 10% to 15% of patients with GERD, and represents the end stage of the natural history of this disease. It is also distinctly different from the congenital condition in which islands of gastric fundic epithelium are found in the upper half of the esophagus.

The definition of BE has evolved considerably over the past decade. Traditionally, BE was identified by the presence of columnar mucosa extending at least 3 cm into the esophagus. It is now recognized that the specialized, intestinal-type epithelium found in the Barrett's mucosa is the only tissue predisposed to malignant degeneration. Consequently, the diagnosis of BE is presently made given any length of endoscopically identifiable columnar mucosa that proves, on biopsy, to show IM. Although long segments of columnar mucosa without IM do occur, they are uncommon and might be congenital in origin.

The hallmark of IM is the presence of intestinal goblet cells. There is a high prevalence of biopsy-demonstrated IM at the cardia, on the gastric side of the squamocolumnar junction, in the absence of endoscopic evidence of a CLE. Evidence is accumulating that these patches of what appears to be Barrett's in the cardia have a similar malignant potential as in the longer segments, and are precursors for carcinoma of the cardia.

The long-term relief of symptoms remains the primary reason for performing antireflux surgery in patients with BE. Healing of esophageal mucosal injury and the prevention of disease progression are important secondary goals. In this regard, patients with BE are no different than the broader population of patients with gastroesophageal reflux. They should be considered for antireflux surgery when patient data suggest severe disease or predict the need for long-term medical management. Most patients with BE are symptomatic. Although it has been argued that some patients with BE may not have symptoms, careful history taking will reveal the presence of symptoms in most, if not all, patients.

Patients with BE have a spectrum of disease ranging from visually identifiable but short segments, to long segments of classic BE. In general, however, they represent a relatively severe stage of gastroesophageal reflux, usually with markedly increased esophageal acid exposure, deficient LES characteristics, poor esophageal body function, and a high prevalence of duodenogastroesophageal reflux. Gastric hypersecretion occurs in 44% of patients. Most will require long-term PPI therapy for relief of symptoms and control of coexistent esophageal mucosal injury. Given such profound deficits in esophageal physiology, antireflux surgery is an excellent means of long-term control of reflux symptoms for most patients with BE.

The typical complications in BE include ulceration in the columnar-lined segment, stricture formation, and a dysplasia-cancer sequence. Barrett's ulceration is unlike the erosive ulceration of reflux esophagitis in that it more closely resembles peptic ulceration in the stomach or duodenum, and has the same propensity to bleed, penetrate, or perforate. Fortunately this complication occurs very rarely. The strictures found in BE occur at the squamocolumnar junction, and are typically higher than peptic strictures in the absence of BE. Ulceration and stricture in association with BE were commonly reported before 1975, but, with the advent of potent acid suppression medication, they have become less common. In contrast, the complication of adenocarcinoma developing in Barrett's mucosa has become more common. Adenocarcinoma developing in Barrett's mucosa was considered a rare tumor before 1975. Today, it occurs at approximately 0.2% to 0.5% per year of follow-up, which represents a risk 40 times that of the general population. Most, if not all, cases of adenocarcinoma of the esophagus arise in Barrett's epithelium (Fig. 25-31). About one-third of all patients with BE present with malignancy.

The long-term risk of progression to dysplasia and adenocarcinoma, although not the driving force behind the decision to perform antireflux surgery, is a significant concern for both patient and physician. Although to date, there have been no prospective randomized studies documenting that antireflux surgery has an effect on the risk of progression to dysplasia and carcinoma, complete control of reflux of gastric juice into the esophagus is clearly a desirable goal.

Respiratory Complications

A significant proportion of patients with GERD will have associated respiratory symptoms. These patients may have laryngopharyngeal reflux-type symptoms, adult-onset asthma,

Philadelphia: W.B. Saunders, 1991, p 113. Copyright Elsevier.)

or even idiopathic pulmonary fibrosis. These symptoms and organ injury may occur in isolation or in conjunction with typical reflux symptoms such as heartburn and regurgitation. Several studies have demonstrated that up to 50% of patients with asthma have either endoscopically evident esophagitis or abnormal distal esophageal acid exposure. These findings support a causal relationship between GERD and aerodigestive symptoms and complications in a proportion of patients.

Etiology of Reflux-Induced Respiratory Symptoms. There are two mechanisms that have been proposed as the cause of reflux-induced respiratory symptoms. The reflux theory suggests that these symptoms are the direct result of laryngopharyngeal exposure and aspiration of gastric contents. The reflex theory suggests that the vagal-mediated afferent fibers result in bronchoconstriction during episodes of distal esophageal acidification. The evidence supporting a mechanism of direct exposure to the aerodigestive system is based in clinical studies that have documented a strong correlation between idiopathic pulmonary fibrosis and hiatal hernia. In addition, the presence of GERD was demonstrated to be highly associated with several pulmonary diseases in a recent Department of Veteran Affairs multivariate analysis. Next, with ambulatory pH testing, acid exposure within the proximal esophagus is more frequently identified in patients with gastroesophageal reflux and respiratory symptoms than in patients who have gastroesophageal reflux symptoms alone. These findings are supported by scintigraphic studies, which have demonstrated aspiration of ingested radioisotope in patients with both gastroesophageal reflux and pulmonary symptoms. In animal studies, tracheal instillation of acid has been demonstrated to profoundly increase airway resistance. Finally, in patients who have undergone multichannel intraluminal impedance testing with a catheter configured to detect laryngopharyngeal reflux, a correlation between proximal fluid movement and laryngopharyngeal symptoms, such as cough, can be demonstrated.

The reflex mechanism is supported by the bronchoconstriction that occurs with the infusion of acid into the distal esophagus. There is a shared embryologic origin of the tracheoesophageal tract and vagus nerve, and this reflex is thought to be an afferent fiber–mediated reflex that protects the aerodigestive system from the aspiration of refluxate. In patients with respiratory symptoms and documented gastroesophageal reflux without proximal esophageal acid exposure, pulmonary symptoms will often times significantly improve or completely resolve

after undergoing laparoscopic fundoplication. It is likely that both of the proposed mechanisms work simultaneously to cause these symptoms in the face of GERD.

The most difficult clinical challenge in formulating a treatment plan for reflux-associated respiratory symptoms resides in establishing the diagnosis. Although the diagnosis made be straightforward in patients with predominately typical reflux symptoms and secondary respiratory complaints, a substantial number of patients will have respiratory symptoms that dominate the clinical scenario. Typical gastroesophageal reflux symptoms, such as heartburn and regurgitation, may often be completely absent only to be uncovered with objective esophageal physiology testing. Traditionally, the diagnosis of reflux-induced respiratory injury is established using ambulatory dual probe pH monitoring, with one probe positioned within the distal esophagus and the other at a proximal location. Proximal probe positioning has included multiple locations such as the trachea, pharynx, and proximal esophagus. Although ambulatory esophageal pH monitoring allows a direct correlation between esophageal acidification and respiratory symptoms, sensitivity of this testing modality is poor, and the temporal relationship between laryngeal or pulmonary symptoms and reflux events is complex. In addition, as the refluxed gastric fluid travels proximally, it may be neutralized by saliva and therefore go undetected with pH monitoring. Impedance testing may also be used to detect the movement of fluid throughout the entire esophageal column regardless of pH content.

Treatment. Once the diagnosis is established, treatment may be initiated with either PPI therapy or antireflux surgery. A trial of high-dose PPI therapy may help establish the facts that reflux is partly or completely responsible for the respiratory symptoms. It is important to note that the persistence of symptoms in the face of aggressive PPI treatment does not necessarily rule out reflux as a possible cofactor or sole etiology.

Although there is probably some elements of a placebo effect, relief of respiratory symptoms can be anticipated in up to 50% of patients with reflux-induced asthma treated with antisecretory medications. However, when examined objectively, <15% of patients can be expected to have improvement in their pulmonary function with medical therapy. In properly selected patients, antireflux surgery improves respiratory symptoms in nearly 90% of children and 70% of adults with asthma and reflux disease. Improvements in pulmonary function can be demonstrated in around 30% of patients. Uncontrolled studies of the two forms of therapy (PPI and surgery) and the evidence from the two randomized controlled trials of medical vs. surgical therapy indicate that surgical valve reconstruction is the most effective therapy for reflux-induced asthma. The superiority of the surgery over PPI is most noticeable in the supine position, which corresponds with the nadir of PPI blood levels and resultant acid breakthrough and is the time in the circadian cycle when asthma symptoms are at their worst.

In asthmatic patients with an esophageal motility disorder, performing an antireflux operation will not prevent the regurgitation and possible aspiration of swallowed liquid or food "upstream" to the valve reconstruction. It is critical that esophageal body function be considered prior to surgical intervention in this patient population.

Medical Therapy for Gastroesophageal Reflux Disease. With the widespread availability of over-the-counter antisecretory medications, most patients with mild or moderate symptoms will carry self-medication. When initially identified with mild symptoms of uncomplicated GERD, patients can be placed on 12 weeks of simple antacids before diagnostic testing is initiated. This approach may successfully and completely resolve the symptoms. Patients should be counseled to elevate the head of the bed; avoid tight-fitting clothing; eat small, frequent meals; avoid eating the nighttime meal immediately prior to bedtime; and avoid alcohol, coffee, chocolate, and peppermint, which are known to reduce resting LES pressure and may aggravate symptoms.

Used in combination with simple antacids, alginic acid may augment the relief of symptoms by creating a physical barrier to reflux, as well as by acid reduction. Alginic acid reacts with sodium bicarbonate in the presence of saliva to form a highly viscous solution that floats like a raft on the surface of the gastric contents. When reflux occurs, this protective layer is refluxed into the esophagus, and acts as a protective barrier against the noxious gastric contents. Medications to promote gastric emptying, such as metoclopramide or domperidone, are beneficial in early disease, but of little value in more severe disease.

In patients with persistent symptoms, the mainstay of medical therapy is acid suppression. High-dosage regimens of hydrogen potassium PPIs, such as omeprazole (up to 40 mg/d), can reduce gastric acidity by as much as 80% to 90%. This usually heals mild esophagitis. In severe esophagitis, healing may occur in only one-half of the patients. In patients who reflux a combination of gastric and duodenal juice, acid-suppression therapy may give relief of symptoms, while still allowing mixed reflux to occur. This can allow persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for GERD, 80% of patients have a recurrence of symptoms.

Once initiated, most patients with GERD will require lifelong treatment with PPIs, both to relieve symptoms and control any coexistent esophagitis or stricture. Although control of symptoms has historically served as the endpoint of therapy, the wisdom of this approach has recently been questioned, particularly in patients with BE. Evidence suggesting that reflux control may prevent the development of adenocarcinoma and lead to regression of dysplastic and nondysplastic Barrett's segments has led many to consider control of reflux, and not symptom control, a better therapeutic endpoint. However, this hypothesis remains controversial. It should be noted that complete control of reflux using PPIs can be difficult, as has been highlighted by studies of acid breakthrough while on PPI therapy, and of persistent reflux following antireflux surgery. Castell, Triadafilopoulos, and others have shown that 40% to 80% of patients with BE continue to have abnormal esophageal acid exposure despite up to 20 mg twice daily of PPIs. Ablation trials have shown that mean doses of 56 mg of omeprazole were necessary to normalize 24-hour esophageal pH studies. It is likely that antireflux surgery results in more reproducible and reliable elimination of reflux of both acid and duodenal contents, although long-term outcome studies suggest that as many as 25% of postfundoplication patients will have persistent pathologic esophageal acid exposure confirmed by positive 24-hour pH studies.

Suggested Therapeutic Approach. Traditionally a stepwise approach is used for the treatment of GERD. First-line therapy entails antisecretory medication, usually PPIs, in most patients. Failure of medication, or the immediate return of symptoms after stopping treatment, suggests either that the patient may

have relatively severe disease or a non-GERD cause for his or her symptoms. Endoscopic examination at this stage of the patient's evaluation is recommended and will provide the opportunity to assess the degree of mucosal injury and presence of BE. Treatment options for these patients entails either long term PPI use vs. antireflux surgery. Laparoscopic antireflux surgery in these patients achieves long-term control of symptoms in 85% to 90%. The measurement of esophageal acid exposure via 24-hour pH should be undertaken when patients are considered for surgery. The status of the LES and esophageal body function with esophageal manometry should also be performed at this stage. These studies will serve to establish the diagnosis and assess esophageal body dysfunction.

Surgical Therapy for Gastroesophageal Reflux Disease

Selection of Patients for Surgery. Studies of the natural history of GERD indicate that most patients have a relatively benign form of the disease that is responsive to lifestyle changes and dietary and medical therapy, and do not need surgical treatment. Approximately 25% to 50% of the patients with GERD have persistent or progressive disease, and it is this patient population that is best suited to surgical therapy. In the past, the presence of esophagitis and a structurally defective LES were the primary indications for surgical treatment, and many internists and surgeons were reluctant to recommend operative procedures in their absence. However, one should not be deterred from considering antireflux surgery in a symptomatic patient with or without esophagitis or a defective sphincter, provided the disease process has been objectively documented by 24-hour pH monitoring. This is particularly true in patients who have become dependent upon therapy with PPIs, or require increasing doses to control their symptoms. It is important to note that a good response to medical therapy in this group of patients predicts an excellent outcome following antireflux surgery.

In general, the key indications for antireflux surgery are (a) objectively proven gastroesophageal reflux disease, and (b) typical symptoms of gastroesophageal reflux disease (heartburn and/or regurgitation) despite adequate medical management, or (c) a younger patient unwilling to take lifelong medication. In addition, a structurally defective LES can also predict which patients are more likely to fail with medical therapy. Patients with normal sphincter pressures tend to remain well controlled with medical therapy, whereas patients with a structurally defective LES may not respond as well to medical therapy, and often develop recurrent symptoms within 1 to 2 years of beginning therapy. Such patients should be considered for an antireflux operation, regardless of the presence or absence of endoscopic esophagitis.

Young patients with documented reflux disease with or without a defective LES are also excellent candidates for antireflux surgery. They usually will require long-term medical therapy for control of their symptoms, and some will go on to develop complications of the disease. An analysis of the cost of therapy based on data from the Veterans Administration Cooperative trial indicates that surgery has a cost advantage over medical therapy in patients <49 years of age.

Severe endoscopic esophagitis in a symptomatic patient with a structurally defective LES is also an indication for early surgical therapy. These patients are prone to breakthrough of their symptoms while receiving medical therapy. Symptoms and mucosal injury can be controlled in such patients, but careful monitoring is required, and increasing dosages of PPIs are necessary. In everyday clinical practice, however, such treatment can be both difficult and impractical, and, in such cases, antireflux surgery can be considered early, especially if PPI therapy is problematic.

The development of a stricture in a patient represents a failure of medical therapy, and is also an indication for a surgical antireflux procedure. In addition, strictures are often associated with a structurally defective sphincter and loss of esophageal contractility. Before proceeding with surgical treatment, malignancy and a drug-related etiology of the stricture should be excluded, and the stricture progressively dilated up to a 50 to 60F bougie. When the stricture is fully dilated, the relief of dysphagia is evaluated and esophageal manometry is performed to determine the adequacy of peristalsis in the distal esophagus. If dysphagia is relieved and the amplitude of esophageal contractions is adequate, an antireflux procedure should be performed; if there is a global loss of esophageal contractility, caution should be exercised in performing an antireflux procedure with a complete fundoplication, and a partial fundoplication should be considered.

Barrett's CLE is commonly associated with a severe structural defect of the LES and often poor contractility of the esophageal body. Patients with BE are at risk of the development of an adenocarcinoma. Whilst surgeons would like to think that an antireflux procedure can reduce the risk of progression to cancer, the evidence supporting this is relatively weak, and for now Barrett's esophagus should be considered to be evidence that the patient has gastroesophageal reflux, and progression to antireflux surgery is indicated for the treatment of reflux symptoms, not cancer progression. If, however, high grade dysplasia or intramucosal carcinoma is found on mucosal biopsy specimens, treatment should then be directed at the BE and the lesion, using either evaluation endoscopic ablation, endoscopic resection or esophageal resection.

The majority of patients requiring treatment for reflux have a relatively mild form of disease and will respond to antisecretory medications. Patients with more severe forms of disease, particularly those who develop persistent or progressive disease, should be considered for definitive therapy. Laparoscopic fundoplication will provide a long-term cure in the majority of these patients, with minimal discomfort and an early return to normal activity.

Preoperative Evaluation. Before proceeding with an antireflux operation, several factors should be evaluated. The clinical symptoms should be consistent with the diagnosis of gastroesophageal reflux. Patients presenting with the typical symptoms of heartburn and/or regurgitation which have responded, at least partly, to PPI therapy, will generally do well following surgery, whereas patients with atypical symptoms have a less predictable response. Reflux should also be objectively confirmed by either the presence of ulcerative esophagitis or an abnormal 24 hour pH study.

The propulsive force of the body of the esophagus should be evaluated by esophageal manometry to determine if it has sufficient power to propel a bolus of food through a newly reconstructed valve. Patients with normal peristaltic contractions can be considered for a 360° Nissen fundoplication or a partial fundoplication, depending on patient and surgeon preferences. When peristalsis is absent a partial fundoplication is probably the procedure of choice, but only if achalasia has been ruled out.

Hiatal anatomy should also be assessed. In patients with smaller hiatal hernias endoscopy evaluation usually provides sufficient information. However, when patients present with a very large hiatus hernia or for revision surgery after previous antireflux surgery, contrast radiology provides better anatomical information. The concept of anatomic shortening of the esophagus is controversial, with divergent opinions held about how common this problem is. Believers claim that anatomic shortening of the esophagus compromises the ability of the surgeon to perform an adequate repair without tension, and that this can lead to an increased incidence of breakdown or thoracic displacement of the repair. Some of those that hold this view claim that esophageal shortening is present when a barium swallow X-ray identifies a sliding hiatal hernia that will not reduce in the upright position, or that measures more than 5 cm in length at endoscopy. When identified these surgeons usually undertake add a gastroplasty to the antireflux procedure. Others claim that esophageal shortening is overdiagnosed and rarely seen, and that the morbidity of adding a gastroplasty outweighs any benefits. These surgeons would recommend a standard antireflux procedure in all patients undergoing primary surgery.

Principles of Surgical Therapy. The primary goal of antireflux surgery is to safely create a new antireflux valve at the gastroesophageal junction, while preserving the patient's ability to swallow normally and to belch to relieve gaseous distention. Regardless of the choice of the procedure, this goal can be achieved if attention is paid to some basic principles when reconstructing the antireflux mechanism. First, the operation should create a flap valve which prevents regurgitation of gastric contents into the esophagus. This will result in an increase in the pressure of the distal esophageal sphincter region. Following a Nissen fundoplication the expected increase is to a level twice the resting gastric pressure (i.e., 12 mmHg for a gastric pressure of 6 mmHg). The extent of the pressure rise is often less following a partial fundoplication, although with all types of fundoplication the length of the reconstructed valve should be at least 3 cm. This not only augments sphincter characteristics in patients in whom they are reduced before surgery, but prevents unfolding of a normal sphincter in response to gastric distention (Fig. 25-32). Preoperative and postoperative esophageal manometry measurements have shown that the resting sphincter pressure and the overall sphincter length can be surgically augmented over preoperative values, and that the change in the former is a function of the degree of gastric wrap around the esophagus (Fig. 25-33). However, the aim of any fundoplication

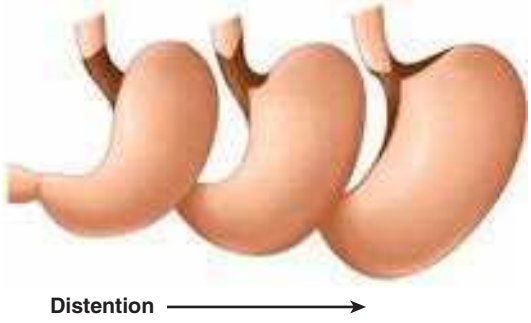

Figure 25-32. A graphic illustration of the shortening of the lower esophageal sphincter that occurs as the sphincter is "taken up" by the cardia as the stomach distends.

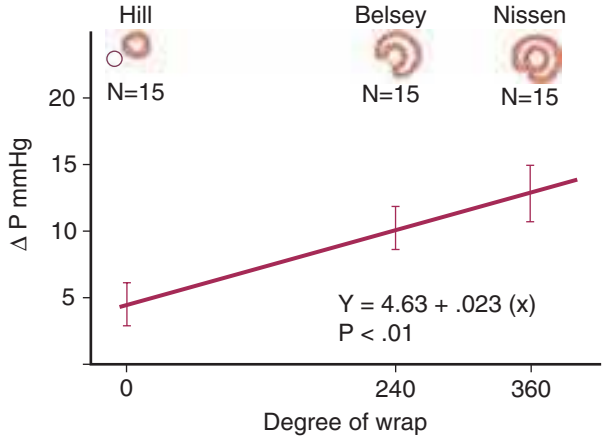

Figure 25-33. The relationship between the augmentation of sphincter pressure over preoperative pressure (ΔP) and the degree of gastric fundic wrap in three different antireflux procedures. *(Reproduced with permission from O'Sullivan GC, et al.: Interaction of lower esophageal pressure and length of sphincter in the abdomen as detriments of gastroesophageal competence.* Am J Surg. *143:43, 1982. Copyright Elsevier.)*

is to create a loose wrap, and to maintain the position of the gastric fundus close to the distal intra-abdominal esophagus, in a flap valve arrangement. The efficacy of this relies on the close relationship between the fundus and the esophagus, not the "tightness" of the wrap.

Second, the operation should place an adequate length of the distal esophageal sphincter in the positive-pressure environment of the abdomen by a method that ensures its response to changes in intra-abdominal pressure. The permanent restoration of 2 or more cm of abdominal esophagus ensures the preservation of the relationship between the fundus and the esophagus. All of the popular antireflux procedures increase the length of the sphincter exposed to abdominal pressure by an average of at least 1 cm.

Third, the operation should allow the reconstructed cardia to relax on deglutition. In normal swallowing, a vagally mediated relaxation of the distal esophageal sphincter and the gastric fundus occurs. The relaxation lasts for approximately 10 seconds and is followed by a rapid recovery to the former tonicity. To ensure relaxation of the sphincter, three factors are important: (a) Only the fundus of the stomach should be used to buttress the sphincter, because it is known to relax in concert with the sphincter; (b) the gastric wrap should be properly placed around the sphincter and not incorporate a portion of the stomach or be placed around the stomach itself, because the body of the stomach does not relax with swallowing; and (c) damage to the vagal nerves during dissection of the thoracic esophagus should be avoided because it may result in failure of the sphincter to relax.

Fourth, the fundoplication should not increase the resistance of the relaxed sphincter to a level that exceeds the peristaltic power of the body of the esophagus. The resistance of the relaxed sphincter depends on the degree, length, and diameter of the gastric fundic wrap, and on the variation in intra-abdominal pressure. A 360° gastric wrap should be no longer than 2 cm and constructed over a large (50 to 60F) bougie. This will ensure that the relaxed sphincter will have an adequate diameter with

minimal resistance. A bougie is not necessary when constructing a partial wrap.

Fifth, the operation should ensure that the fundoplication can be placed in the abdomen without undue tension, and maintained there by approximating the crura of the diaphragm above the repair. Leaving the fundoplication in the thorax converts a sliding hernia into a PEH, with all the complications associated with that condition. Maintaining the repair in the abdomen under tension predisposes to an increased incidence of recurrence. How common this problem is encountered is disputed, with some surgeons advocating lengthening the esophagus by gastroplasty and constructing a partial fundoplication, and others claiming that this issue is now rarely encountered.

Procedure Selection. A laparoscopic approach is now used routinely in all patients undergoing primary antireflux surgery. Some surgeons advocate the use of a single antireflux procedure for all patients, whereas others advocate a tailored approach. Advocates of the laparoscopic Nissen fundoplication as the procedure of choice for a primary antireflux repair would generally apply this procedure in all patients with normal or near normal esophageal motility, and reserve a partial fundoplication for use in individuals with poor esophageal body motility. Others, based on the good longer term outcomes now reported following partial fundoplication procedures, advocate the routine application of a partial fundoplication procedure, thereby avoiding any concerns about constructing a fundoplication in individuals with poor esophageal motility.

Experience and randomized studies have shown that both the Nissen fundoplication and various partial fundoplication procedures are all effective and durable antireflux repairs, and generate an excellent outcome in approximately 90% of patients at longer term follow-up.

Primary Antireflux Repairs

Nissen Fundoplication. The most common antireflux procedure is the Nissen fundoplication. In the past this procedure has been performed through an open abdominal or a chest incision, but with the development of laparoscopic approaches primary antireflux surgery is now routinely undertaken using the laparoscope. Rudolph Nissen described this procedure as a 360° fundoplication around the lower esophagus for a distance of 4 to 5 cm, without division of the short gastric blood vessels. Although this provided good control of reflux, it was associated with a number of side effects that have encouraged modifications of the procedure as originally described. These include using only the gastric fundus to envelop the esophagus in a fashion analogous to a Witzel jejunostomy, sizing the fundoplication with a large (50 to 60F) bougie, limiting the length of the fundoplication to 1 to 2 cm, and dividing the short gastric vessels. The essential elements necessary for the performance of a transabdominal fundoplication are common to both the laparoscopic and open procedures and include the following:

1. Hiatal dissection and preservation of both vagi along their entire length
2. Circumferential esophageal mobilization
3. Hiatal closure, usually posterior to the esophagus
4. Creation of a short and floppy fundoplication over an esophageal dilator

In addition, many surgeons also routinely divide the short gastric blood vessels, although this step is not universally applied, and the results of several randomized trials have failed to show that this step yields any benefit.

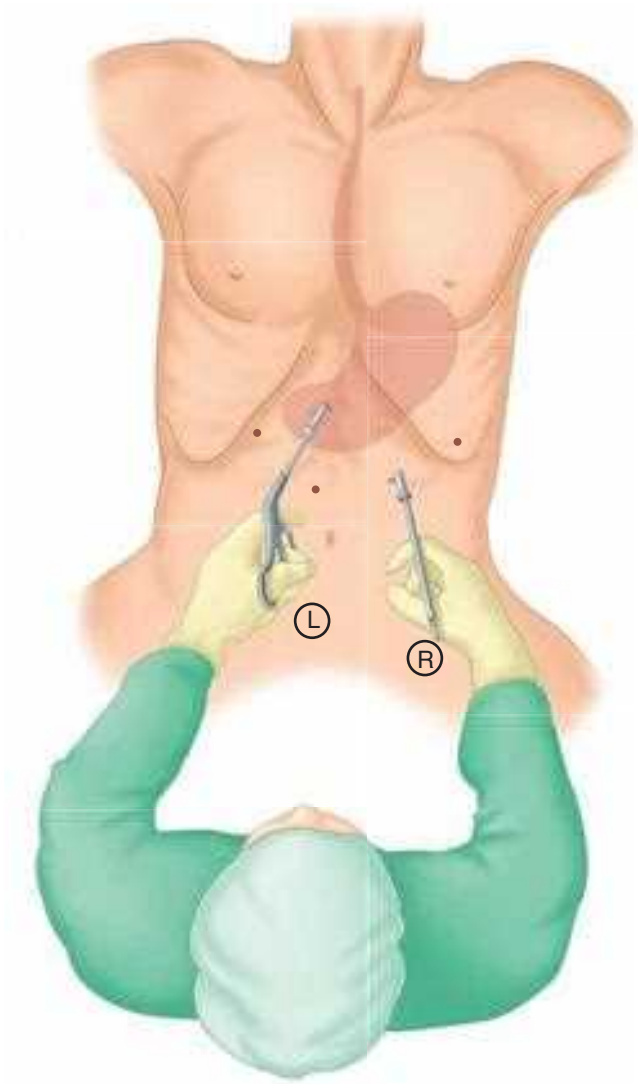

Figure 25-34. Patient positioning and trocar placement for laparoscopic antireflux surgery. The patient is placed with the head elevated approximately 30° in the modified lithotomy position. The surgeon stands between the patient's legs, and the procedure is completed using five abdominal access ports.

The laparoscopic approach to fundoplication has now replaced the open abdominal Nissen fundoplication as the procedure of choice. Five ports are usually used (Fig. 25-34), and dissection is begun by incising the gastrohepatic omentum above and below the hepatic branch of the anterior vagus nerve, which is usually preserved. The circumference of the diaphragmatic hiatus is dissected and the esophagus is mobilized by careful dissection of the anterior and posterior soft tissues within the hiatus. The esophagus is held anterior and to the left and the hiatal pillars are approximated with interrupted non-absorbable sutures, starting posteriorly and working anteriorly. A tension-free fundoplication should be constructed. This can usually be achieved either with or without division of the short gastric blood vessels, according to surgeon preference. If the vessels are divided, the upper one third of the greater curvature is mobilized by sequentially dissecting and divided these vessels, commencing distally and working proximally. Following complete fundal mobilization,

the posterior wall of the fundus is brought behind the esophagus to the right side, and the anterior wall of the fundus is brought anterior to the esophagus. The fundic lips are manipulated to allow the fundus to envelop the esophagus without twisting. A 50 to 60F bougie is passed to properly size the fundoplication, and it is sutured using non-absorbable sutures. Some surgeons use a single U-stitch of 2-0 polypropylene buttressed with felt pledgets (Fig. 25-35), and others use 2-4 interrupted sutures.

Posterior Partial Fundoplication. Partial fundoplications were developed as an alternative to the Nissen procedure in an attempt to minimize the risk of postfundoplication side effects, such as dysphagia, inability to belch, and flatulence. The commonest approach has been a posterior partial or Toupet fundoplication. Some surgeons use this type of procedure for all patients presenting for antireflux surgery, whereas others apply a tailored approach in which a partial fundoplication is

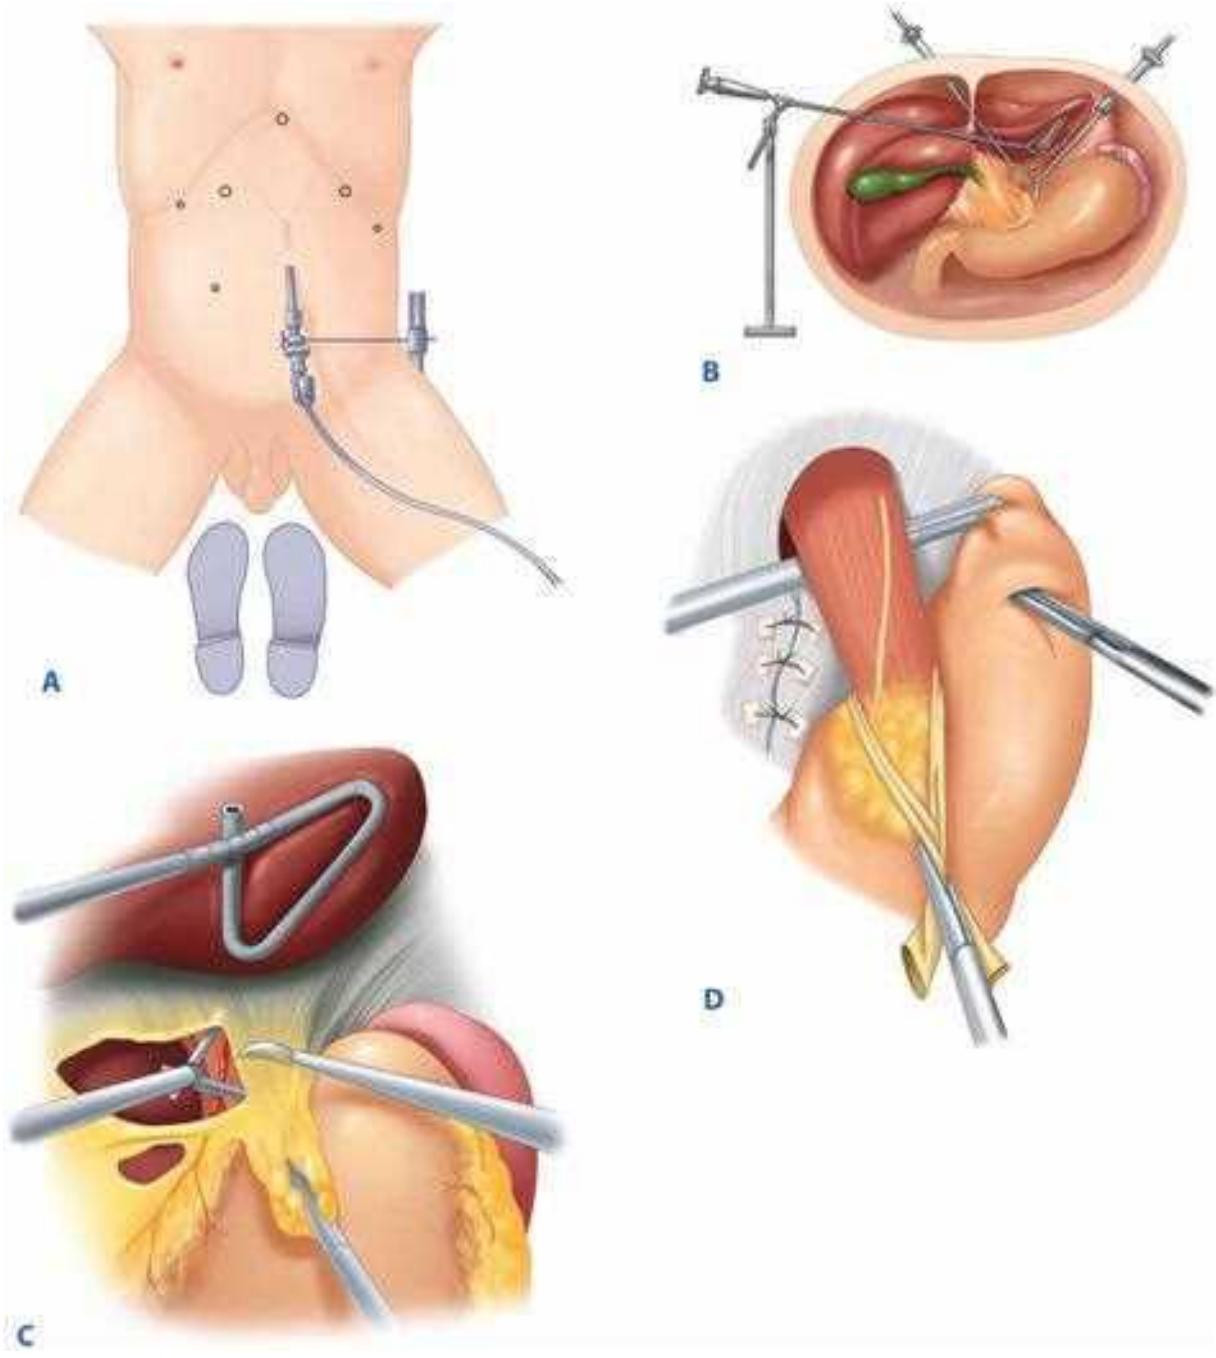

Figure 25-35. **A.** Laparoscopic Nissen fundoplication is performed with a five-trocar technique. **B.** The liver retractor is affixed to a mechanical arm to hold it in place throughout the operation. **C.** After division of the gastrohepatic omentum above the hepatic branch of the vagus (pars flaccida), the surgeon places a blunt atraumatic grasper beneath the phrenoesophageal ligament. **D.** After completion of the crural closure, an atraumatic grasper is placed right to left behind the gastroesophageal junction. The grasper is withdrawn, pulling the posterior aspect of the gastric fundus behind the esophagus. **E.** Once the suture positions are chosen, the first stitch (2-0 silk, 20 cm long) is introduced through the 10-mm trocar, and the needle is passed first through the left limb of the fundus, then the esophagus (2.5 cm above the gastroesophageal junction), then through the right limb of the fundus. **F.** Final position of the fundoplication. *(Illustration continued on next page.)*

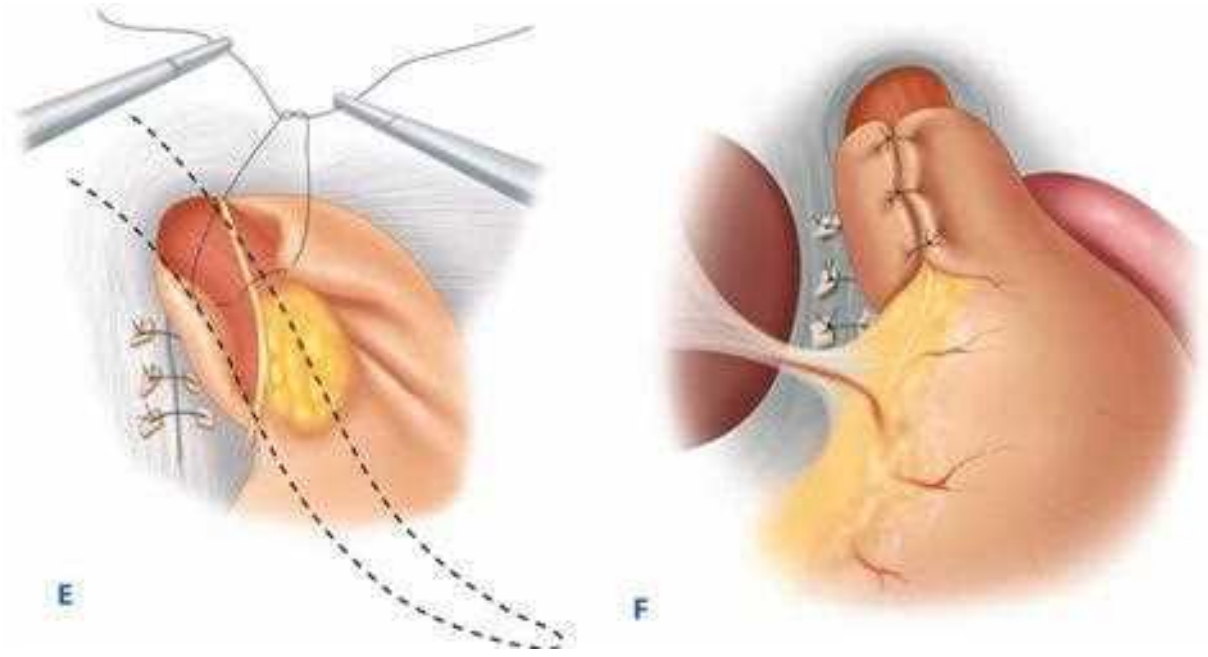

Figure 25-35. (*Continued*)

constructed in patients with impaired esophageal motility, in which the propulsive force of the esophagus is thought to be insufficient to overcome the outflow obstruction of a complete fundoplication. The Toupet posterior partial fundoplication consists of a 270° gastric fundoplication around the distal 4 cm of esophagus (Fig. 25-36). It is usually stabilized by anchoring the wrap posteriorly to the hiatal rim.

Anterior Partial Fundoplication. An alternative approach to partial fundoplication is to construct an anterior partial fundoplication. Following posterior hiatal repair, the anterior fundus is rolled over the front of the esophagus and sutured to the hiatal rim and the esophageal wall. Division of the short gastric vessels is never needed when constructing this type of fundoplication. Various degrees of anterior partial fundoplication have been described—90°, 120°, 180°. The anterior 180° partial fundoplication (Fig. 25-37) provides a more robust fundoplication and achieves an excellent longer term outcome in approximately 90% of patients at follow-up of at least 10 years. With this procedure the fundus and esophagus are sutured to the right side of the hiatal rim to create a flap valve at the gastroesophageal junction, and to stabilize a 3-4 cm length of intra-abdominal esophagus.

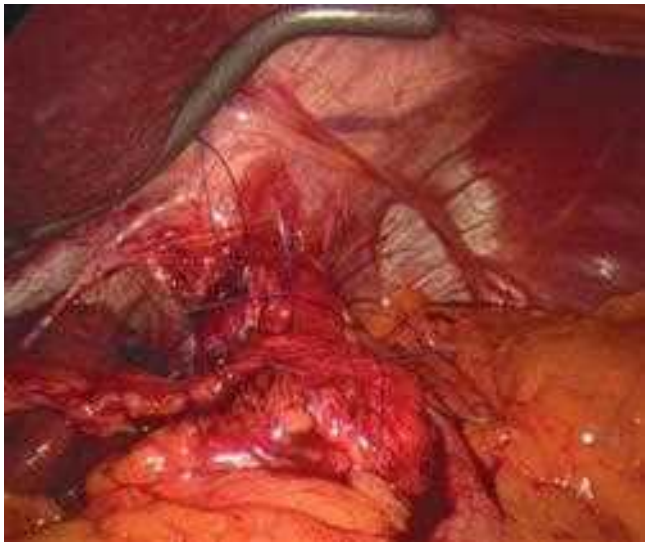

Figure 25-36. Completed laparoscopic posterior partial (Toupet) fundoplication. The fundoplication does not cover the anterior surface of the esophagus, and is stabilized by suturing the fundus to the side of the esophagus, and posteriorly to the right hiatal pillar.

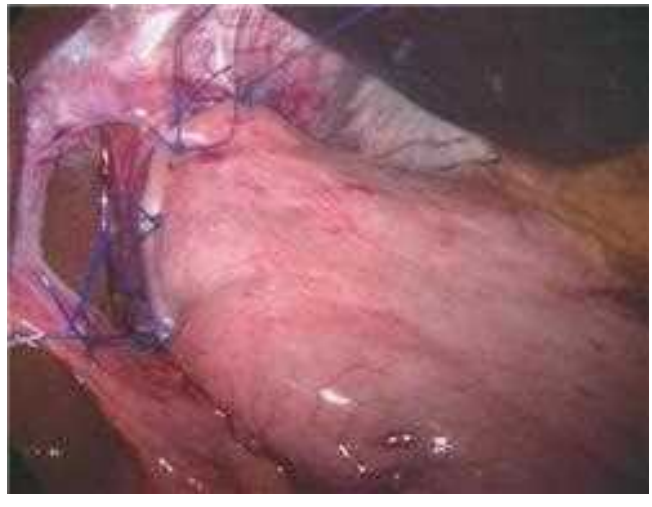

Figure 25-37. Completed laparoscopic anterior 180^0 partial fundoplication. The fundoplication fully covers the anterior surface of the esophagus, and is stabilized by suturing the fundus to the right side of the esophagus, and to the right hiatal pillar. Unlike the Nissen procedure, the fundus is not pulled behind the esophagus.

Collis Gastroplasty. When a shortened esophagus is encountered, many surgeons choose to add an esophageal lengthening procedure before fundoplication, to reduce the tension on the gastro-esophageal junction, believing this will minimize the risk of failure due to postoperative hiatus hernia. The commonest approach to this is the Collis gastroplasty. This entails using a stapler to divide the cardia and upper stomach, parallel to the lesser curvature of the stomach, thereby creating a gastric tube in continuity with the esophagus, and effectively lengthening the esophagus by several centimeters. Laparoscopic techniques for Collis gastroplasty have been described (Fig. 25-38). Following gastroplasty a fundoplication is constructed, with the highest suture is placed on the native esophagus when constructing a Nissen fundoplication.Not all surgeons choose to undertake a Collis procedure, however, as there is controversy about the actual incidence of the shortened esophagus and widely divergent views are held about how often this problem is encountered. In addition, some surgeons have questioned the wisdom of creating an amotile tube of gastric wall, which can secrete acid, and then placing a Nissen fundoplication below this.

Outcome after Fundoplication. Studies of long-term outcome following both open and laparoscopic fundoplication document the ability of laparoscopic fundoplication to relieve typical reflux symptoms (heartburn, regurgitation, and dysphagia) in more than 90% of patients at follow-up intervals averaging 2 to 3 years and 80% to 90% of patients 5 years or more following surgery. This includes evidence-based reviews of antireflux surgery, prospective randomized trials comparing antireflux surgery to PPI therapy and open to laparoscopic

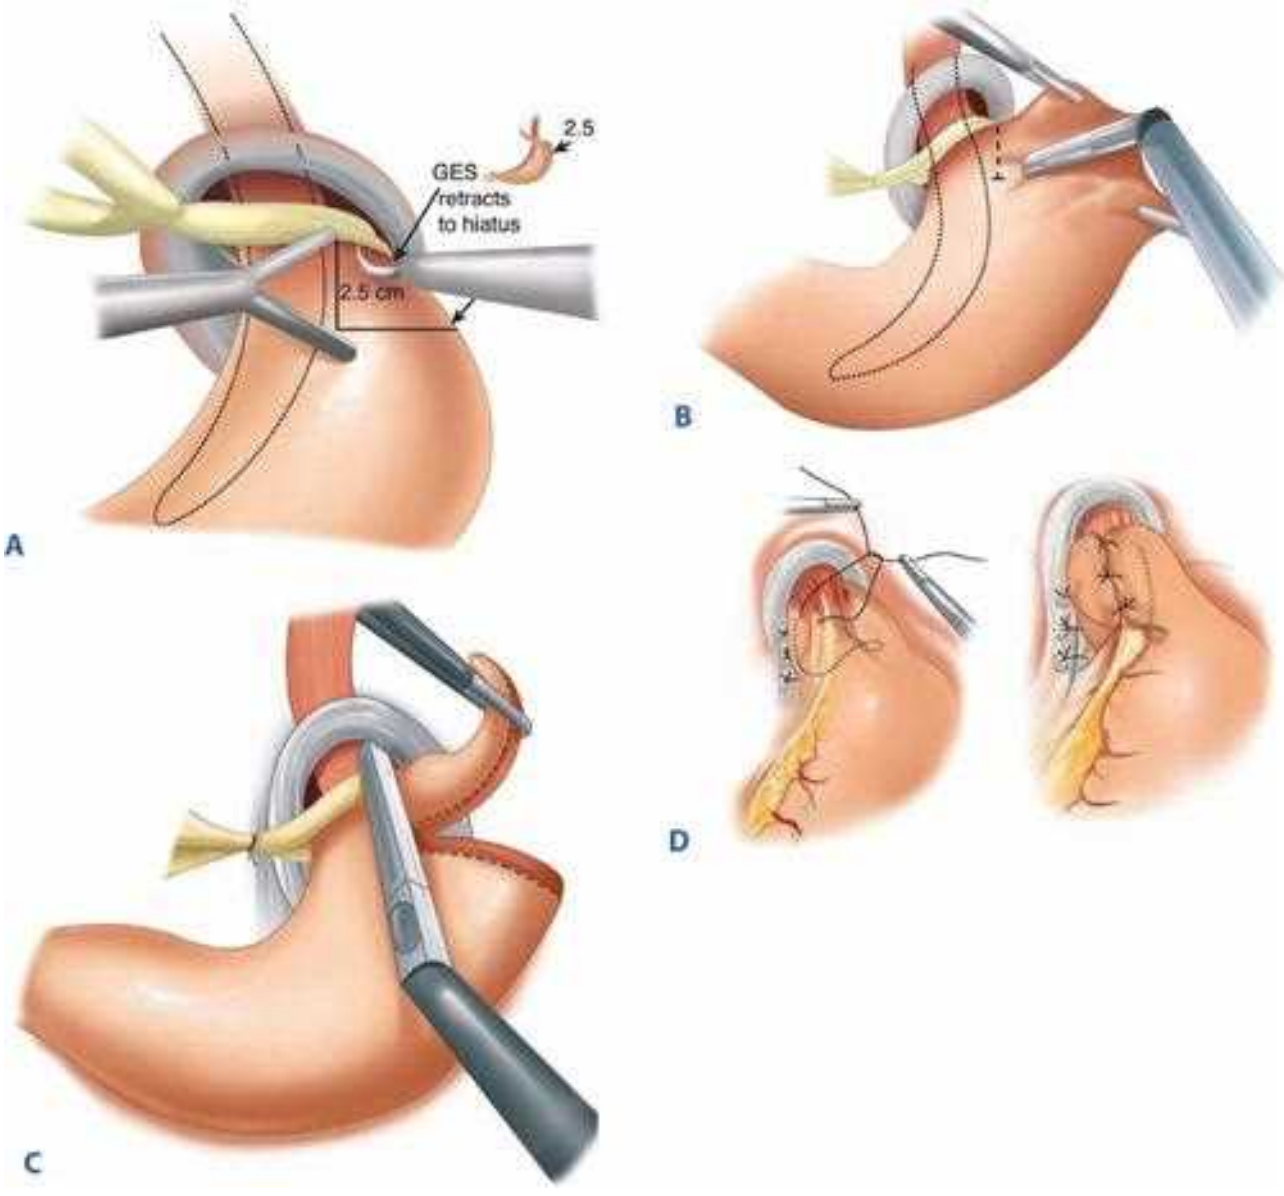

Figure 25-38. **A.** After removal of the fat pad and release of tension on the Penrose drain, the gastroesophageal junction (GES) retracts to the level of the hiatus. The interior end of the staple line is marked $^{2}/_{5}$ cm below the angle of His. **B.** The first horizontal firing of the stapler occurs by maximally articulating the stapler to the left, aiming toward the previously marked spot adjacent to the dilator. **C.** The vertical staple line is created by a single firing of the GIA placed parallel and flush against the 48F dilator. **D.** The highest Nissen fundoplication suture is placed on the native esophagus, and the second suture tucks in the apex of the staple line.

fundoplication and analysis of U.S. national trends in use and outcomes. Postoperative pH studies indicate that more than 90% of patients will normalize their pH tracings. The results of laparoscopic fundoplication compare favorably with those of the "modern" era of open fundoplication. They also indicate the less predictable outcome of atypical reflux symptoms (cough, asthma, laryngitis) after surgery, being relieved in only two-thirds of patients.

The goal of surgical treatment for GERD is to relieve the symptoms of reflux by re-establishing the gastroesophageal barrier. The challenge is to accomplish this without inducing dysphagia or other untoward side effects. Dysphagia, existing before surgery, usually improves following laparoscopic fundoplication. Temporary dysphagia is common after surgery and generally resolves within 3 months, but can take up to 12 months in some individuals, and dysphagia sufficient to require ongoing dietary modification persists in up to 5% of individuals following Nissen fundoplication. Other side effects common to antireflux surgery include the inability to belch and vomit and increased flatulence. Most patients cannot vomit through an intact wrap, though this is rarely clinically relevant. Most patients are unable to belch gas from the stomach in the first 3 to 6 months after fundoplication, but 80%-90% regain the ability to belch normally beyond the first 12 months follow-up. Hyperflatulence is a common and noticeable problem, likely related to increased air swallowing that is present in most patients with reflux disease, aggravated by the inability to belch in some patients.

Randomized Controlled Trials Addressing Surgical Technique

Division of the Short Gastric Blood Vessels Originally, Nissen's description of a total fundoplication entailed a 360° fundoplication during which the short gastric blood vessels were left intact. However, with reports of troublesome postoperative dysphagia division of these vessels, to achieve full fundal mobilization and thereby ensure a loose fundoplication, was promoted and has entered common practice. The evidence supporting dividing these vessels has been based on the outcomes from uncontrolled case series of patients undergoing Nissen fundoplication either with vs. without division of the short gastric vessels. However, the results from these studies have been conflicting with different proponents reporting good results irrespective of whether these vessels have been divided or not. To address this issue 6 randomized trials which enrolled a total of 438 patients have been reported. None of these trials demonstrated any differences for the postoperative dysphagia or recurrent gastro-esophageal reflux. However, in the 3 largest of the 6 trials an increased incidence of flatulence and bloating symptoms, as well as greater difficulty with belching, was seen in patients in whom the short gastric vessels were divided.

A recent meta-analysis from Engstrom et al, generated by combining the raw data from Australian and Swedish trials, evaluated a larger cohort of 201 patients, with 12 years follow-up in 170, and also confirmed equivalent reflux control, but more abdominal bloating after division of the short gastric vessels. Overall, these trials fail to support the belief that dividing the short gastric vessels improves any outcome following Nissen fundoplication. The trials actually suggest that dividing the vessels increases the complexity of the procedure, and leads to a poorer outcome due to the increase in bloating symptoms.

Nissen vs. Posterior Partial Fundoplication Eleven randomized trials have compared Nissen vs. posterior partial fundoplication. Some of the trials were relatively small and underpowered, so contribute little to the pool of evidence as they are either small or underpowered, and failed to show significant outcome differences. The larger trials, however, have consistently demonstrated equivalent reflux control, but a reduced incidence of wind related side-effects (flatulence, bloating, and inability to belch) following posterior partial fundoplication procedures, although less dysphagia following a posterior fundoplication was only demonstrated in 2 of the 11 trials. Lundell et al reported the outcomes of Nissen vs. Toupet partial fundoplication in a trial which enrolled 137 patients with reported follow-up to 18 years. Reflux control and dysphagia symptoms were similar, but flatulence was commoner after Nissen fundoplication at some medium-term follow-up time points and revision surgery was more common following Nissen fundoplication, mainly to correct postoperative paraoesophageal herniation. At 18 years follow-up, success rates of more than 80% were reported for both procedures, as well as no significant differences in the incidence of side effects. The data from this trial suggested that the mechanical side effects following Nissen fundoplication progressively improve with very long term follow-up. Strate et al reported 2 year follow-up in a trial that enrolled 200 patients. Approximately 85% of each group was satisfied with the clinical outcome, but dysphagia was significantly more common following Nissen fundoplication (19 vs. 8 patients).

Other trials (Guérin et al–140 patients, Booth et al–127, Khan et al–121, Shaw et al–100) also report similar reflux control within the first few years of follow-up. Only Booth et al. demonstrated less dysphagia following posterior fundoplication. Subgroup analysis in 3 trials (Booth, Shaw, Zornig) did not reveal differences between patients with vs. without poor preoperative oesophageal motility. Overall these trials suggest that some side-effects, mainly wind-related issues, are less common following posterior partial fundoplication. However, the hypothesis that dysphagia is less of a problem following posterior partial fundoplication has only been substantiated in 2 of 11 trials.

Nissen vs. Anterior Fundoplication Six trials have evaluated Nissen vs. anterior partial fundoplication variants. Four have assessed Nissen vs. anterior 180° partial fundoplication (Watson et al–107 patients, Baigrie et al–161, Cao et al–100, Raue et al–64). These trials all demonstrated equivalent reflux control, but less dysphagia and less wind-related side effects after anterior 180° partial fundoplication at up to 5 years follow-up. Only the study from Watson et al has reported follow-up to 10 years, and at late follow-up in their trial there were no significant outcome differences for the 2 procedures, with equivalent control of reflux, and no differences for side effects due to a progressive decline in dysphagia as follow-up extended beyond 5 years.

Two trials compared laparoscopic anterior 90° partial fundoplication vs. Nissen fundoplication (Watson et al–112 patients, Spence et al–79). In both of these trials side-effects were less common following anterior 90° fundoplication, but this was offset by a slightly higher incidence of recurrent reflux at up to 5 years follow-up. Satisfaction with the overall outcome was similar for both fundoplication variants.

Anterior vs. posterior partial fundoplication Two randomized trials have directly compared anterior vs. posterior partial fundoplication. Hagedorn et al randomized 95 patients to undergo either Toupet vs. anterior 120° partial fundoplication, and Khan et al enrolled 103 patients to anterior 180° vs.

posterior partial fundoplication. Both studies demonstrated better reflux control, offset by more side effects following posterior partial fundoplication. The anterior 120° partial fundoplication performed by Hagedorn et al was similar to the anterior 90° variant described above. However, the outcomes following this procedure were much worse in this trial than the outcomes in other studies, with the average exposure time to acid (pH <4%–5.6%) following anterior fundoplication in their study unusually high compared to other studies. Khan et al only reported 6 months follow-up and longer term outcomes are awaited before drawing firm conclusions. The overall results from all 8 trials which included an anterior fundoplication variant suggests that this type of fundoplication achieves satisfactory reflux control, with less dysphagia and other side-effects, yielding a good overall outcome. However, the reduced incidence of troublesome side-effects is traded off against a higher risk of recurrent reflux.

Outcome of Antireflux Surgery in Patients with Barrett's Esophagus. Few studies have focused on the alleviation of symptoms after antireflux surgery in patients with BE (Table 25-7). Those that are available document excellent to good results in 72% to 95% of patients at 5 years following surgery. Several non-randomized studies have compared medical and surgical therapy and report better outcomes after antireflux surgery. Parrilla and colleagues reported the only randomized trial to evaluate this issue. They enrolled 101 patients over 18 years (1982 to 2000), and median follow-up was 6 years. Medical therapy consisted of 20 mg of omeprazole (PPI) twice daily since 1992 in all medically treated patients, and surgical therapy consisted of an open Nissen fundoplication. The symptomatic outcome in the two groups was nearly identical, although esophagitis and/or stricture persisted in 20% of the medically treated patients, compared to only 3% to 7% of patients following antireflux surgery. About 15 % of patients had abnormal acid exposure after surgery. Although pH data were not routinely collected in patients on PPI therapy, in the subgroup of 12 patients that did have 24-hour monitoring on treatment, 3 of 12 (25%) had persistently high esophageal acid exposure, and most (75%) had persistently high bilirubin exposure.

The common belief that Barrett's epithelium cannot be reversed by antireflux surgery is may not be correct. Within the control arm of a randomized trial of ablation vs. surveillance, Bright and associates identified approximately 50% regression in the length of Barrett's esophagus in 20 patients within the control arm of a randomized trial of ablation vs. surveillance.

Current data indicate that patients with BE should remain in an endoscopic surveillance program following antireflux surgery. Biopsy specimens should be reviewed by a pathologist with expertise in the field. If low-grade dysplasia is confirmed, biopsy specimens should be repeated after 12 weeks of high-dose acid suppression therapy. If high-grade dysplasia or intramucosal cancer is evident on more than one biopsy specimen, then treatment is escalated. Treatment options include endoscopic mucosal resection, endoscopic ablation of the BE, or esophageal resection. Esophageal resection is advisable when an invasive cancer (stage T1b or deeper) is present, or for multifocal long segment BE in younger and fit patients in whom endoscopic treatments are unlikely to be adequate. Endoscopic mucosal resection allows smaller intramucosal tumors to be removed with clear pathology margins, and it can be used as a "big biopsy" to obtain better pathological staging, and even to excise shorter segments of BE in a piecemeal fashion. Ablation, commonly using radiofrequency ablation, has been shown at short term follow-up in a randomized trial to reduce the rate of progression from high grade dysplasia to invasive cancer by approximately 50%. However, following any endoscopic treatment patients need to continue with close endoscopic surveillance as recurrence can occur and the longer term outcome following these treatments remains uncertain. Early detection and treatment have been shown to decrease the mortality rate from esophageal cancer in these patients.

If the dysplasia is reported as lower grade or indeterminant, then inflammatory change that is often confused with dysplasia should be suppressed by a course of acid suppression therapy in high doses for 2 to 3 months, followed by rebiopsy of the Barrett's segment.

Reoperation for Failed Antireflux Repairs. Failure of an antireflux procedure occurs when, after the repair, the patient is unable to swallow normally, experiences upper abdominal discomfort during and after meals, or has recurrence or persistence of reflux symptoms. The assessment of these symptoms and the selection of patients who need further surgery are challenging problems. Functional assessment of patients who have recurrent, persistent, or emergent new symptoms following a primary antireflux repair is critical to identifying the cause of the failure. Analysis of patients requiring reoperation after a previous antireflux procedure shows that placement of the wrap around the stomach is the most frequent cause for failure after open procedures, while herniation of the repair into the chest is the most frequent cause of failure after a laparoscopic procedure. Partial or complete breakdown of the fundoplication and construction of a too-tight a fundoplication or over narrowing the esophageal hiatus occurs with both open and closed procedures.

Table 25-7

Symptomatic outcome of surgical therapy for Barrett's esophagus

AUTHOR	YEAR	NO. OF PATIENTS	% EXCELLENT TO GOOD RESPONSE	MEAN FOLLOW-UP, YEARS
Starnes	1984	8	75	2
Williamson	1990	37	92	3
DeMeester	1990	35	77	3
McDonald	1996	113	82.2	6.5
Ortiz	1996	32	90.6	5

Patients who have recurrence of heartburn and regurgitation without dysphagia and have good esophageal motility are most amenable to reoperation, and can be expected to have an excellent outcome. When dysphagia is the cause of failure, the situation can be more difficult to manage. If the dysphagia occurred immediately following the repair, it is usually due to a technical failure, most commonly a misplaced fundoplication around the upper stomach, or over-narrowing of the esophageal diaphragmatic hiatus and reoperation is usually satisfactory. When dysphagia is associated with poor motility and multiple previous repairs, further revision fundoplication is unlikely to be successful and in otherwise fit patients it is appropriate to seriously consider esophageal resection. With each reoperation the esophagus is damaged further, and the chances of preserving function become less. Also, blood supply is reduced, and ischemic necrosis of the esophagus can occur after several previous mobilizations.

GIANT DIAPHRAGMATIC (HIATAL) HERNIAS

With the advent of clinical radiology, it became evident that a diaphragmatic hernia was a relatively common abnormality and was not always accompanied by symptoms. Three types of esophageal hiatal hernia were identified: (a) the sliding hernia, type I, characterized by an upward dislocation of the cardia in the posterior mediastinum (Fig. 25-39A); (b) the rolling or PEH, type II, characterized by an upward dislocation of the gastric fundus alongside a normally positioned cardia (Fig. 25-39B); and (c) the combined sliding-rolling or mixed hernia, type III, characterized by an upward dislocation of both the cardia and the gastric fundus (Fig. 25-39C). The end stage of type I and type II hernias occurs when the whole stomach migrates up into the chest by rotating 180° around its longitudinal axis, with the cardia and pylorus as fixed points. In this situation the abnormality is usually referred to as an intrathoracic stomach (Fig. 25-39D). In some taxonomies, a type IV hiatal hernia is declared when an additional organ, usually the colon, herniates as well. Type II-IV hiatal hernias are also referred to as *paraesophageal hernia* (PEH), as a portion of the stomach is situated adjacent to the esophagus, above the gastroesophageal junction.

Incidence and Etiology

The true incidence of a hiatal hernia is difficult to determine because of the absence of symptoms in a large number of patients who are subsequently shown to have a hernia. When radiographic

Figure 25-39. (*Continued*)

examinations are done in response to GI symptoms, the incidence of a sliding hiatal hernia is seven times higher than that of a PEH. The PEH is also known as the giant hiatal hernia. Over time the pressure gradient between the abdomen and chest enlarges the hiatal hernia. In many cases the type 1 sliding hernia will evolve into a type III mixed hernia. Type II hernias are quite rare. The age distribution of patients with PEHs is significantly different from that observed in sliding hiatal hernias. The median age of the former is 61 years old; of the latter, 48 years old. PEHs are more likely to occur in women by a ratio of 4:1.

Structural deterioration of the phrenoesophageal membrane over time may explain the higher incidence of hiatal hernias in the older age group. These changes involve thinning of the upper fascial layer of the phrenoesophageal membrane (i.e., the supradiaphragmatic continuation of the endothoracic fascia) and loss of elasticity in the lower fascial layer (i.e., the infradiaphragmatic continuation of the transversalis fascia). Consequently, the phrenoesophageal membrane yields to stretching in the cranial direction due to the persistent intra-abdominal pressure and the tug of esophageal shortening on swallowing. Interestingly, the stretching and thinning occurs more anteriorly and posteriorly, with fixation of the left crus of the diaphragm to the stomach at the 3 o'clock position, as viewed from the foot. This creates an anterior and posterior hernia sac, the latter of which is often filled with epiphrenic and retroperitoneal fat. These observations point to the conclusion that the development of a hiatal hernia is an age-related phenomenon secondary to repetitive upward stretching of the phrenoesophageal membrane.

Clinical Manifestations

The clinical presentation of a giant hiatal (paraesophageal) hernia differs from that of a sliding hernia. There is usually a higher prevalence of symptoms of dysphagia and postprandial fullness with PEHs, but the typical symptoms of heartburn and regurgitation present in sliding hiatal hernias can also occur. Both are caused by gastroesophageal reflux secondary to an underlying mechanical deficiency of the cardia. The symptoms of dysphagia and postprandial fullness in patients with a PEH are explained by the compression of the adjacent esophagus by a distended cardia, or twisting of the GEJ by the torsion of the stomach that occurs as it becomes progressively displaced in the chest. The postprandial fullness or retrosternal chest pain is a thought to be a result of distension of the stomach with gas or food in the hiatal hernia. Many patients with sliding hernias and reflux symptoms will lose the reflux symptoms when the hernia evolves into the paraesophageal variety. This can be explained by the re-creation of the cardiophrenic angle when the stomach herniates alongside the GEJ or becomes twisted in the sac. Repair of the hernia without addressing the reflux can create extremely bothersome heartburn. Respiratory complications are frequently associated with a PEH, and consist of dyspnea and recurrent pneumonia from aspiration. New research demonstrates that the cause of dyspnea in the presence of a giant PEH is more likely to be left atrial compression, decreasing cardiac output, than a restrictive pulmonary effect, as has been hypothesized for many years.

Approximately one third of patients with a PEH are found to be anemic, which is due to recurrent bleeding from ulceration of the gastric mucosa in the herniated portion of the stomach, even if ulcerations are not detected at the time of endoscopy. The association of anemia and PEH is best proven by fixing the hernia. Anemia is corrected in >90% of patients with this condition. With time, more and more stomach migrates into the chest and can cause intermittent foregut obstruction due to the

rotation that has occurred. In contrast, many patients with PEH are asymptomatic or complain of minor symptoms. However, the presence of a PEH can be life threatening in that the hernia can lead to sudden catastrophic events, such as excessive bleeding or volvulus with acute gastric obstruction or infarction. With mild dilatation of the stomach, the gastric blood supply can be markedly reduced, causing gastric ischemia, ulceration, perforation, and sepsis. The probability of incarceration/strangulation is not well known, although recent studies suggest that the lifetime risk is less than 5%, making this concern an insufficient concern for routine repair of the asymptomatic PEH.

The symptoms of sliding hiatal hernias are usually due to functional abnormalities associated with gastroesophageal reflux and include heartburn, regurgitation, and dysphagia. These patients have a mechanically defective LES, giving rise to the reflux of gastric juice into the esophagus and the symptoms of heartburn and regurgitation. The symptom of dysphagia occurs from the presence of mucosal edema, Schatzki's ring, stricture, or the inability to organize peristaltic activity in the body of the esophagus as a consequence of the disease.

There is a group of patients with sliding hiatal hernias not associated with reflux disease who have dysphagia without any obvious endoscopic or manometric explanation. Video barium radiograms have shown that the cause of dysphagia in these patients is an obstruction of the swallowed bolus by diaphragmatic impingement on the herniated stomach. Manometrically, this is reflected by a double-humped high-pressure zone at the GEJ. The first pressure rise is due to diaphragmatic impingement on the herniated stomach, and the second to the true distal esophageal sphincter. These patients usually have a mechanically competent sphincter, but the impingement of the diaphragm on the stomach can result in propelling the contents of the supradiaphragmatic portion of the stomach up into the esophagus and pharynx, resulting in complaints of pharyngeal regurgitation and aspiration. Consequently, this abnormality is often confused with typical GERD. Surgical reduction of the hernia results in relief of the dysphagia in 91% of patients.

Diagnosis

A chest X ray with the patient in the upright position can diagnose a hiatal hernia if it shows an air-fluid level behind the cardiac shadow. This is usually caused by a PEH or an intrathoracic stomach. The accuracy of the upper GI barium study in detecting a paraesophageal hiatal hernia is greater than for a sliding hernia because the latter can often spontaneously reduce. The paraesophageal hiatal hernia is a permanent herniation of the stomach into the thoracic cavity, so a barium swallow provides the diagnosis in virtually every case. Attention should be focused on the position of the GEJ, when seen, to differentiate it from a type II hernia (see Fig. 25-39B and C). Fiber-optic esophagoscopy is useful in the diagnosis and classification of a hiatal hernia because the scope can be retroflexed. In this position, a sliding hiatal hernia can be identified by noting a gastric pouch lined with rugal folds extending above the impression caused by the crura of the diaphragm, or measuring at least 2 cm between the crura, identified by having the patient sniff, and the squamocolumnar junction on withdrawal of the scope (Fig. 25-40). A PEH is identified on retroversion of the scope by noting a separate orifice adjacent to the GEJ into which gastric rugal folds ascend. A sliding-rolling or mixed hernia can be identified by noting a gastric pouch lined with rugal folds above the diaphragm, with the GEJ entering about midway up the side of the pouch.

Figure 25-40. Endoscopic view through a retroflexed fiber-optic gastroscope showing the shaft of the scope (arrow) coming down through a sliding hernia. Note the gastric rugal folds extending above the impression caused by the crura of the diaphragm. *(Reproduced with permission from DeMeester TR, Bonavina L: Paraesophageal hiatal hernia, in Nyhus LM, Condon RE (eds):* Hernia, *3rd ed. Philadelphia: Lippincott, 1989, p 689.)*

Pathophysiology

Physiologic testing with 24-hour esophageal pH monitoring has shown increased esophageal exposure to acid gastric juice in 60% of the patients with a paraesophageal hiatal hernia, compared with the observed 71% incidence in patients with a sliding hiatal hernia. It is now recognized that paraesophageal hiatal hernia can be associated with pathologic gastroesophageal reflux.

Physiologic studies have also shown that the competency of the cardia depends on an interrelationship between distal esophageal sphincter pressure, the length of the sphincter that is exposed to the positive-pressure environment of the abdomen, and the overall length of the sphincter. A deficiency in any one of these manometric characteristics of the sphincter is associated with incompetency of the cardia regardless of whether a hernia is present. Patients with a PEH who have an incompetent cardia have been shown to have a distal esophageal sphincter with normal pressure, but a shortened overall length and displacement outside the positive-pressure environment of the abdomen. One might expect esophageal body function to be diminished with the esophagus "accordioned" up into the chest. Surprisingly, esophageal peristalsis in patients with PEH is normal in 88%.

Treatment

The treatment of paraesophageal hiatal hernia is largely surgical. Controversial aspects include: (a) indications for repair, (b) diaphragmatic repair, (c) role of fundoplication, and (d) existence and treatment of the short esophagus.

Indications and Surgical Approach. The presence of a paraesophageal hiatal hernia has traditionally been considered an indication for surgical repair. This recommendation is largely

based upon two clinical observations. First, retrospective studies have shown a significant incidence of catastrophic, life-threatening complications of bleeding, infarction, and perforation in patients being followed with known paraesophageal herniation. Second, emergency repair carries a high mortality. In the classic report of Skinner and Belsey, six of 21 patients with a PEH, treated medically because of minimal symptoms, died from the complications of strangulation, perforation, exsanguinating hemorrhage, or acute dilatation of the herniated intrathoracic stomach. For the most part, these catastrophes occurred without warning. Others have reported similar findings.

Recent studies suggest that catastrophic complications may be somewhat less common. Allen and colleagues followed 23 patients for a median of 78 months with only four patients progressively worsening. There was a single mortality secondary to aspiration that occurred during a barium swallow examination to investigate progressive symptoms. Although emergency repairs had a median hospital stay of 48 days compared to a stay of 9 days in those having elective repair, there were only three cases of gastric strangulation in 735 patient-years of follow-up.

If surgery is delayed and repair is done on an emergency basis, operative mortality is high, compared to <1% for an elective repair. With this in mind, patients with a PEH are generally counseled to have elective repair of their hernia, particularly if they are symptomatic. Watchful waiting of asymptomatic PEHs may be an acceptable option.

The surgical approach to repair of a paraesophageal hiatal hernia may be either transabdominal (laparoscopic or open) or transthoracic. Each has its advantages and disadvantages. A transthoracic approach facilitates complete esophageal mobilization but is rarely used because the access trauma and postoperative pain are significantly greater than a laparoscopic approach.

4▶

The transabdominal approach facilitates reduction of the volvulus that is often associated with PEHs. Although some degree of esophageal mobilization can be accomplished transhiatally, complete mobilization to the aortic arch is difficult or impossible without risk of injury to the vagal nerves.

Laparoscopic repair of PEH would appear to have become the standard approach. Laparoscopic repair of a pure type II, or mixed type III PEH is an order of magnitude more difficult than a standard laparoscopic Nissen fundoplication. Most would recommend that these procedures are best avoided until the surgeon has accumulated considerable experience with laparoscopic antireflux surgery. There are several reasons for this. First, the vertical and horizontal volvulus of the stomach often associated with PEHs makes identification of the anatomy, in particular the location of the esophagus, difficult. Second, dissection of a large PEH sac may result in significant bleeding if the surgeon deviates from the correct plane of dissection between the peritoneal sac and the endothoracic fascia. Finally, redundant tissue present at the GEJ following dissection of the sac frustrates the creation of a fundoplication. This tissue, which includes the epiphrenic fat pad and hernia sac should be removed at the time of PEH repair. Mindful of these difficulties, and given appropriate experience, patients with PEH may be approached laparoscopically, with expectation of success in the majority.

Diaphragmatic Repair

It has been shown that PEH repair has a relatively high incidence of recurrence (10%–40%) when the crura is closed primarily with permanent suture. Techniques to reduce hernia recurrence continue to evolve. Most surgeons believe that recurrence may be reduced with the use of synthetic or biologic mesh to reinforce the standard crural closure. Randomized controlled studies have demonstrated a reduction in PEH recurrence rate when mesh was used. Nonabsorbable synthetic mesh must be used carefully and not in a keyhole fashion at the hiatus because of a potential risk of esophagus or gastric erosion and mesh infection. Biologic mesh (acellular porcine dermis, acellular human dermis, porcine small intestinal submucosa) has become more widely used, but these meshes are significantly more expensive than synthetic mesh and the only randomized study supporting biologic mesh usage failed to demonstrate superiority over suture alone, after 5 years of rigorous follow up.

Role of Fundoplication in Giant Hiatal Hernia Repair. Controversy remains as to whether to perform an antireflux procedure at all, in selected cases only, or in all patients. The case against an antireflux procedure rests on the frequency of significant postoperative complications secondary to the fundoplication, as well as the slightly longer operative time and increased cost that additional surgery entails. Most advocate the routine addition of an antireflux procedure following repair of the hernia defect. There are several reasons for this. Physiologic testing with 24-hour esophageal pH monitoring has shown increased esophageal exposure to acid gastric juice in 60% to 70% of patients with a paraesophageal hiatal hernia, nearly identical to the observed 71% incidence in patients with a sliding hiatal hernia. Furthermore, there is no relation between the symptoms experienced by the patient with a PEH and the competency of the cardia. Finally, dissection of the gastroesophageal esophagus may lead to postoperative reflux despite a negative preoperative pH score.

The Short Esophagus and PEH

Giant PEH can be associated with a short esophagus in up to 5% to 20% of patients as a result of chronic cephalad displacement of the GEJ. The presence of a short esophagus increases the difficulty of laparoscopic PEH repair. Approximately 10% to 20% of surgical failures with PEH repair is due to the lack of recognition of a short esophagus. Preoperative results of barium swallow and esophagogastroduodenoscopy may provide an indication of short esophagus, but no combination of preoperative clinical variables reliably predict the presence of short esophagus, defined as the failure to achieve 2.5 cm of intra-abdominal esophagus with standard mediastinal dissection techniques. Hence, the diagnosis of this entity continues to be made definitively only in the operating room. Collis gastroplasty achieves esophageal lengthening by creation of a neoesophagus using the gastric cardia. The totally laparoscopic approach to the short esophagus has evolved from a method using an end-to-end anastomosis circular stapler to the current approach that uses a linear stapler creating a stapled wedge gastroplasty. Elements of importance in fashioning the fundoplication after Collis gastroplasty include placement of the initial suture of the fundoplication on the esophagus, immediately above the GEJ to ensure that acid-secreting (gastric) mucosa does not reside above the fundoplication. A second element that ensures safety and avoids wrap deformation is to place the gastric portion of the staple line against the neoesophagus, such that the tip of the gastric staple line sits adjacent to the middle suture of the fundoplication on the right side of the esophagus.

Results

Most outcome studies report relief of symptoms following surgical repair of PEHs in more than 90% of patients. The current literature suggests that laparoscopic repair of a paraesophageal hiatal hernia can be successful. Most authors report symptomatic improvement in 80% to 90% of patients, and <10% to 15% prevalence of recurrent symptomatic hernia. However, the problem of recurrent asymptomatic or minimally symptomatic hernia following PEH repair, open or laparoscopic, is becoming increasingly appreciated. Recurrent hiatal hernia is the most common cause of anatomic failure following laparoscopic Nissen fundoplication done for GERD (5%–10%), but this risk is compounded for the giant hernia where radiologic recurrence is detected in 25% to 40% of patients. It appears that optimal results with open or laparoscopic giant hiatal hernia repair should include options for mesh buttressing of hiatal closure and selective esophageal lengthening with one of the many techniques developed for the creation of a Collis gastroplasty. Despite this high incidence of radiologic recurrence, and the surgical pursuit of a remedy, it must be reinforced that asymptomatic recurrent hernia, like primary PEH, do not need to be repaired. The risk of incarceration, strangulation, or obstruction is minimal.

SCHATZKI'S RING

Schatzki's ring is a thin submucosal circumferential ring in the lower esophagus at the squamocolumnar junction, often associated with a hiatal hernia. Its significance and pathogenesis are unclear (Fig. 25-41). The ring was first noted by Templeton, but Schatzki and Gary defined it as a distinct entity in 1953. Its prevalence varies from 0.2% to 14% in the general population, depending on the technique of diagnosis and the criteria used. Stiennon believed the ring to be a pleat of mucosa formed by infolding of redundant esophageal mucosa due to shortening of the esophagus. Others believe the ring to be congenital, and still others suggest it is an early stricture resulting from inflammation of the esophageal mucosa caused by chronic reflux.

Figure 25-41. Barium esophagogram showing Schatzki's ring (i.e., a thin circumferential ring in the distal esophagus at the squamocolumnar junction). Below the ring is a hiatal hernia.

Schatzki's ring is a distinct clinical entity having different symptoms, upper GI function studies, and response to treatment compared with patients with a hiatal hernia, but without a ring. Twenty-four-hour esophageal pH monitoring has shown that patients with a Schatzki's ring have a lower incidence of reflux than hiatal hernia controls. They also have better LES function. This, together with the presence of a ring, could represent a protective mechanism to prevent gastroesophageal reflux.

Symptoms associated with Schatzki's ring are brief episodes of dysphagia during hurried ingestion of solid foods. Its treatment has varied from dilation alone to dilation with antireflux measures, antireflux procedure alone, incision, and even excision of the ring. Little is known about the natural progression of Schatzki's rings. Using radiologic techniques, Chen and colleagues showed progressive stenosis of rings in 59% of patients, whereas Schatzki found that the rings decreased in diameter in 29% of patients and remained unchanged in the rest.

Symptoms in patients with a ring are caused more by the presence of the ring than by gastroesophageal reflux. Most patients with a ring but without proven reflux respond to one dilation, while most patients with proven reflux require repeated dilations. In this regard, the majority of Schatzki's ring patients without proven reflux have a history of ingestion of drugs known to be damaging to the esophageal mucosa. Bonavina and associates have suggested drug-induced injury as the cause of stenosis in patients with a ring, but without a history of reflux. Because rings also occur in patients with proven reflux, it is likely that gastroesophageal reflux also plays a part. This is supported by the fact that there is less drug ingestion in the history of these patients. Schatzki's ring is probably an acquired lesion that can lead to stenosis from chemical-induced injury by pill lodgment in the distal esophagus, or from reflux-induced injury to the lower esophageal mucosa.

The best form of treatment of a symptomatic Schatzki's ring in patients who do not have reflux consists of esophageal dilation for relief of the obstructive symptoms. In patients with a ring who have proven reflux and a mechanically defective sphincter, an antireflux procedure is necessary to obtain relief and avoid repeated dilation.

SCLERODERMA

Scleroderma is a systemic disease accompanied by esophageal abnormalities in approximately 80% of patients. In most, the disease follows a prolonged course. Renal involvement occurs in a small percentage of patients and signals a poor prognosis. The onset of the disease is usually in the third or fourth decade of life, occurring twice as frequently in women as in men.

Small vessel inflammation appears to be an initiating event, with subsequent perivascular deposition of normal collagen, which may lead to vascular compromise. In the GI tract, the predominant feature is smooth muscle atrophy. Whether the atrophy in the esophageal musculature is a primary effect or occurs secondary to a neurogenic disorder is unknown. The results of pharmacologic and hormonal manipulation, with agents that act either indirectly via neural mechanisms or directly on the muscle, suggest that scleroderma is a primary neurogenic disorder. Methacholine, which acts directly on smooth muscle receptors, causes a similar increase in LES pressure in normal

controls and in patients with scleroderma. Edrophonium, a cholinesterase inhibitor that enhances the effect of acetylcholine when given to patients with scleroderma, causes an increase in LES pressure that is less marked in these patients than in normal controls, suggesting a neurogenic rather than myogenic etiology. Muscle ischemia due to perivascular compression has been suggested as a possible mechanism for the motility abnormality in scleroderma. Others have observed that in the early stage of the disease, the manometric abnormalities may be reversed by reserpine, an agent that depletes catecholamines from the adrenergic system. This suggests that, in early scleroderma, an adrenergic overactivity may be present that causes a parasympathetic inhibition, supporting a neurogenic mechanism for the disease. In advanced disease manifested by smooth muscle atrophy and collagen deposition, reserpine no longer produces this reversal. Consequently, from a clinical perspective, the patient can be described as having a poor esophageal pump and a poor valve.

The diagnosis of scleroderma can be made manometrically by the observation of normal peristalsis in the proximal striated esophagus, with absent peristalsis in the distal smooth muscle portion (Fig. 25-42). The LES pressure is progressively weakened as the disease advances. Because many of the systemic sequelae of the disease may be nondiagnostic, the motility pattern is frequently used as a specific diagnostic indicator. Gastroesophageal reflux commonly occurs in patients with scleroderma, because they have both hypotensive sphincters and poor esophageal clearance. This combined defect can lead to severe esophagitis and stricture formation. The typical barium swallow shows a dilated, barium-filled esophagus, stomach, and duodenum, or a hiatal hernia with distal esophageal stricture and proximal dilatation (Fig. 25-43).

Traditionally, esophageal symptoms have been treated with PPIs, antacids, elevation of the head of the bed, and

multiple dilations for strictures, with generally unsatisfactory results. The degree of esophagitis is usually severe and may lead to marked esophageal shortening as well as stricture. Scleroderma patients have frequently had numerous dilations before they are referred to the surgeon. The surgical management is somewhat controversial, but the majority of opinion suggests that a partial fundoplication (anterior or posterior) performed laparoscopically is the procedure of choice. The need for a partial fundoplication is dictated by the likelihood of severe dysphagia if a total fundoplication is performed in the presence of aperistalsis. Esophageal shortening may require a Collis gastroplasty in combination with a partial fundoplication. Surgery reduces esophageal acid exposure, but does not return it to normal because of the poor clearance function of the body of the esophagus. Only 50% of the patients have a good-to-excellent result. If the esophagitis is severe, or there has been a previous failed antireflux procedure and the disease is associated with delayed gastric emptying, a gastric resection with Roux-en-Y gastrojejunostomy has proved the best option.

Eosinophilic Esophagitis

Eosinophilic esophagitis (EE) was first described in 1977, but has become well known only in the last two decades. The condition

Figure 25-44. The esophagus on the left shows a stacking of rings, demonstrating eosinophilic esophagus. The esophagus on the right is a normal barium swallow.

is characterized by a constellation of symptoms, endoscopic and radiologic findings, and distinctive pathology. The etiology of eosinophilic esophagitis is not entirely known but its similarities, immunologically, to asthma suggest that it is a form of "allergic esophagitis."

Symptoms

The presentation of eosinophilic esophagitis is chest pain, (often postprandial) and dysphagia. Dysphagia may occur with liquids or solids, but solid food dysphagia is most common. Because dysphagia and chest pain are characteristic of GERD, EE is often confused with GERD; however, EE does not respond to proton pump inhibitors. The evaluation of the patient with EE and dysphagia and chest pain with esophagram and endoscopy usually reveals the diagnosis.

Signs

A barium swallow should be the first test obtained in the patient with dysphagia. EE has a characteristic finding often called the "ringed esophagus" or the "feline esophagus," as the esophageal rings are felt to look like the stripes on a housecat (Fig. 25-44). The endoscopic appearance of EE is also characteristic, and also appears as a series of rings (Fig. 25-45).

Pathology

Endoscopic biopsy specimens should be taken when eosinophilic esophagus is suspected. To make the diagnosis of EE, the pathologist should see a minimum of 15 eosinophils per high powered field, usually at the base of the epithelium (Fig. 25-46).

Treatment

The treatment of EE is largely symptomatic and includes testing for food allergies, and elimination of identified items from the diet. Second line therapy includes inhaled or ingested corticosteroids, as would be used to treat asthma. If dysphagia is not relieved with steroids, it may be necessary to dilate the esophagus. Because of the length of esophageal involvement, rigid dilators (Maloney or Savary) are often used. Great care must be exercised, as the inflamed EE is quite friable. The mucosal tears easily, and esophageal perforation (full thickness laceration) has been reported with EE dilation.

MOTILITY DISORDERS OF THE PHARYNX AND ESOPHAGUS

Clinical Manifestations

Dysphagia (i.e., difficulty in swallowing) is the primary symptom of esophageal motor disorders. Its perception by the patient is a balance between the severity of the underlying abnormality causing the dysphagia, and the adjustment made by the patient in altering eating habits. Consequently, any complaint of dysphagia must include an assessment of the patient's dietary history. It must be known whether the patient experiences pain, chokes, or vomits with eating; whether the patient requires liquids with the meal, is the last to finish, or is forced to interrupt or avoid a social meal; and whether he or she has been admitted to the hospital for food impaction. These assessments, plus an evaluation of the patient's nutritional status, help to determine how severe the dysphagia is and judge the need for surgical

Figure 25-45. The endoscopic appearance of eosinophilic esophagitis is characteristically a series of stacked mucosal rings.

Figure 25-46. A cluster of eosinophils are visualized in the esophageal epithelium in a patient with EE.

intervention, rather than more conservative methods of treating dysphagia.

Motility Disorders of the Pharynx and Upper Esophagus – Transit Dysphagia

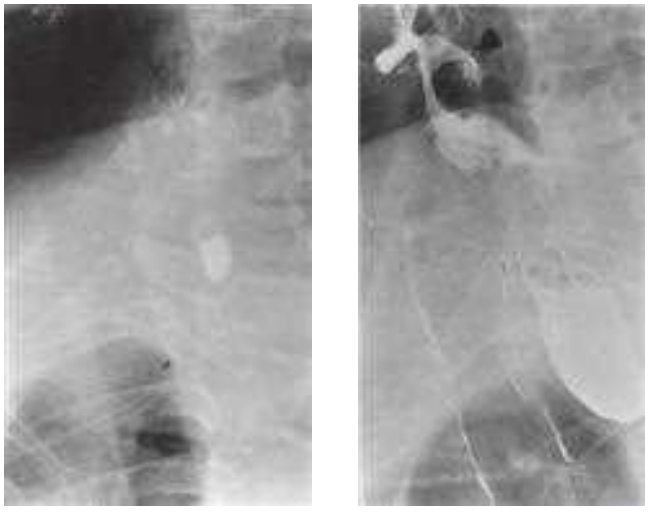
Disorders of the pharyngeal phase of swallowing result from a discoordination of the neuromuscular events involved in chewing, initiation of swallowing, and propulsion of the material from the oropharynx into the cervical esophagus. They can be categorized into one or a combination of the following abnormalities: (a) inadequate oropharyngeal bolus transport; (b) inability to pressurize the pharynx; (c) inability to elevate the larynx; (d) discoordination of pharyngeal contraction and cricopharyngeal relaxation; and (e) decreased compliance of the pharyngoesophageal segment secondary to neuromuscular disease. The latter may result in incomplete relaxation of the cricopharyngeus and cervical esophagus during swallowing. Taken together, these disorders are termed transit dysphagia by many

Transit dysphagia is usually congenital or results from acquired disease involving the central and peripheral nervous system. This includes cerebrovascular accidents, brain stem tumors, poliomyelitis, multiple sclerosis, Parkinson's disease, pseudobulbar palsy, peripheral neuropathy, and operative damage to the cranial nerves involved in swallowing. Pure muscular diseases such as radiation-induced myopathy, dermatomyositis, myotonic dystrophy, and myasthenia gravis are less common causes. Rarely, extrinsic compression of the cervical esophagus by thyromegaly, lymphadenopathy, or hyperostosis of the cervical spine can cause transit dysphagia.

Diagnostic Assessment of the Cricopharyngeal Segment.

Transit dysphagia difficult to assess with standard manometric techniques because of the rapidity of the oropharyngeal phase of swallowing, the elevation of the larynx, and the asymmetry of the cricopharyngeus. Video- or cineradiography is currently the most objective test to evaluate oropharyngeal bolus transport, pharyngeal compression, relaxation of the pharyngoesophageal segment, and the dynamics of airway protection during swallowing. It readily identifies a diverticulum (Fig. 25-47), stasis of the contrast medium in the valleculae, a cricopharyngeal bar, and/or narrowing of the pharyngoesophageal segment. These are anatomic manifestations of neuromuscular disease, and result from the loss of muscle compliance in portions of the pharynx and esophagus composed of skeletal muscle.

Careful analysis of video- or cineradiographic studies combined with manometry using specially designed catheters can identify the cause of a pharyngoesophageal dysfunction in



A **B**

most situations (Fig. 25-48). Motility studies may demonstrate inadequate pharyngeal pressurization, insufficient or lack of cricopharyngeal relaxation, marked discoordination of pharyngeal pressurization, cricopharyngeal relaxation and cervical esophageal contraction, or a hypopharyngeal bolus pressure suggesting decreased compliance of the skeletal portion of the cervical esophagus.

In many patients with cricopharyngeal dysfunction, including those with Zenker's diverticulum, it has been difficult to consistently demonstrate a motility abnormality or discoordination of pharyngoesophageal events. The abnormality most apt to be present is a loss of compliance in the pharyngoesophageal segment manifested by an increased bolus pressure. Cook and colleagues have demonstrated an increased resistance to the movement of a bolus through what appears on manometry to be a completely relaxed cricopharyngeal sphincter. Using simultaneous manometry and videofluoroscopy, they showed that, in these patients, the cricopharyngeus is only partially relaxed; that is, the sphincter is relaxed enough to allow a drop of its pressure to esophageal baseline on manometry, but insufficiently relaxed to allow unimpaired passage of the bolus into the esophagus. This incomplete relaxation is due to a loss of compliance of the muscle in the pharyngoesophageal segment, and may be associated with a cricopharyngeal bar or Zenker's diverticulum. This decreased compliance of the cricopharyngeal sphincter can be recognized on esophageal manometry by a "shoulder" on the pharyngeal pressure wave, the amplitude of which correlates directly with the degree of outflow obstruction (Fig. 25-49). Increasing the diameter of this noncompliant segment reduces the resistance imposed on the passage of a bolus. Consequently, patients with low pharyngeal pressure (i.e., poor piston function of the pharynx), or patients with increased resistance of the pharyngocervical esophageal segment from loss of skeletal muscle compliance, are improved by a cricopharyngeal myotomy. This enlarges the pharyngoesophageal segment and reduces outflow resistance. Esophageal muscle biopsy specimens from patients with Zenker's diverticulum have shown histologic evidence of the restrictive myopathy in the cricophayngeous muscle. These findings correlate well with the observation of a decreased compliance of the upper esophagus demonstrated by videoradiography and the findings on detailed manometric studies of the pharynx and cervical esophagus. They suggest that the diverticulum develops as a consequence of the outflow resistance to bolus transport through the noncompliant muscle of the pharyngoesophageal segment.

The requirements for a successful pharyngoesophageal myotomy are: (a) adequate oropharyngeal bolus transport; (b) the presence of an intact swallowing reflex; (c) reasonable coordination of pharyngeal pressurization with cricopharyngeal relaxation; and (d) a cricopharyngeal bar, Zenker's diverticulum, or a narrowed pharyngoesophageal segment on videoesophagogram and/or the presence of excessive pharyngoesophageal shoulder pressure on motility study.

Zenker's Diverticulum. In the past, the most common recognized sign of cricopharyngeal dysfunction was the presence of a Zenker's diverticulum, originally described by Ludlow in 1769. The eponym resulted from Zenker's classic clinicopathologic descriptions of 34 cases published in 1878. Pharyngoesophageal diverticula have been reported to occur in 1 of 1000 routine barium examinations, and classically occur in elderly, white males. Zenker's diverticula tend to enlarge progressively with

time due to the decreased compliance of the skeletal portion of the cervical esophagus that occurs with aging.

Presenting symptoms include dysphagia associated with the spontaneous regurgitation of undigested, bland material, often interrupting eating, or drinking. On occasion, the dysphagia can be severe enough to cause debilitation and significant weight loss. Chronic aspiration and repetitive respiratory infection are common associated complaints. Once suspected, the diagnosis is established by a barium swallow. Endoscopy is usually difficult in the presence of a cricopharyngeal diverticulum, and potentially dangerous, owing to obstruction of the true esophageal lumen by the diverticulum and the attendant risk of diverticular perforation.

Cricopharyngeal Myotomy. The low morbidity and mortality associated with cricopharyngeal and upper esophageal myotomy have encouraged a liberal approach toward its use for almost any problem in the oropharyngeal phase of swallowing. This attitude has resulted in an overall success rate in the relief of symptoms of only 64%. When patients are selected for surgery using radiographic or motility markers of disease, a much higher proportion will benefit. Two methods of cricopharyngoesophageal myotomy are in common use, one using traditional surgical approaches, and one using rigid laryngoscopy and a linear cutting stapler.

Open Cricopharyngeal Myotomy, Diverticulopexy, and Diverticulectomy. The myotomy can be performed under local or general anesthesia through an incision along the anterior border of the left sternocleidomastoid muscle. The pharynx and cervical esophagus are exposed by retracting the sternocleidomastoid muscle and carotid sheath laterally, and the thyroid, trachea, and larynx medially (Fig. 25-50). When a pharyngoesophageal diverticulum is present, localization of the pharyngoesophageal segment is easy. The diverticulum is carefully freed from the overlying areolar tissue to expose its neck, just below the inferior pharyngeal constrictor and above the cricopharyngeus muscle. It can be difficult to identify the cricopharyngeus muscle in the absence of a diverticulum. A benefit of local anesthesia is that the patient can swallow and demonstrate an area of persistent narrowing at the pharyngoesophageal junction. Furthermore, before closing the incision, gelatin can be fed to the patient to ascertain whether the symptoms have been relieved, and to inspect the opening of the previously narrowed pharyngoesophageal segment. Under general anesthesia, and in the absence of a diverticulum, the placement of a nasogastric tube to the level of the manometrically determined cricopharyngeal sphincter helps in localization of the structures. The myotomy is extended cephalad by dividing 1 to 2 cm of inferior constrictor muscle of the pharynx, and caudad by dividing the cricopharyngeal muscle and the cervical esophagus for a length of 4 to 5 cm. The cervical wound is closed only when all oozing of blood has ceased, because a hematoma after this procedure is common, and is often associated with temporary dysphagia while the hematoma absorbs. Oral alimentation is started the day after surgery. The patient is usually discharged on the first or second postoperative day.

If a diverticulum is present and is large enough to persist after a myotomy, it may be sutured in the inverted position to the prevertebral fascia using a permanent suture (i.e., diverticulopexy) (Fig. 25-51). If the diverticulum is excessively large so that it would be redundant if suspended, or if its walls are thickened, a diverticulectomy should be performed. This is best performed under general anesthesia by placing a Maloney dilator (48F) in the esophagus, after controlling the neck of the diverticulum and after myotomy. A linear stapler is placed across the neck of the diverticulum and the diverticulum is excised distal to the staple line. The security of this staple line and effectiveness of the myotomy may be tested before hospital discharge with a water soluble contrast esophagogram. Postoperative complications include fistula formation, abscess, hematoma, recurrent nerve paralysis, difficulties in phonation, and Horner's syndrome. The incidence of the first two can be reduced by performing a diverticulopexy rather than diverticulectomy.

Endoscopic Cricopharyngotomy. Endoscopic stapled cricopharyngotomy and diverticulotomy recently has been described. This procedure is most effective for larger diverticula (>2 cm), and may be impossible to perform for the small diverticulum. The procedure uses a specialized "diverticuloscope" with two retractable valves passed into the hypopharynx. The lips of the diverticuloscope are positioned so that one lip lies in the esophageal lumen and the other in the diverticular lumen. The valves of the diverticuloscope are retracted appropriately so as to visualize the septum interposed between the diverticulum and the esophagus. An endoscopic linear stapler is introduced into the diverticuloscope and positioned against the common septum with

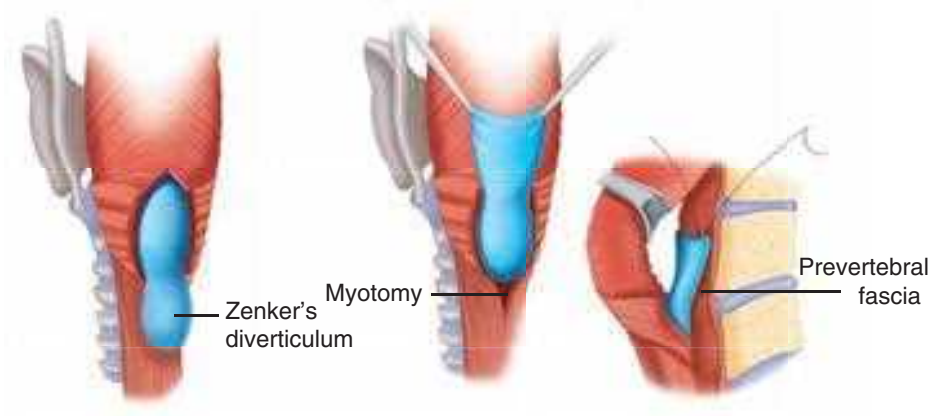

Figure 25-51. Posterior of the anatomy of the pharynx and cervical esophagus showing pharyngoesophageal myotomy and pexing of the diverticulum to the prevertebral fascia.

the anvil in the diverticulum and the cartridge in the esophageal lumen. Firing of the stapler divides the common septum between the posterior esophageal and the diverticular wall over a length of 30 mm, placing three rows of staples on each side. More than one stapler application may be needed, depending on the size of the diverticulum (Fig. 25-52). The patient is allowed to resume liquid feeds immediately, and is usually discharged the day after surgery. Complications are rare and may include perforation at the apex of the diverticulum, and failure to relieve dysphagia resulting from incomplete myotomy. The former complication can usually be treated with antibiotics, but may rarely require neck drainage.

Recurrence of a Zenker's diverticulum may occur with long follow-up, and is more common after diverticulectomy without myotomy, presumably due to persistence of the underlying loss of compliance of the cervical esophagus when a myotomy is not performed. After endoscopic cricopharyngotomy lateral residual "pouches" may be seen on radiographs, but are rarely responsible for residual or recurrent symptoms if the myotomy has been complete.

Postoperative motility studies have shown that the peak pharyngeal pressure generated on swallowing is not affected, the resting cricopharyngeal pressure is reduced but not eliminated, and the cricopharyngeal sphincter length is shortened. Consequently, after myotomy, there is protection against esophagopharyngeal regurgitation.

Motility Disorders of the Esophageal Body and Lower Esophageal Sphincter

Disorders of the esophageal phase of swallowing result from abnormalities in the propulsive pump action of the esophageal body or the relaxation of the LES. These disorders result from either primary esophageal abnormalities, or from generalized neural, muscular, or collagen vascular disease (Table 25-8). The use of standard and high-resolution esophageal manometry techniques has allowed specific primary esophageal motility disorders to be identified out of a pool of nonspecific motility abnormalities. Primary esophageal motor disorders include achalasia, DES, nutcracker esophagus, and the hypertensive LES. The manometric characteristics of these disorders are shown in Table 25-9.

The boundaries between the primary esophageal motor disorders are vague, and intermediate types exist, some of which may combine more than one type of motility pattern. These findings indicate that esophageal motility disorders should be looked at as a spectrum of abnormalities that reflects various stages of destruction of esophageal motor function.

Achalasia. The best known and best understood primary motility disorder of the esophagus is achalasia, with an incidence of six per 100,000 population per year. Although complete absence of peristalsis in the esophageal body has been proposed as the major abnormality, present evidence indicates achalasia is a primary disorder of the LES. This is based on 24-hour outpatient esophageal motility monitoring, which shows that, even in advanced disease, up to 5% of contractions can be peristaltic. Simultaneous esophageal waves develop as a result of the increased resistance to esophageal emptying caused by the

Table 25-8

Esophageal motility disorders

Primary esophageal motility disorders
Achalasia, "vigorous" achalasia
Diffuse and segmental esophageal spasm
Nutcracker esophagus
Hypertensive lower esophageal sphincter
Nonspecific esophageal motility disorders
Secondary esophageal motility disorders
Collagen vascular diseases: progressive systemic sclerosis, polymyositis and dermatomyositis, mixed connective tissue disease, systemic lupus erythematosus, etc.
Chronic idiopathic intestinal pseudoobstruction
Neuromuscular diseases
Endocrine and metastatic disorders

Table 25-9

Manometric characteristics of the primary esophageal motility disorders

Achalasia
Incomplete lower esophageal sphincter (LES) relaxation (<75% relaxation)
Aperistalsis in the esophageal body
Elevated LES pressure ≤26 mmHg
Increased intraesophageal baseline pressures relative to gastric baseline
Diffuse esophageal spasm (DES)
Simultaneous (nonperistaltic contractions) (>20% of wet swallows)
Repetitive and multipeaked contractions
Spontaneous contractions
Intermittent normal peristalsis
Contractions may be of increased amplitude and duration
Nutcracker esophagus
Mean peristaltic amplitude (10 wet swallows) in distal esophagus ≥180 mmHg
Increased mean duration of contractions (>7.0 s)
Normal peristaltic sequence
Hypertensive lower esophageal sphincter
Elevated LES pressure (≥26 mmHg)
Normal LES relaxation
Normal peristalsis in the esophageal body
Ineffective esophageal motility disorders
Decreased or absent amplitude of esophageal peristalsis (<30 mmHg)
Increased number of nontransmitted contractions

nonrelaxing LES. This conclusion is supported by experimental studies in which a band placed loosely around the GEJ in experimental models did not change sphincter pressures, but resulted in impaired relaxation of the LES and outflow resistance. This led to a markedly increased frequency of simultaneous waveforms and a decrease in contraction amplitude. The changes were associated with radiographic dilation of the esophagus and were reversible after removal of the band. Observations in patients with pseudoachalasia due to tumor infiltration, a tight stricture in the distal esophagus, or an antireflux procedure that is too tight also provide evidence that dysfunction of the esophageal body can be caused by the increased outflow obstruction of a nonrelaxing LES. The observation that esophageal peristalsis can return in patients with classic achalasia following dilation or myotomy provides further support that achalasia is a primary disease of the LES.

The pathogenesis of achalasia is presumed to be a neurogenic degeneration, which is either idiopathic or due to infection. In experimental animals, the disease has been reproduced by destruction of the nucleus ambiguus and the dorsal motor nucleus of the vagus nerve. In patients with the disease, degenerative changes have been shown in the vagus nerve and in the ganglia in the myenteric plexus of the esophagus itself. This degeneration results in hypertension of the LES, a failure of the sphincter to relax on swallowing, elevation of intraluminal esophageal pressure, esophageal dilatation, and a subsequent loss of progressive peristalsis in the body of the esophagus. The esophageal dilatation results from the combination of a nonrelaxing sphincter, which causes a functional retention of ingested material in the esophagus, and elevation of intraluminal pressure from repetitive pharyngeal air swallowing (Fig. 25-53). With time, the functional disorder results in anatomic alterations seen on radiographic studies, such as a dilated esophagus with a tapering, "bird's beak"-like narrowing of the distal end (Fig. 25-54). There is usually an air-fluid level in the esophagus from the retained food and saliva, the height of which reflects the degree of resistance imposed by the nonrelaxing sphincter. As the disease progresses, the esophagus becomes massively dilated and tortuous.

A subgroup of patients with otherwise typical features of classic achalasia has simultaneous contractions of their esophageal body that can be of high amplitude. This manometric pattern has been termed vigorous achalasia, and chest pain episodes

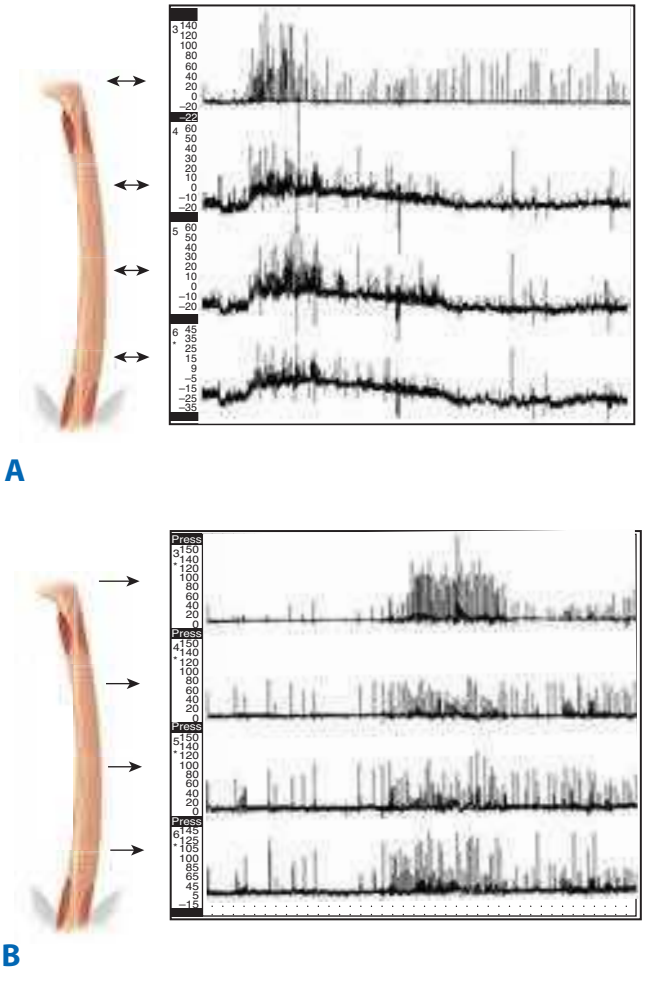

Figure 25-53. Pressurization of esophagus: Ambulatory motility tracing of a patient with achalasia. **A.** Before esophageal myotomy. **B.** After esophageal myotomy. The tracings have been compressed to exaggerate the motility spikes and baseline elevations. Note the rise in esophageal baseline pressure during a meal represented by the rise off the baseline to the left of panel **A.** No such rise occurs postmyotomy (panel **B**).

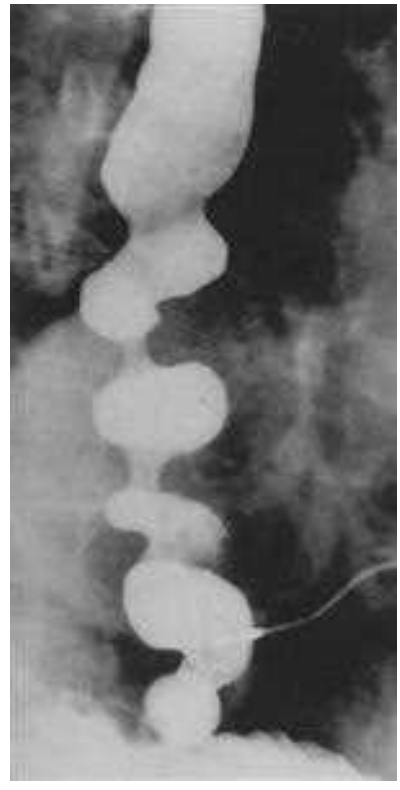

Figure 25-55. Barium esophagogram of patient with diffuse spasm showing the corkscrew deformity.

are a common finding in these patients. Since the development of high resolution esophageal manometry technology, the term *vigorous achalasia* has been replaced with Chicago type 3 achalasia, Differentiation of type 3 achalasia from DES can be difficult. In both diseases, videoradiographic examination may show a corkscrew deformity of the esophagus and diverticulum formation.

Diffuse and Segmental Esophageal Spasm. DES is characterized by substernal chest pain and/or dysphagia. DES differs from classic achalasia in that it is primarily a disease of the esophageal body, produces a lesser degree of dysphagia, causes more chest pain, and has less effect on the patient's general condition. Nonetheless, it is impossible to differentiate achalasia from DES on the basis of symptoms alone. Esophagogram and esophageal manometry are required to distinguish these two entities. True symptomatic DES is a rare condition, occurring about five times less frequently than achalasia.

The causation and neuromuscular pathophysiology of DES are unclear. The basic motor abnormality is rapid wave progression down the esophagus secondary to an abnormality in the latency gradient. Hypertrophy of the muscular layer of the esophageal wall and degeneration of the esophageal branches of the vagus nerve have been observed in this disease, although these are not constant findings. Manometric abnormalities in DES may be present over the total length of the esophageal body, but usually are confined to the distal two thirds. In segmental esophageal spasm, the manometric abnormalities are confined to a short segment of the esophagus.

The classic manometric findings in these patients are characterized by the frequent occurrence of simultaneous waveforms and multipeaked esophageal contractions, which may be of abnormally high amplitude or long duration. Key to the diagnosis of DES is that there remain some peristaltic waveforms in excess of those seen in achalasia. A criterion of 30% or more peristaltic waveforms out of 10 wet swallows has been used to differentiate DES from vigorous achalasia. However, this figure is arbitrary and often debated.

The LES in patients with DES usually shows a normal resting pressure and relaxation on swallowing. A hypertensive sphincter with poor relaxation may also be present. In patients with advanced disease, the radiographic appearance of tertiary contractions appears helical, and has been termed corkscrew esophagus or pseudodiverticulosis (Fig. 25-55). Patients with segmental or diffuse esophageal spasm can compartmentalize the esophagus and develop an epiphrenic or midesophageal diverticulum between two areas of high pressure occurring simultaneously (Fig. 25-56).

Nutcracker Esophagus. The disorder, termed nutcracker or supersqueezeresophagus, was recognized in the late 1970s. Other terms used to describe this entity are hypertensive peristalsis or high-amplitude peristaltic contractions. It is the most common of the primary esophageal motility disorders. By definition the so-called nutcracker esophagus is a manometric abnormality in patients who are characterized by peristaltic esophageal contractions with peak amplitudes greater than two SDs above the normal values in individual laboratories. Contraction amplitudes in these patients can easily be above 400 mmHg. At the lower end of peak pressure, it is unclear whether nutcracker esophagus causes any symptoms. In fact,

Figure 25-56. Barium esophagogram showing a high epiphrenic diverticulum in a patient with diffuse esophageal spasm. *(Reproduced with permission from DeMeester TR, Stein HJ: Surgery for esophageal motor disorders, in Castell DO (ed):* The Esophagus. *Boston: Little, Brown, 1992, p 415.)*

chest pain symptoms in nutcracker esophagus patients may be related to GERD rather than intraluminal hypertension. Treatment in these patients should be aimed at the treatment of GERD. At the high end (peak pressures >300 mmHg) chest pain may be the result of the nutcracker physiology, as treatment directed at reducing intraluminal pressure is more effective than when used for those with lower peak pressures.

Hypertensive Lower Esophageal Sphincter. Hypertensive lower esophageal sphincter (LES) in patients with chest pain or dysphagia was first described as a separate entity by Code and associates. This disorder is characterized by an elevated basal pressure of the LES with normal relaxation and normal propulsion in the esophageal body. About one-half of these patients, however, have associated motility disorders of the esophageal body, particularly hypertensive peristalsis and simultaneous waveforms. In the remainder, the disorder exists as an isolated abnormality. Dysphagia in these patients may be caused by a lack of compliance of the sphincter, even in its relaxed state. Myotomy of the LES may be indicated in patients not responding to medical therapy or dilation. When the symptom contribution of the hypertensive sphincter is in doubt, it is possible to inject the LES with botulinum toxin, endoscopically. If symptoms are relieved (temporarily) with this technique, then it is likely that myotomy will provide more permanent benefit.

Secondary Esophageal Motility Disorders. Connective tissue disease, particularly scleroderma and the CREST syndrome, exhibits severe esophageal motility disorders. Additionally, patients treated as infants for esophageal atresia will often develop secondary motility disorders manifest later in life. Symptoms of these disorders are heartburn and dysphagia. The latter may be a result of a peptic stricture rather than the esophageal dysmotility. An esophageal motility study will usually show severely reduced or absent peristalsis with severely reduced or absent LES pressure. The role of antireflux surgery under these conditions is controversial, but, if performed, should be limited to partial fundoplication, as full (Nissen) fundoplication may result in severe dysphagia.

Nonspecific Esophageal Motor Disorders and Ineffective Esophageal Motility. Many patients complaining of dysphagia or chest pain of noncardiac origin demonstrate a variety of wave patterns and contraction amplitudes on esophageal manometry that are clearly out of the normal range, but do not meet the criteria of a primary esophageal motility disorder. Esophageal motility in these patients frequently shows an increased number of multipeaked or repetitive contractions, contractions of prolonged duration, nontransmitted contractions, an interruption of a peristaltic wave at various levels of the esophagus, or contractions of low amplitude. These motility abnormalities have been termed nonspecific esophageal motility disorders. Their significance in the causation of chest pain or dysphagia is still unclear. Surgery plays no role in the treatment of these disorders unless there is an associated diverticulum.

A clear distinction between primary esophageal motility disorders and nonspecific esophageal motility disorders is often not possible. Patients diagnosed as having nonspecific esophageal motility abnormalities on repeated studies will occasionally show abnormalities consistent with nutcracker esophagus. Similarly, progression from a nonspecific esophageal motility disorder to classic DES has been demonstrated. Therefore, the finding of a nonspecific esophageal motility disorder may represent only a manometric marker of an intermittent, more severe esophageal motor abnormality. Combined ambulatory 24-hour esophageal pH and motility monitoring has shown that an increased esophageal exposure to gastric juice is common in patients diagnosed as having a nonspecific esophageal motility disorder. In some situations, the motor abnormalities may be induced by the irritation of refluxed gastric juice; in other situations, it may be a primary event unrelated to the presence of reflux. High-amplitude peristalsis (nutcracker esophagus) and low-amplitude peristalsis (ineffective esophageal motility) are frequently associated with GERD.

Diverticula of the Esophageal Body. Diverticula of the esophagus may be characterized by their location in the esophagus (proximal, mid-, or distal esophagus), or by the nature of concomitant pathology. Diverticula associated with motor disorders are termed pulsion diverticula and those associated with inflammatory conditions are termed traction diverticula. Pulsion diverticula occur most commonly with nonspecific motility disorders, but can occur with all of the primary motility disorders. In the latter situation, the motility disorder is usually diagnosed before the development of the diverticulum. When associated with achalasia, the development of a diverticulum may temporarily alleviate the symptom of dysphagia by becoming a receptacle for ingested food, and substitute the symptom of dysphagia for postprandial pain and regurgitation of undigested food. If a motility abnormality of the esophageal body or LES cannot be identified, a traction or congenital cause for the diverticulum should be considered.

Because development in radiology preceded development in motility monitoring, diverticula of the esophagus were considered historically to be a primary abnormality, the cause, rather than the consequence, of motility disorders. Consequently, earlier texts focused on them as specific entities based upon their location.

Epiphrenic diverticula arise from the terminal third of the thoracic esophagus and are usually found adjacent to the diaphragm. They have been associated with distal esophageal muscular hypertrophy, esophageal motility abnormalities, and increased luminal pressure. They are "pulsion" diverticula, and are associated with diffuse spasm, achalasia, or nonspecific motor abnormalities in the body of the esophagus.

Whether the diverticulum should be surgically resected or suspended depends on its size and proximity to the vertebral body. When diverticula are associated with esophageal motility disorders, esophageal myotomy from the proximal extent of the diverticulum to the stomach should be combined with diverticulectomy. If diverticulectomy alone is performed, one can expect a high incidence of suture line rupture due to the same intraluminal pressure that initially gave rise to the diverticulum. If the diverticulum is suspended to the prevertebral fascia of the thoracic vertebra, a myotomy is begun at the neck of the diverticulum and extended across the LES. If the diverticulum is excised by dividing the neck, the muscle is closed over the excision site and a myotomy is performed on the opposite esophageal wall, starting just above the level of the diverticulum or at the proximal extent of the spastic segment of the esophagus if high resolution motility is used. If complete, the myotomy will cross the LES, reducing distal esophageal peak pressure, and will increase the likelihood that dysphagia will be replaced with GERD symptoms. Increasingly, partial fundoplication (anterior or posterior) is performed after LES myotomy to decrease the frequency of disabling GERD developing after myotomy and diverticulectomy. When a large diverticulum is associated with a hiatal hernia, then hiatal hernia repair is added. All these procedures may be performed with traditional or minimally invasive techniques.

Midesophageal or traction diverticula were first described in the nineteenth century (Fig. 25-57). At that time, they were frequently noted in patients who had mediastinal LN involvement with tuberculosis. It was theorized that adhesions formed between the inflamed mediastinal nodes and the esophagus. By contraction, the adhesions exerted traction on the esophageal wall and led to a localized diverticulum (Fig. 25-58). This theory was based on the findings of early dissections, where adhesions between diverticula and LNs were commonly found. Other conditions associated with mediastinal lymphadenopathy, such as pulmonary fungal infections (e.g., aspergillosis), lymphoma, or sarcoid, may create traction esophageal diverticula after successful treatment. Rarely, when no underlying inflammatory pathology is identified, a motility disorder may be identified.

Most midesophageal diverticula are asymptomatic and incidentally discovered during investigation for nonesophageal complaints. In such patients, the radiologic abnormality may be ignored. Patients with symptoms of dysphagia, regurgitation, chest pain, or aspiration, in whom a diverticulum is discovered, should be thoroughly investigated for an esophageal motor abnormality. Occasionally, a patient will present with a bronchoesophageal fistula manifested by a chronic cough on ingestion of meals. The diverticulum in such patients is most likely to have an inflammatory etiology.

Figure 25-57. Barium esophagogram showing a midesophageal diverticulum. Despite the anatomic distortion, the patient was asymptomatic. *(Reproduced with permission from Waters PF, DeMeester TR: Foregut motor disorders and their surgical management*. Med Clin North Am. *65:1255, 1981. Copyright Elsevier.)*

The indication for surgical intervention is dictated by the degree of symptomatic disability. Usually, midesophageal diverticula can be suspended due to their proximity to the spine. If a motor abnormality is documented, a myotomy should be performed as described for an epiphrenic diverticulum.

OPERATIONS FOR ESOPHAGEAL MOTOR DISORDERS AND DIVERTICULA

Long Esophageal Myotomy for Motor Disorders of the Esophageal Body

A long esophageal myotomy is indicated for dysphagia caused by any motor disorder characterized by segmental or generalized simultaneous waveforms in a patient whose symptoms are not relieved by medical therapy. Such disorders include diffuse and segmental esophageal spasm, vigorous or Type 3 achalasia, and nonspecific motility disorders associated with a mid- or epiphrenic esophageal diverticulum. However, the decision to operate must be made by a balanced evaluation of the patient's symptoms, diet, lifestyle adjustments, and nutritional status, with the most important factor being the possibility of improving the patient's swallowing disability. The symptom of chest pain alone is not an indication for a surgical procedure.

The identification of patients with symptoms of dysphagia and chest pain who might benefit from a surgical myotomy is difficult. Ambulatory motility studies have shown that when the prevalence of "effective contractions" (i.e., peristaltic waveforms consisting of contractions with an amplitude above 30 mmHg) drops below 50% during meals, the patient is likely to experience dysphagia (Fig. 25-59). This would suggest that relief from the symptom can be expected with an improvement of esophageal contraction amplitude or amelioration of nonperistaltic waveforms. Prokinetic agents may increase esophageal contraction amplitude, but do not alter the prevalence of simultaneous waveforms. Patients in whom the efficacy of esophageal propulsion is severely compromised because of a high prevalence of simultaneous waveforms usually receive little benefit from medical therapy. In these patients, a surgical myotomy of the esophageal body can improve the patients' dysphagia, provided the loss of contraction amplitude in the remaining peristaltic waveforms, caused by the myotomy, has less effect on swallowing function than the presence of the excessive simultaneous contractions. This situation is reached when the prevalence of effective waveforms during meals drops below 30%, (i.e., 70% of esophageal waveforms are ineffective).

In patients selected for surgery, preoperative high resolution manometry is essential to determine the proximal extent of

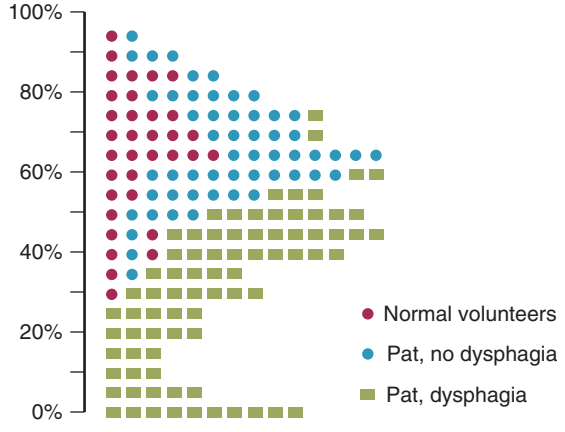

Figure 25-59. Prevalence of effective contractions, (i.e., peristaltic contractions with an amplitude >30 mm Hg) during meal periods in individual normal volunteers, patients (Pat) without dysphagia, and patients with nonobstructive dysphagia.

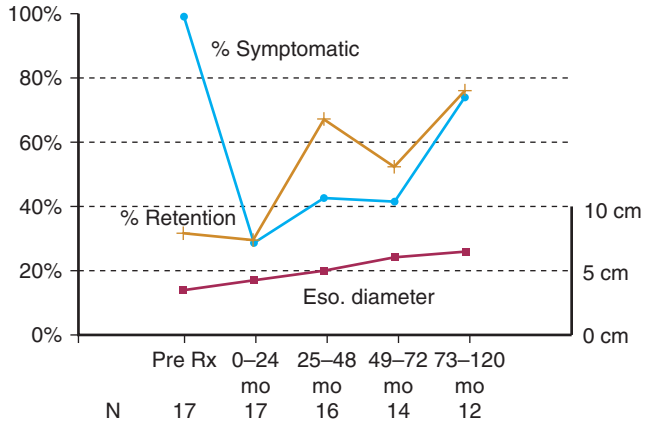

Figure 25-60. Esophageal (Eso.) diameter, dysphagia, and esophageal retention in patients with achalasia treated with myotomy and Nissen fundoplication, 10 years after treatment (Rx). *(Based on Topart P, et al.: Long-term effect of total fundoplication on the myotomized esophagus.* Ann Thorac Surg. *54:1046, 1992.)*

the esophageal myotomy. Most surgeons extend the myotomy distally across the LES to reduce outflow resistance. Consequently, some form of antireflux protection is needed to avoid gastroesophageal reflux if there has been extensive dissection of the cardia. In this situation, most authors prefer a partial, rather than a full, fundoplication, in order not to add back-resistance that will further interfere with the ability of the myotomized esophagus to empty (Fig. 25-60). If the symptoms of reflux are present preoperatively, 24-hour pH monitoring is required to confirm its presence.

The procedure may be performed either open or via thoracoscopy. The open technique is performed through a left thoracotomy in the sixth intercostal space (Fig. 25-61). An incision is made in the posterior mediastinal pleura over the esophagus, and the left lateral wall of the esophagus is exposed. The esophagus is not circumferentially dissected unless necessary. A 2-cm incision is made into the abdomen through the parietal peritoneum at the midportion of the left crus. A tongue of gastric fundus is pulled into the chest. This exposes the GEJ and its associated fat pad. The latter is excised to give a clear view of the junction. A myotomy is performed through all muscle layers, extending distally over the stomach 1 to 2 cm below the GEJ, and proximally on the esophagus over the distance of the manometric abnormality. The muscle layer is dissected from the mucosa laterally for a distance of 1 cm. Care is taken to divide all minute muscle bands, particularly in the area of the GEJ. The gastric fundic tongue is sutured to the margins of the myotomy over a distance of 3 to 4 cm and replaced into the abdomen. This maintains separation of the muscle and acts as a partial fundoplication to prevent reflux.

If an epiphrenic diverticulum is present, it is excised by dividing the neck with a stapler sized for the thickness of the diverticulum (2.0- to 4.8-mm staple leg length) followed by a closure of the muscle over the staple line, when possible. The myotomy is then performed on the opposite esophageal wall. If a midesophageal diverticulum is present, the myotomy is made so that it includes the muscle around the neck, and the diverticulum is suspended by attaching it to the paravertebral fascia of the thoracic vertebra above the level of the diverticular neck. Before performing any operation for an esophageal diverticulum,

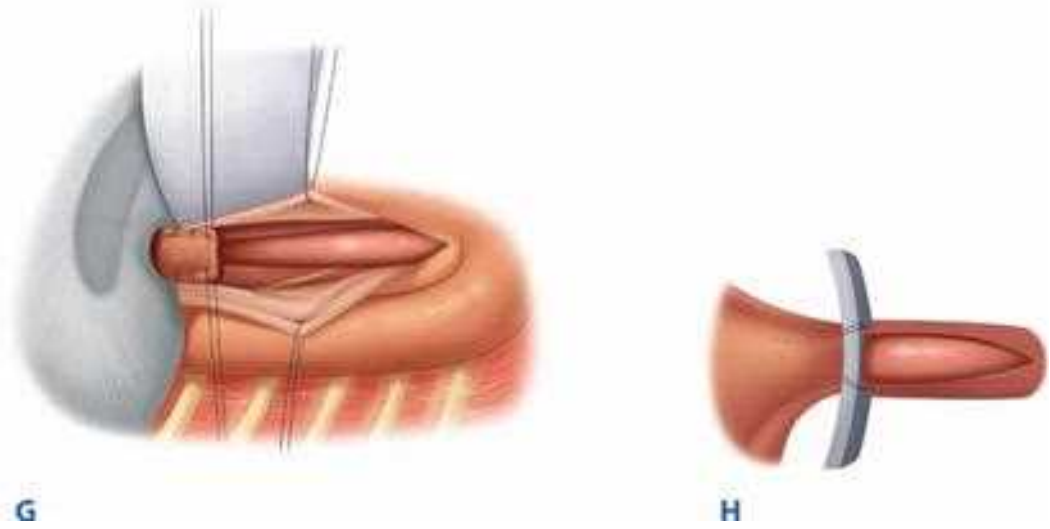

Figure 25-61. (*Continued*)

it is wise to endoscope the patient to wash all food and other debris from the diverticulum.

The results of myotomy for motor disorders of the esophageal body have improved in parallel with the improved preoperative diagnosis afforded by manometry. Previous published series report between 40% and 92% improvement of symptoms, but interpretation is difficult due to the small number of patients involved and the varying criteria for diagnosis of the primary motor abnormality. When myotomy is accurately done, 93% of the patients have effective palliation of dysphagia after a mean follow-up of 5 years, and 89% would have the procedure again, if it was necessary. Most patients gain or maintain rather than lose weight after the operation. Postoperative motility studies show that the myotomy reduces the amplitude of esophageal contractions to near zero and eliminates simultaneous peristaltic waves. If the benefit of obliterating the simultaneous waves exceeds the adverse effect on bolus propulsion caused by the loss of peristaltic waveforms, the patient's dysphagia is likely to be improved by the procedure. If not, the patient is likely to continue to complain of dysphagia and to have little improvement as a result of the operation.

The thoracoscopic technique may be performed through the left or right chest. There has been little experience gained with doing adequate operations (as described previously with the open exposure) through left thoracoscopy, so most surgeons will combine a right thoracoscopic long myotomy with an abdominal approach for Heller myotomy and partial fundoplication. These two procedures may be done at the same setting, by double positioning the patient, or they may be done at two operations. If this is the case, it is best to do the abdominal component first, as the esophageal outflow obstruction is the source of most of the symptoms. Performing abdominal myotomy (and diverticulectomy, if present) may be all that is required.

A new procedure, peroral endoscopic myotomy (POEM) allows a long myotomy to be performed from the lumen of the esophagus with an endoscope. This procedure is attractive for– at a minimum- those with Type 3 achalasia (vigorous achalasia) where it is necessary to divide esophagogastric circular muscle on both sides of the diaphragm to the extent that might not be possible with laparoscopy or thoracoscopy alone. The POEM procedure is started by opening the esophageal mucosa several centimeters above the spastic segment with a needle–knife electrosurgery device passed through an endoscope. A long submucosal plane is developed with the endoscope, down to and below the LES. The circular muscle of the LES and the esophagus is divided with endoscopic electrosurgery all the way back until normal (nonspastic) esophagus is reached. The submucosal entry site in the esophagus is then closed with endoscopic clips. While the results of POEM are still accumulating, the procedure is attractive because it is extremely minimally invasive, and can be done as an outpatient.

Epiphrenic diverticula cannot be treated with POEM and are most frequently addressed with laparoscopic access, in combination with a laparoscopic division of the LES (Heller myotomy) (Fig. 25-62). If the diverticulum can be completely mobilized through the hiatus, it may be safely excised from below. The neck of the diverticulum is transected with a GIA stapler after passage of a 48F dilator. Not infrequently, the diverticulum is sufficiently large that access to the neck of the diverticulum across the hiatus is quite difficult. Additionally, the inflammatory reaction to the diverticulum may further make the transhiatal dissection difficult. Under these circumstances, it is safer to perform the diverticulectomy through a right thoracoscopic approach either at the time of the initial procedure or at a later date, depending upon the frailty of the patient. Following diverticulectomy, it is critical that the esophageal staple line be treated with a great deal of care. Closure of the muscle over the staple line is preferable. Additionally, the patient is kept NPO or on clear liquids for 5 to 7 days and a contrast study is obtained before advancing to a full liquid or "mushy food" diet. Solid foods are withheld for 2 weeks to decrease the likelihood of staple line leak. Buttressing or sealing the staple line with fibrin glue is also an attractive option.

Myotomy of the Lower Esophageal Sphincter (Heller Myotomy)

Second only to reflux disease, achalasia is the most common functional disorder of the esophagus to require surgical intervention. The goal of treatment is to relieve the functional outflow obstruction secondary to the loss of relaxation and

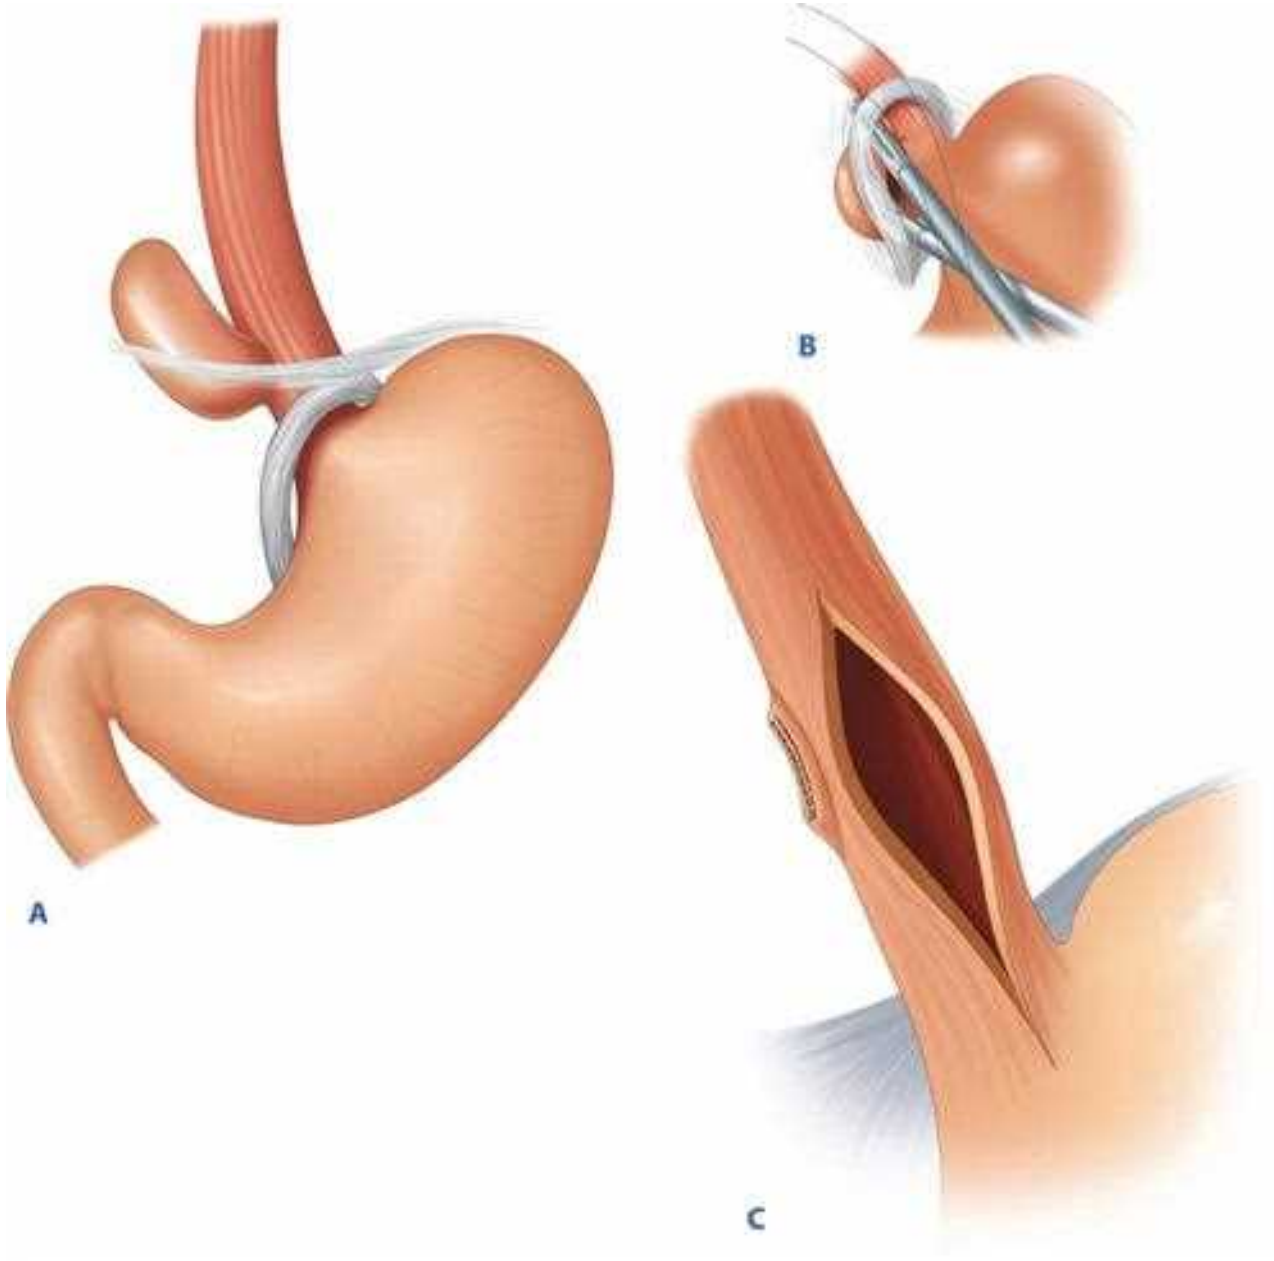

Figure 25-62. **A.** Epiphrenic diverticula are situated above the lower esophageal sphincter on right side of esophagus. **B.** Stapler amputates neck of diverticulum. **C.** Muscle reapproximated over staple line, and Heller myotomy is performed.

compliance of the LES. This requires disrupting the LES muscle. When performed adequately (i.e., reducing sphincter pressure to <10 mmHg), and done early in the course of disease, LES myotomy results in symptomatic improvement with the occasional return of esophageal peristalsis. Reduction in LES resistance can be accomplished intraluminally by hydrostatic balloon dilation, which ruptures the sphincter muscle, by botulinum toxin injection, or by a surgical myotomy that cuts the sphincter. The difference between these three methods appears to be the greater likelihood of reducing sphincter pressure to <10 mmHg by surgical myotomy compared with hydrostatic balloon dilation. However, patients whose sphincter pressure has been reduced by hydrostatic balloon dilation to <10 mmHg have an outcome similar to those after surgical myotomy (Fig. 25-63). Botulinum toxin injection may achieve similar results, but has a longer duration of action that may be measured in weeks or months, rather than years. Botulinum toxin injection may best be used as a diagnostic tool, when it is not clear whether a hypertensive LES is the primary cause of dysphagia. Responsiveness to botulinum toxin injection may predict a good response to Heller myotomy.

The therapeutic decisions regarding the treatment of patients with achalasia center on four issues. The first issue is the question of whether newly diagnosed patients should be treated with pneumatic dilation or a surgical myotomy. Long-term follow-up studies have shown that pneumatic dilation achieves adequate relief of dysphagia and pharyngeal regurgitation in 50% to 60% of patients (Fig. 25-64). Close follow-up is required, and if dilation fails, myotomy is indicated. For those patients who have a dilated and tortuous esophagus or

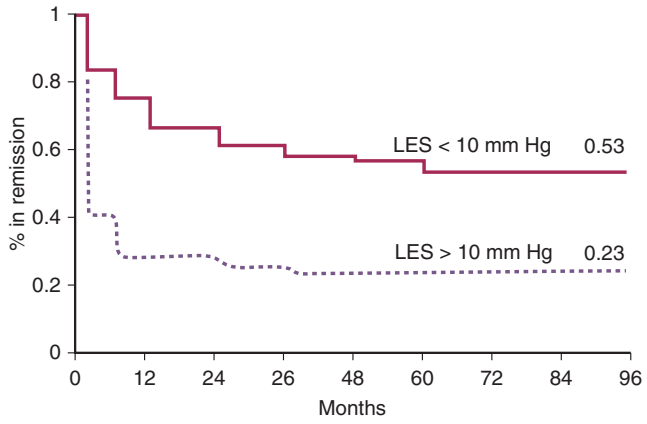

Figure 25-63. Prevalence of clinical remission in 122 patients stratified according to postdilatation lower esophageal sphincter (LES) pressures greater than or <10 mmHg. With kind permission from Springer Science+Business Media.)

an associated hiatal hernia, balloon dilation is dangerous and surgery is the better option. The outcome of the one controlled randomized study (38 patients) comparing the two modes of therapy suggests that surgical myotomy as a primary treatment gives better long-term results. Several randomized trials comparing laparoscopic cardiomyotomy with balloon dilation or botulinum toxin injection have favored the surgical approach as well. Although it has been reported that a myotomy after previous balloon dilation is more difficult, this has not been the experience of these authors unless the cardia has been ruptured in a sawtooth manner. In this situation, operative intervention, either immediately or after healing has occurred, can be difficult. Similarly, myotomy after botulinum toxin injection has reported to be more difficult, but this is largely a function of the submucosal inflammatory response, which may be a bit unpredictable, and is most intense in the first 6 to 12 weeks after injection. It is important to wait at least 3 months after botulinum toxin injection to perform cardiomyotomy to minimize the risk of encountering dense inflammation.

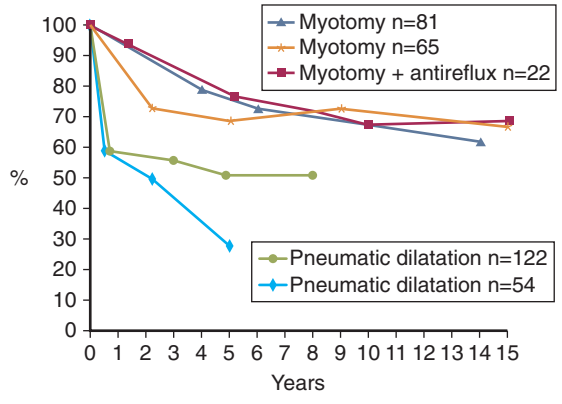

Figure 25-64. Summary of long-term studies reporting the proportion of patients with complete relief or minimal dysphagia (Stage 0–1) stratified according to type of treatment. *(Data reproduced from: Ellis FH Jr.: Oesophagomyotomy for achalasia: A 22-year experience.* Br J Surg. *80:882, 1993; Goulbourne IA, Walbaum PR: Long-term results of Heller's operation for achalasia.* J Royal Coll Surg. *30:101, 1985; Malthaner RA, Todd TR, Miller L, et al.: Long-term results in surgically managed esophageal achalasia.* Ann Thorac Surg. *58:1343, 1994; Ponce J, Garrigues V, Pertejo V, et al.: Individual prediction of response to pneumatic dilation in patients with achalasia.* Dig Dis Sci. *41:2135, 1996; Eckardt V, Aignherr C, Bernhard G: Predictors of outcome in patients with achalasia treated by pneumatic dilation.* Gastroenterology. *103:1732, 1992.)*

The second issue is the question of whether a surgical myotomy should be performed through the abdomen or the chest. Myotomy of the LES can be accomplished via either an abdominal or thoracic approach. In the absence of a previous upper abdominal surgery, most surgeons prefer the abdominal approach to LES myotomy as laparoscopy results in less pain and a shorter length of stay than thoracoscopy. In addition, it is a bit easier to ensure a long gastric myotomy when the approach is transabdominal.

The third issue—and one that has been long debated—is the question of whether an antireflux procedure should be added to a surgical myotomy. Excellent results have been reported following meticulously performed myotomy without an antireflux component. Retrospective studies, with long-term follow-up of large cohorts of patients undergoing Heller myotomy demonstrated that, after 10 years, more than 50% of patients had reflux symptoms without a fundoplication. In a recent randomized clinical trial, 7% of patients undergoing Dor fundoplication following LES myotomy had abnormal 24-hour pH probes, and 42% of patients with a myotomy only had abnormal reflux profiles. If an antireflux procedure is used as an adjunct to esophageal myotomy, a complete 360° fundoplication should be avoided. Rather, a 270° Belsey fundoplication, a Toupet posterior 180° fundoplication, or a Dor anterior 180° fundoplication should be used to avoid the long-term esophageal dysfunction secondary to the outflow obstruction afforded by the fundoplication itself.

The fourth issue centers on whether or not a cure of this disease is achievable. Long-term follow-up studies after surgical myotomy have shown that late deterioration in results occurs after this procedure, regardless of whether an antireflux procedure is done, and also after balloon dilation, even when the sphincter pressure is reduced to below 10 mm Hg. It may be that, even though a myotomy or balloon rupture of the LES muscle reduces the outflow obstruction at the cardia, the underlying motor disorder in the body of the esophagus persists and deteriorates further with the passage of time, leading to increased impairment of esophageal emptying. The earlier an effective reduction in outflow resistance can be accomplished, the better the outcome will be, and the more likely some esophageal body function can be restored.

In performing a surgical myotomy of the LES, there are four important principles: (a) complete division of all circular and collar-sling muscle fibers, (b) adequate distal myotomy to reduce outflow resistance, (c) "undermining" of the muscularis to allow wide separation of the esophageal muscle, and (d) prevention of postoperative reflux. In the past, the drawback of a surgical myotomy was the need for an open procedure, which often deterred patients from choosing the best treatment option for achalasia. With the advent of minimally invasive surgical techniques two decades ago, laparoscopic cardiomyotomy (Heller myotomy) has become the treatment of choice for most patients with achalasia.

Open Esophageal Myotomy

Open techniques of distal esophageal myotomy are rarely used outside reoperations. In fact, primary procedures can almost always be successfully completed via laparoscopy. A modified Heller myotomy can be performed through a left thoracotomy incision in the sixth intercostal space along the upper border of the seventh rib. The esophagus and a tongue of gastric fundus are exposed as described for a long myotomy. A myotomy through all muscle layers is performed, extending distally over the stomach to 1 to 2 cm below the junction, and proximally on the esophagus for 4 to 5 cm. The cardia is reconstructed by suturing the tongue of gastric fundus to the margins of the myotomy, to prevent rehealing of the myotomy site, and to provide reflux protection in the area of the divided sphincter. If an extensive dissection of the cardia has been done, a more formal Belsey repair is performed. The tongue of gastric fundus is allowed to retract into the abdomen. Traditionally, nasogastric drainage is maintained for 6 days to prevent distention of the stomach during healing. An oral diet is resumed on the seventh day, after a barium swallow study shows unobstructed passage of the bolus into the stomach without extravasation.

In a randomized, long-term follow-up by Csendes and colleagues of 81 patients treated for achalasia, either by forceful dilation or by surgical myotomy, myotomy was associated with a significant increase in the diameter at the GEJ and a decrease in the diameter at the middle third of the esophagus on follow-up radiographic studies. There was a greater reduction in sphincter pressure and improvement in the amplitude of esophageal contractions after myotomy. After dilation, 13% of patients regained some peristalsis, compared with 28% after surgery. These findings were shown to persist over a 5-year follow-up period, at which time 95% of those treated with surgical myotomy were doing well. Of those who were treated with dilation, only 54% were doing well, while 16% required redilation, and 22% eventually required surgical myotomy to obtain relief.

If simultaneous esophageal contractions are associated with the sphincter abnormality, the so-called vigorous achalasia, then the myotomy should extend over the distance of the abnormal motility as mapped by the preoperative motility study. Failure to do this will result in continuing dysphagia and a dissatisfied patient. The best objective evaluation of improvement in the patient following either balloon dilation or myotomy is a scintigraphic measurement of esophageal emptying time. A good therapeutic response improves esophageal emptying toward normal. However, some degree of dysphagia may persist despite improved esophageal emptying, due to disturbances in esophageal body function. When an antireflux procedure is added to the myotomy, it should be a partial fundoplication. A 360° fundoplication is associated with progressive retention of swallowed food, regurgitation, and aspiration to a degree that exceeds the patient's preoperative symptoms.

Laparoscopic Cardiomyotomy

More commonly known as a laparoscopic Heller myotomy, after Ernst Heller, a German surgeon who described a "double myotomy" in 1913, the laparoscopic approach is similar to the Nissen fundoplication in terms of the trocar placement and exposure and dissection of the esophageal hiatus (Fig. 25-65). The procedure begins by division of the short gastric vessels in preparation for fundoplication. Exposure of the GEJ via removal of the gastroesophageal fat pad follows. The anterior vagus nerve is swept right laterally along with the fat pad. Once completed, the GEJ and distal 4 to 5 cm of esophagus should be bared of any overlying tissue, and generally follows dissection of the GEJ. A distal esophageal myotomy is performed. It is generally easiest to begin the myotomy 1 to 2 cm above the GEJ, in an area above that of previous botulinum toxin injections or balloon dilation. Either scissors or a hook-type electrocautery can be used to initiate the incision in the longitudinal and circular muscle. Distally, the myotomy is carried across the GEJ and onto the proximal stomach for approximately 2 to 3 cm. After completion, the muscle edges are separated bluntly from the esophageal mucosa for approximately 50% of the esophageal circumference. An antireflux procedure follows completion of the myotomy. Either an anterior hemifundoplication augmenting the angle of His (Dor) or posterior partial fundoplication (Toupet) can be performed. The Dor type fundoplication is slightly easier to perform, and does not require disruption of the normal posterior gastroesophageal attachments (a theoretical advantage in preventing postoperative reflux).

Per Oral Endoscopic Myotomy (POEM)

The POEM procedure was developed in Japan. It is the ultimate minimally invasive myotomy as it requires no incisions through the skin. With the POEM procedure a very effective myotomy is performed entirely from the lumen of the esophagus. The POEM procedure is started by opening the esophageal mucosa 10 cm above the lower esophageal sphincter with a needle–knife electrosurgery device passed through an endoscope. A long submucosal plane is developed with the endoscope, down to and below the LES. The circular muscle of the LES, above and below the gastroesophageal junction is divided with endoscopic electrosurgery. The submucosal entry site in the esophagus is then closed with endoscopic clips. While the results of POEM are still accumulating, the procedure is attractive because it is extremely minimally invasive, and can be done as an outpatient. The major downside of POEM is that an effective antireflux valve cannot be created, exposing the patient to a 40%–50% risk of GERD post procedure.

Outcome Assessment of the Therapy for Achalasia

Critical analysis of the results of therapy for motor disorders of the esophagus requires objective measurement. The use of symptoms alone as an endpoint to evaluate therapy for achalasia may be misleading. The propensity for patients to unconsciously modify their diet to avoid difficulty swallowing is underestimated, making an assessment of results based on symptoms unreliable. Insufficient reduction in outflow resistance may allow progressive esophageal dilation to develop slowly, giving the impression of improvement because the volume of food able to be ingested with comfort increases. A variety of objective measurements may be used to assess success, including LES pressure, esophageal baseline pressure, and scintigraphic assessment of esophageal emptying time. Esophageal baseline pressure is usually negative compared to gastric pressure. Given that the goal of therapy is to eliminate the outflow resistance of a nonrelaxing sphincter, measurement of improvements in esophageal baseline pressure and scintigraphic transit time may be better indicators of success, but are rarely reported.

Eckardt and associates investigated whether the outcome of pneumatic dilation in patients with achalasia could be predicted on the basis of objective measurements. Postdilation LES pressure was the most valuable measurement for predicting

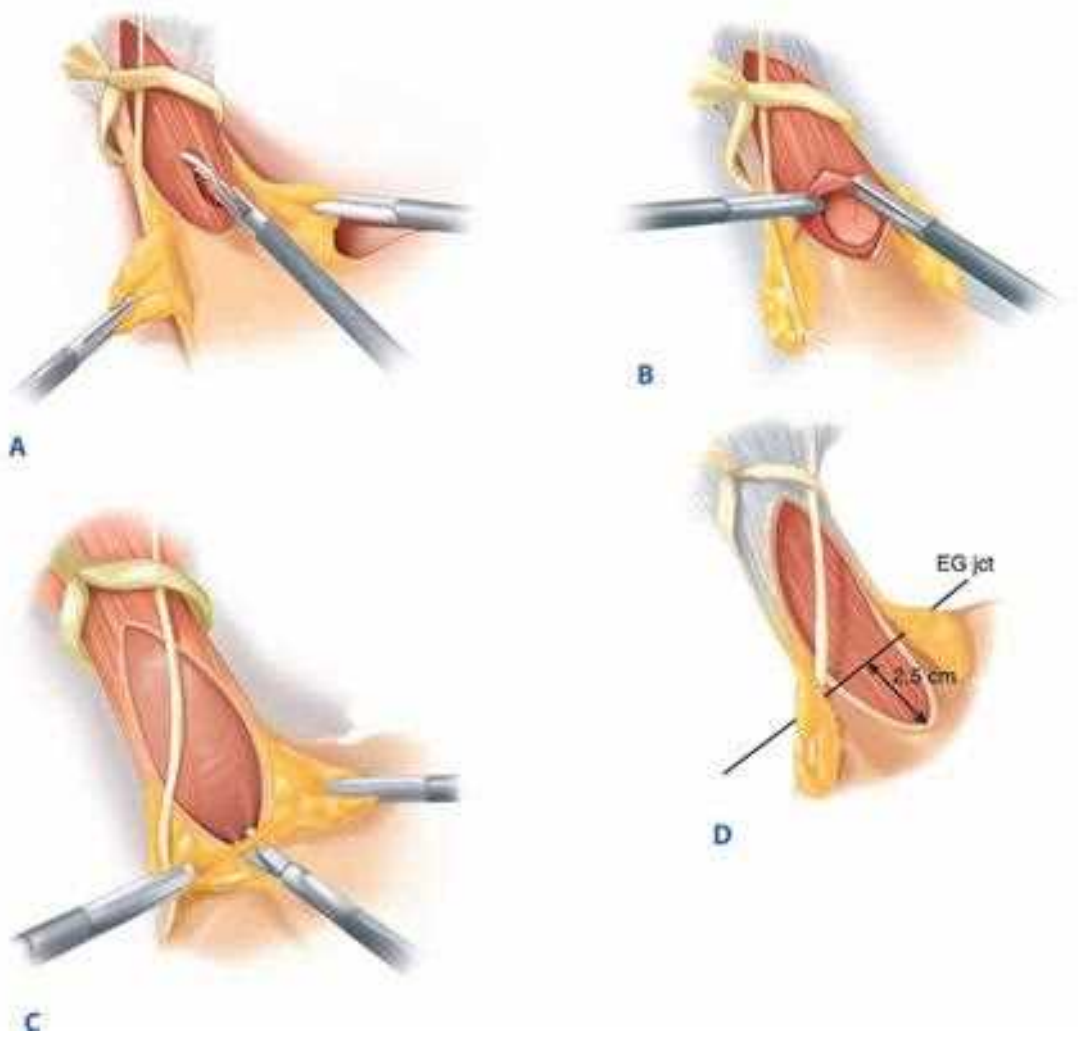

Figure 25-65. **A.** Longitudinal muscle is divided. **B.** Mechanical disruption of lower esophageal sphincter muscle fibers. **C.** Myotomy must be carried across gastroesophageal junction. **D.** Gastric extension should equal 2 to 3 cm. **E.** Anterior (Dor) fundoplication is sutured to the diaphragmatic arch. **F.** Posterior (Toupet) fundoplication is sutured to cut edges of myotomy. EG jct = esophagogastric junction. *(Illustration continued on next page.)*

long-term clinical response. A postdilatation sphincter pressure <10 mmHg predicted a good response. Approximately 50% of the patients studied had postdilatation sphincter pressures between 10 and 20 mmHg, with a 2-year remission rate of 71%. More important, 16 of 46 patients were left with a postdilatation sphincter pressure of >20 mmHg, and had an unacceptable outcome. Overall, only 30% of patients dilated remained in symptomatic remission at 5 years.

Bonavina and colleagues reported good to excellent results with transabdominal myotomy and Dor fundoplication in 94% of patients after a mean follow-up of 5.4 years. No operative mortality occurred in either of these series, attesting to the safety of the procedure. Malthaner and Pearson reported the long-term clinical results in 35 patients with achalasia, having a minimum follow-up of 10 years (Table 25-10). Twenty-two of these patients underwent primary esophageal myotomy and Belsey hemifundoplication at the Toronto General Hospital. Excellent to good results were noted in 95% of patients at 1 year, declining to 68%, 69%, and 67% at 10, 15, and 20 years, respectively. Two patients underwent early reoperation for an incomplete myotomy, and three underwent an esophagectomy for progressive disease. They concluded that there was a deterioration of the initially good results after surgical myotomy and hiatal repair for achalasia, which is due to late complications of gastroesophageal reflux.

Ellis reported his lifetime experience with transthoracic short esophageal myotomy without an antireflux procedure. One hundred seventy-nine patients were analyzed at a mean follow-up of 9 years, ranging from 6 months to 20 years. Overall, 89% of patients were improved at the 9-year mark. He also observed that the level of improvement deteriorated with time, with excellent results (patients continuing to be symptom free) decreasing from 54% at 10 years to 32% at 20 years. He concluded that a short transthoracic myotomy without an antireflux procedure provides excellent long-term relief of dysphagia, and, contrary to Malthaner and Pearson's experience, does not result in complications of gastroesophageal reflux. Both studies document nearly identical results 10 to 15 years following the procedure, and both report deterioration over time, probably due to progression of the underlying disease. The addition of an antireflux procedure if the operation is performed transthoracically has no significant effect on the outcome.

The outcome of laparoscopic myotomy and hemifundoplication has been well documented. Two reports of over

100 patients have documented relief of dysphagia in 93% of patients. Richter and coworkers reviewed published reports to date, including 254 patients with an average success rate of 93% at 2.5 years. Conversion to an open procedure occurs in 0% to 5% of patients. Complications are uncommon, occurring in <5% of patients. Intraoperative complications consist largely of mucosal perforation, and have been more likely to occur after botulinum toxin injection. The incidence of objective reflux disease as evidenced by abnormal acid exposure is <10%.

A number of randomized clinical trials in the past decade have compared the outcomes of laparoscopic Heller myotomy to pneumatic dilation and to botulinum toxin injection. In each of these trials, laparoscopic Heller myotomy and partial fundoplication was superior to the alternative treatment. Lastly, a randomized clinical trial examining the need for fundoplication following Heller myotomy demonstrated a great deal more reflux in patients without fundoplication, and no better swallowing in the Heller-only group. The best treatment for achalasia is a laparoscopic Heller myotomy and partial fundoplication. The role of POEM in the management of classic (nonspastic) achalasia is yet to be established.

Esophageal Resection for End-Stage Motor Disorders of the Esophagus

Patients with dysphagia and long-standing benign disease, whose esophageal function has been destroyed by the disease process or multiple previous surgical procedures, are best managed by esophagectomy. Fibrosis of the esophagus and cardia can result in weak contractions and failure of the distal esophageal sphincter to relax. The loss of esophageal contractions can result in the stasis of food, esophageal dilatation, regurgitation, and aspiration. The presence of these abnormalities signals end-stage motor disease. In these situations esophageal replacement is usually required to establish normal alimentation. Before proceeding with esophageal resection for patients with end-stage benign disease, the choice of the organ to substitute for the esophagus (i.e., stomach, jejunum, or colon) should be considered. The choice of replacement is affected by a number of factors, as described later in the section on Techniques of Esophageal Reconstruction. If minimally invasive esophagectomy is to be performed, thoracoscopic dissection should be combined with abdominal dissection. Attempts at MIS transhiatal esophagectomy for the massively dilated esophagus may result in large volume bleeding from mediastinal vessels that become enlarged with esophageal dilation, and must be directly controlled for hemostasis to be adequate, and the operation to be safe.

CARCINOMA OF THE ESOPHAGUS

Squamous carcinoma accounts for the majority of esophageal carcinomas worldwide. Its incidence is highly variable, ranging from approximately 20 per 100,000 in the United States and Britain, to 160 per 100,000 in certain parts of South Africa and the Honan Province of China, and even 540 per 100,000 in the Guriev district of Kazakhstan. The environmental factors responsible for these localized high-incidence areas have not been conclusively identified, though additives to local foodstuffs (nitroso compounds in pickled vegetables and smoked meats) and mineral deficiencies (zinc and molybdenum) have been suggested. In Western societies, smoking and alcohol consumption are strongly linked with squamous carcinoma. Other definite associations link squamous carcinoma with long-standing achalasia, lye strictures, tylosis (an autosomal dominant disorder characterized by hyperkeratosis of the palms and soles), and human papillomavirus.

Adenocarcinoma of the esophagus, once an unusual malignancy, is diagnosed with increasing frequency (Fig. 25-66), and now accounts for more than 50% of esophageal cancer in most Western countries. The shift in the epidemiology of esophageal cancer from predominantly squamous carcinoma seen in association with smoking and alcohol, to adenocarcinoma in the setting of BE, is one of the most dramatic changes that have occurred in the history of human neoplasia. Although esophageal carcinoma is a relatively uncommon malignancy, its prevalence is exploding, largely secondary to the well-established association between gastroesophageal reflux, BE, and esophageal adenocarcinoma. Once a nearly uniformly lethal disease, survival has improved slightly because of advances in the understanding of its molecular biology, screening and surveillance practices, improved staging, minimally invasive surgical techniques, and neoadjuvant therapy.

Furthermore, the clinical picture of esophageal adenocarcinoma is changing. It now occurs not only considerably more frequently, but in younger patients, and is often detected at an earlier stage. These facts support rethinking the traditional approach of assuming palliation is appropriate in all patients. The historical focus on palliation of dysphagia in an elderly patient with comorbidities should change when dealing with a young patient with dependent children and a productive life ahead. The potential for cure becomes of paramount importance.

The gross appearance resembles that of squamous cell carcinoma. Microscopically, adenocarcinoma almost always originates in Barrett's mucosa, and resembles gastric cancer. Rarely, it arises in the submucosal glands, and forms intramural growths that resemble the mucoepidermal and adenoid cystic carcinomas of the salivary glands.

The most important etiologic factor in the development of primary adenocarcinoma of the esophagus is a metaplastic columnar-lined or Barrett's esophagus, which occurs in approximately 10% to 15% of patients with GERD. When studied prospectively, the incidence of adenocarcinoma in a patient with BE is one in 100 to 200 patient-years of follow-up (i.e., for every 100 patients with BE followed for 1 year, one will develop adenocarcinoma). Although this risk appears to be small, it is at least 40 to 60 times that expected for a similar population without BE. This risk is similar to the risk for developing lung cancer in a person with a 20-pack-per-year history of smoking. Endoscopic surveillance for patients with BE is recommended for two reasons: (a) at present there is no reliable evidence that medical therapy removes the risk of neoplastic transformation, and (b) malignancy in BE is curable if detected at an early stage.

Clinical Manifestations

Esophageal cancer generally presents with dysphagia, although increasing numbers of relatively asymptomatic patients are now identified on surveillance endoscopy, or present with nonspecific upper GI symptoms and undergo screening endoscopy. Extension of the primary tumor into the tracheobronchial tree can occur primarily with squamous cell carcinoma and can cause stridor, tracheoesophageal fistula and resultant coughing, choking, and aspiration pneumonia. Rarely, severe bleeding from the primary tumor or from erosion into the aorta or pulmonary vessels occurs. Either vocal cord may

6▶

be invaded, causing paralysis, but most commonly, paralysis is caused by invasion of the left recurrent laryngeal nerve by the primary tumor or LN metastasis. Systemic organ metastases are usually manifested by jaundice or bone pain. The situation is different in high-incidence areas where screening is practiced. In these communities, the most prominent early symptom is pain on swallowing rough or dry food. In patients that present with back pain at the time of esophageal cancer diagnosis, there is usually distant metastasis or celiac encasement.

Dysphagia usually presents late in the natural history of the disease, because the lack of a serosal layer on the esophagus allows the smooth muscle to dilate with ease. As a result, the dysphagia becomes severe enough for the patient to seek medical advice only when more than 60% of the esophageal circumference is infiltrated with cancer. Consequently, the disease is usually advanced if symptoms herald its presence. Tracheoesophageal fistula may be present in some patients on their first visit to the hospital, and more than 40% will have evidence of distant metastases. With tumors of the cardia, anorexia and weight loss usually precede the onset of dysphagia. The physical signs of esophageal tumors are those associated with the presence of distant metastases.

General Approach to Esophageal Cancer

Therapy of esophageal cancer is dictated by the stage of the cancer at the time of diagnosis. Put simply, one needs to determine if the disease is confined to the esophagus, (T1–T2, N0), locally advanced (T1–3, N1), or disseminated (any T, any N, M1). If cancer is confined to the esophagus, removal of the tumor with adjacent lymph nodes may be curative. Very early tumors confined to the mucosa (T in situ, T1a, intramucosal cancer) may be addressed with endoscopic treatment. When the tumor is locally aggressive, modern therapy dictates a multimodality approach in a surgically fit patient. Multimodality therapy is either chemotherapy followed by surgery or radiation and chemotherapy followed by surgery. When given before surgery, these treatments are referred to as neoadjuvant or induction therapy. For disseminated cancer, treatment is aimed at palliation of symptoms. If the patient has dysphagia, as many do, the most rapid form of palliation is the endoscopic placement of an expandable esophageal stent. For palliation of GEJ cancer, radiation may be the first choice, as stents placed across the GEJ create a great deal of gastroesophageal reflux.

Staging of Esophageal Cancer

Choosing the best therapy for an individual patient requires accurate staging. Staging starts with the history and physical. LN disease remote from the tumor, particularly in the cervical region, may be palpable on neck examination and generally indicates cancer dissemination. This is often referred to as M1a disease, indicating that these patients should not be treated with therapy directed toward locally advanced cancer. Other metastatic LNs are rarely palpable but are equally ominous, especially the umbilical LN in GEJ cancer.

Computed tomographic (CT) scanning of the chest, abdomen, and pelvis provides information on local invasion of the primary cancer, LN involvement, or disseminated disease. The most common sites of esophageal cancer metastases are lung, liver, and peritoneal surfaces, including the omentum and small bowel mesentery. If masses are identified that are not characteristic for cancer or are in a location that precludes resection with the cancer specimen, positron emission tomography

(PET) scanning may be able to tell whether the masses are metabolically active (likely to be cancer) or not. A PET active focus corresponding to a mass on CT scan outside of the field of esophageal resection should be biopsied before resection is performed.

The introduction of endoscopic ultrasound (EUS) has made it possible to identify patients who are potentially curable before surgical therapy. Using an endoscope, the depth of the wall penetration by the tumor and the presence of LN metastases can be determined with 80% accuracy. A curative resection should be encouraged if EUS indicates that the tumor has not invaded adjacent organs (T4b), and/or fewer than six enlarged LNs are imaged. Thoracoscopic and laparoscopic staging of esophageal cancer may add benefit when the nature of enlarged LNs remote from the cancer cannot be determined, or when advanced imaging systems (PET and high-resolution spiral CT) are not available.

Occasionally, diagnostic laparoscopy and jejunostomy tube placement may precede induction chemoradiation in the patient with severe dysphagia and weight loss from a locally advanced cancer. In summary, esophageal cancer is diagnosed with endoscopic biopsy and is staged with CT scanning of the chest and abdomen, EUS, and PET scan for all patients with CT or EUS evidence of advanced disease (T2 or greater, N1-2 or NX). Experience with esophageal resection in patients with early stage disease has identified characteristics of esophageal cancer that are associated with improved survival. A number of studies suggest that only metastasis to LNs and tumor penetration of the esophageal wall have a significant and independent influence on prognosis. Factors known to be important in the survival of patients with advanced disease, such as cell type, degree of cellular differentiation, or location of tumor in the esophagus, have no effect on survival of patients who have undergone resection for early disease. Studies also showed that patients having five or fewer LN metastases have a better outcome. Using these data, Skinner developed the wall penetration, LN, and distant organ metastases system for staging.

The wall penetration, LN, and distant organ metastases system differed somewhat from the previous efforts to develop a satisfactory staging criteria for carcinoma of the esophagus. Most surgeons agreed that the 1983 tumor, nodes, and metastasis system left much to be desired. In the third edition of the manual for Staging of Cancer of the American Joint Committee on Cancer (AJCC) in 1988, an effort was made to provide a finer discrimination between stages than had been contained in the previous edition in 1983. In 2010, further refinements of the staging system of esophageal cancer were approved by the AJCC, recognizing the difference in survival afforded by resection of limited LN disease adjacent to the tumor, compared to multilevel LN disease and positive LNs remote from the primary. Table 25-11 shows the AJCC definitions for the primary tumor, lymph nodes, distant metastasis, and overall staging schema for both squamous cell carcinoma and adenocarcinoma.

Clinical Approach to Carcinoma of the Esophagus and Cardia

The selection of a curative vs. a palliative operation for cancer of the esophagus is based on the location of the tumor, the patient's age and health, the extent of the disease, and preoperative staging. Figure 25-67 shows an algorithm of the clinical decisions important in the selection of curative or palliative therapy.

Tumor Location. The selection of surgical therapy for patients with carcinoma of the esophagus depends not only on the anatomic stage of the disease and an assessment of the swallowing capacity of the patient, but also on the location of the primary tumor.

It is estimated that 8% of the primary malignant tumors of the esophagus occur in the cervical portion (Fig. 25-68). They are almost always squamous cell cancer, with a rare adenocarcinoma arising from a congenital inlet patch of columnar lining. These tumors, particularly those in the postcricoid area, represent a separate pathologic entity for two reasons: (a) They are more common in females and appear to be a unique entity in this regard; and (b) The efferent lymphatics from the cervical esophagus drain completely differently from those of the thoracic esophagus. The latter drain directly into the paratracheal and deep cervical or internal jugular LNs with minimal flow in a longitudinal direction. Except in advanced disease, it is unusual for intrathoracic LNs to be involved.

Cervical esophageal cancer is frequently unresectable because of early invasion of the larynx, great vessels, or trachea. Radical surgery, including esophagolaryngectomy may occasionally be performed for these lesions, but the ensuing morbidity makes this a less than desirable approach in the face of uncertain cure. Thus, for most patients with cervical esophageal cancer, stereotactic radiation with concomitant chemotherapy is the most desirable treatment.

Tumors that arise within the middle third of the esophagus are squamous carcinomas most commonly and are frequently associated with LN metastasis, which are usually in the thorax but may be in the neck or abdomen, and may skip areas in between. Although it is generally felt that individuals with midthoracic cancer and abdominal LN metastases are incurable with surgery, there are some emerging data that suggest that cervical LN metastases, if isolated, can be resected with benefit. Generally, T1 and T2 cancers without LN metastases are treated with resection only, but there is more and more data to suggest that LN involvement or transmural cancer (T3) warrants treatment with neoadjuvant chemoradiation therapy followed by resection. Although some surgeons prefer a transhiatal esophagectomy for all tumor locations, most surgeons believe that resection of midesophageal cancer should be performed under direct vision with either thoracoscopy (video-assisted thoracic surgery [VATS]) or with thoracotomy.

Tumors of the lower esophagus and cardia are usually adenocarcinomas. Unless preoperative and intraoperative staging clearly demonstrate an incurable lesion, resection in continuity with a LN dissection should be performed. Because of the propensity of GI tumors to spread for long distances submucosally, long lengths of grossly normal GI tract should be resected The longitudinal lymph flow in the esophagus can result in skip areas, with small foci of tumor above the primary lesion, which underscores the importance of a wide resection of esophageal tumors. Wong has shown that local recurrence at the anastomosis can be prevented by obtaining a 10-cm margin of normal esophagus above the tumor. Anatomic studies have also shown that there is no submucosal lymphatic barrier between the esophagus and the stomach at the cardia, and Wong has shown that 50% of the local recurrences in patients with esophageal cancer who are resected for cure occur in the intrathoracic stomach along the line of the gastric resection. Considering that the length of the esophagus ranges from 17 to 25 cm, and the length of the lesser curvature of the stomach is approximately 12 cm, a curative resection requires a cervical division of the esophagus and a >50% proximal gastrectomy in most patients with carcinoma of the distal esophagus or cardia.

Table 25-11

American Joint Committee on Cancer (AJCC) Staging Schema for Esophageal Cancer

TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor.
Tis	High-grade dysplasia.
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa.
T1a	Tumor invades lamina propria or muscularis mucosae.
T1b	Tumor invades submucosa.
T2	Tumor invades muscularis propria.
T3	Tumor invades adventitia.
T4	Tumor invades adjacent structures.
T4a	Resectable tumor invading pleura, pericardium, or diaphragm.
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc.
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis.
N1	Metastases in 1–2 regional lymph nodes.
N2	Metastases in 3–6 regional lymph nodes.
N3	Metastases in ≥7 regional lymph nodes.
M0	No distant metastasis.
M1	Distant metastasis.

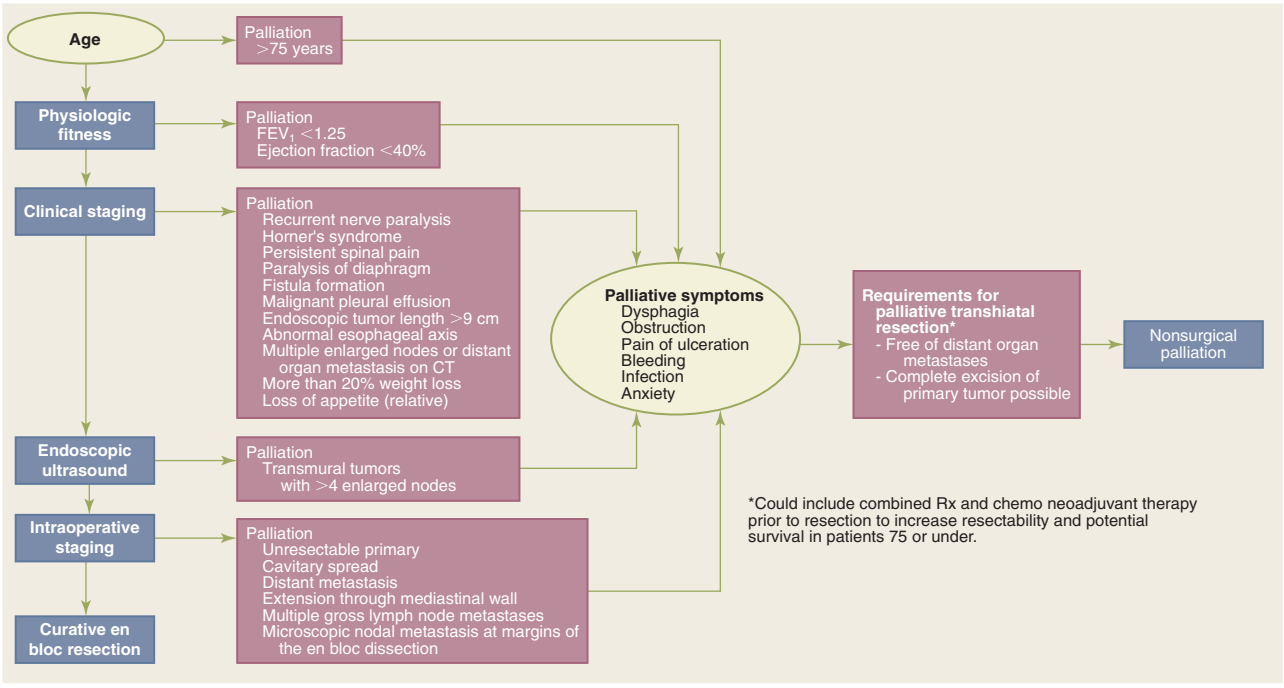

Figure 25-67. Algorithm for the evaluation of esophageal cancer patients to select the proper therapy: curative en bloc resection, palliative transhiatal resection, or nonsurgical palliation. CT = computed tomography; FEV_1 = forced expiratory volume in 1 second. *(Reproduced with permission from DeMeester TR: Esophageal carcinoma: Current controversies.* Sem Surg Oncol. *13:217, 1997.)*

Age. Resection for cure of carcinoma of the esophagus in a patient older than 80 years is rarely indicated, because of the additional operative risk and the shorter life expectancy. Despite this general guideline, octogenarians with a high performance status and excellent cardio-pulmonary reserve may be considered candidates for esophagectomy and recent case series have established its success in highly selected patients. It is in this group of patients that the lesser physiologic impact of minimally invasive surgery may reduce the morbidity and mortality associated with open two- or three-field esophagectomy.

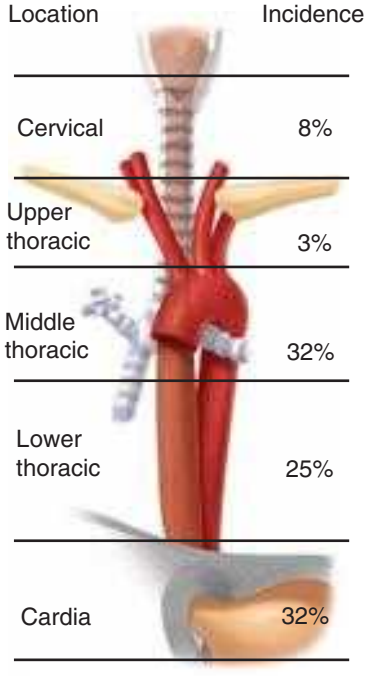

Figure 25-68. Incidence of carcinoma of the esophagus and cardia based on tumor location.

Cardiopulmonary Reserve. Patients undergoing esophageal resection should have sufficient cardiopulmonary reserve to tolerate the proposed procedure. The respiratory function is best assessed with the forced expiratory volume in 1 second, which ideally should be 2 L or more. Any patient with a forced expiratory volume in 1 second of <1.25 L is a poor candidate for thoracotomy, because he or she has a 40% risk of dying from respiratory insufficiency within 4 years. In patients with poor pulmonary reserve, the transhiatal esophagectomy should be considered, as the pulmonary morbidity of this operation is less than is seen following thoracotomy. Clinical evaluation and electrocardiogram are not sufficient indicators of cardiac reserve. Echocardiography and dipyridamole thallium imaging provide accurate information on wall motion, ejection fraction, and myocardial blood flow. A defect on thallium imaging may require further evaluation with preoperative coronary angiography. A resting ejection fraction of <40%, particularly if there is no increase with exercise, is an ominous sign. In the absence of invasive testing, observed stair-climbing is an economical (albeit not quantitative) method of assessing cardiopulmonary reserve. Most individuals who can climb three flights of stairs without stopping will do well with two-field open esophagectomy, especially if an epidural catheter is used for postoperative pain relief.

Nutritional Status. The factor most predictive of postoperative complication is the nutritional status of the patient. Profound weight loss, more than 20 lb, associated with hypoalbuminemia (albumin <3.5 g/dL) is associated with a much higher rate of complications and mortality than patients who enter curative

surgery in better nutritional condition. Because malnourished patients generally have locally advanced esophageal cancer, if not metastatic disease, one should consider the placement of a feeding tube before the beginning of induction chemoradiation therapy. Although mild amounts of dysphagia are improved by induction chemoradiation therapy, more pronounced dysphagia and associated malnutrition should be addressed before the initiation of chemoradiation. A laparoscopic jejunostomy tube can be placed prior to induction therapy or at the time of esophagectomy. There are emerging data that 5 days' pretreatment with immune-enhancing nutrition, rich in fish oils, decreases cardiac and other complications, following esophagectomy.

Clinical Staging. Clinical factors that indicate an advanced stage of carcinoma and exclude surgery with curative intent are recurrent nerve paralysis, Horner's syndrome, persistent spinal pain, paralysis of the diaphragm, fistula formation, and malignant pleural effusion. Factors that make surgical cure unlikely include a tumor >8 cm in length, abnormal axis of the esophagus on a barium radiogram, more than four enlarged LNs on CT, a weight loss more than 20%, and loss of appetite. Studies indicate that there are several favorable parameters associated with tumors <4 cm in length, there are fewer with tumors between 4 and 8 cm, and there are no favorable criteria for tumors >8 cm in length. Consequently, the finding of a tumor >8 cm in length should exclude curative resection; the finding of a smaller tumor should encourage an aggressive approach.

Preoperative Staging with Advanced Imaging. For years, clinical staging, contrast radiography, endoscopy, and CT scanning formed the backbone of esophageal cancer staging. More recently, preoperative decision making is guided by endoscopic ultrasonography and PET scanning.

EUS provides the most reliable method of determining depth of cancer invasion. In the absence of enlarged LNs, the degree of wall invasion dictates surgical therapy. If a small focus of esophageal cancer is confined to the mucosa, endoscopic mucosal resection (EMR) is a preferable option. If the tumor invades in to the submucosa, without visible lymph node involvement, most individuals would suggest esophagectomy with LN dissection, as positive nodes can be found in 20% to 25% of those with cancer limited to the mucosa and submucosa. If EUS demonstrates spread through the wall of the esophagus, especially if LNs are enlarged, then induction chemoradiation therapy (neoadjuvant therapy) should be strongly considered. Lastly, when the EUS demonstrates invasion of the trachea, bronchus, aorta, or spine, then surgical resection is rarely indicated. If there is invasion into the pleura (T4a), then surgical resection can be considered in the absence of a malignant effusion. Thus, it can be seen that the therapy of esophageal cancer is largely driven by the findings of an endoscopic ultrasonography. It is difficult to provide modern treatment of esophageal cancer without access to this modality.

PET scanning, usually combined with an axial CT scan (CTPET), usually is performed on patients with locally advanced cancer or questionable lesions on CT scan to determine whether metastases are present. The PET scan uses the injection of radiolabeled deoxyglucose, which is taken up in metabolically active tissues such as cancer. PET-positive areas must be correlated with the CT scan findings to assess the significance of "hot spots." CTPET scanning has been especially useful before the initiation of chemoradiation therapy. An early response to chemoradiotherapy, by PET scan, improves the prognosis whether or not resection is ultimately performed. Conversely, if a PET-avid tumor shows no change in metabolic activity after 2 weeks of induction chemoradiation therapy, it is unlikely that further chemo- or radiation therapy will be of any benefit. These patients have a worse prognosis, and may be referred for resection or palliation without incurring the morbidity or expense of a full course of chemo- and radiation therapy.

Palliation of Esophageal Cancer

Palliation of esophageal cancer is indicated for individuals with metastatic esophageal cancer or cancer invading adjacent organs (T4b) who are unable to swallow, or individuals with fistulae into the tracheobronchial tree. Aortic esophageal fistulas are extremely rare and nearly 100% lethal. Dysphagia as a result of esophageal cancer can be graded from Grade I, eating normally, to grade VI, unable to swallow saliva (Table 25-12). Grades I–III often can be managed with radiation therapy, usually in combination with chemotherapy. When surgical resection is not anticipated in the future, this is termed definitive chemoradiation therapy and usually is palliative. Radiation dose is increased from 45 Gy to 60 Gy administered over 8 weeks, rather than the 4 weeks given for chemoradiation induction therapy. In 20% of patients, a complete response to chemoradiation therapy will not only palliate the symptoms, but leave the patient with undetectable cancer of the esophagus. Although some of these patients are truly cured, cancer will recur in many either locally or systemically 1 to 5 years following definitive chemoradiation. In a few patients, definitive chemoradiation will be successful in all sites but the esophagus. After a 12-month wait from initial treatment and no other sites of tumor detectable except the esophagus, some of these patients may be candidates for salvage esophagectomy.

For individuals with dysphagia grades IV and higher, additional treatment generally is necessary. The mainstay of therapy is in-dwelling esophageal stents. Covered removable stents may be used to seal fistulae or when stent removal becomes desirable in the future. When large, locally invasive tumors or metastatic esophageal cancer precludes any future hope of resection, uncovered expandable metal stents are the treatment of choice. The major limitations to stenting exist in cancers at the GEJ. A stent placed across the GEJ will result in severe gastroesophageal

Table 25-12

Functional grades of dysphagia

GRADE	DEFINITION	INCIDENCE AT DIAGNOSIS (%)
I	Eating normally	11
II	Requires liquids with meals	21
III	Able to take semisolids but unable to take any solid food	30
IV	Able to take liquids only	40
V	Unable to take liquids, but able to swallow saliva	7
VI	Unable to swallow saliva	12

reflux and heartburn that can be quite disabling. In cancers at this level, radiation therapy alone may be preferable. If feeding access is desirable, a laparoscopic jejunostomy is usually the procedure of choice.

Surgical Treatment

The surgical treatment of esophageal cancer is dependent upon the location of the cancer, the depth of invasion, LN metastases, the fitness of the patient for operation, and the culture and beliefs of the individuals and institutions in which the treatment is performed. In an ideal world, there would be a single, stage-specific method of treating esophageal cancer, because the evidence would be unassailable and noncontroversial. Randomized clinical trials and meta-analyses would prove beyond a shadow of a doubt the value of surgery vs. nonoperative therapy and would dictate the type and extent of surgery that would optimally balance immediate morbidity and mortality with duration and quality of life conferred by the procedure and the perioperative management of the esophagectomy patient. Despite many noble attempts to establish this high level of evidence, many questions relating to the appropriate therapy of esophageal cancer remain controversial. About the only area of complete agreement is that esophagectomy should not be performed if an R0 resection is not possible. In other words, if the surgeon does not believe he or she can remove all LNs invaded by cancer and provide a tumor-free radial margin and esophagus and stomach margins that are tumor free, then a resection should not be performed.

Mucosally Based Cancer. In patients with BE, and especially those with high-grade dysplasia, subcentimeter nodules are frequently discovered. Nodules should be resected in entirety, as they often harbor adenocarcinoma. Five years ago, such resection was performed with a transhiatal esophagectomy, but more recently EMR offers another method for removing intramucosal cancer. In this clinical situation, EMR is typically combined with EUS to rule out more invasive disease. EUS however, is unable to differentiate between cancer that is confined to the mucosa (T1a) and that which invades the submucosa (T1b). Tumors invading the submucosa are not amenable to endoscopic mucosal resection because of the high-frequency (20%–25%) concurrent finding of positive LNs, which cannot be removed without esophagectomy. On the other hand, intramucosal cancers have little risk of spreading to regional LNs. The current approach used involves performing EMR on all nodules identified in a field of Barrett's esophagus and then T staging is performed by histologic analysis. This approach dictates the need for future therapy such as esophagectomy.

For this reason, small intramucosal carcinomas may be removed with EMR in the following manner: The area beneath the nodule is infiltrated with saline through a sclerotherapy needle. A specialized suction cap is mounted on the end of the endoscope and the nodule is drawn up into the cap, following which a snare is applied to resect the tissue. Alternatively, a rubber band can be delivered and the snare can be used to resect above the level of the rubber band. This specimen is then removed and sent to pathology. As long as the tumor is found to be confined to the mucosa and all margins are negative, the resection is complete. A positive margin or involvement of the submucosa warrants esophagectomy. Most importantly, these patients are at high risk for developing small nodular carcinomas elsewhere in their Barrett's segment, and routine surveillance on a 3- to 6-month basis must be continued indefinitely. Alternatively, one can consider radiofrequency ablation of the remainder of the high-grade dysplasia after careful surveillance biopsy specimens demonstrate no further sign of cancer. This approach to the early esophageal cancer should not be used when there is any suspicion of mediastinal or abdominal lymphadenopathy. Although it is currently rare that EMR provides definitive therapy of small nodular esophageal cancers, this may become more of the norm as greater surveillance reveals earlier cancers, and proficiency of the technique by surgeons and gastroenterologists increases.

Minimally Invasive Transhiatal Esophagectomy. Minimally invasive transhiatal esophagectomy is an increasingly popular procedure; however, the number of these operations performed around the world remains small. Mini-invasive surgery (MIS) transhiatal esophagectomy was first performed by Aureo DePaula in Brazil and has been modified and adopted by many individuals around the world. This operation combines the advantages of transhiatal esophagectomy at minimizing pulmonary complications with the advantages of laparoscopy (less pain, quicker rehabilitation). Several variations of MIS transhiatal esophagectomy have been developed. For the earliest lesions, such as high-grade dysplasia or intramucosal carcinoma, a vagal sparing procedure can be entertained. In such a procedure, the vagal trunks are separated from the esophagus at the level of the diaphragm and the lesser curvature dissection of the stomach allows the vagus and left gastric pedicle to remain intact. Clearly, this dissection, which hugs the stomach and esophagus, provides no LN staging and is thus inadequate for all high-grade dysplasia and intramucosal cancer.

MIS transhiatal esophagectomy is usually performed through five or six small incisions in the upper abdomen and a transverse cervical incision for removing the specimen and performing the cervical esophagogastrostomy. To remove the esophagus from the posterior mediastinum, especially the area behind the pulmonary vessels and the tracheal bifurcation, which cannot be visualized even with a long laparoscope placed in the posterior mediastinum, it is preferred to use a vein stripping "inversion" technique (Fig. 25-69A). The details of this operation are too lengthy to include in this text, but include the laparoscopic creation of a neo-esophagus (gastric conduit) along the greater curvature of the stomach using the right gastroepiploic artery as the primary vascular pedicle. The conduit can be created through a mini-laparotomy or laparoscopically. A Kocher maneuver releases the duodenum, and a pyloroplasty may be performed (optional). Retrograde esophageal stripping is performed by dividing the esophagus below the GEJ and sliding a vein stripper from the neck down into the abdomen followed by an inversion of the esophagus in the posterior mediastinum and removal through the neck (Fig. 25-69B). This technique is reserved for patients with high-grade dysplasia. For small cancers at the GEJ, the esophagus can be stripped in an antegrade fashion by sliding the vein stripper down from the cervical incision and out the tail of the lesser curvature (Fig. 25-69C). The tail of the lesser curvature is pulled out a port site high in the epigastrium while the esophagus is inverted into itself. For GEJ cancers, a wide celiac access LN dissection, splenic artery, hepatic artery, and posterior mediastinal LN dissection can be performed as well or better than through a laparotomy. The gastric conduit is pulled up to the neck with a chest tube and anastomosed to the cervical esophagus in an end-to-side fashion using a surgical stapler or with a handsewn anastomosis. Complications of this technique are primarily limited to leak from the

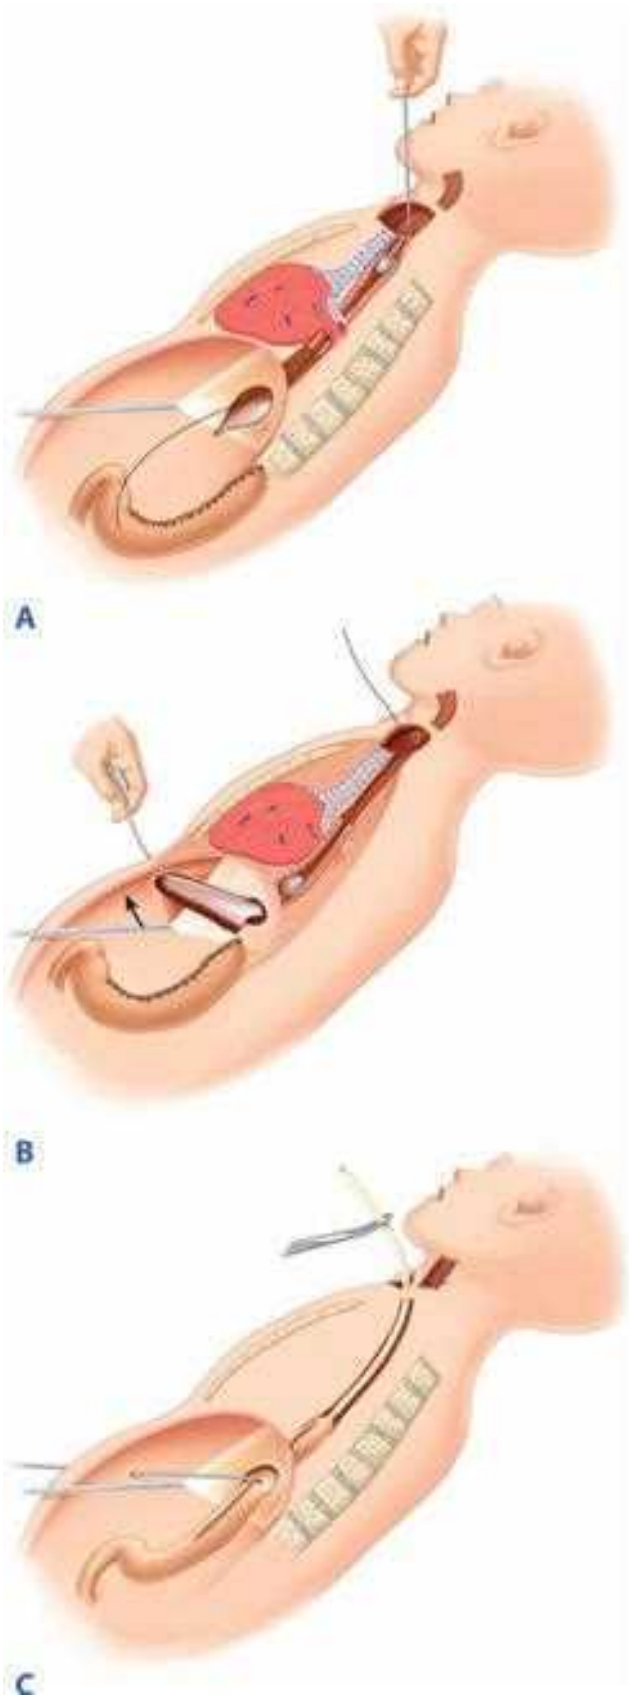

Figure 25-69. **A.** Laparoscopic retrograde inversion. **B.** Laparoscopic antegrade inversion. esophagogastric anastomosis, which is self-limited and usually heals within 1 to 3 weeks, spontaneously.

Open Transhiatal Esophagectomy. Transhiatal esophagectomy, also known as blunt esophagectomy or esophagectomy without a thoracotomy, was first performed in 1933 by a British surgeon, but was popularized in the last quarter of the twentieth century by Mark Orringer from the University of Michigan. Although this operation may violate many of the principles of cancer resection, including extended radical LN dissection this operation has performed as well as any of the more radical procedures in randomized trials, and in large database analyses. With transhiatal esophagectomy, the elements of dissection are similar to that described in the section entitled Minimally Invasive Transhiatal Esophagectomy, including the creation of the gastric tube and the posterior mediastinal dissection through the hiatus. Because this dissection is performed with the fingertips rather than under direct vision with surgical instruments, it requires an enlargement of the diaphragmatic hiatus. The lower mediastinal LN basins can be resected as can the upper abdominal LNs, making this an attractive option for GEJ cancers. The mediastinal LNs above the inferior pulmonary vein are not removed with this technique, but rarely result in a point of isolated cancer recurrence.

Of all procedures for esophageal cancer, this operation is the quickest to perform in experienced hands and lies in an intermediate position between minimally invasive esophagectomy and the Ivor Lewis procedure with respect to complications and recovery.

Minimally Invasive Two- and Three-Field Esophagectomy. After a rocky start, minimally invasive esophagectomy using a thoracic dissection through VATS has become reasonably popular. In general, this operation is performed with an anastomosis created in the neck (three-field), but may be performed with the anastomosis stapled in the high thorax (two-field). Both procedures will be described.

With a minimally invasive three-field esophagectomy, the patient is placed in the left lateral decubitus position. Double lumen intubation is required. Videoscopic access to the thorax is obtained in the midaxillary line in the ninth intercostal space and an angled telescope illuminates the chest superiorly. A minithoracotomy at about the sixth intercostal space anteriorly allows introduction of conventional surgical instruments, and a high trocar allows retraction of the lung away from the esophagus. In a three-field approach, the esophagus is dissected along its length to include division of the azygos vein and harvesting of the LNs in the upper, middle, and lower posterior mediastinum. Hilar, and posterior mediastinal nodes are all removed and sent with the specimen or individually. The thoracic duct is divided at the level of the diaphragm and removed with the specimen.

Following complete intrathoracic dissection, the patient is placed in the supine position and five laparoscopic ports are placed as with the MIS transhiatal esophagectomy. The abdominal portions of the operation are identical to those described previously in the section entitled Minimally Invasive Transhiatal Esophagectomy, and the gastric conduit is then sewn to the tip of the fully mobilized GEJ and lesser curvature sleeve. A feeding tube is placed and the pyloroplasty may be performed laparoscopically. A transverse cervical incision and dissection between the sternocleidomastoid and the anterior strap muscles allows access to the cervical esophagus. Great care is made to avoid stretching the recurrent laryngeal nerve. The esophagus

and proximal stomach is then pulled up into the neck with the gastric conduit following. Cervical anastomosis is then performed.

The MIS transthoracic two-field esophagectomy is slightly different. In this operation, the abdominal portions of the operation are done first, including placement of the feeding tube, the creation of the conduit, and the sewing of the tip of the conduit to the fully dissected GEJ. The patient is then rolled into the left lateral decubitus position and, through right thoracoscopy, the esophagus is dissected and divided 10 cm above the tumor. Once freed, the specimen is pulled out through the mini-thoracotomy and an end-to-end anastomosis stapler is introduced through the high corner of the gastric conduit and out a stab wound along the greater curvature. The anvil of the stapler is placed in the proximal esophagus and held with a purse-string, the stapler is docked, the anastomosis is created, and a gastrotomy is then closed with another firing of the GIA stapler. The three-field esophagectomy has the advantage of placing the anastomosis in the neck where leakage is unlikely to create a severe systemic consequence. On the other hand, placement of the anastomosis in the high chest minimizes the risks of injury to structures in the neck, particularly the recurrent laryngeal nerve. Although the leak of the intrathoracic anastomosis may be more likely to bear septic consequences, the incidence of leak is diminished. Other complications of this approach relate to pulmonary and cardiac status. In many series, the most common complication is pneumonia, the second is atrial fibrillation, and the third is anastomotic leak.

Ivor Lewis (En Bloc) Esophagectomy. The theory behind radical transthoracic esophagectomy is that greater removal of LNs and periesophageal tissues diminishes the chance of a positive radial margin and LN recurrence. Although there are no randomized data demonstrating this to be superior to other forms of esophagectomy, there are many retrospective data demonstrating improved survival with greater numbers of LNs harvested. A recent study from Sloan-Kettering demonstrates a direct relationship between the number of negative nodes harvested and long-term survival. Although such a survival advantage may be related to the completeness of resection, extended radical resections may also be a surrogate for experienced surgeons working in great institutions. As a time-honored operation, there is no doubt that en bloc esophagectomy is the standard to which less radical techniques must be compared.

Generally, this operation is started in the abdomen with an upper midline laparotomy and extensive LN dissection in and about the celiac access and its branches, extending into the porta hepatis and along the splenic artery to the tail of the pancreas. All LNs are removed en bloc with the lesser curvature of the stomach. Unless the tumor extends into the stomach, reconstruction is performed with a greater curvature gastric tube. For GEJ cancers extending significantly into the gastric cardia or fundus, the proximal stomach is removed and reconstruction is performed with an isoperistaltic section of left colon between the upper esophagus and the remnant stomach, or the colon is connected to a Roux-en-Y limb of jejunum, if total gastrectomy is necessary. In the majority of cases, colon interposition is unnecessary, and a gastric conduit is used.

Following closure of the abdominal incision, the patient is placed in the left lateral decubitus position and an anterolateral thoracotomy is performed through the sixth intercostal space. The azygos vein is divided and the posterior mediastinum is entirely cleaned out to include the thoracic duct, all periaortic tissues, and all tissue in the upper mediastinum along the course of the current laryngeal nerves and in the peribronchial, hilar, and tracheal LN stations. The proximal stomach is pulled up into the thorax where a conduit is created (if not performed previously) and a handsewn or stapled anastomosis is made between the upper thoracic esophagus and the gastric conduit or transverse colon. Chest tubes are placed, and the patient is taken to the intensive care unit.

Because this is the most radical of dissections, complications are most common, including pneumonia, respiratory failure, atrial fibrillation, chylothorax, anastomotic leak, conduit necrosis, gastrocutaneous fistula, and, if dissection is too near the recurrent laryngeal nerves, hoarseness will occur with an increased risk of aspiration. Tracheobronchial injury resulting in fistulas between the bronchus and conduit may also occur, however rarely. Although this procedure and three-field esophagectomy are fraught with the highest complication rate, the long-term outcome of this procedure provides the greatest survival in many single-center series and retrospective reviews.

Three-Field Open Esophagectomy. *Three-field open esophagectomy* is very similar to a minimally invasive three-field except that all access is through open incisions. This procedure is preferred by certain Japanese surgeons and LN counts achieved through this kind of operation may run from 45 to 60 LNs. Most Western surgeons question the benefit of such radical surgery when it is hard to define a survival advantage. Nonetheless, high intrathoracic cancers probably deserve such an aggressive approach if cure is the goal.

Salvage Esophagectomy. *Salvage esophagectomy* is the nomenclature applied to esophagectomy performed after failure of definitive radiation and chemotherapy. The most frequent scenario is one in which distant disease (bone, lung, brain, or wide LN metastases) renders the patient nonoperable at initial presentation. Then, systemic chemotherapy, usually with radiation of the primary tumor, destroys all foci of metastasis, as demonstrated by CT and CT-PET, but the primary remains present and symptomatic. Following a period of observation, to make sure no new disease will become evident, salvage esophagectomy is performed, usually with an open two-field approach. Surprisingly, the cure rate of salvage esophagectomy is not inconsequential. One in four patients undergoing this operation will be disease free 5 years later, despite the presence of residual cancer in the operative specimen. Because of the dense scarring created by radiation treatment, this procedure is the most technically challenging of all esophagectomy techniques.

Comparative Studies of Esophagectomy Technique

Transthoracic vs. Transhiatal Esophagectomy. There has been a great debate as to whether en bloc esophagectomy will provide a greater long-term benefit and cure rate in esophageal cancer than transhiatal esophagectomy. In a recent 7-year follow-up of a Dutch study addressing GEJ and lower esophageal cancers, there does not appear to be any benefit to the more extensive dissection despite higher morbidity and mortality. In a subgroup analysis of those with one to eight positive LNs, it did appear that the en bloc transthoracic resection may add to longevity. In another large database analysis of the Surveillance, Epidemiology, and End Results database, transthoracic and transhiatal esophagectomy were compared. In this study,

the transhiatal esophagectomy had a greater long-term survival, but, when adjusted by cancer stage, this survival benefit disappeared. The mortality and morbidity after transhiatal esophagectomy appeared to be less. Suffice it to say that this debate over the best procedure for esophagectomy remains an open question.

The role of the minimally invasive surgical procedures for a cancer cure will require further study and longer follow-up. It would appear from preliminary analysis that the transhiatal esophagectomy, like its open cousin, may be performed with less morbidity and mortality than the VATS procedure. Long-term survival analyses will require careful follow-up for at least 5 to 10 years after cancer treatment. A recent European multicenter randomized trial comparing open and minimally invasive approaches revealed a highly significant reduction in pulmonary complications in the patients who underwent the minimally invasive approach. There was no difference in procedure-related mortality between the approaches.

Alternative Therapies

Radiation Therapy. Primary treatment with radiation therapy does not produce results comparable with those obtained with surgery. Currently, the use of radiotherapy is restricted to patients who are not candidates for surgery, and is usually combined with chemotherapy. Radiation alone is used for palliation of dysphagia but the benefit is short lived, lasting only 2 to 3 months. Furthermore, the length and course of treatment are difficult to justify in patients with a limited life expectancy. Radiation is effective in patients who have hemorrhage from the primary tumor.

Adjuvant Chemotherapy. The proposal to use adjuvant chemotherapy in the treatment of esophageal cancer began when it became evident that most patients develop postoperative systemic metastasis without local recurrence. This observation led to the hypothesis that undetected systemic micrometastasis had been present at the time of diagnosis, and, if effective systemic therapy was added to local regional therapy, survival should improve.

Recently, this hypothesis has been supported by the observation of epithelial tumor cells in the bone marrow in 37% of patients with esophageal cancer who were resected for cure. These patients had a greater prevalence of relapse at 9 months after surgery compared to those patients without such cells. Such studies emphasize that hematogenous dissemination of viable malignant cells occurs early in the disease, and that systemic chemotherapy may be helpful if the cells are sensitive to the agent. On the other hand, systemic chemotherapy may be a hindrance, because of its immunosuppressive properties, if the cells are resistant. Unfortunately, current technology is not able to test tumor cell sensitivity to chemotherapeutic drugs. This requires that the choice of drugs be made solely on the basis of their clinical effectiveness against grossly similar tumors.

The decision to use preoperative rather than postoperative chemotherapy was based on the ineffectiveness of chemotherapeutic agents when used after surgery, and animal studies suggesting that agents given before surgery were more effective. The claim that patients who receive chemotherapy before resection are less likely to develop resistance to the drugs is unsupported by hard evidence. The claim that drug delivery is enhanced because blood flow is more robust before patients undergo surgical dissection is similarly flawed, due to the fact that if enough blood reaches the operative site to heal the wound or anastomosis, then the flow should be sufficient to deliver chemotherapeutic drugs. There are, however, data supporting the claim that preoperative chemotherapy in patients with esophageal carcinoma can, if effective, facilitate surgical resection by reducing the size of the tumor. This is particularly beneficial in the case of squamous cell tumors above the level of the carina. Reducing the size of the tumor may provide a safer margin between the tumor and the trachea, and allow an anastomosis to a tumor-free cervical esophagus just below the cricopharyngeus. Involved margin at this level usually requires a laryngectomy to prevent subsequent local recurrence.

Preoperative Chemotherapy. Eight randomized prospective studies of neoadjuvant chemotherapy vs. surgery alone have demonstrated mixed results. For adenocarcinomas of the distal esophagus and proximal stomach, preoperative neoadjuvant 5-fluorouracil (5-FU) and cisplatin chemotherapy has been shown to provide a survival advantage over surgery alone in a well-powered study from the United Kingdom (MRC trial). This trial is one of the few to include enough patients (800) to detect small differences. The trial had a 10% absolute survival benefit at 2 years for the neoadjuvant chemotherapy group. In a second trial from the United Kingdom (MAGIC trial) of distal esophageal and proximal gastric adenocarcinomas, the use of epirubicin in combination with cisplatin and 5-FU also demonstrated a survival advantage for the induction chemotherapy arm with 4 years median follow-up. As a result of these two trials, standard treatment of locally advanced adenocarcinoma in Europe calls for neoadjuvant chemotherapy with one of these two regimens. Most failures are due to distant metastatic disease, underscoring the need for improved systemic therapy. Postoperative septic and respiratory complications may be more common in patients receiving chemotherapy.

Preoperative Combination Chemo- and Radiotherapy. Preoperative chemoradiotherapy using cisplatin and 5-FU in combination with radiotherapy has been reported by several investigators to be beneficial in both adenocarcinoma and squamous cell carcinoma of the esophagus. There have been 10 randomized prospective studies (Table 25-13). A recent meta-analysis of these trials demonstrates a 13% survival advantage for neoadjuvant chemoradiation therapy, which is more pronounced for patients with adenocarcinoma than for those with squamous carcinoma (Table 25-14). It was also observed that the benefit for chemotherapy alone (7%) was not as dramatic as for chemoradiotherapy used in the neoadjuvant setting. Additionally, other work has demonstrated the importance of obtaining an R0 (tumor-free) resection as the most important variable determining long-term survival. Although there are not direct, randomized comparisons between chemotherapy and chemoradiation therapy, it appears that the addition of radiation may improve local response of the tumor, and may allow a greater opportunity for the surgeon to obtain an R0 resection.

The timing of surgery after chemoradiation induction is generally felt to be optimal between 6 and 8 weeks following the completion of induction therapy. Earlier than this time, active inflammation may make the resection hazardous, and the patients have not had time to recover fully from the chemoradiation. After 8 weeks, edema in the periesophageal tissue starts to turn to scar tissue, making dissection more difficult.

With chemoradiation, the complete response rates for adenocarcinoma range from 17% to 24% (Table 25-15). No tumor

is detected in the specimen after esophagectomy. Patients demonstrating a complete response to chemoradiation have a better survival rate than those without complete response, but distant failure remains common.

At present, the strongest predictors of outcome of patients with esophageal cancer are the anatomic extent of the tumor at diagnosis and the completeness of tumor removal by surgical resection. After incomplete resection of an esophageal cancer, the 5-year survival rates are 0% to 5%. In contrast, after complete resection, independent of stage of disease, 5-year survival ranges from 15% to 40%, according to selection criteria and stage distribution. The importance of early recognition and adequate surgical resection cannot be overemphasized. Figure 25-70 is a global algorithm for the management of esophageal carcinoma.

SARCOMA OF THE ESOPHAGUS

Sarcomas and carcinosarcomas are rare neoplasms, accounting for approximately 0.1% to 1.5% of all esophageal tumors. They present with the symptom of dysphagia, which does not differ from the dysphagia associated with the more common epithelial carcinoma. Tumors located within the cervical or high thoracic esophagus can cause symptoms of pulmonary aspiration secondary to esophageal obstruction. Large tumors originating at the level of the tracheal bifurcation can produce symptoms of airway obstruction and syncope by direct compression of the tracheobronchial tree and heart (Fig. 25-71). The duration of dysphagia and age of the patients affected with these tumors are similar to those with carcinoma of the esophagus.

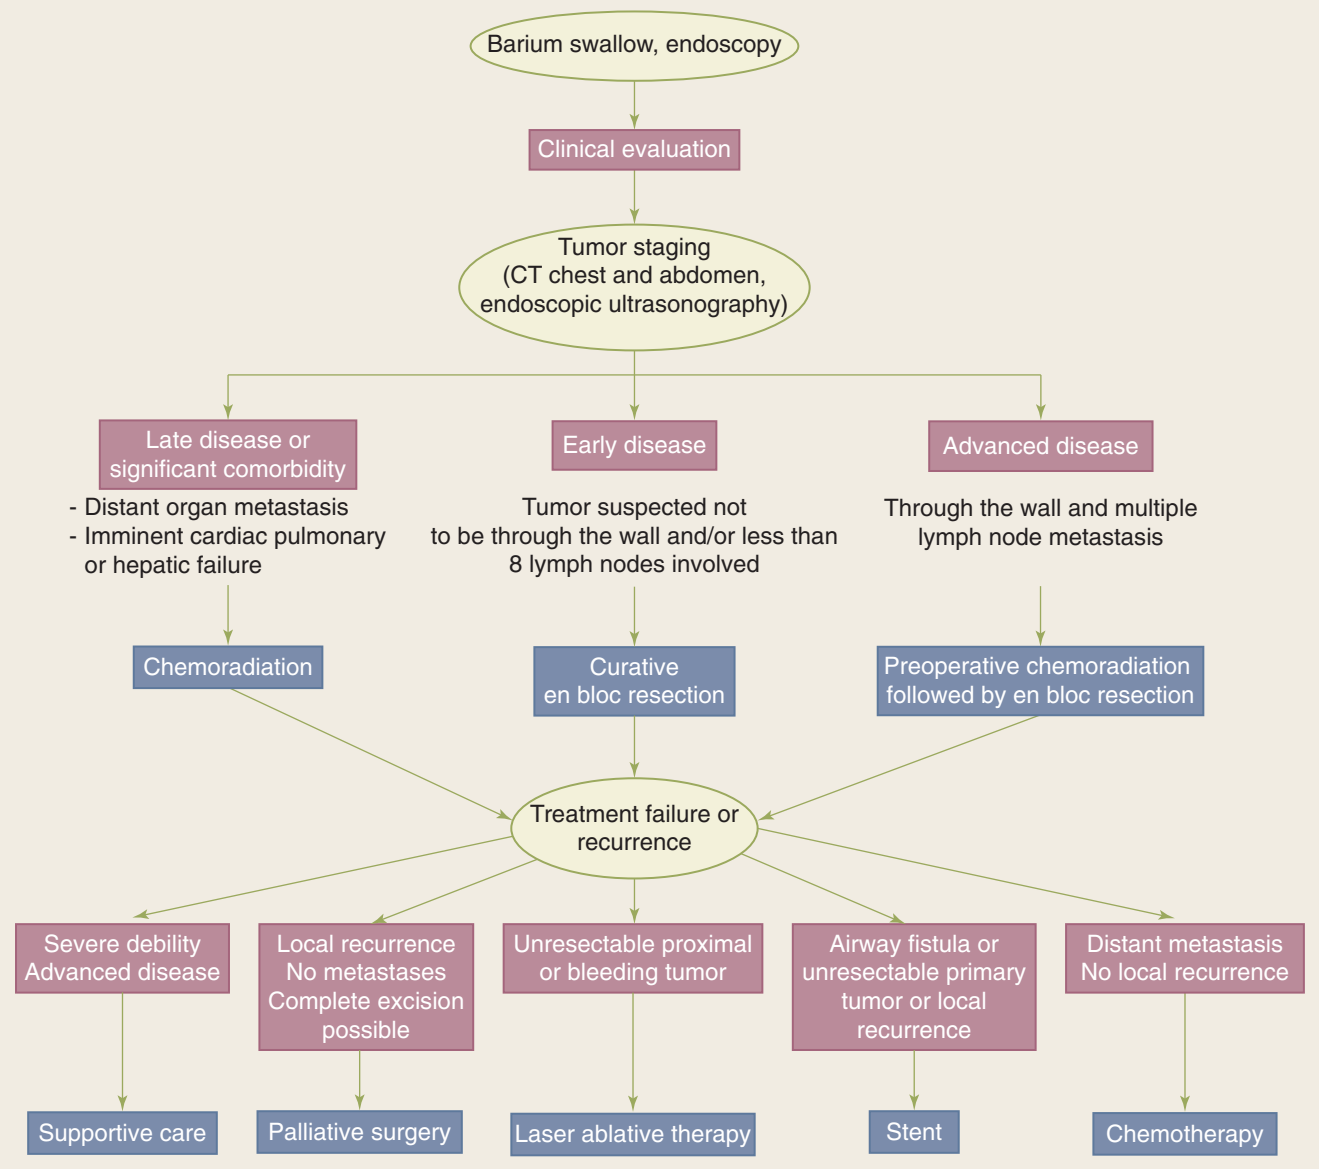

Figure 25-70. Suggested global algorithm for the management of carcinoma of the esophagus. CT = computed tomography.

A barium swallow usually shows a large polypoid intraluminal esophageal mass, causing partial obstruction and dilatation of the esophagus proximal to the tumor (Fig. 25-72). The smooth polypoid nature of the lesion, although not diagnostic, is distinctive enough to suggest the presence of a sarcoma rather than the more common ulcerating, stenosing carcinoma.

Esophagoscopy commonly shows an intraluminal necrotic mass. When biopsy is attempted, it is important to remove the necrotic tissue until bleeding is seen on the tumor's surface. When this is not done, the biopsy specimen will show only tissue necrosis. Even when viable tumor is obtained on biopsy, it has been these authors' experience that it cannot be definitively identified as carcinoma, sarcoma, or carcinosarcoma on the basis of the histology of the portion biopsied. Biopsy results cannot be totally relied on to identify the presence of sarcoma, and it is often the polypoid nature of the lesion that arouses suspicion that it may be something other than carcinoma.

Polypoid sarcomas of the esophagus, in contrast to infiltrating carcinomas, remain superficial to the muscularis propria and are less likely to metastasize to regional LNs. In one series of 14 patients, local extension or tumor metastasis would have prevented a potentially curative resection in only five. Thus, the presence of a large polypoid tumor should not deter the surgeon from resecting the lesion.

Sarcomatous lesions of the esophagus can be divided into epidermoid carcinomas with spindle cell features, such as carcinosarcoma, and true sarcomas that arise from mesenchymal tissue, such as leiomyosarcoma, fibrosarcoma, and rhabdomyosarcoma. Based on current histologic criteria for diagnosis, fibrosarcoma and rhabdomyosarcoma of the esophagus are extremely rare lesions.

Surgical resection of polypoid sarcoma of the esophagus is the treatment of choice, because radiation therapy has little success and the tumors remain superficial, with local invasion or distant metastases occurring late in the course of the disease. As with carcinoma, the absence of both wall penetration and LN metastases is necessary for curative treatment, and surgical resection is consequently responsible for the majority of the

reported 5-year survivals. Resection also provides an excellent means of palliating the patient's symptoms. The surgical technique for resection and the subsequent restoration of the GI continuity is similar to that described for carcinoma.

In these authors' experience, four of the eight patients with carcinosarcoma survived for 5 years or longer. Even though this number is small, it suggests that resection produces better results in epithelial carcinoma with spindle cell features than in squamous cell carcinoma of the esophagus. Similarly, with leiomyosarcoma of the esophagus, the same scattered reports exist with little information on survival. Of seven patients with leiomyosarcoma, two died from their disease—one in 3 months and the other 4 years and 7 months after resection. The other five patients were reported to have survived more than 5 years.

It is difficult to evaluate the benefits of resection for leiomyoblastoma of the esophagus, due to the small number of reported patients with tumors in this location. Most leiomyoblastomas occur in the stomach, and 38% of these patients succumb to the cancer in 3 years. Fifty-five percent of patients with extragastric leiomyoblastoma also die from the disease, within an average of 3 years. Consequently, leiomyoblastoma should be considered a malignant lesion and apt to behave like a leiomyosarcoma. The presence of nuclear hyperchromatism, increased mitotic figures (more than one per high-power field), tumor size larger than 10 cm, and clinical symptoms of longer than 6 months' duration are associated with a poor prognosis.

BENIGN TUMORS AND CYSTS

Benign tumors and cysts of the esophagus are relatively uncommon. From the perspectives of both the clinician and the pathologist, benign tumors may be divided into those that are within the muscular wall and those that are within the lumen of the esophagus.

Intramural lesions are either solid tumors or cysts, and the vast majority are leiomyomas. They are made up of varying portions of smooth muscle and fibrous tissue. Fibromas, myomas, fibromyomas, and lipomyomas are closely related and occur rarely. Other histologic types of solid intramural tumors have been described, such as lipomas, neurofibromas, hemangiomas, osteochondromas, granular cell myoblastomas, and glomus tumors, but they are medical curiosities.

Intraluminal lesions are polypoid or pedunculated growths that usually originate in the submucosa, develop mainly into the lumen, and are covered with normal stratified squamous epithelium. The majority of these tumors are composed of fibrous tissue of varying degrees of compactness with a rich vascular supply. Some are loose and myxoid (e.g., myxoma and myxofibroma), some are more collagenous (e.g., fibroma), and some contain adipose tissue (e.g., fibrolipoma). These different types of tumor are frequently collectively designated fibrovascular polyps, or simply as polyps. Pedunculated intraluminal tumors should be removed. If the lesion is not too large, endoscopic removal with a snare is feasible.

Leiomyoma

Leiomyomas constitute more than 50% of benign esophageal tumors. The average age at presentation is 38, which is in sharp contrast to that seen with esophageal carcinoma. Leiomyomas are twice as common in males. Because they originate in smooth muscle, 90% are located in the lower two thirds of the esophagus. They are usually solitary, but multiple tumors have been found on occasion. They vary greatly in size and shape. Actually tumors as small as 1 cm in diameter and as large as 10 lb have been removed.

Figure 25-73. Barium esophagogram showing a classical, smooth, contoured, punched-out defect of a leiomyoma.

Typically, leiomyomas are oval. During their growth, they remain intramural, having the bulk of their mass protruding toward the outer wall of the esophagus. The overlying mucosa is freely movable and normal in appearance. Dysphagia and pain are the most common complaints, the two symptoms occurring more frequently together than separately. Bleeding directly related to the tumor is rare, and when hematemesis or melena occurs in a patient with an esophageal leiomyoma, other causes should be investigated.

A barium swallow is the most useful method to demonstrate a leiomyoma of the esophagus (Fig. 25-73). In profile, the tumor appears as a smooth, semilunar, or crescent-shaped filling defect that moves with swallowing, is sharply demarcated, and is covered and surrounded by normal mucosa. Esophagoscopy should be performed to exclude the reported observation of a coexistence with carcinoma. The freely movable mass, which bulges into the lumen, should not be biopsied because of an increased chance of mucosal perforation at the time of surgical enucleation. Endoscopic ultrasound is also a useful adjunct in the workup of leiomyoma and provides detail related to the anatomic extent and relationship to surrounding structures.

Despite their slow growth and limited potential for malignant degeneration, leiomyomas should be removed unless there are specific contraindications. The majority can be removed by simple enucleation. If, during removal, the mucosa is inadvertently entered, the defect can be repaired primarily. After tumor removal, the outer esophageal wall should be reconstructed by closure of the muscle layer. The location of the lesion and the extent of surgery required will dictate the approach. Lesions of the proximal and middle esophagus require a right thoracotomy, whereas distal esophageal lesions require a left thoracotomy. Videothoracoscopic and laparoscopic approaches are now frequently used. The mortality rate associated with enucleation is low, and success in relieving the dysphagia is near 100%.

Large lesions or those involving the GEJ may require esophageal resection.

Esophageal Cyst

Cysts may be congenital or acquired. Congenital cysts are lined wholly or partly by columnar ciliated epithelium of the respiratory type, by glandular epithelium of the gastric type, by squamous epithelium, or by transitional epithelium. In some, epithelial lining cells may be absent. Confusion over the embryologic origin of congenital cysts has led to a variety of names, such as enteric, bronchogenic, duplication, and mediastinal cysts. Acquired retention cysts also occur, probably as a result of obstruction of the excretory ducts of the esophageal glands.

Enteric and bronchogenic cysts are the most common, and arise as a result of developmental abnormalities during the formation and differentiation of the lower respiratory tract, esophagus, and stomach from the foregut. During its embryologic development, the esophagus is lined successively with simple columnar, pseudostratified ciliated columnar, and, finally, stratified squamous epithelium. This sequence probably accounts for the fact that the lining epithelium may be any or a combination of these; the presence of cilia does not necessarily indicate a respiratory origin.

Cysts vary in size from small to very large, and are usually located intramurally in the middle- to lower-third of the esophagus. Their symptoms are similar to those of a leiomyoma. The diagnosis similarly depends on radiographic, endoscopic, and endosonographic findings. Surgical excision by enucleation is the preferred treatment. During removal, a fistulous tract connecting the cysts to the airways should be sought, particularly in patients who have had repetitive bronchopulmonary infections.

ESOPHAGEAL PERFORATION

Perforation of the esophagus constitutes a true emergency. It most commonly occurs following diagnostic or therapeutic procedures. Spontaneous perforation, referred to as Boerhaave's syndrome, accounts for only 15% of cases of esophageal perforation, foreign bodies for 14%, and trauma for 10%. Pain is a striking and consistent symptom and strongly suggests that an esophageal rupture has occurred, particularly if located in the cervical area following instrumentation of the esophagus, or substernally in a patient with a history of resisting vomiting. If subcutaneous emphysema is present, the diagnosis is almost certain.

Spontaneous rupture of the esophagus is associated with a high mortality rate because of the delay in recognition and treatment. Although there usually is a history of resisting vomiting, in a small number of patients, the injury occurs silently, without any antecedent history. When the chest radiogram of a patient with an esophageal perforation shows air or an effusion in the pleural space, the condition is often misdiagnosed as a pneumothorax or pancreatitis. An elevated pleural amylase caused by the extrusion of saliva through the perforation may fix the diagnosis of pancreatitis in the mind of an unwary physician. If the chest radiogram is normal, a mistaken diagnosis of myocardial infarction or dissecting aneurysm is often made.

Spontaneous rupture usually occurs into the left pleural cavity or just above the GEJ. About 50% of patients have concomitant GERD, suggesting that minimal resistance to the transmission of abdominal pressure into the thoracic esophagus is a factor in the pathophysiology of the lesion. During vomiting, high peaks of intragastric pressure can be recorded, frequently exceeding 200 mmHg, but because extragastric pressure remains almost equal to intragastric pressure, stretching of the gastric wall is minimal. The amount of pressure transmitted to the esophagus varies considerably, depending on the position of the GEJ. When it is in the abdomen and exposed to intra-abdominal pressure, the pressure transmitted to the esophagus is much less than when it is exposed to the negative thoracic pressure. In the latter situation, the pressure in the lower esophagus will frequently equal intragastric pressure if the glottis remains closed. Cadaver studies have shown that when this pressure exceeds 150 mmHg, rupture of the esophagus is apt to occur. When a hiatal hernia is present and the sphincter remains exposed to abdominal pressure, the lesion produced is usually a Mallory-Weiss mucosal tear, and bleeding rather than perforation is the problem. This is due to the stretching of the supradiaphragmatic portion of the gastric wall. In this situation, the hernia sac represents an extension of the abdominal cavity, and the GEJ remains exposed to abdominal pressure.

Diagnosis

Abnormalities on the chest radiogram can be variable and should not be depended upon to make the diagnosis. This is because the abnormalities are dependent on three factors: (a) the time interval between the perforation and the radiographic examination, (b) the site of perforation, and (c) the integrity of the mediastinal pleura. Mediastinal emphysema, a strong indicator of perforation, takes at least 1 hour to be demonstrated, and is present in only 40% of patients. Mediastinal widening secondary to edema may not occur for several hours. The site of perforation also can influence the radiographic findings. In cervical perforation, cervical emphysema is common and mediastinal emphysema rare; the converse is true for thoracic perforations. Frequently, air will be visible in the erector spinae muscles on a neck radiogram before it can be palpated or seen on a chest radiogram (Fig. 25-74). The integrity of the mediastinal pleura influences the radiographic abnormality in that rupture of the pleura results in a pneumothorax, a finding that is seen in 77% of patients. In two thirds of patients, the perforation is on the left side; in one fifth, it is on the right side; and in one tenth, it is bilateral. If pleural integrity is maintained, mediastinal emphysema (rather than a pneumothorax) appears rapidly. A pleural effusion secondary to inflammation of the mediastinum occurs late. In 9% of patients, the chest radiogram is normal.

The diagnosis is confirmed with a contrast esophagram, which will demonstrate extravasation in 90% of patients. The use of a water-soluble medium such as Gastrografin is preferred. Of concern is that there is a 10% false-negative rate. This may be due to obtaining the radiographic study with the patient in the upright position. When the patient is upright, the passage of water-soluble contrast material can be too rapid to demonstrate a small perforation. The studies should be done with the patient in the right lateral decubitus position (Fig. 25-75). In this, the contrast material fills the entire length of the esophagus, allowing the actual site of perforation and its interconnecting cavities to be visualized in almost all patients.

Management

The key to optimum management is early diagnosis. The most favorable outcome is obtained following primary closure of the perforation within 24 hours, resulting in 80% to 90% survival. Figure 25-76 is an operative photograph taken through a left

Figure 25-74. Chest radiogram showing air in the deep muscles of the neck following perforation of the esophagus (*arrow*). This is often the earliest sign of perforation and can be present without evidence of air in the mediastinum.

thoracotomy of an esophageal rupture following a pneumatic dilation for achalasia. The most common location for the injury is the left lateral wall of the esophagus, just above the GEJ. To get adequate exposure of the injury, a dissection similar to that described for esophageal myotomy is performed. A flap of stomach is pulled up and the soiled fat pad at the GEJ is

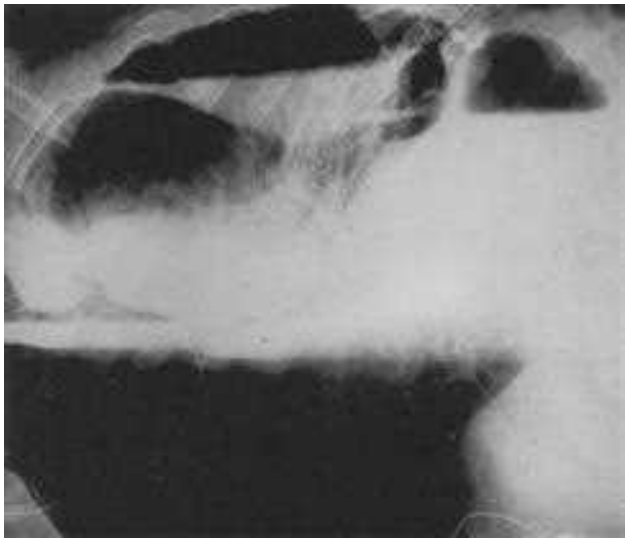

Figure 25-75. Radiographic study of a patient with a perforation of the esophagus using water-soluble contrast material. The patient is placed in the lateral decubitus position with the left side up to allow complete filling of the esophagus and demonstration of the defect.

Figure 25-76. Left thoracotomy in a patient with an esophageal rupture at the gastroesophageal junction following forceful dilation of the lower esophagus for achalasia (the surgical clamp is on the stomach, and the Penrose drain encircles the esophagus). The injury consists of a mucosal perforation and extensive splitting of the esophageal muscle from just below the Penrose drain to the stomach.

removed. The edges of the injury are trimmed and closed primarily (Fig. 25-77). The closure is reinforced with the use of a pleural patch or construction of a Nissen fundoplication.

Mortality associated with immediate closure varies between 8% and 20%. After 24 hours, survival decreases to <50%, and is not influenced by the type of operative therapy (i.e., drainage alone or drainage plus closure of the perforation). If the time delay before closing a perforation approaches 24 hours and the tissues are inflamed, division of the cardia and resection of the diseased portion of the esophagus are recommended. The remainder of the esophagus is mobilized, and as much normal esophagus as possible is saved and brought out as an end cervical esophagostomy. In some situations, the retained esophagus may be so long that it loops down into the chest. The contaminated mediastinum is drained and a feeding jejunostomy tube is inserted. The recovery from sepsis is often immediate, dramatic, and reflected by a marked improvement in the patient's condition over a 24-hour period. On recovery from the sepsis, the patient is discharged and returns on a subsequent date for reconstruction with a substernal colon interposition. Failure to apply this aggressive therapy can result in a mortality rate in excess of 50% in patients in whom the diagnosis has been delayed.

Nonoperative management of esophageal perforation has been advocated in select situations. The choice of conservative therapy requires skillful judgment and necessitates careful radiographic examination of the esophagus. This course of management usually follows an injury occurring during dilation of esophageal strictures or pneumatic dilations of achalasia. Conservative management should not be used in patients who have free perforations into the pleural space. Cameron proposed three criteria for the nonoperative management of esophageal perforation: (a) the esophagram must show the perforation to be contained within the mediastinum and drain well back into the esophagus (Fig. 25-78), (b) symptoms should be mild, and (c) there should be minimal evidence of clinical sepsis. If these conditions are met, it is reasonable to treat the patient with

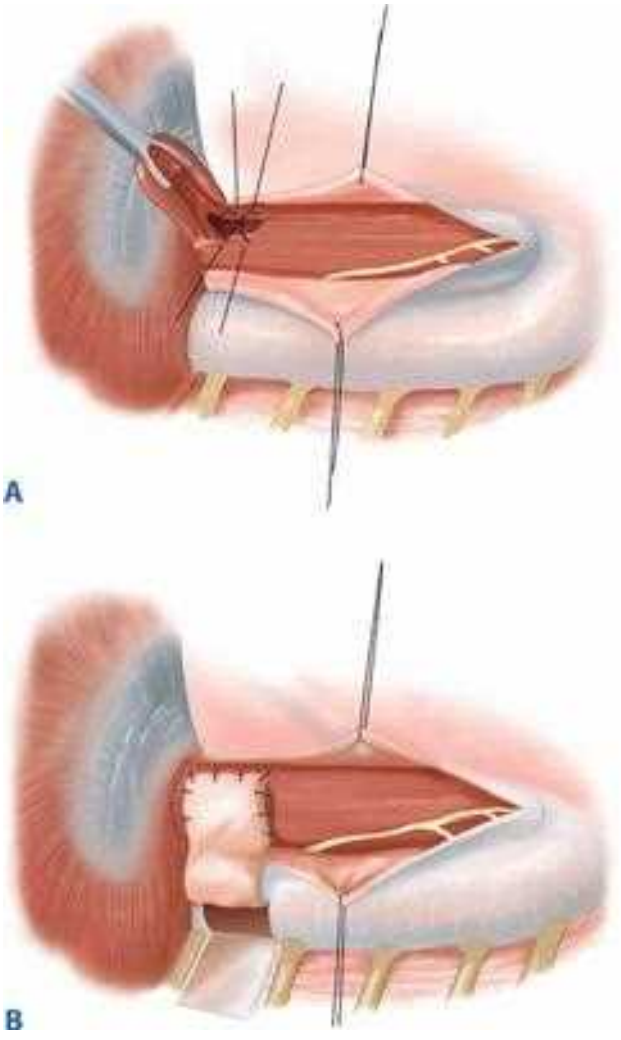

Figure 25-77. The technique of closure of an esophageal perforation through a left thoracotomy. **A.** A tongue of stomach is pulled up through the esophageal hiatus, and the gastroesophageal fat pad is removed; the edges of the mucosal injury are trimmed and closed using interrupted modified Gambee stitches. **B.** Reinforcement of the closure with a parietal pleural patch.

Figure 25-78. Barium esophagogram showing a stricture and a contained perforation following dilation. The injury meets Cameron criteria: It is contained within the mediastinum and drawn back into the esophagus, the patient had mild symptoms, and there was no evidence of clinical sepsis. Nonoperative management was successful.

hyperalimentation, antibiotics, and cimetidine to decrease acid secretion and diminish pepsin activity. Oral intake is resumed in 7 to 14 days, dependent on subsequent radiographic examinations.

MALLORY-WEISS SYNDROME

In 1929, Mallory and Weiss described four patients with acute upper GI bleeding who were found at autopsy to have mucosal tears at the GEJ. This syndrome, characterized by acute upper GI bleeding following vomiting, is considered to be the cause of up to 15% of all severe upper GI bleeds. The mechanism is similar to spontaneous esophageal perforation: an acute increase in intra-abdominal pressure against a closed glottis in a patient with a hiatal hernia.

Mallory-Weiss tears are characterized by arterial bleeding, which may be massive. Vomiting is not an obligatory factor, as there may be other causes of an acute increase in intra-abdominal pressure, such as paroxysmal coughing, seizures, and retching. The diagnosis requires a high index of suspicion, particularly in the patient who develops upper GI bleeding following prolonged vomiting or retching. Upper endoscopy confirms the suspicion by identifying one or more longitudinal fissures in the mucosa of the herniated stomach as the source of bleeding.

In the majority of patients, the bleeding will stop spontaneously with nonoperative management. In addition to blood replacement, the stomach should be decompressed and antiemetics administered, as a distended stomach and continued vomiting aggravate further bleeding. A Sengstaken-Blakemore tube will not stop the bleeding, as the pressure in the balloon is not sufficient to overcome arterial pressure. Endoscopic injection of epinephrine may be therapeutic if bleeding does not stop spontaneously. Only occasionally will surgery be required to stop blood loss. The procedure consists of laparotomy and high gastrotomy with oversewing of the linear tear. Mortality is uncommon, and recurrence is rare.

CAUSTIC INJURY

Accidental caustic lesions occur mainly in children, and, in general, rather small quantities of caustics are taken. In adults or teenagers, the swallowing of caustic liquids is usually deliberate, during a suicide attempt, and greater quantities are swallowed. Alkalis are more frequently swallowed accidentally than acids, because strong acids cause an immediate burning pain in the mouth.

Pathology

The swallowing of caustic substances causes an acute and a chronic injury. During the acute phase, care focuses on controlling the immediate tissue injury and the potential for perforation. During the chronic phase, the focus is on treatment

of strictures and disturbances in pharyngeal swallowing. In the acute phase, the degree and extent of the lesion are dependent on several factors: the nature of the caustic substance, its concentration, the quantity swallowed, and the time the substance is in contact with the tissues.

Acids and alkalis affect tissue in different ways. Alkalis dissolve tissue, and therefore penetrate more deeply, while acids cause a coagulative necrosis that limits their penetration. Animal experiments have shown that there is a correlation between the depth of the lesion and the concentration of sodium hydroxide solution. When a solution of 3.8% comes into contact with the esophagus for 10 seconds, it causes necrosis of the mucosa and the submucosa, but spares the muscular layer. A concentration of 22.5% penetrates the whole esophageal wall and into the periesophageal tissues. Cleansing products can contain up to 90% sodium hydroxide. The strength of esophageal contractions varies according to the level of the esophagus, being weakest at the striated muscle–smooth muscle interface. Consequently, clearance from this area may be somewhat slower, allowing caustic substances to remain in contact with the mucosa longer. This explains why the esophagus is preferentially and more severely affected at this level than in the lower portions.

The lesions caused by lye injury occur in three phases. First is the acute necrotic phase, lasting 1 to 4 days after injury. During this period, coagulation of intracellular proteins results in cell necrosis, and the living tissue surrounding the area of necrosis develops an intense inflammatory reaction. Second is the ulceration and granulation phase, starting 3 to 5 days after injury. During this period, the superficial necrotic tissue sloughs, leaving an ulcerated, acutely inflamed base, and granulation tissue fills the defect left by the sloughed mucosa. This phase lasts 10 to 12 days, and it is during this period that the esophagus is the weakest. Third is the phase of cicatrization and scarring, which begins the third week following injury. During this period, the previously formed connective tissue begins to contract, resulting in narrowing of the esophagus. Adhesions between granulating areas occur, resulting in pockets and bands. It is during this period that efforts must be made to reduce stricture formation.

Clinical Manifestations

The clinical picture of an esophageal burn is determined by the degree and extent of the lesion. In the initial phase, complaints consist of pain in the mouth and substernal region, hypersalivation, pain on swallowing, and dysphagia. The presence of fever is strongly correlated with the presence of an esophageal lesion. Bleeding can occur, and frequently, the patient vomits. These initial complaints disappear during the quiescent period of ulceration and granulation. During the cicatrization and scarring phase, the complaint of dysphagia reappears and is due to fibrosis and retraction, resulting in narrowing of the esophagus. Of the patients who develop strictures, 60% do so within 1 month, and 80% within 2 months. If dysphagia does not develop within 8 months, it is unlikely that a stricture will occur. Serious systemic reactions such as hypovolemia and acidosis resulting in renal damage can occur in cases in which the burns have been caused by strong acids. Respiratory complications such as laryngospasm, laryngoedema, and occasionally pulmonary edema can occur, especially when strong acids are aspirated.

Inspection of the oral cavity and pharynx can indicate that caustic substances were swallowed, but does not reveal that the esophagus has been burned. Conversely, esophageal burns can be present without apparent oral injuries. Because of this poor correlation, early esophagoscopy is advocated to establish the presence of an esophageal injury. To lessen the chance of perforation, the scope should not be introduced beyond the proximal esophageal lesion. The degree of injury can be graded according to the criteria listed in Table 25-16. Even if the esophagoscopy is normal, strictures may appear later. Radiographic examination is not a reliable means to identify the presence of early esophageal injury, but is important in later follow-up to identify strictures. The most common locations of caustic injuries are shown in Table 25-17.

Table 25-16

Endoscopic grading of corrosive esophageal and gastric burns

First degree: Mucosal hyperemia and edema
Second degree: Limited hemorrhage, exudate ulceration, and pseudomembrane formation
Third degree: Sloughing of mucosa, deep ulcers, massive hemorrhage, complete obstruction of lumen by edema, charring, and perforation

Treatment

Treatment of a caustic lesion of the esophagus is directed toward management of both the immediate and late consequences of the injury. The immediate treatment consists of limiting the burn by administering neutralizing agents. To be effective, this must be done within the first hour. Lye or other alkali can be neutralized with half-strength vinegar, lemon juice, or orange juice. Acid can be neutralized with milk, egg white, or antacids. Sodium bicarbonate is not used because it generates carbon dioxide, which might increase the danger of perforation. Emetics are contraindicated, because vomiting renews the contact of the caustic substance with the esophagus and can contribute to perforation if too forceful. Hypovolemia is corrected and broad-spectrum antibiotics are administered to lessen the inflammatory reaction and prevent infectious complications. If necessary, a feeding jejunostomy tube is inserted to provide nutrition. Oral feeding can be started when the dysphagia of the initial phase has regressed.

Table 25-17

Location of caustic injury (n = 62)

Pharynx	10%
Esophagus	70%
Upper	15%
Middle	65%
Lower	2%
Whole	18%
Stomach	20%
Antral	91%
Whole	9%
Both stomach and esophagus	14%

In the past, surgeons waited until the appearance of a stricture before starting treatment. Currently, dilations are started the first day after the injury, with the aim of preserving the esophageal lumen by removing the adhesions that occurred in the injured segments. However, this approach is controversial in that dilations can traumatize the esophagus, causing bleeding, and perforation, and there are data indicating that excessive dilations cause increased fibrosis secondary to the added trauma. The use of steroids to limit fibrosis has been shown to be effective in animals, but their effectiveness in human beings has not been established.

Extensive necrosis of the esophagus frequently leads to perforation, and is best managed by resection. When there is extensive gastric involvement, the esophagus is nearly always necrotic or severely burned, and total gastrectomy and near-total esophagectomy are necessary. The presence of air in the esophageal wall is a sign of muscle necrosis and impending perforation and is a strong indication for esophagectomy.

Management of acute injury is summarized in the algorithm in Fig. 25-79. Some authors have advocated the use of an intraluminal esophageal stent (Fig. 25-80) in patients who are operated on and found to have no evidence of extensive esophagogastric necrosis. In these patients, a biopsy of the posterior gastric wall should be performed to exclude occult injury. If, histologically, there is a question of viability, a second-look operation should be done within 36 hours. If a stent is inserted, it should be kept in position for 21 days, and removed after a satisfactory barium esophagogram. Esophagoscopy should be done, and, if strictures are present, dilations initiated.

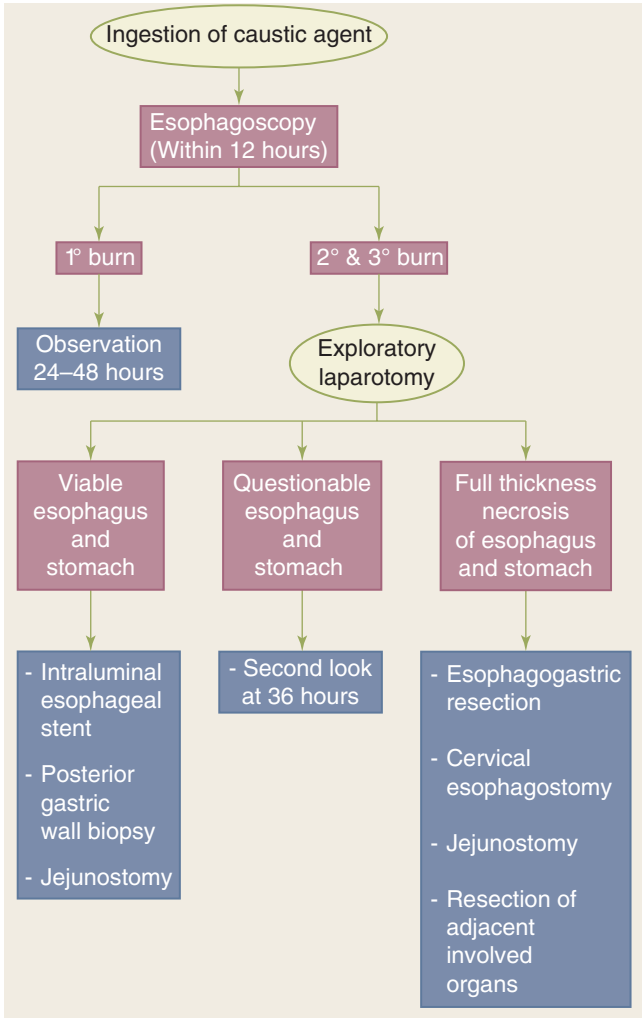

Figure 25-79. Algorithm summarizing the management of acute caustic injury.

Figure 25-80. The use of an esophageal stent to prevent stricture. The stent is constructed from a chest tube and placed in the esophagus at the time of an exploratory laparotomy. A Penrose drain is placed over the distal end as a flap valve to prevent reflux. The stent is supported at its upper end by attaching it to a suction catheter that is secured to the nares. Continuous suction removes saliva and mucus trapped in the pharynx and upper esophagus.

Once the acute phase has passed, attention is turned to the prevention and management of strictures. Both antegrade dilation with a Hurst or Maloney bougie and retrograde dilation with a Tucker bougie have been satisfactory. In a series of 1079 patients, early dilations started during the acute phase gave excellent results in 78%, good results in 13%, and poor results in 2%. During the treatment 55 patients died. In contrast, of 333 patients whose strictures were dilated when they became symptomatic, only 21% had excellent results, 46% good, and 6% poor, with three dying during the process. The length of time the surgeon should persist with dilation before consideration of esophageal resection is problematic. An adequate lumen should be re-established within 6 months to 1 year, with progressively longer intervals between dilations. If, during the course of treatment, an adequate lumen cannot be established or maintained (i.e., smaller bougies must be used), operative intervention should be considered. Surgical intervention is indicated when there is (a) complete stenosis in which all attempts from above and below have failed to establish a lumen, (b) marked irregularity and pocketing on barium swallow, (c) the development of a severe periesophageal reaction or mediastinitis with dilatation, (d) a fistula, (e) the inability to dilate or maintain the lumen above a 40F bougie, or (f) a patient who is unwilling or unable to undergo prolonged periods of dilation.

The variety of abnormalities seen requires that creativity be used when considering esophageal reconstruction. Skin tube

esophagoplasties are now used much less frequently than they were in the past, and are mainly of historical interest. Currently, the stomach, jejunum, and colon are the organs used to replace the esophagus, through either the posterior mediastinum or the retrosternal route. A retrosternal route is chosen when there has been a previous esophagectomy or there is extensive fibrosis in the posterior mediastinum. When all factors are considered, the order of preference for an esophageal substitute is (a) colon, (b) stomach, and (c) jejunum. Free jejunal grafts based on the superior thyroid artery have provided excellent results. Whatever method is selected, it must be emphasized that these procedures cannot be taken lightly; minor errors of judgment or technique may lead to serious or even fatal complications.

Critical in the planning of the operation is the selection of cervical esophagus, pyriform sinus, or posterior pharynx as the site for proximal anastomosis. The site of the upper anastomosis depends on the extent of the pharyngeal and cervical esophageal damage encountered. When the cervical esophagus is destroyed and a pyriform sinus remains open the anastomosis can be made to the hypopharynx (Fig. 25-81). When the pyriform sinuses are completely stenosed, a transglottic approach is used to perform an anastomosis to the posterior oropharyngeal wall (Fig. 25-82). This allows excision of supraglottic strictures and elevation and anterior tilting of the larynx. In both of these situations, the patient must relearn to swallow. Recovery is long and difficult and may require several endoscopic dilations, and often reoperations. Sleeve resections of short strictures are not successful because the extent of damage to the wall of the esophagus can be greater than realized, and almost invariably the anastomosis is carried out in a diseased area.

The management of a bypassed damaged esophagus after injury is problematic. If the esophagus is left in place, ulceration from gastroesophageal reflux or the development of carcinoma must be considered. The extensive dissection necessary to remove the esophagus, particularly in the presence of marked periesophagitis, is associated with significant morbidity. Leaving the esophagus in place preserves the function of the vagus nerves, and, in turn, the function of the stomach. On the other hand, leaving a damaged esophagus in place can result in multiple blind sacs and subsequent development of mediastinal abscesses years later. Most experienced surgeons recommend that the esophagus be removed unless the operative risk is unduly high.

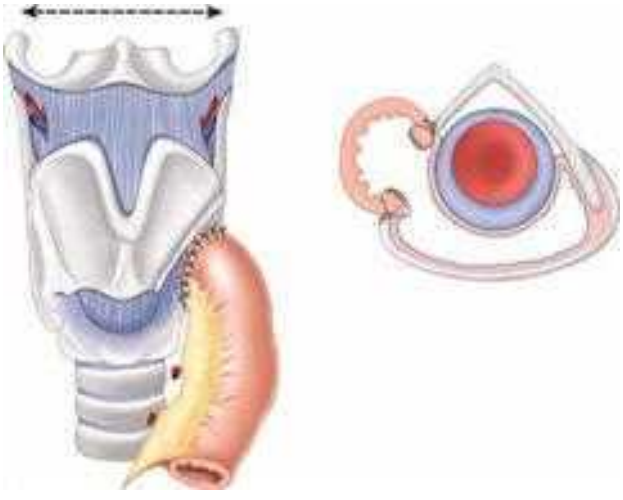

Figure 25-81. Anastomosis of the bowel to a preserved pyriform sinus. To identify the site, a finger is inserted into the free pyriform sinus through a suprahyoid incision (*dotted line*). This requires removing the lateral inferior portion of the thyroid cartilage as shown in cross-section. *(Reproduced with permission from Tran Ba Huy P, Celerier M: Management of severe caustic stenosis of the hypopharynx and esophagus by ileocolic transposition via suprahyoid or transepiglottic approach. Analysis of 18 cases.* Ann Surg. *207:439, 1988.)*

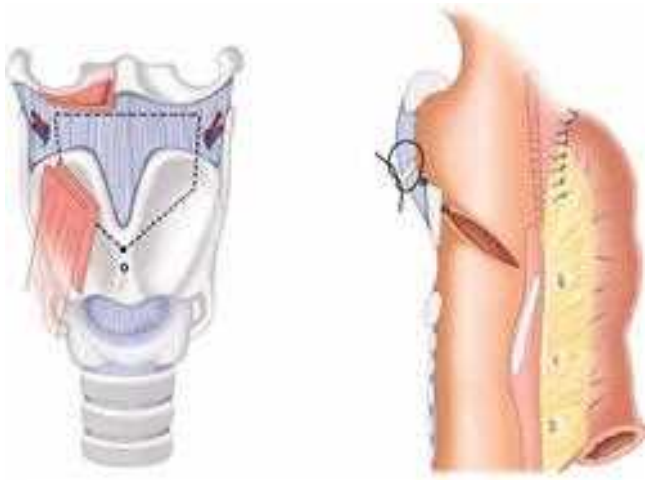

Figure 25-82. Anastomosis of the bowel to the posterior oropharynx. The anastomosis is done through an inverted trapezoid incision above the thyroid cartilage (*dotted line*). A triangle-shaped piece of the upper half of the cartilage is resected. Closure of the oropharynx is done so that the larynx is pulled up (sagittal section). *(Reproduced with permission from Tran Ba Huy P, Celerier M: Management of severe caustic stenosis of the hypopharynx and esophagus by ileocolic transposition via suprahyoid or transepiglottic approach. Analysis of 18 cases.* Ann Surg. *207:439, 1988.)*

ACQUIRED FISTULA

The esophagus lies in close contact with the membranous portion of the trachea and left bronchus, predisposing to the formation of fistula to these structures. Most acquired esophageal fistulas are to the tracheobronchial tree, and secondary to either esophageal or pulmonary malignancy. Traumatic fistulas and those associated with esophageal diverticula account for the remainder. Fistulas associated with traction diverticula are usually due to mediastinal inflammatory disease, and traumatic fistulas usually occur secondary to penetrating wounds, lye ingestion, or iatrogenic injury.

These fistulas are characterized by paroxysmal coughing following the ingestion of liquids, and by recurrent or chronic pulmonary infections. The onset of cough immediately after swallowing suggests aspiration, whereas a brief delay (30–60 seconds) suggests a fistula.

Spontaneous closure is rare, owing to the presence of malignancy or a recurrent infectious process. Surgical treatment of benign fistulas consists of division of the fistulous tract, resection of irreversibly damaged lung tissue, and closure of the esophageal defect. To prevent recurrence, a pleural flap should be interposed. Treatment of malignant fistulas is difficult, particularly in the presence of prior irradiation. Generally, only palliative treatment is indicated. This can best be done by using a

specially designed esophageal endoprosthesis that bridges and occludes the fistula, allowing the patient to eat. A salivary tube is also a good option for proximal esophageal fistulas. This tube has a proximal "lip" that rests on the cricopharyngeal muscle and thereby directs the saliva into the tube and past the fistula. Rarely, esophageal diversion, coupled with placement of a feeding jejunostomy, can be used as a last resort.

TECHNIQUES OF ESOPHAGEAL RECONSTRUCTION

Options for esophageal substitution include gastric advancement, colonic interposition, and either jejunal free transfer or advancement into the chest. Rarely, combinations of these grafts will be the only possible option. The indications for esophageal resection and substitution include malignant and end-stage benign disease. The latter includes reflux- or drug-induced stricture formation that cannot be dilated without damage to the esophagus, a dilated and tortuous esophagus secondary to severe motility disorders, lye-induced strictures, and multiple previous antireflux procedures. The choice of esophageal substitution has significant impact upon the technical difficulty of the procedure, and influences the long-term outcome.

Partial Esophageal Resection

Distal benign lesions, with preserved proximal esophageal function, are best treated with the interposition of a segment of proximal jejunum into the chest and primary anastomosis. A jejunal interposition can reach to the inferior border of the pulmonary hilum with ease, but the architecture of its blood supply rarely allows the use of the jejunum proximal to this point. Because the anastomosis is within the chest, a thoracotomy is necessary.

The jejunum is a dynamic graft and contributes to bolus transport, whereas the stomach and colon function more as a conduit. The stomach is a poor choice in this circumstance because of the propensity for the reflux of gastric contents into the proximal remaining esophagus following an intrathoracic esophagogastrostomy. It is now well recognized that this occurs, and can lead to incapacitating symptoms and esophageal destruction in some patients. Short segments of colon, on the other hand, lack significant motility and have a propensity for the development of esophagitis proximal to the anastomosis.

Replacement of the cervical portion of the esophagus, while preserving the distal portion, is occasionally indicated in cervical esophageal or head and neck malignancy, and following the ingestion of lye. Free transfer of a portion of jejunum to the neck has become a viable option and is successful in the majority of cases. Revascularization is achieved via use of the internal mammary artery and the internal mammary or innominate vein. Removal of the sternoclavicular joint aids in performing the vascular and distal esophageal anastomosis (Fig. 25-83).

Reconstruction after Total Esophagectomy

Neither the intrathoracic stomach nor the intrathoracic colon functions as well as the native esophagus after an esophagogastrectomy. The choice between these organs will be influenced by several factors, such as the adequacy of their blood supply and the length of resected esophagus that they are capable of bridging. If the stomach shows evidence of disease, or has been contracted or reduced by previous gastric surgery, the length available for esophageal replacement may not be adequate. The presence of diverticular disease, unrecognized carcinoma, or colitis prohibits the use of the colon. The blood supply of the colon is more affected by vascular disease than the blood supply of the stomach, which may prevent its use. Of the two, the colon provides the longest graft. The stomach can usually reach to the neck if the amount of lesser curvature resected does not interfere with the blood supply to the fundus. Gastric interposition has the advantage that only one anastomosis is required. On the other hand, there is greater potential for aspiration of gastric juice or stricture of the cervical anastomosis from chronic reflux when stomach is used for replacement.

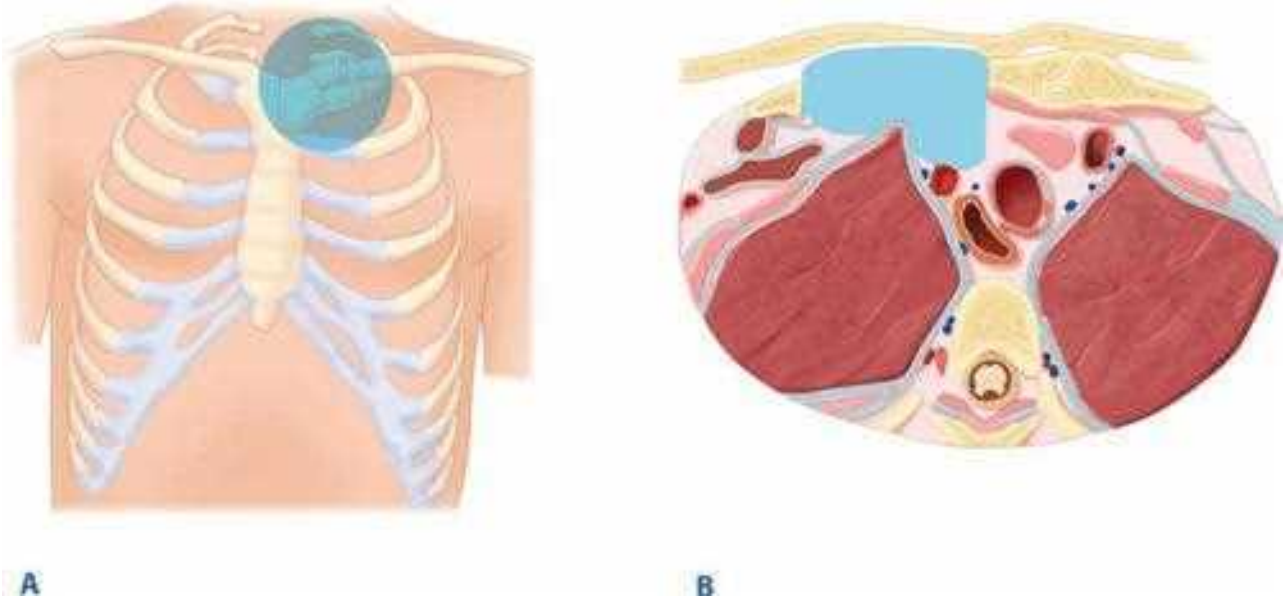

Figure 25-83. **A.** The portion of the thoracic inlet to be resected to provide space for a free jejunal graft and access to the internal mammary artery (*shaded area*). **B.** Cross-section showing the space available after resection of the sternoclavicular joint and one- half of the manubrium. *[Reproduced with permission from Rothberg M, DeMeester TR: Exposure of the cervical esophagus, in Shields TW (ed):* General Thoracic Surgery, *3rd ed. Philadelphia: Lea & Febiger, 1989, p 419.]*

Following an esophagogastrectomy, patients may have discomfort during or shortly after eating. The most common symptom is a postprandial pressure sensation or a feeling of being full, which probably results from the loss of the gastric reservoir. This symptom is less common when the colon is used as an esophageal substitute, probably because the distal third of the stomach is retained in the abdomen and the interposed colon provides an additional reservoir function.

King and Hölscher have reported a 40% and 50% incidence of dysphagia after re-establishing GI continuity with the stomach following esophagogastrectomy. This incidence is similar to Orringer's results after using the stomach to replace the esophagus in patients with benign disease. More than one-half of the patients experienced dysphagia postoperatively; two-thirds of this group required postoperative dilation and one-fourth had persistent dysphagia and required home dilation. In contrast, dysphagia is uncommon and the need for dilation is rare following a colonic interposition. Isolauri reported on 248 patients with colonic interpositions and noted a 24% incidence of dysphagia 12 months after the operation. When it occurred, the most common cause was recurrent mediastinal tumor. The high incidence of dysphagia with the use of the stomach is probably related to the esophagogastric anastomosis in the neck and the resulting difficulty of passing a swallowed bolus.

Another consequence of the transposition of the stomach into the chest is the development of postoperative duodenogastric reflux, probably due to pyloric denervation, and adding a pyloroplasty may worsen this problem. Following gastric advancement, the pylorus lies at the level of the esophageal hiatus, and a distinct pressure differential develops between the intrathoracic gastric and intra-abdominal duodenal lumina. Unless the pyloric valve is extremely efficient, the pressure differential will encourage reflux of duodenal contents into the stomach. Duodenogastric reflux is less likely to occur following colonic interposition, because there is sufficient intra-abdominal colon to be compressed by the abdominal pressure, and the pylorus and duodenum remain in their normal intra-abdominal position.

Although there is general acceptance of the concept that an esophagogastric anastomosis in the neck results in less postoperative esophagitis and stricture than one at a lower level, reflux esophagitis following a cervical anastomosis does occur, albeit at a lower rate than when the anastomosis is at a lower level. Most patients undergo cervical esophagogastrostomy for malignancy; thus the long-term sequelae of an esophagogastric anastomosis in the neck are not of concern. However, patients who have had a cervical esophagogastrostomy for benign disease may develop problems associated with the anastomosis in the fourth or fifth postoperative year that are severe enough to require anastomotic revision. This is less likely in patients who have had a colonic interposition for esophageal replacement. Consequently, in patients who have a benign process or a potentially curable carcinoma of the esophagus or cardia, a colonic interposition is used to obviate the late problems associated with a cervical esophagogastrostomy. Colonic interposition for esophageal substitution is a more complex procedure than gastric advancement, with the potential for greater perioperative morbidity, particularly in inexperienced hands.

Composite Reconstruction

Occasionally, a combination of colon, jejunum, and stomach is the only reconstructive option available. This situation may arise when there has been previous gastric or colonic resection, when dysphagia has recurred after a previous esophageal resection, or following postoperative complications such as ischemia of an esophageal substitute. Although not ideal, combinations of colon, jejunum, and stomach used to restore GI continuity function surprisingly well, and allow alimentary reconstruction in an otherwise impossible situation.

Vagal Sparing Esophagectomy with Colon Interposition

Traditional esophagectomy typically results in bilateral vagotomy and its attendant consequences. It is likely that symptoms such as dumping, diarrhea, early satiety, and weight loss seen in 15% to 20% of patients postesophagectomy are at least in part, if not completely, due to vagal interruption. The technique of vagal sparing esophagectomy with colon interposition has been described in an effort to avoid the morbidities associated with standard esophagectomy.

Through an upper midline abdominal incision, the right and left vagal nerves are identified, circled with a tape, and retracted to the right. A limited, highly selective proximal gastric vagotomy is performed along the cephalad 4 cm of the lesser curvature. The stomach is divided with an Endo-GIA stapler just below the GEJ. The colon is prepared to provide an interposed segment as previously described. A neck incision is made along the anterior border of the left sternocleidomastoid muscle, and the strap muscles are exposed. The omohyoid muscle is divided at its pulley, and the sternohyoid and sternothyroid muscles are divided at their manubrial insertion. The left carotid sheath is retracted laterally and the thyroid and trachea medially. The left inferior thyroid artery is ligated laterally as it passes under the left common carotid artery. The left recurrent laryngeal nerve is identified and protected. The esophagus is dissected circumferentially in an inferior direction, from the left neck to the apex of the right chest, to avoid injury to the right recurrent laryngeal nerve. The esophagus is divided at the level of the thoracic inlet, leaving about 3 to 4 cm of cervical esophagus. The proximal esophagus is retracted anteriorly and to the right with the use of two sutures to keep saliva and oral contents from contaminating the neck wound.

Returning to the abdomen, the proximal staple line of the gastric division is opened and the esophagus is flushed with povidone-iodine solution. A vein stripper is passed up the esophagus into the neck wound. The distal portion of the esophagus in the neck is secured tightly around the stripping cable with "endoloops" and an umbilical tape for a trailer. The tip of the stripper is exchanged for a mushroom head, and the stripper is pulled back into the abdomen, inverting the esophagus as it transverses the posterior mediastinum. This maneuver strips the branches of the esophageal plexus off the longitudinal muscle of the esophagus, preserving the esophageal plexus along with the proximal vagal nerves and the distal vagal nerve trunks. In patients with end-stage achalasia, only the mucosa is secured around the stripping cable, so that it alone is stripped and the dilated muscular wall of the esophagus, with its enriched blood supply, remains. The resulting mediastinal tunnel, or in the case of achalasia the muscular tube, is dilated with a Foley catheter containing 90 mL of fluid in the balloon. The previously prepared interposed portion of the transverse colon is passed behind the stomach and up through the mediastinal tunnel into the neck. An end-to-end anastomosis is performed to the cervical esophagus using a single layer technique. The colon is pulled taut and secured to the left crus with four or

five interrupted sutures. Five centimeters below the crura, an opening is made in the mesentery adjacent to the colon along its mesenteric border, through which an Endo-GIA stapler is passed and the colon is divided. The proximal end, which is the distal end of the interposed colon, is anastomosed high on the posterior fundic wall of the stomach, using a triangular stapling anastomotic technique. This is done by stapling longitudinally the stomach and colon together with a 75-mm Endo-GIA stapler, spreading the base of the incision apart, and closing it with a T-55 stapler. Colonic continuity is re-established by bringing the proximal right colon to the distal staple line in the left colon and performing an end-to-end anastomosis using a double layer technique.

Although conceptually appealing, preservation of vagal nerve integrity or the gastric reservoir function after vagal sparing esophagectomy only recently has been validated. Banki and associates compared patients undergoing vagal sparing esophagectomy to those with conventional esophagectomy and colon or gastric interposition. This study showed that vagal sparing esophagectomy preserved gastric secretion, gastric emptying, meal capacity, and body mass index, compared to esophagogastrectomy with colon interposition or standard esophagectomy with gastric pull-up. Vagal sparing esophagectomy patients functioned, for the most part, similarly to normal subjects, allowing them to eat a normal meal, free of dumping or diarrhea. These results indicate that the vagal sparing esophagectomy procedure does indeed preserve the vagal nerves, and may be considered in the treatment of benign and early malignant lesions requiring esophagectomy.

chapter 26

Stomach

Yuko Kitagawa and Daniel T. Dempsey

The stomach is a remarkable organ with important digestive, nutritional, and endocrine functions. The stomach stores and facilitates the digestion and absorption of ingested food, and it helps regulate appetite. Treatable diseases of the stomach are common, and it is accessible and relatively forgiving. Thus, the stomach is a favorite therapeutic target. To provide intelligent diagnosis and treatment, the physician and surgeon must understand gastric anatomy, physiology, and pathophysiology. This includes a sound understanding of the mechanical, secretory, and endocrine processes through which the stomach accomplishes its important functions; and a familiarity with the common benign and malignant gastric disorders of clinical significance. The surgeon must also understand the indications, complications, and outcomes of procedures utilized to treat diseases of the stomach. The purpose of this chapter is to enhance the reader's current understanding and familiarity with these concepts and topics. Some important milestones in the history of gastric surgery[1–6] are listed in Table 26-1.

ANATOMY

Anatomic Relationships and Gross Morphology

The stomach is readily recognizable as the asymmetrical, pear-shaped, most proximal abdominal organ of the digestive tract (Fig. 26-1).[7] The part of the stomach attached to the esophagus is called the cardia. Just proximal to the cardia at the gastroesophageal (GE) junction is the anatomically indistinct but physiologically demonstrable lower esophageal sphincter. At the distal end, the readily apparent pyloric sphincter connects the stomach to the proximal duodenum. The stomach is relatively fixed at these points, but the large midportion is quite mobile with the shorter lesser curvature on the right and the longer greater curvature on the left.

The superior-most part of the stomach is the distensible fundus, bounded superiorly by the diaphragm and laterally by the spleen. The angle of His is where the fundus meets the left side of the GE junction. Generally, the inferior extent of the

Key Points

1. Any patient admitted to a hospital because of peptic ulcer disease should be considered for lifelong acid suppression.
2. Lifelong acid suppressive medication may be equivalent to surgical vagotomy in preventing recurrent peptic ulcer or ulcer complications.
3. Roux-en-Y gastrojejunostomy should be avoided unless more than half of the stomach has been removed. Otherwise marginal ulceration and/or gastric stasis (Roux syndrome) may become problematic.
4. Gastric resection for peptic ulcer should be avoided in the asthenic or high-risk patient, if possible.
5. Many patients with locally advanced gastric cancer (T2b, T3, T4) are cured by an oncologically sound operation that includes wide margins and adequate lymphadenectomy.
6. Most patients with primary gastric lymphoma can be treated without gastric resection.
7. Gastric carcinoids should usually be removed either endoscopically or surgically. The surgeon should treat gastric carcinoid without hypergastrinemia (type III) as if it were malignant.

Table 26-1

Historic milestones in gastric surgery

DATE	EVENT	DATE	EVENT
350 B.C. – 201 A.D.	Existence of gastric ulceration was acknowledged by Diocles of Carystos (350 B.C.), Celsus, and Galen (131–201 A.D.).	1886	Heineke performs pyloroplasty.
		1888	Mikulicz performs similar operation.
		1892	Jaboulay describes bypassing the intact pylorus with gastroduodenostomy.
1363	Guy de Chauliac describes closure of gastric wound.	1902	Finney from Baltimore describes pyloroplasty technique.
1586	Marcellus Donatus of Mantua describes gastric ulcer at autopsy.	1891–1913	Different techniques of gastrostomy are described by Witzel (1891), Stamm (1894), and Janeway (1913).
1600–1700	Reports of surgeons cutting stomach to remove foreign bodies.	1920–1950	Subtotal gastrectomy grows popular as an operation for peptic ulcer. Von Haberer and Finsterer proponents.
1688	Muralto describes duodenal ulcer at autopsy.	1943	Dragstedt and Owen describe transthoracic truncal vagotomy to treat peptic ulcer disease. By the early 1950s, it is well recognized that some patients developed gastric stasis after this procedure, and transabdominal truncal vagotomy and drainage (pyloroplasty or gastrojejunostomy) become a standard ulcer operation.
1737	Morgagni describes both gastric and duodenal ulcer at autopsy.		
1833	William Beaumont reports data recorded during his care of Alexis St. Martin who developed a gastric fistula from a left upper quadrant musket wound.		
1869	Maury reportedly performs feeding gastrostomy to palliate esophageal stricture following consultation with Samuel D. Gross.	1952	Farmer and Smithwick describe good results with truncal vagotomy and hemigastrectomy for peptic ulcer.
		1953	Edwards and Herrington (Nashville) describe truncal vagotomy and antrectomy for peptic ulcer.
1875	Sidney Jones in London publishes the first successful gastrostomy for feeding.	1955	Zollinger and Ellison describe the eponymous syndrome.
1879	Paen performed distal gastrectomy and gastroduodenostomy. The patient died 5 d later.	1957	Griffith and Harkins (Seattle) describe parietal cell vagotomy (highly selective vagotomy) for the elective treatment of peptic ulcer disease.
1880	Rydygier resected a distal gastric cancer, and the patient died 12 h later.	1980–2000	Japanese surgeons and other surgical groups from East Asia demonstrate that more aggressive lymphadenectomy may improve survival in patients with gastric cancer.
1880	Billroth resects distal gastric cancer and performs gastroduodenostomy (Billroth I). Patient Therese Heller recovers and survives 4 mo.	1990–current	Evolving role of laparoscopic techniques in the treatment of surgical gastric disease.
1881	Anton Wolfler performs loop gastrojejunostomy to palliate an obstructing distal gastric cancer.	1995–current	Dramatic increase in bariatric operations.
1884	Rydygier reports an unsuccessful gastrojejunostomy for benign gastric outlet obstruction.	2000–current	Development of natural orifice translumenal endoscopic surgery.
1885	Billroth performs a successful distal gastrectomy and gastrojejunostomy (Billroth II) for gastric cancer.

fundus is considered to be the horizontal plane of the GE junction, where the body (corpus) of the stomach begins. The body of the stomach contains most of the parietal (oxyntic) cells, some of which are also present in the cardia and fundus. At the angularis, incisura the lesser curvature turns rather abruptly to the right, marking the anatomic beginning of the antrum, which comprises the distal 25% to 30% of the stomach.

The organs that commonly abut the stomach are the liver, colon, spleen, pancreas, and occasionally the kidney (Fig. 26-2). The left lateral segment of the liver usually covers a large part of the anterior stomach. Inferiorly, the stomach is attached to the transverse colon by the gastrocolic omentum. The lesser curvature is tethered to the liver by the hepatogastric ligament, also referred to as the lesser omentum or pars flaccida. Posterior to the stomach is the lesser omental bursa and the pancreas.

Arterial and Venous Blood Supply

The stomach is the most richly vascularized portion of the alimentary tube with ample blood flow and a dense intramural vascular anastomotic network. The large majority of the gastric blood supply is from the celiac axis via four named arteries (Fig. 26-3). The left and right gastric arteries form an anastomotic arcade along the lesser curvature, and the right and left gastroepiploic arteries form an arcade along the greater gastric curvature. The consistently largest artery to the stomach is the left gastric artery, which usually arises directly from the celiac trunk and divides into an ascending and descending branch along the lesser gastric curvature. Approximately 20% of the time, the left gastric artery supplies an aberrant vessel that travels in the gastrohepatic ligament (lesser omentum) to the left side of the liver. Rarely, this is the only arterial blood supply to this part of the liver, and inadvertent ligation may lead to clinically significant hepatic ischemia in this unusual circumstance. The more common smaller aberrant left hepatic artery may be ligated without significant consequences.

The second largest artery to the stomach is the right gastroepiploic artery, which arises consistently from the gastroduodenal artery behind the first portion of the duodenum. The left gastroepiploic artery arises from the splenic artery, and, together with the right gastroepiploic artery, forms the rich gastroepiploic arcade along the greater curvature. The right gastric artery usually arises from the hepatic artery near the pylorus and hepatoduodenal ligament, and runs proximally along the distal stomach. In the fundus along the proximal greater curvature, the short gastric arteries and veins arise from the splenic circulation. There also may be additional vascular branches to the proximal stomach from the phrenic and splenic circulation.

The veins draining the stomach generally parallel the arteries. The left gastric (coronary vein) and right gastric veins usually drain into the portal vein, though occasionally the coronary vein drains into the splenic vein. The right gastroepiploic vein drains into the superior mesenteric vein near the inferior border of the pancreatic neck, and the left gastroepiploic vein drains into the splenic vein.

The richness of the gastric blood supply and the extensiveness of the anastomotic connections have some important clinical implications, such as: a) At least two of the four named gastric arteries may be occluded or ligated with impunity. This is

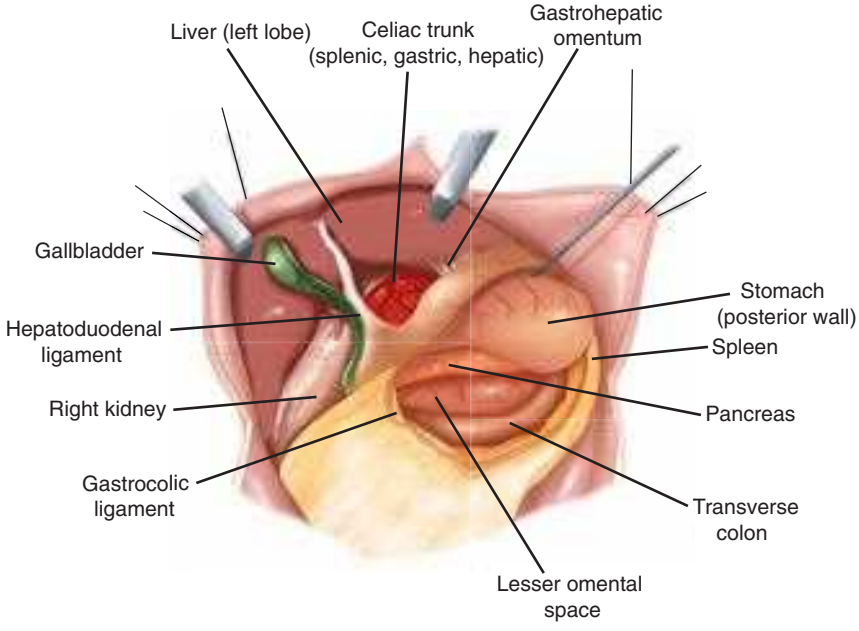

Figure 26-2. Anatomic relationships of the stomach. *[Reproduced with permission from Mercer DW, Liu TH, Castaneda A: Anatomy and physiology of the stomach, in Zuidema GD, Yeo CJ (eds):* Shackelford's Surgery of the Alimentary Tract, *5th ed., Vol. II. done routinely when the stomach is mobilized and pedicled on the right gastric and right gastroepiploic vessels to reach into the neck as an esophageal replacement (see Chapter 25) or during sleeve gastrectomy for weight loss when the gastroepiploic arcade is interrupted distally and resected (see Chapter 27), b) Following radical subtotal gastrectomy during which the right and left gastric arteries and both gastroepiploic arteries are all ligated, the gastric remnant is adequately supplied by short gastric arteries as long as the splenic artery is patent and intact; c) Angiographic control of gastric bleeding from deep ulcer or tumor often requires embolization of more than one feeding artery; d) Because of the rich venous interconnections in the stomach, a distal splenorenal shunt, which connects the distal end of the divided splenic vein to the side of the left renal vein, can effectively decompress esophagogastric varices in patients with portal hypertension.[8,9]

Lymphatic Drainage

Generally speaking, the gastric lymphatics parallel the blood vessels (Fig. 26-4).[10] The cardia and medial half of the corpus commonly drain to nodes along the left gastric and celiac axis. The lesser curvature side of the antrum usually drains to the right gastric and pyloric nodes, while the greater curvature half of the distal stomach drains to the nodes along the right gastroepiploic chain. The proximal greater curvature side of the stomach usually drains into nodes along the left gastroepiploic or splenic hilum. The nodes along both the greater and lesser curvature commonly drain into the celiac nodal basin. There is a rich anastomotic network of lymphatics that drain the stomach, often in a somewhat unpredictable fashion. Thus, a tumor arising in the distal stomach may give rise to positive lymph nodes in the splenic hilum. The rich intramural plexus of lymphatics and veins accounts for the fact that there can be microscopic evidence of malignant cells in the gastric wall at a resection margin that is several centimeters away from palpable malignant tumor. It also helps explain the not infrequent finding of positive lymph nodes which may be many centimeters away from the primary tumor, with closer nodes that remain negative.

Extensive and meticulous lymphadenectomy is considered by many surgeons to be an important part of the operation for gastric cancer. Surgeons and pathologists have numbered the primary and secondary lymph node groups to which the stomach drains (see Fig. 26-4).[11,12]

Innervation[13]

The vagus nerves provide the extrinsic parasympathetic innervation to the stomach, and acetylcholine is the most important neurotransmitter. From the vagal nucleus in the floor of the fourth cerebral ventricle, the vagus traverses the neck in the carotid sheath and enters the mediastinum, where it gives off the recurrent laryngeal nerve and divides into several branches around the esophagus. These branches come together again above the esophageal hiatus and form the *l*eft (*a*nterior) and *r*ight (*p*osterior) vagal trunks (mnemonic LARP). Near the GE junction the anterior vagus sends a branch (or branches) to the liver in the gastrohepatic ligament, and continues along the lesser curvature as the anterior nerve of Latarjet (Fig. 26-5). Similarly, the posterior vagus sends branches to the celiac plexus and continues along the posterior lesser curvature. The nerves of Latarjet send segmental branches to the body of the stomach before they terminate near the angularis incisura as the "crow's foot," sending branches to the antropyloric region. There may be additional branches to the distal stomach and pylorus that travel near the right gastric and/or gastroepiploic arteries. In 50% of patients, there are more than two vagal nerves at the esophageal hiatus. The branch that the posterior vagus sends to the posterior fundus

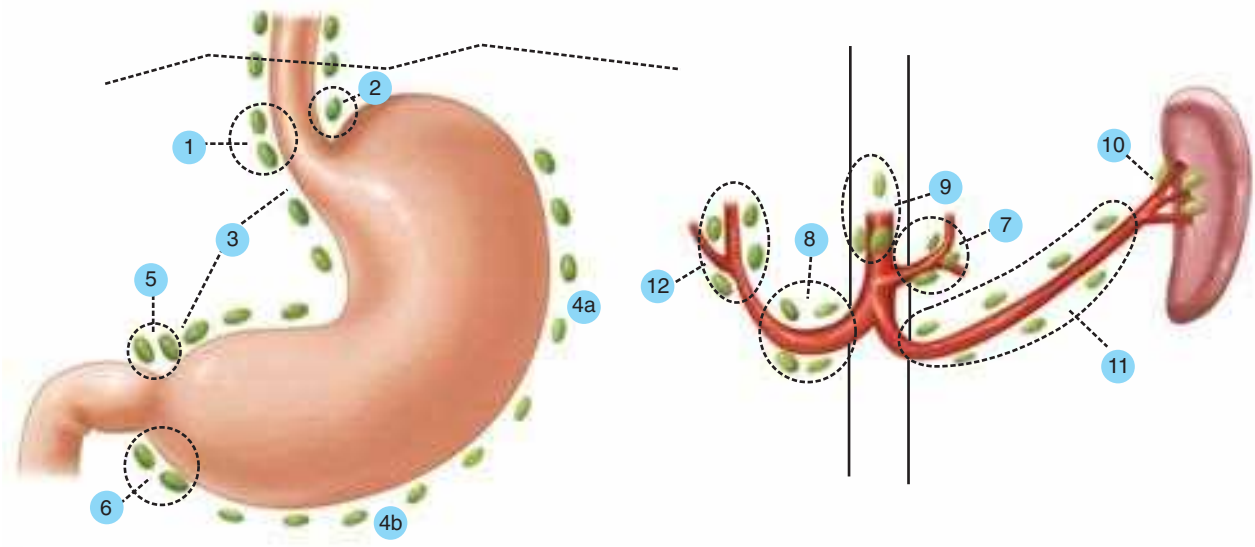

Figure 26-4. Lymph node stations draining the stomach according to the Japanese Research Society for Gastric Cancer. Stations 3 to 6 are commonly removed with D1 gastrectomy. Stations 1, 2, and 7 to 12 are commonly removed with D2 gastrectomy. *[Reproduced with permission from Hermanek P, et al (eds):* TNM Atlas: Illustrated Guide to the TNM/pTNM Classification of Malignant Tumours, *4th ed. Berlin: Springer-Verlag, 1997, p 82–83. Used with the permission of the International Union Against Cancer (UICC), Geneva, Switzerland.]*

is termed the *criminal nerve of Grassi*. This branch typically arises above the esophageal hiatus and is easily missed during truncal or highly selective vagotomy (HSV). Vagal fibers originating in the brain synapse with neurons in Auerbach's myenteric plexus and Meissner's submucosal plexus. In the stomach the vagus nerves affect secretion (including acid), motor function, and mucosal bloodflow and cytoprotection. They also play a role in appetite control and perhaps even mucosal immunity and inflammation. Most of the axons contained in the vagal trunks are afferent (i.e., carrying stimuli from the viscera to the brain).

The extrinsic sympathetic nerve supply to the stomach originates at spinal levels T5 through T10 and travels in the splanchnic nerves to the celiac ganglion. Postganglionic sympathetic nerves then travel from the celiac ganglion to the stomach along the blood vessels.

Neurons in the myenteric and submucosal plexuses constitute the intrinsic nervous system of the stomach. There may be more intrinsic gastric neurons than extrinsic neurons, but their function is poorly understood.

It is obviously an oversimplification (and incorrect) to think exclusively of the vagus as the cholinergic system and the sympathetic system as the adrenergic system of innervation. Although acetylcholine is an important neurotransmitter mediating vagal function, and epinephrine is important in the sympathetic nerves, both systems (as well as the intrinsic neurons) have various and diverse neurotransmitters, including cholinergic, adrenergic, and peptidergic (e.g., substance P and somatostatin).

Histology

There are four distinct layers of the gastric wall: mucosa, submucosa, muscularis propria, and serosa (Fig. 26-6).[7] The inner layer of the stomach is the mucosa, which is lined with columnar epithelial cells of various types. Beneath the basement membrane of the epithelial cells is the lamina propria, which contains connective tissue, blood vessels, nerve fibers, and inflammatory cells. Beneath the lamina propria is a thin muscle layer called the *muscularis mucosa*, the deep boundary of the mucosal layer of the gut. The epithelium, lamina propria, and muscularis mucosa constitute the mucosa (Fig. 26-7).[14] The epithelium of the gastric mucosa is columnar glandular. A scanning electron micrograph shows a smooth mucosal carpet punctuated by the openings of the gastric glands. The gastric glands are lined with different types of epithelial cells, depending upon their location in the stomach (Fig. 26-8, Table 26-2).[15,16] There are also endocrine cells present in the gastric glands. Progenitor cells at the base of the glands differentiate and replenish sloughed cells on a regular basis. Throughout the stomach, the carpet consists primarily of mucus-secreting surface epithelial cells (SECs) that

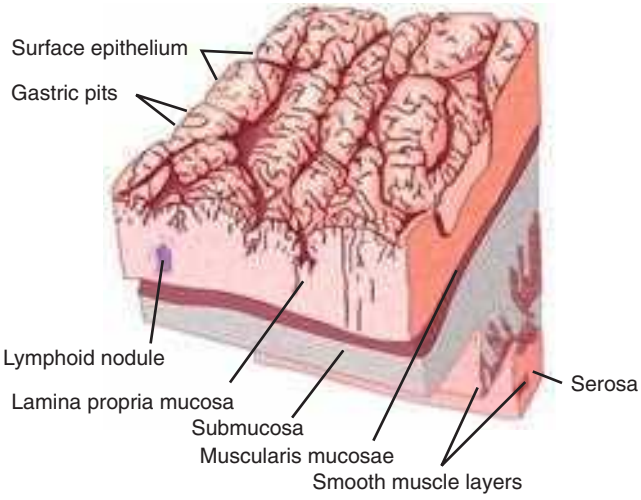

Figure 26-6. Layers of the gastric wall. *[Reproduced with permission from The esophagus and stomach, in Fawcett DW:* Bloom and Fawcett's Textbook of Histology, *11th ed. Philadelphia: Saunders, 1986, p 625. Copyright Elsevier.]*

extend down into the gland pits for variable distances. These cells also secrete bicarbonate and play an important role in protecting the stomach from injury due to acid, pepsin, and/or ingested irritants. In fact, all epithelial cells of the stomach (except the endocrine cells) contain carbonic anhydrase and are capable of producing bicarbonate.

In the cardia, the gastric glands are branched and secrete primarily mucus and bicarbonate, but not much acid. In the fundus and body, the glands are more tubular and the pits are deep. Parietal and chief cells are common in these glands (Fig. 26-9). Histamine-secreting enterochromaffin-like (ECL) cells and somatostatin-secreting D cells are also found. Parietal cells secrete acid and intrinsic factor into the gastric lumen, and bicarbonate into the intercellular space. They have a characteristic ultrastructural appearance with secretory canaliculi (deep invaginations of the surface membrane), and cytoplasmic tubulovesicles containing the acid-producing apparatus H^+/K^+-ATPase (proton pump) (see Fig. 26-9). There are numerous mitochondria; in fact the parietal cell is the most mitochondria rich cell in the body. When the parietal cell is stimulated,

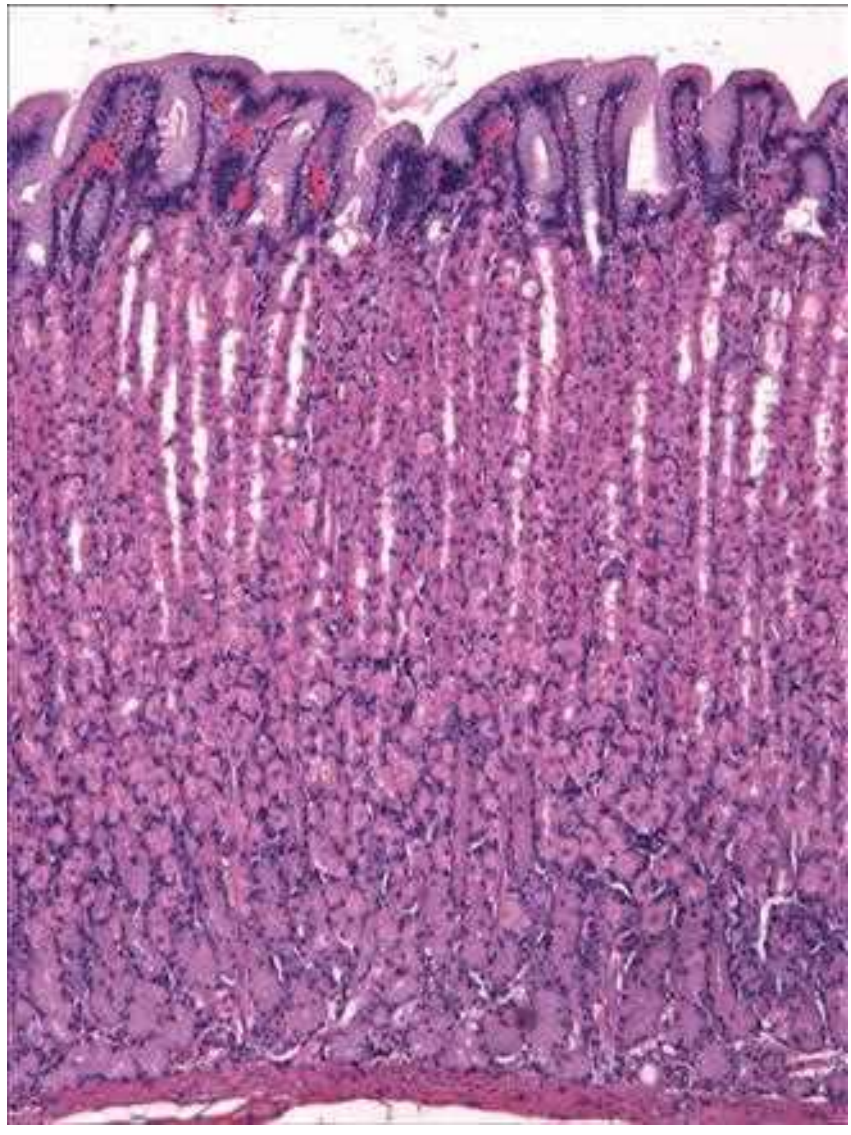

Figure 26-7. Gastric mucosa. (*Reproduced with permission from Bloom W, Fawcett DW:* A Textbook of Histology, *10th ed. Philadelphia: Saunders, 1975, p 639.*)

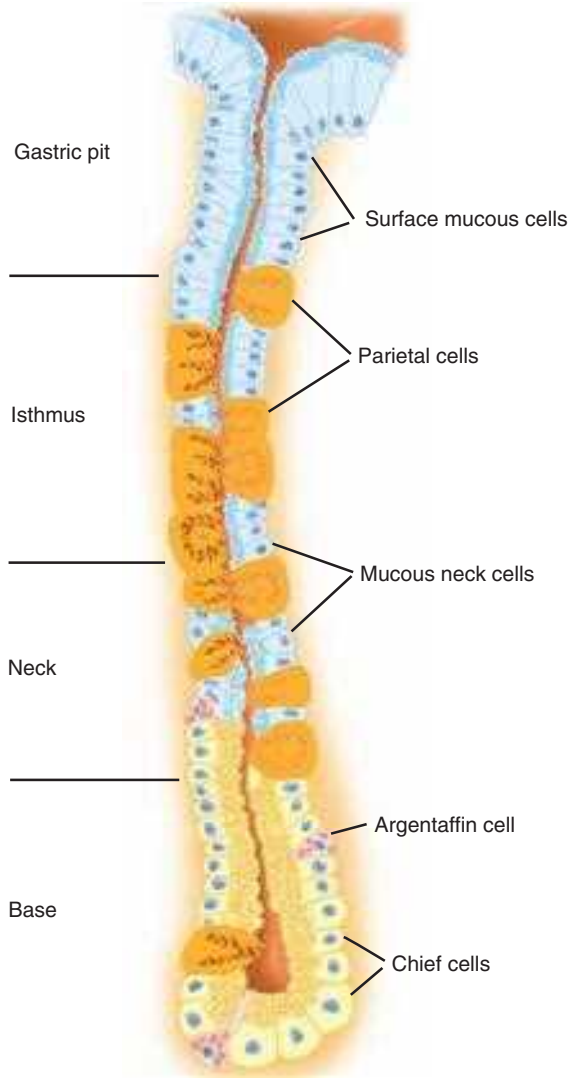

Figure 26-8. Mammalian gastric gland from the body of the stomach. *[Reproduced with permission from Ito S, Winchester RJ: The fine structure of the gastric mucosa in the bat.* J Cell Biol *16:541, 1963. Copyright © 1963 The Rockefeller University Press. doi: 10.1083/jcb.16.3.541.]*

the cytoplasmic tubulovesicles fuse with the membrane of the secretory canaliculus; when acid production ceases, the process is reversed. Arguably, parietal cells produce the only truly essential substance made by the stomach (i.e., intrinsic factor). Parietal cells tend to occupy the midportion of the gastric glands found in the corpus of the stomach.

Chief cells (also called *zymogenic cells*) secrete pepsinogen I, which is maximally activated at a pH of 2.5. They tend to be clustered toward the base of the gastric glands and have a low columnar shape. Ultrastructurally, chief cells have the characteristics of protein-synthesizing cells: basal granular endoplasmic reticulum, supranuclear Golgi apparatus, and apical zymogen granules (Fig. 26-10). When stimulated, the chief cells produce two immunologically distinct proenzyme forms of pepsinogen: predominantly pepsinogen I and some pepsinogen II, most of which is produced by SECs. These proenzymes are activated in an acidic luminal environment.

In the antrum, the gastric glands are again more branched and shallow, parietal cells are rare, and gastrin-secreting G cells and somatostatin-secreting D cells are present. A variety of hormone-secreting cells are present in various proportions throughout the gastric mucosa (Fig. 26-11).[17] Histologic analysis suggests that in the normal stomach, 13% of the epithelial cells are oxyntic (parietal) cells, 44% are chief (zymogenic) cells, 40% are mucous cells, and 3% are endocrine cells. In general, the antrum produces gastrin but not acid, and the proximal stomach produces acid but not gastrin. The border between the corpus and antrum migrates proximally with age (especially on the lesser curvature side of the stomach).

Deep to the muscularis mucosa is the submucosa, which is rich in branching blood vessels, lymphatics, collagen, various inflammatory cells, and nerve fibers and ganglion cells of Meissner's autonomic submucosal plexus. The collagen-rich submucosa gives strength to GI anastomoses. The mucosa and submucosa are folded into the grossly visible gastric rugae, which tend to flatten out as the stomach becomes distended.

Below the submucosa is the thick muscularis propria (also referred to as the *muscularis externa*), which consists of an incomplete inner oblique layer, a complete middle circular layer (continuous with the esophageal circular muscle and the circular muscle of the pylorus), and a complete outer longitudinal layer (continuous with the longitudinal layer of the esophagus and duodenum). Within the muscularis propria is the rich network of autonomic ganglia and nerves that make up Auerbach's myenteric plexus. Specialized pacemaker cells, the interstitial cells of Cajal (ICC), also are present.

The outer layer of the stomach is the serosa, also known as the *visceral peritoneum*. This layer provides significant tensile strength to gastric anastomoses. When tumors originating in the mucosa penetrate and breach the serosa, microscopic or gross peritoneal metastases are common, presumably from shedding of tumor cells that would not have occurred if the serosa had not been penetrated. In this way, the serosa may be thought of as an outer envelope of the stomach.

PHYSIOLOGY

The stomach stores food and facilitates digestion through a variety of secretory and motor functions. Important secretory functions include the production of acid, pepsin, intrinsic factor, mucus, and a variety of GI hormones. Important motor functions include food storage (receptive relaxation and accommodation), grinding and mixing, controlled emptying of ingested food, and periodic interprandial "housekeeping."

Acid Secretion

Hydrochloric acid in the stomach hastens both the physical and (with pepsin) the biochemical breakdown of ingested food. In an acidic environment, pepsin and acid facilitate proteolysis. Gastric acid also inhibits the proliferation of ingested pathogens, which protects against both infectious gastroenteritis and intestinal bacterial overgrowth. Long-term acid suppression with proton pump inhibitors (PPIs) has been associated with an increased risk of community acquired *Clostridium difficile* colitis and other gastroenteritis, presumably because of the absence of this protective germicidal barrier.[18,19]

Parietal Cell. The parietal cell is stimulated to secrete acid (Fig. 26-12) when one or more of three membrane receptor types is stimulated by acetylcholine (from vagal nerve fibers), gastrin (from D cells), or histamine (from ECL cells).[7,20,21] The enzyme H^+/K^+-ATPase is the proton pump. It is stored within the intracellular tubulovesicles and is the final common pathway for gastric

Table 26-2

Epithelial cells of the stomach

CELL TYPE	DISTINCTIVE ULTRASTRUCTURAL FEATURES	MAJOR FUNCTIONS
Surface-foveolar mucous cells	Apical stippled granules up to 1 μm in diameter	Production of neutral glycoprotein and bicarbonate to form a gel on the gastric luminal surface; neutralization of hydrochloric acid[a]
Mucous neck cell	Heterogeneous granules 1–2 μm in diameter dispersed throughout the cytoplasm	Progenitor cell for all other gastric epithelial cells; glycoprotein production; production of pepsinogens I and II
Oxyntic (parietal) cell	Surface membrane invaginations (canaliculi); tubulovesicle structures; numerous mitochondria	Production of hydrochloric acid; production of intrinsic factor; production of bicarbonate
Chief cell	Moderately dense apical granules up to 2 μm in diameter; prominent supranuclear Golgi apparatus; extensive basolateral granular endoplasmic reticulum	Production of pepsinogens I and II, and of lipase
Cardiopyloric mucous cell	Mixture of granules like those in mucous neck and chief cells; extensive basolateral granular endoplasmic reticulum	Production of glycoprotein; production of pepsinogen II
Endocrine cells	See Figure 26-11	

[a]Bicarbonate is probably produced by other gastric epithelial cells in addition to surface-foveolar mucous cells.

acid secretion. When the parietal cell is stimulated, there is a cytoskeletal rearrangement and fusion of the tubulovesicles with the apical membrane of the secretory canaliculus. The heterodimer assembly of the enzyme subunits into the microvilli of the secretory canaliculus results in acid secretion, with extracellular potassium being exchanged for cytosolic hydrogen. Although electro-neutral, this is an energy requiring process because the hydrogen is secreted against a gradient of at least 1 million-fold, which explains why the parietal cell is packed with energy producing mitochondria. During acid production, potassium and chloride are also secreted into the apical secretory canaliculus through separate channels, providing potassium to exchange for H^+ via the H^+/K^+-ATPase, and chloride to accompany the secreted hydrogen. At the basolateral membrane, the combined activity of various cotransporters and ion exchangers accomplishes intracellular pH regulation and electrolyte homeostasis.[20]

The normal human stomach contains approximately 1 billion parietal cells, and total gastric acid production is proportional to parietal cell mass. The potent acid-suppressing PPI drugs irreversibly interfere with the function of the H^+/K^+-ATPase molecule.

These agents must be incorporated into the activated enzyme to be effective, and thus work best when taken before or during a meal (when the parietal cell is stimulated). When PPI therapy is stopped, acid secretory capability gradually returns (within days) as new H^+/K^+-ATPase is synthesized.

Gastrin, acetylcholine, and histamine stimulate the parietal cell to secrete hydrochloric acid (see Fig. 26-12). Gastrin binds to type B cholecystokinin (CCK) receptors, and acetylcholine binds to M_3 muscarinic receptors. Both stimulate phospholipase C via a G-protein–linked mechanism leading to increased production of inositol trisphosphate from membrane bound phospholipids. Inositol trisphosphate stimulates the release of calcium from intracellular stores, which leads to activation of protein kinases and activation of H^+/K^+-ATPase. Histamine binds to the histamine 2 (H_2) receptor, which stimulates adenylatecyclase, also via a G-protein–linked mechanism. Activation of adenylatecyclase results in an increase in intracellular cyclic adenosine monophosphate which activates protein kinases, leading to increased levels of phosphoproteins and activation of the proton pump. Somatostatin from mucosal D cells binds to membrane receptors and inhibits the activation of adenylatecyclase through an inhibitory G protein.

Physiologic Acid Secretion. Food ingestion is the physiologic stimulus for acid secretion (Fig. 26-13). The acid secretory response that occurs after a meal is traditionally described in three phases: cephalic, gastric, and intestinal.[22,23] The cephalic or vagal phase begins with the thought, sight, smell, and/or taste of food. These stimuli activate several cortical and hypothalamic sites (e.g., tractus solitarius, dorsal motor nucleus, and dorsal vagal complex), and signals are transmitted to the stomach by the vagal nerves. Acetylcholine is released, leading to stimulation of ECL cells and parietal cells. Although the acid secreted per unit of time in the cephalic phase is greater than in the other two phases, the cephalic phase is shorter. Thus, the cephalic phase accounts for no more than 30% of total acid secretion in response to a meal. Sham feeding (chewing and spitting) stimulates gastric acid secretion only via the cephalic phase, and results in acid secretion that is about half of that seen in response to IV pentagastrin or histamine.

When food reaches the stomach, the gastric phase of acid secretion begins. This phase lasts until the stomach is empty, and accounts for about 60% of the total acid secretion in response to a meal. The gastric phase of acid secretion has several components. Amino acids and small peptides directly stimulate antral G cells to secrete gastrin, which is carried in the bloodstream to the parietal cells and stimulates acid secretion in an endocrine fashion. In addition, proximal gastric distention

stimulates acid secretion via a vagovagal reflex arc, which is abolished by truncal or HSV. Antral distention also stimulates antral gastrin secretion. Acetylcholine stimulates gastrin release and gastrin stimulates histamine release from ECL cells.

The intestinal phase of gastric secretion is poorly understood. It is thought to be mediated by a hormone released from the proximal small bowel mucosa in response to luminal chyme. This phase starts when gastric emptying of ingested food begins, and continues as long as nutrients remain in the proximal small intestine. It accounts for about 10% of meal-induced acid secretion.

Interprandial basal acid secretion is 2 to 5 mEq hydrochloric acid per hour, about 10% of maximal acid output (MAO), and it is greater at night. Basal acid secretion probably contributes to the relatively low bacterial counts found in the stomach. Basal acid secretion is reduced 75% to 90% by vagotomy or H_2 receptor blockade.

The pivotal role that ECL cells play in the regulation of gastric acid secretion is emphasized in Fig. 26-13. A large part of the acid stimulatory effects of both acetylcholine and gastrin are mediated by histamine released from mucosal ECL cells. H2 receptor knockout mice do not secrete acid in response to gastrin.[20] This explains why the histamine 2 receptor antagonists (H_2RAs) are such effective inhibitors of acid secretion, even though histamine is only one of three parietal cell stimulants. The mucosal D cell, which releases somatostatin, is also an important regulator of acid secretion. Somatostatin inhibits histamine release from ECL cells and gastrin release from antral G cells. The function of D cells is inhibited by *Helicobacter pylori* infection, and this leads to an exaggerated acid secretory response (see section *Helicobacter pylori* Infection).

Pepsinogen Secretion

The most potent physiologic stimulus for pepsinogen secretion from chief cells is food ingestion; acetylcholine is the most important mediator. Somatostatin inhibits pepsinogen secretion. Pepsinogen I is produced by chief cells in acid producing glands, whereas pepsinogen II is produced by SECs in both acid producing and gastrin producing (i.e., antral) glands. Pepsinogen is cleaved to the active pepsin enzyme in an acidic environment and is maximally active at pH 2.5, and inactive at pH >5, although pepsinogen II may be activated over a wider pH range than pepsinogen I. Pepsin catalyzes the hydrolysis of proteins and is denatured at alkaline pH.

Intrinsic Factor

Activated parietal cells secrete intrinsic factor in addition to hydrochloric acid. Presumably the stimulants are similar, but acid secretion and intrinsic factor secretion may not be linked. Intrinsic factor binds to luminal vitamin B_{12}, and the complex is absorbed in the terminal ileum via mucosal receptors. Vitamin B_{12} deficiency can be life threatening, and patients with total gastrectomy or pernicious anemia (i.e., patients with no parietal cells) require B_{12} supplementation by a nonenteric route. Some patients develop vitamin B_{12} deficiency following gastric bypass, presumably because there is insufficient intrinsic factor present in the small proximal gastric pouch and oral B_{12} intake may be decreased. Under normal conditions, a significant excess of intrinsic factor is secreted, and acid-suppressive medication does not appear to inhibit intrinsic factor production and release.

Gastric Mucosal Barrier

The stomach's durable resistance to autodigestion by caustic hydrochloric acid and active pepsin is intriguing. Some of the important elements of gastric barrier function and cytoprotection are listed in Table 26-3.[24,25] When these defenses break down, ulceration occurs. A variety of factors are important in maintaining an intact gastric mucosal layer. The mucus and bicarbonate secreted by SECs form an unstirred mucous gel with a favorable pH gradient. Cell membranes and tight junctions prevent hydrogen

ions from gaining access to the interstitial space. Hydrogen ions that do break through are buffered by the alkaline tide created by basolateral bicarbonate secretion from stimulated parietal cells. Any sloughed or denuded SECs are rapidly replaced by migration of adjacent cells, a process known as *restitution*. Mucosal blood flow plays a crucial role in maintaining a healthy mucosa, providing nutrients and oxygen for the cellular functions involved in cytoprotection. "Back-diffused" hydrogen is buffered and rapidly removed by the rich blood supply. When "barrier breakers" such as bile or aspirin lead to increased back-diffusion of hydrogen ions from the lumen into the lamina propria and submucosa, there is a protective increase in mucosal blood flow. If this protective response is blocked, gross ulceration can occur. Important mediators of these protective mechanisms include prostaglandins, nitric oxide, intrinsic nerves, and peptides (e.g., calcitonin gene-related peptide, gastrin-releasing peptide [GRP], gastrin, and heat shock proteins). Sucralfate acts locally to enhance mucosal defenses. Protective reflexes involve afferent sensory neurons, and can be blocked by the application of topical anesthetics to the gastric mucosa, or the experimental destruction of the afferent sensory nerves. In addition to these local defenses, there are important protective factors in saliva, duodenal secretions, and pancreatic or biliary secretions.

Gastric Hormones[13,26]

Gastrin. Gastrin is produced by antral G cells and is the major hormonal stimulant of acid secretion during the gastric phase. A variety of molecular forms exist: big gastrin (34 amino acids; G_{34}), little gastrin (17 amino acids; G_{17}), and mini-gastrin (14 amino acids; G_{14}). The large majority of gastrin released by the human antrum is G_{17}. The biologically active pentapeptide sequence at the C-terminal end of gastrin is identical to that of CCK. Luminal peptides and amino acids are the most potent stimulants of gastrin release, and luminal acid is the most potent inhibitor of gastrin secretion. The latter effect is predominantly mediated in a paracrine fashion by somatostatin released from antral D cells. Gastrin-stimulated acid secretion is significantly blocked by H_2 antagonists, suggesting that the principal mediator of gastrin-stimulated acid production is histamine from mucosal ECL cells (see Fig. 26-13). In fact, chronic hypergastrinemia is associated with hyperplasia of gastric ECL cells and, rarely, gastric carcinoid. Gastrin is trophic to gastric parietal cells and to other GI mucosal cells. Important causes of hypergastrinemia include pernicious anemia, acid-suppressive medication, gastrinoma, retained antrum following distal gastrectomy and Billroth II surgery, and vagotomy.

Somatostatin. Somatostatin is produced by D cells located throughout the gastric mucosa. The predominant form in humans is somatostatin 14, though somatostatin 28 is present as well. The major stimulus for somatostatin release is antral acidification; acetylcholine from vagal nerve fibers inhibits its release. Somatostatin inhibits acid secretion from parietal cells and gastrin release from G cells. It also decreases histamine release from ECL cells. The proximity of the D cells to these target cells suggests that the primary effect of somatostatin is mediated in a paracrine fashion, but an endocrine (i.e., bloodstream) effect also is possible.

Gastrin-Releasing Peptide. GRP is the mammalian equivalent of bombesin, a hormone discovered more than two decades ago in an extract of skin from a frog. In the antrum, GRP stimulates both gastrin and somatostatin release by binding to receptors on the G and D cells. There are nerve terminals ending near the mucosa in the gastric body and antrum, which are rich in GRP immunoreactivity. When GRP is given peripherally, it stimulates acid secretion, but when it is given centrally into the cerebral ventricles of animals, it inhibits acid secretion, apparently via a pathway involving the sympathetic nervous system. GRP is a mediator of gastroprotective increased mucosal blood flow in response to luminal irritants.

Leptin. Leptin is a protein primarily synthesized in adipocytes. It is also made by chief cells in the stomach, the main source of leptin in the GI tract.[26] Leptin works at least in part via vagally mediated pathways to decrease food intake in animals. Not surprisingly, leptin, a satiety signal hormone, and ghrelin, a hunger signal hormone, are both primarily synthesized in the stomach, an organ increasingly recognized as central to the mechanisms of appetite control.[26,27]

Ghrelin. Ghrelin is a small peptide described in 1999 that is produced primarily in the stomach.[28] Ghrelin is a potent secretagogue of pituitary growth hormone (but not adrenocorticotropic hormone, follicle-stimulating hormone, luteinizing hormone, prolactin, or thyroid-stimulating hormone). Ghrelin appears to be an orexigenic regulator of appetite (i.e., when ghrelin is elevated, appetite is stimulated, and when it is suppressed, appetite is suppressed). Resection of the primary source of this hormone (i.e., the stomach) may partly account for the anorexia and weight loss seen in some patients following gastric resection including sleeve gastrectomy (Fig. 26-14).[29] The gastric bypass operation, a very effective treatment for morbid obesity, has been shown by some investigators to be associated with suppression of plasma ghrelin levels (and appetite) in humans (Fig. 26-15A).[30,31]

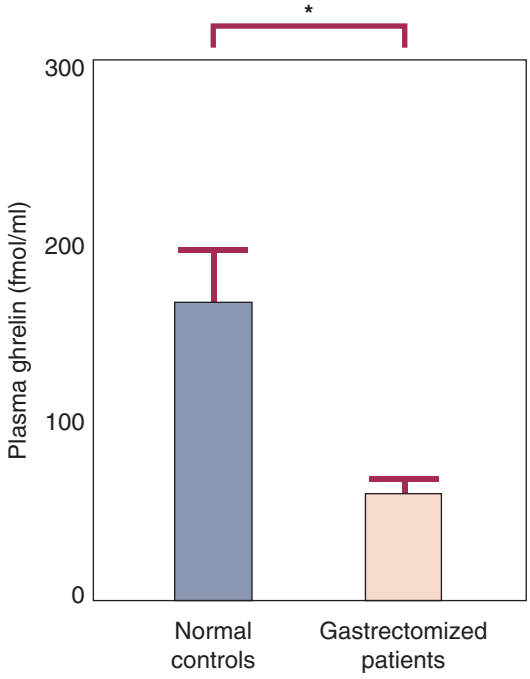

Figure 26-14. Ghrelin levels are decreased after gastrectomy. (*Reproduced with permission from Ariyasu H, Takaya K, Tagami T, et al: Stomach is a major source of circulating ghrelin, and feeding state determines plasma ghrelin-like immunoreactivity levels in humans.* J Clin Endocrinol Metab. *86:4753, 2001.*)

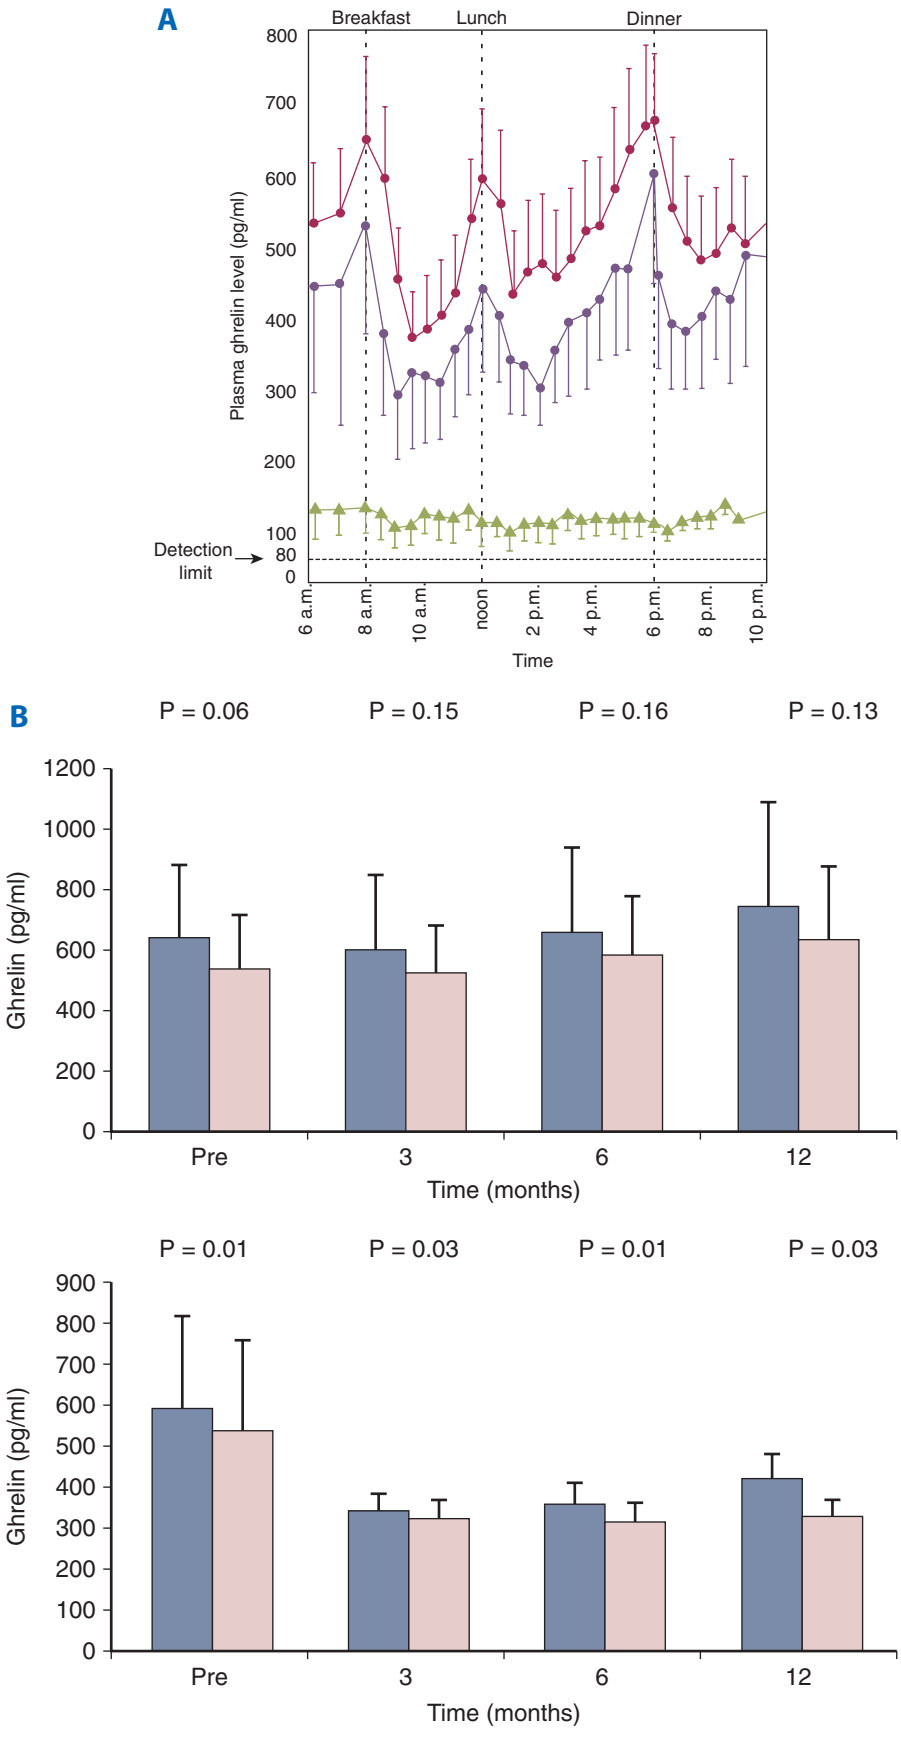

Figure 26-15. A and **B.** Ghrelin secretion after bariatric surgery. Some investigators have suggested that ghrelin secretion is dramatically decreased after gastric bypass. Other groups have shown statistically insignificant changes in ghrelin levels after gastric bypass, (RYGBP) but significant decreases after sleeve gastrectomy (SG). **A:** green = gastric bypass; blue = obese controls; red = normal weight controls; **B:** blue = fasting; pink = postprandial. B. Top = RYGBP; B bottom = SG. (*Fig. 26-15A reproduced with permission from Cummings DE, et al: Plasma ghrelin levels after diet-induced weight loss or gastric bypass surgery.* N Engl J Med *346:1623, 2002. Fig. 26-15B reproduced with permission from Karamanakos SN, et al: Weight loss, appetite suppression, and changes in fasting and postprandial ghrelin and peptide-YY levels after Roux-en-Y gastric bypass and sleeve gastrectomy: A prospective, double blind study.* Ann Surg *247:401, 2008.*)

Other groups have failed to show a significant decrease in ghrelin levels following gastric bypass but have found such decreases following sleeve gastrectomy, another effective weight loss operation (Fig. 26-15B).[31] Possibly subtle differences in operative technique, patient selection, and/or experimental conditions account for the findings that multiple studies have reported disparate results on the effect of bariatric surgery on ghrelin levels in obese patients. Obviously appetite control is complex with redundant and overlapping orexigenic and anorexigenic pathways and signals.[26,27]

Gastric Motility and Emptying

Gastric motor function has several purposes.[13,32,33,34] Interprandial motor activity clears the stomach of undigested debris, sloughed cells, and mucus. When feeding begins, the stomach relaxes to accommodate the meal. Regulated motor activity then breaks down the food into small particles and controls the output into the duodenum. The stomach accomplishes these functions by coordinated smooth muscle relaxation and contraction of the various gastric segments (proximal, distal, and pyloric). Smooth muscle myoelectric potentials are translated into muscular activity, which is modulated by extrinsic and intrinsic innervation and hormones. The mechanisms by which gastric distention is translated into a neurohormonal satiety signal have only been partially elucidated.[26,27]

Intrinsic Gastric Innervation. The extrinsic parasympathetic and sympathetic gastric innervation was discussed previously under Innervation. The intrinsic innervation consists of ganglia and nerves that constitute the enteric nervous system (Fig. 26-16).[35] There are a variety of neurotransmitters, which are generally grouped as excitatory (augment muscular activity) and inhibitory (decrease muscular activity). Important excitatory neurotransmitters include acetylcholine, the tachykinins, substance P, and neurokinin A. Important inhibitory neurotransmitters include nitric oxide (NO) and vasoactive intestinal peptide (VIP). Serotonin has been shown to modulate both contraction and relaxation. A variety of other molecules affect motility, including GRP, histamine, neuropeptide Y, norepinephrine, and endogenous opioids.

Specialized cells in the muscularis propria also are important modulators of GI motility. These cells, called *interstitial cells of Cajal*, are distinguishable histologically from neurons and myocytes, and appear to amplify both cholinergic excitatory and nitrergic inhibitory input to the smooth muscle of the stomach and intestine.[36] They are thought to be the cell of origin for gastrointestinal stromal tumors (GISTs) which are the most common mesenchymal neoplasm in the GI tract.

Segmental Gastric Motility. [13,36,37] In general, the proximal stomach serves a short-term food storage function and helps regulate basal intragastric tone, and the distal stomach mixes and grinds the food. The pylorus helps the latter process when closed, facilitating retropulsion of the solid food bolus back into the body of the stomach for additional breakdown. The pylorus opens intermittently to allow metered emptying of liquids and small solid particles into the duodenum.

Most of the motor activity of the proximal stomach consists of slow tonic contractions and relaxations, lasting up to 5 minutes. This activity is the main determinant of basal intragastric pressure, an important determinant of liquid emptying. Rapid phasic contractions may be superimposed on the slower tonic motor activity. When food is ingested, intragastric pressure falls as the proximal stomach relaxes. This proximal relaxation is mediated by two important vagovagal reflexes: receptive relaxation and gastric accommodation. Receptive relaxation refers to the reduction in proximal gastric tone associated with the act of swallowing. This occurs before the food reaches the stomach, and can be reproduced by mechanical stimulation of the pharynx or esophagus. Gastric accommodation refers to the proximal gastric relaxation associated with distention of the stomach. Accommodation is mediated through stretch receptors in the gastric wall and does not require esophageal or pharyngeal stimulation. Because both of these reflexes are mediated by afferent and efferent vagal fibers, they are significantly altered by truncal and highly selective vagotomy. Both these operations result in decreased gastric compliance, shifting the volume/pressure curve to the left. That is, interference with normal receptive relaxation and/or accommodation results in decreased gastric compliance, such that for any given amount of

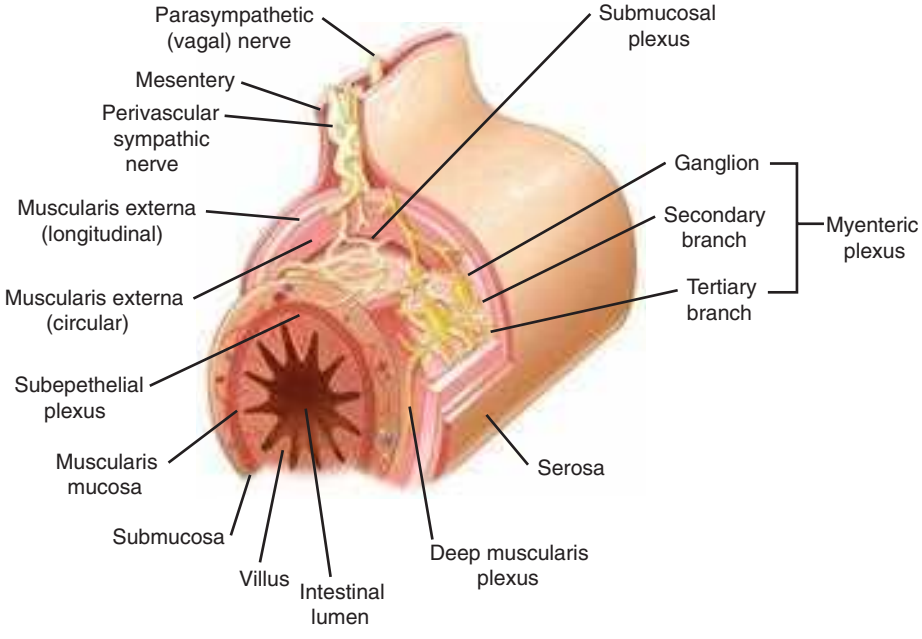

Figure 26-16. Enteric nervous system. *[Reproduced with permission from Chial HJ, Camilleri M: Motility disorders of the stomach and small intestine, in Friedman SL, McQuaid KR, Grendell JH (eds):* Current Diagnosis and Treatment in Gastroenterology, *2nd ed. Figure 26-17. The relationship between intracellular electrical activity and muscle cell contraction. Note that contractile activity is always associated with electrical activity, but the converse is not so. During mechanical quiescence, there are regular depolarizations that do not reach threshold. In the stimulated state, the threshold for contraction is reached, and motor activity is demonstrable. *[Reproduced with permission from Kim CH: Electrical activity of the stomach: clinical implications.* Mayo Clin Proc. *61:205, 1986.]*

food or liquid ingested, the intragastric pressure is greater. This may increase the rate of liquid emptying, perhaps contributing to dumping symptoms after vagotomy.

NO and VIP are the principal mediators of proximal gastric relaxation. But a variety of other agents increase proximal gastric relaxation and compliance, including dopamine, gastrin, CCK, secretin, GRP, and glucagon. Proximal gastric tone also is decreased by duodenal distention, colonic distention, and ileal perfusion with glucose (ileal brake).

The distal stomach breaks up solid food and is the main determinant of gastric emptying of solids. Slow waves of myoelectric depolarization sweep down the distal stomach at a rate of about three per minute. These waves originate from the proximal gastric pacemaker, high on the greater curvature. The pacing cells may be interstitial cells of Cajal, which have been shown to have a similar function in the small intestine and colon. Most of these myoelectric waves are below the threshold for smooth muscle contraction in the quiescent state, and thus are associated with negligible changes in pressure. Neural and/or hormonal input, which increases the plateau phase of the action potential, can trigger muscle contraction, resulting in a peristaltic wave associated with the electrical slow wave, and of the same frequency (three per minute) (Fig. 26-17). It is possible that implantable gastric pacemakers benefit some patients with gastroparesis by favorably impacting this myoelectric coupling.

During fasting, distal gastric motor activity is controlled by the migrating motor complex (MMC), the "gastrointestinal housekeeper" (Fig. 26-18). The purported function of the MMC is to sweep along any undigested food, debris, sloughed cells, and mucus after the fed phase of digestion is complete. The MMC lasts approximately 100 minutes (longer at night, shorter during daytime) and is divided into four phases. Phase I (about half the length of the entire cycle) is a period of relative motor inactivity. High-amplitude muscular contractions do not occur in phase I of the MMC. Phase II (about 25% of the entire MMC cycle) consists of some irregular, high-amplitude, generally nonpropulsive contractions. Phase III, a period of intense, regular, (about three per minute) propulsive contractions, only lasts about 5 to 10 minutes. Most phase III complexes of the GI MMC begin in the stomach, and the frequency approximates that of the myoelectric gastric slow wave. Phase IV is a transition period.

Neurohormonal control of the MMC is poorly understood, but it appears that different phases are regulated by different mechanisms. For example, vagotomy abolishes phase II of the gastric MMC but has little influence on phase III that persists

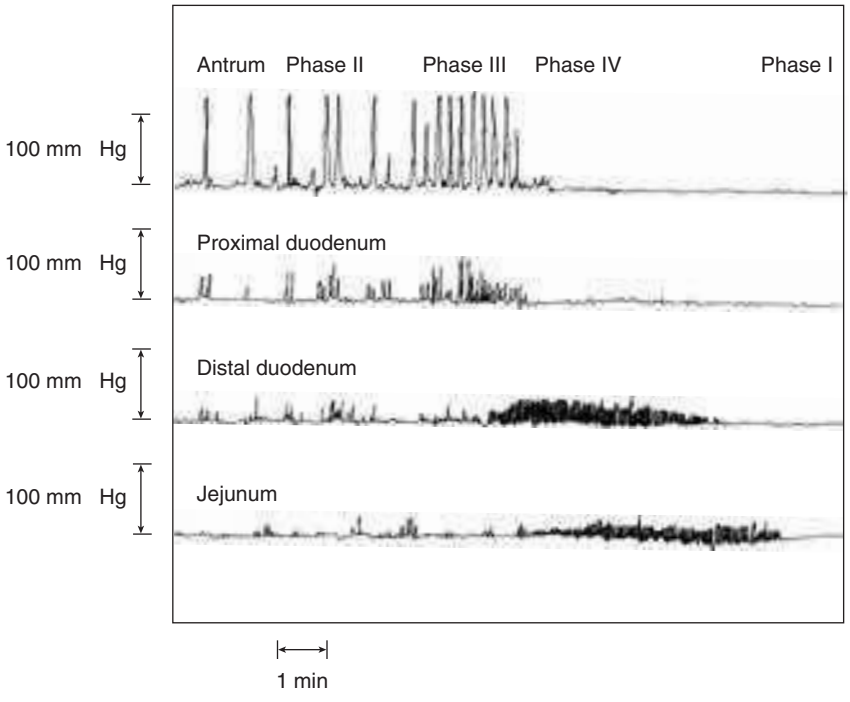

Figure 26-18. Migrating motor complex, the fasting pattern of GI activity. During phase III of the migrating motor complex, effective peristaltic waves progress from the stomach to the distal small intestine. *[Reproduced with permission from Rees WDW, et al: Human interdigestive and postprandial gastrointestinal motor and gastrointestinal hormone patterns.* Dig Dis Sci. *27(4):321, 1982. Copyright 1982, with kind permission of Springer Science + Business Media.]*

even in the autotransplanted stomach, totally devoid of extrinsic neural input. This suggests that phase III is regulated by intrinsic nerves and/or hormones. Indeed, the initiation of phase III of the MMC in the distal stomach corresponds temporally to elevation in serum levels of motilin, a hormone produced in the duodenal mucosa. Resection of the duodenum abolishes distal gastric phase III in dogs, and resection of the duodenum in humans (e.g., with pancreaticoduodenectomy, the Whipple procedure) commonly results in early postoperative delayed gastric emptying. There are clearly motilin receptors on antral smooth muscle and nerves. Other modulators of gastric MMC activity include NO, endogenous opioids, intrinsic cholinergic and adrenergic nerves, and duodenal pH.

Feeding abolishes the MMC and leads to the fed motor pattern. The fed motor pattern of gastric activity starts within 10 minutes of food ingestion and persists until all the food has left the stomach. The neurohormonal initiator of this change is unknown, but CCK and the vagus appear to play some role: Sham feeding transiently induces antral motor activity resembling the fed motor pattern, and this is blocked by the CCK receptor antagonist loxiglumide. Gastric motility during the fed pattern resembles phase II of the MMC, with irregular but continuous phasic contractions of the distal stomach. During the fed state, about half of the myoelectric slow waves are associated with strong distal gastric contractions. Some are prograde and some are retrograde, serving to mix and grind the solid components of the meal. The magnitude of gastric contractions and the duration of the pattern are influenced by the consistency and composition of the meal.

The pylorus functions as an effective regulator of gastric emptying and an effective barrier to duodenogastric reflux. Bypass, transection, or resection of the pylorus may lead to uncontrolled gastric emptying of food and the dumping syndrome (see Postgastrectomy Problems). Pyloric dysfunction or disruption may also result in uncontrolled entry of duodenal contents into the stomach. Perfusion of the duodenum with lipids, glucose, amino acids, hypertonic saline, or hydrochloric acid results in closure of the pylorus and decreased transpyloric flow. Ileal perfusion with fat has the same effect. A variety of neurohumoral pathways are involved with these physiologic responses, and there is evidence that different pathways may be involved for different stimuli.

The pylorus is readily apparent grossly as a thick ring of muscle and connective tissue. The density of nerve tissue in the pyloric smooth muscle is several folds higher than in the antrum, with increased numbers of neurons staining positive for substance P, neuropeptide Y, VIP, and galanin. Interstitial cells of Cajal are is more closely associated with pyloric myocytes, and the myoelectric slow wave of the pylorus has the same frequency as that seen in the distal stomach. The motor activity of the pylorus is both tonic and phasic. During phase III of the MMC, the pylorus is open as gastric contents are swept into the duodenum. During the fed phase, the pylorus is closed most of the time. It relaxes intermittently, usually in synchronization with lower-amplitude, minor antral contractions. The higher-amplitude, more major antral contractions are usually met with a closed pylorus, facilitating retropulsion and further grinding of food.

Modulation of pyloric motor activity is complex. There is evidence of both inhibitory and excitatory vagal pathways. Some contractile vagal effects are mediated by opioid pathways, because they are blocked by naloxone. Electrical stimulation of the duodenum causes the pylorus to contract, whereas electrical stimulation of the antrum causes pyloric relaxation. Nitric oxide is an important mediator of pyloric relaxation. Other molecules that may play a physiologic role in controlling pyloric smooth muscle include serotonin, VIP, prostaglandin E_1, and galanin (pyloric relaxation); and histamine, CCK, and secretin (pyloric contraction).

Gastric Emptying.[13] The control of gastric emptying is complex. In general, liquid emptying is faster than solid emptying. Osmolarity, acidity, caloric content, nutrient composition, and particle size are important modulators of gastric emptying. Stimulation of duodenal osmoreceptors, glucoreceptors, and pH receptors clearly inhibits gastric emptying by a variety of neurohumoral mechanisms. CCK has been consistently shown to inhibit gastric emptying at physiologic doses (Fig. 26-19). Recently, it has been noted that the anorexigenic hormone leptin, secreted by fat and gastric mucosa, inhibits gastric emptying, perhaps through the same pathway as CCK (which also has properties of a satiety hormone). The orexigenic hormone ghrelin has the opposite effect.

Liquid Emptying. The gastric emptying of water or isotonic saline follows first-order kinetics, with a half emptying time around 12 minutes. Thus, if one drinks 200 mL of water, about 100 mL enters the duodenum by 12 minutes, whereas if one drinks 400 mL of water, about 200 mL enters the duodenum by 12 minutes. This emptying pattern of liquids is modified considerably as the caloric density, osmolarity, and nutrient composition of the liquid changes (Fig. 26-20). Up to an osmolarity of about 1 M, liquid emptying occurs at a rate of about 200 kcal per hour. Duodenal osmoreceptors and hormones (e.g., secretin and VIP) are important modulators of liquid gastric emptying. Generally, liquid emptying is delayed in the supine position.

Traditionally, liquid emptying has been attributed to the activity of the proximal stomach, but it is probably more complicated than previously thought. Clearly, receptive relaxation and gastric accommodation play a role in gastric emptying of liquids. Patients with a denervated (e.g., vagotomized),

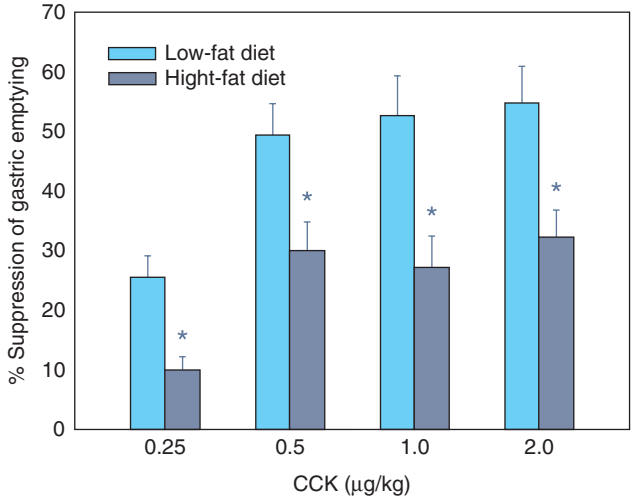

Figure 26-19. Cholecystokinin (CCK) inhibits gastric emptying. *[Reproduced with permission from Covasa M, Ritter RC: Adaptation to high-fat diet reduces inhibition of gastric emptying by CCK and intestinal oleate.* Am J Physiol Regulatory Integrative Comp Physiol *278:R166, 2000.]*

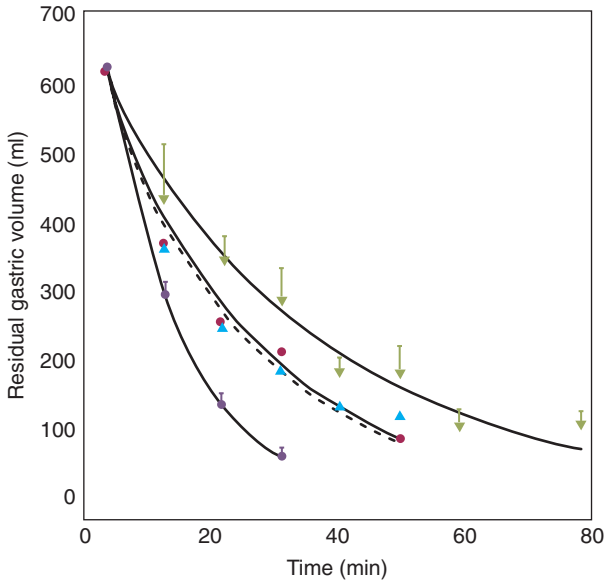

Figure 26-20. Nutrient composition and caloric density affect liquid gastric emptying. Glucose solution (purple circles), the least calorically dense, emptied the fastest. Other more calorically dense solutions, such as milk protein (green triangles) and peptide hydrolysates (red circles and blue triangles), emptied slower. *[Reproduced with permission from Calbet JA, MacLean DA: Role of caloric content on gastric emptying in humans.* J Physiol. *498:533, 1997.]*

resected, or plicated (e.g., fundoplication) proximal stomach have decreased gastric compliance and may show accelerated gastric emptying of liquids.

Some observations suggest an active role for the distal stomach in liquid emptying. For instance even if the proximal intragastric pressure is lower than duodenal pressure, normal gastric emptying of liquids can occur. Also, diabetic patients may have normal proximal gastric motor function and profoundly delayed gastric emptying of liquids. Indeed, antral contractile activity does correlate with liquid gastric emptying, and this distal gastric activity appears to vary with the nutrient composition and caloric content of the liquid meal. Depending on the circumstances, distal gastric motor activity can promote or inhibit gastric emptying of liquids. Distal gastrectomy and pyloric stenting both obviously interfere with distal gastric motor activity, and both accelerate the initial rapid phase of liquid gastric emptying.

Solid Emptying. Normally, the half-time of solid gastric emptying is less than 2 hours. Unlike liquids, which display an initial rapid phase followed by a slower linear phase of emptying, solids have an initial lag phase during which little emptying of solids occurs. It is during this phase that much of the grinding and mixing occurs. A linear emptying phase follows, during which the smaller particles are metered out to the duodenum. Solid gastric emptying is a function of meal particle size, caloric content, and composition (especially fat). When liquids and solids are ingested together, the liquids empty first. Solids are stored in the fundus and delivered to the distal stomach at constant rates for grinding. Liquids also are sequestered in the fundus, but they appear to be readily delivered to the distal stomach for early emptying. The larger the solid component of the meal, the slower the liquid emptying. Patients bothered by dumping syndrome are advised to limit the amount of liquid consumed with the solid meal, taking advantage of this effect. Three prokinetic agents are commonly used to treat delayed gastric emptying. Typical doses and mechanism of action are shown in Table 26-4.

Table 26-4

Drugs that accelerate gastric emptying

AGENT	TYPICAL ADULT DOSE	MECHANISM OF ACTION
Metoclopramide	10 mg PO qid	Dopamine antagonist
Erythromycin	250 mg PO qid	Motilin agonist
Domperidone	10 mg PO qid	Dopamine antagonist

DIAGNOSIS OF GASTRIC DISEASE

Signs and Symptoms

The most common symptoms of gastric disease are pain, weight loss, early satiety, and anorexia. Nausea, vomiting, bloating, and anemia also are frequent complaints. Several of these symptoms (pain, bloating, nausea, and early satiety) are often described by physicians as dyspepsia, synonymous with the common nonmedical term *indigestion*. Common causes of dyspepsia include gastroesophageal reflux disease (GERD) and disorders of the stomach, gallbladder, and pancreas. Although none of the above symptoms alone is specific for gastric disease, when elicited in the context of a careful history and physical examination, they point to a differential diagnosis, which can be refined with certain tests.

Diagnostic Tests

Esophagogastroduodenoscopy. Patients with one or more of the alarm symptoms listed in Table 26-5 should undergo expeditious upper endoscopy. Esophagogastroduodenoscopy (EGD) is a safe and accurate outpatient procedure performed under conscious sedation.[38] Smaller flexible scopes with excellent optics and a working channel are easily passed transnasally in the unsedated patient. Following an 8-hour fast, the flexible scope is advanced under direct vision into the esophagus, stomach, and duodenum. The fundus and GE junction are inspected by retroflexing the scope. To rule out cancer with a high degree of accuracy, all patients with gastric ulcer diagnosed on upper GI series or found at EGD should have multiple biopsy specimens of the base and rim of the lesion. Brush cytology also should

Table 26-5

Alarm symptoms that indicate the need for upper endoscopy

Weight loss
Recurrent vomiting
Dysphagia
Bleeding
Anemia

be considered. Gastritis should be biopsied both for histologic examination and for a tissue urease test to rule out the presence of *H. pylori*. If Helicobacter infection is detected, it should probably be treated because of the etiologic association with peptic ulcers, mucosa-associated lymphoid tissue (MALT), and gastric cancer. The most serious complications of EGD are perforation (which is rare, but can occur anywhere from the cervical esophagus to the duodenum), aspiration, and respiratory depression from excessive sedation. Although EGD is a more sensitive test than double-contrast upper GI series, these modalities should be considered complementary rather than mutually exclusive.

Radiologic Tests. Plain abdominal X-rays may be helpful in the diagnosis of gastric perforation (pneumoperitoneum) or delayed gastric emptying (large air-fluid level).

Double-contrast upper GI series may be better than EGD at elucidating gastric diverticula, fistula, tortuosity, stricture location, and size of hiatal hernia. Although there are radiologic characteristics of ulcers that suggest the presence or absence of malignancy, gastric ulcers always require adequate biopsy.

Computed Tomographic Scanning and Magnetic Resonance Imaging. Usually, significant gastric disease can be diagnosed without these sophisticated imaging studies. However, one or the other should be part of the routine staging work-up for most patients with a malignant gastric tumor. Magnetic resonance imaging (MRI) may prove clinically useful as a quantitative test for gastric emptying, and may even hold some promise for the analysis of myoelectric derangements in patients with gastroparesis. Virtual gastroscopy using multi detector CT scan or MRI is not yet widely used but these techniques may prove useful for screening and staging of gastric disease.[39–41] (Fig. 26-21).

Arteriography may be helpful in the occasional poor-risk patient with exsanguinating gastric hemorrhage, or in the patient with occult gastric bleeding.

Endoscopic Ultrasound. Endoscopic ultrasound (EUS) is useful in the evaluation and management of some gastric lesions.[42–44] Local staging of gastric adenocarcinoma with EUS is quite accurate, and this modality can be used to plan therapy. At some centers, patients with transmural and/or node positive adenocarcinoma of the stomach are considered for preoperative (neoadjuvant) chemoradiation therapy. EUS is the best way to clinically stage these patients locoregionally. Suspicious nodes can be sampled with EUS-guided endoscopic needle biopsy. Malignant tumors that are confined to the mucosa on EUS may be amenable to endoscopic mucosal resection (EMR). EUS also can be used to assess tumor response to chemotherapy. Submucosal masses are commonly discovered during routine EGD. Large submucosal masses should be resected because of the risk of malignancy, but observation may be appropriate for some small submucosal masses (e.g., lipoma or small GIST). There are endoscopic characteristics of benign and malignant mesenchymal tumors, and thus, EUS can provide reassurance, but no guarantee, that small lesions under observation are probably benign. Submucosal varices also can be assessed by EUS.

Gastric Secretory Analysis. Analysis of gastric acid output requires gastric intubation, and it is performed infrequently nowadays. This test may be useful in the evaluation of patients with hypergastrinemia, including the Zollinger-Ellison syndrome (ZES), patients with refractory ulcer or GERD, and patients with recurrent ulcer after operation. Historically, gastric analysis was performed most commonly to test for the adequacy of vagotomy in postoperative patients with recurrent or persistent ulcer. Now this can be done by assessing peripheral pancreatic polypeptide levels in response to sham feeding.[45] A 50% increase in pancreatic polypeptide within 30 minutes of sham feeding suggests vagal integrity.

Normal basal acid output (BAO) is greater than 5 mEq/h. MAO is the average of the two final stimulated 15-minute periods and is usually 10 to 15 mEq/h. Peak acid output is defined as the highest of the four stimulated periods. Patients with a gastrinoma commonly have a high BAO, often above 30 mEq/h, but consistently above 15 mEq/h unless there has been previous vagotomy or gastric resection. In patients with gastrinoma, the ratio of BAO to MAO exceeds 0.6. Normal acid output in the patient prescribed acid-suppressive medication usually means that the patient is noncompliant. To assess acid-secretory capacity in the absence of medication effect, H_2 blockers and PPIs should be withheld before gastric analysis.

Scintigraphy. The standard scintigraphic evaluation of gastric emptying involves the ingestion of a test meal with one or two isotopes, and scanning the patient under a gamma camera. A curve for liquid and solid emptying is plotted, and the half-time calculated. Normal standards exist for each facility. Duodenogastric reflux can be quantitated by the IV administration of hepatobiliary iminodiacetic acid (HIDA scan), which is concentrated and excreted by the liver into the duodenum. Software allows a semiquantitative assessment of how much of the isotope refluxes into the stomach. Positron emission tomography (PET) scan or CT/PET scan may be useful in staging certain patients with gastric malignancy.

Tests for *Helicobacter pylori*. A variety of tests can help the clinician to determine whether the patient has active *H. pylori* infection.[46] The predictive value (positive and negative) of any of these tests when used as a screening tool depends on the prevalence of *H. pylori* infection in the screened population. A positive test is quite accurate in predicting *H. pylori* infection, but a negative test is characteristically unreliable. Thus, in the appropriate clinical setting, treatment for *H. pylori* should be initiated on the basis of a positive test, but not necessarily withheld if the test is negative. Because of the association between *H. pylori* infection and gastric lymphoma and carcinoma, many clinicians recommend treating *Helicobacter* infection when the diagnosis is made.

A positive serologic test is presumptive evidence of active infection if the patient has never been treated for *H. pylori*. Histologic examination of an antral mucosal biopsy using special stains is the gold standard test. Other sensitive tests include commercially available rapid urease tests, which assay for the presence of urease in mucosal biopsy specimens (strong presumptive evidence of infection). Urease is an omnipresent enzyme in *H. pylori* strains that colonize the gastric mucosa. The labeled carbon-13 urea breath test has become the standard test to confirm eradication of *H. pylori* following appropriate treatment.[47] In this test, the patient ingests urea labeled with nonradioactive ^{13}C. The labeled urea is acted upon by the urease present in the *H. pylori* and converted into ammonia and carbon dioxide. The radiolabeled carbon dioxide is excreted from the lungs and can be detected in the expired air (Fig. 26-22). It also can be detected in a blood sample. The fecal antigen test also is quite sensitive and specific for active *H. pylori* infection and may prove more practical in confirming a cure.

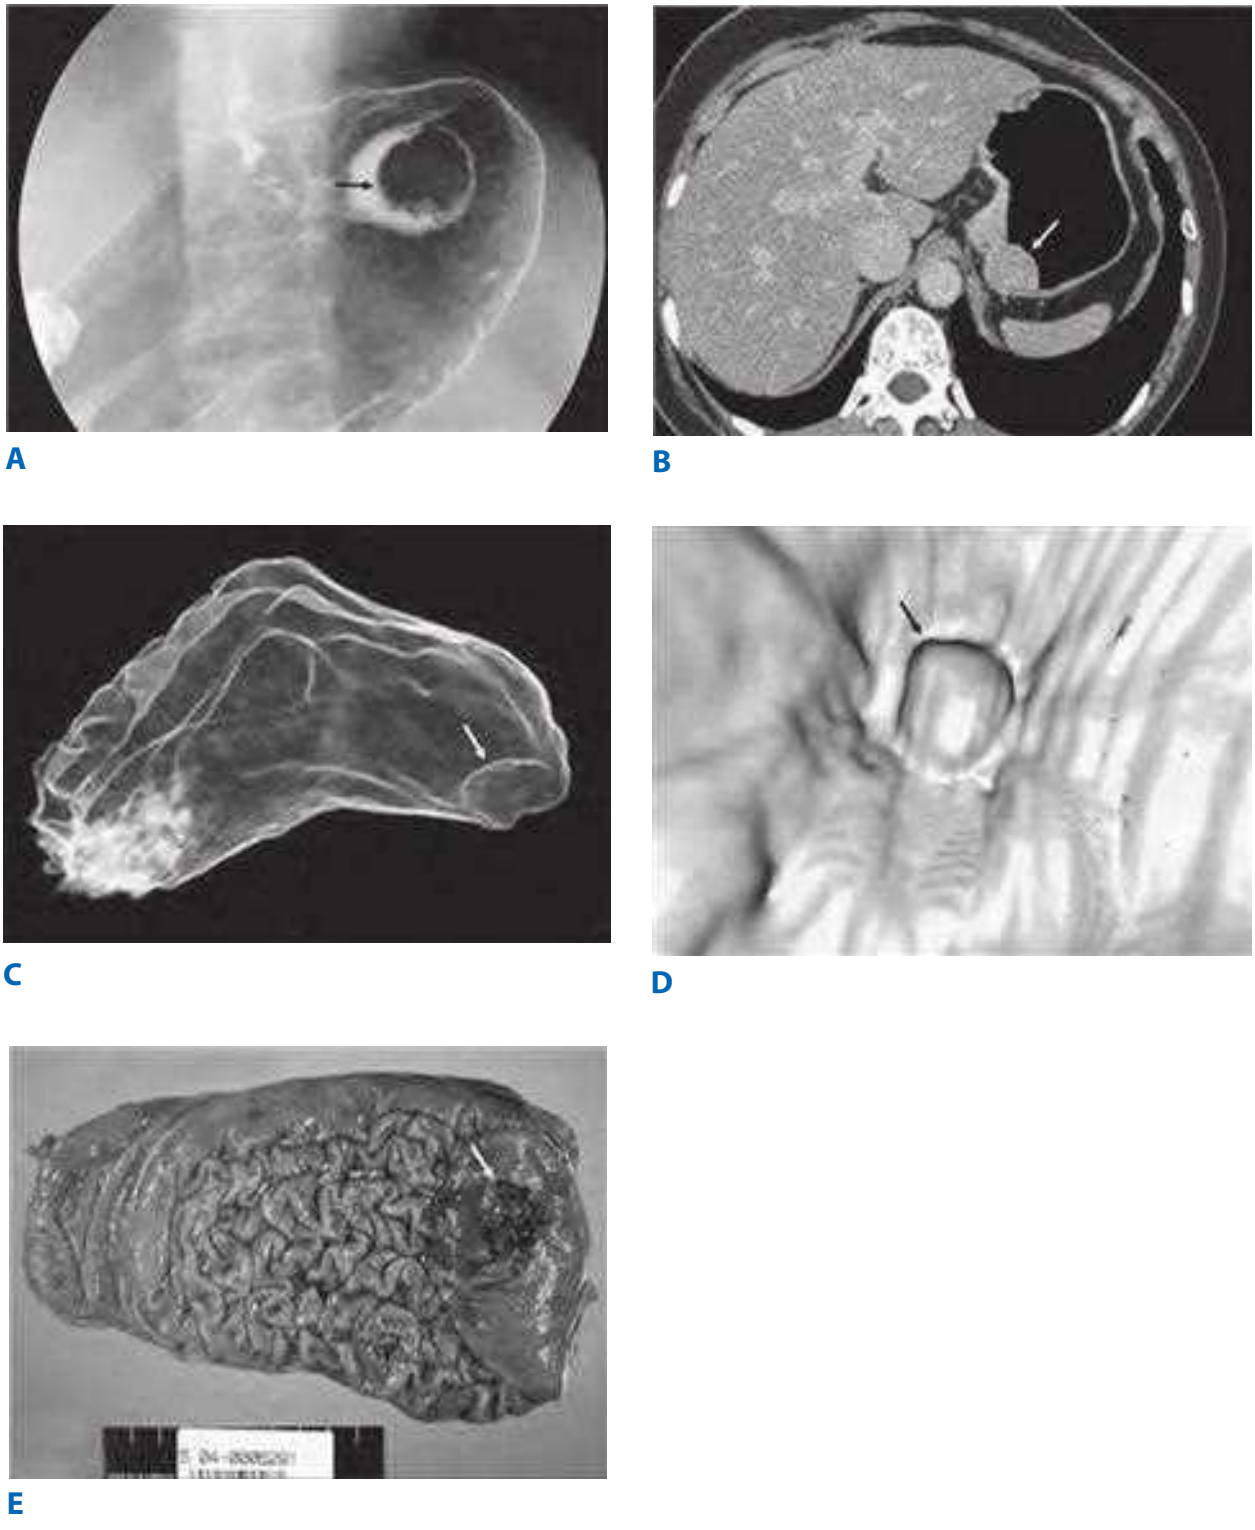

Figure 26-21. Conventional double-contrast barium study (**A**) shows a focal protruding mass (*arrow*) on the gastric fundus. Axial computed tomographic scan (**B**) also shows a protruding polyp (*arrow*). The three dimensional computed tomographic gastrographic images in the transparent (**C**) and virtual endoscopic (**D**) modes show an elevated lesion on the gastric fundus (*arrows*). Photograph of the total gastrectomy specimen (**E**) shows a well-demarcated polypoid mass (*arrow*); this lesion was confirmed as early gastric carcinoma type I on microscopic examination (not shown). Antroduodenal Motility Testing and Electrogastrography. Antroduodenal motility testing and electrogastrography (EGG) are performed in specialized centers and may be useful in the evaluation of the patient with anomalous epigastric symptoms. EGG consists of the transcutaneous recording of gastric myoelectric activity. Antroduodenal motility testing is done with a tube placed transnasally or transorally into the distal duodenum. There are pressure-recording sensors extending from the stomach to the distal duodenum. The combination of these two tests together with scintigraphy provides a thorough assessment of gastric motility.

PEPTIC ULCER DISEASE

Peptic ulcers are focal defects in the gastric or duodenal mucosa that extend into the submucosa or deeper. They may be acute or chronic and, ultimately, are caused by an imbalance between mucosal defenses and acid/peptic injury (Fig. 26-23).[48,49] Peptic ulcer remains a common outpatient diagnosis, but the number of physician visits, hospital admissions, and elective operations for PUD has decreased steadily and dramatically over the past three decades. Interestingly, the start of these trends all predated the use of H_2 receptor blockers, or proton pump inhibitors, fiberoptic endoscopy, and highly selective vagotomy. However, the incidence of emergency surgery and the death rate associated with peptic ulcers has not decreased nearly so dramatically.

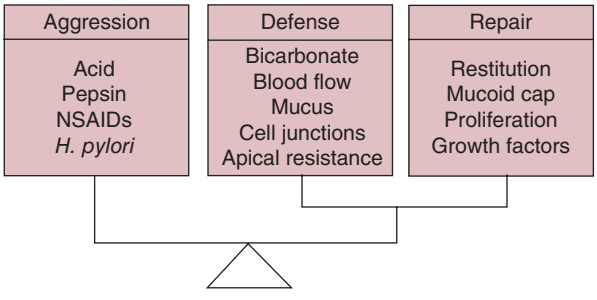

Figure 26-23. Balance of aggressive and defensive factors in the gastric mucosa. (*Reproduced with permission from Mertz HR, Walsh JH: Peptic ulcer pathophysiology.* Med Clin North Am *75:799, 1991. Copyright Elsevier.*)

These epidemiologic changes probably represent the net effect of several factors, including (beneficially) decreased prevalence of *H. pylori* infection, better medical therapy, and increased outpatient management; and (detrimentally) the use of NSAIDs and aspirin (with and without ulcer prophylaxis) in an aging population with multiple risk factors.

PUD is one of the most common GI disorders in the United States with a prevalence of about 2%, and a lifetime cumulative prevalence of about 10%, peaking around age 70 years.[50] The costs of PUD, including lost work time and productivity, are estimated to be above $8 billion per year in the United States. In 1998, approximately 1.5% of all Medicare hospital costs were spent treating PUD, and the crude mortality rate for peptic ulcer was 1.7 per 100,000 individuals. Using the National Inpatient Sample, it can be estimated that the mortality rate in patients hospitalized in 2006 with duodenal ulcer was 3.7% compared to 2.1% for gastric ulcer.[51] Recent studies have shown an increase in the rates of hospitalization and mortality in elderly patients for the peptic ulcer complications of bleeding and perforation. This may be due in part to the increasingly common use of NSAIDs and aspirin in this elderly cohort, many of whom also have *H. pylori* infection.

Pathophysiology and Etiology

A variety of factors may contribute to the development of PUD. Although it is now recognized that the large majority of duodenal and gastric ulcers are caused by *H. pylori* infection and/or NSAID use[17,52] (Fig. 26-24), the final common pathway to ulcer formation is acid-peptic injury of the gastroduodenal mucosal barrier. Thus, the adage "no acid, no ulcer" remains true. Acid suppression heals both duodenal and gastric ulcers and prevents recurrence. In general *H. pylori* predisposes to ulceration, both by acid hypersecretion and by compromise of mucosal defense mechanisms. NSAID use causes ulcers predominantly by compromise of mucosal defenses. Duodenal ulcer was traditionally viewed as a disease of increased acid-peptic action on the duodenal mucosa, whereas gastric ulcer was viewed as a disease of weakened mucosal defenses. An increased understanding of peptic ulcer pathophysiology has blurred this overly simplistic distinction. Clearly, weakened mucosal defenses play a role in both duodenal and gastric ulcers and acid hypersecretion may

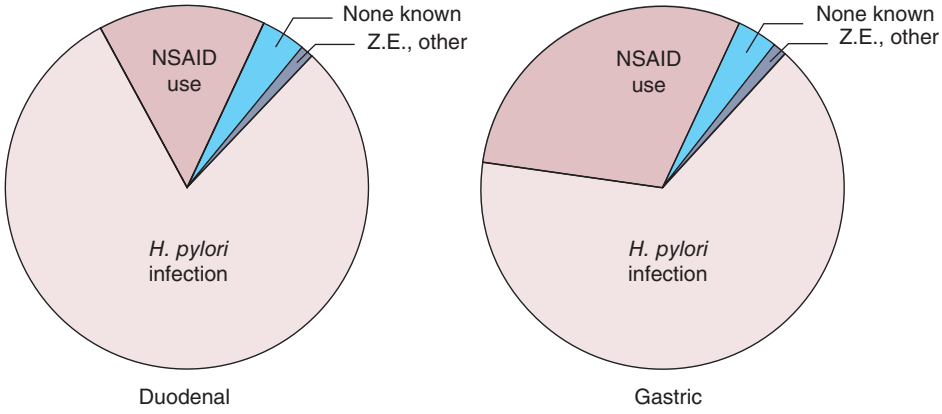

Figure 26-24. "Causes" of peptic ulcer disease. Z.E. = Zollinger-Ellison syndrome. *[Reproduced with permission from Spechler SJ: Peptic ulcer disease and its complications, in Feldman M (ed):* Sleisinger and Fordtran's Gastrointestinal and Liver Disease, *7th ed. Philadelphia: Saunders, 2002, p 747. Copyright Elsevier.]*

result in a duodenal or gastric ulcer in the setting of normal mucosal defenses.

Elimination of *H. pylori* infection or NSAID use is important for optimal ulcer healing, and perhaps is even more important in preventing ulcer recurrence and/or complications. A variety of other diseases are known to cause peptic ulcer, including ZES (gastrinoma), antral G-cell hyperfunction and/or hyperplasia, systemic mastocytosis, trauma, burns, and major physiologic stress. Other causative agents include drugs (all NSAIDs, aspirin, and cocaine), smoking, and psychologic stress. In the United States, probably more than 90% of serious peptic ulcer complications can be attributed to *H. pylori* infection, NSAID use, and/or cigarette smoking.

***Helicobacter pylori* Infection.** With specialized flagella and a rich supply of urease, *H. pylori* is uniquely equipped for survival in the hostile environment of the stomach.[53–55] About 50% of the world's population is infected with *H. pylori*, a major cause of chronic gastritis. The same sequence of inflammation to metaplasia to dysplasia to carcinoma, that is well known to occur in the esophagus from reflux-induced inflammation (and in the colon from inflammatory bowel disease), is now increasingly well recognized to occur in the stomach with *Helicobacter*-induced gastritis. The influence of prolonged acid suppression with PPIs or H_2RAs on these esophagogastric processes is largely unknown. *Helicobacter* also clearly has an etiologic role in the development of gastric lymphoma.

The organism possesses the enzyme urease, which converts urea into ammonia and bicarbonate, thus creating an environment around the bacteria that buffers the acid secreted by the stomach. The ammonia is damaging to the surface epithelial cells. Mutant strains of *H. pylori* that do not produce urease are unable to colonize the stomach. The organism lives in the mucus layer atop the gastric SECs, and some attach to these cells (Fig. 26-25).[53,54] Apparently *Helicobacter* strains that lack flagella are unable to navigate through the unstirred mucus layer to get to the apical membrane of the SEC for attachment, and are nonpathogenic. One of the mechanisms by which *Helicobacter* causes gastric injury may be through a disturbance in gastric acid secretion. This is due, in part, to the inhibitory effect that *H. pylori* exerts on antral D cells that secrete somatostatin, a potent inhibitor of antral G-cell gastrin production. *H. pylori* infection is associated with decreased levels of somatostatin, decreased

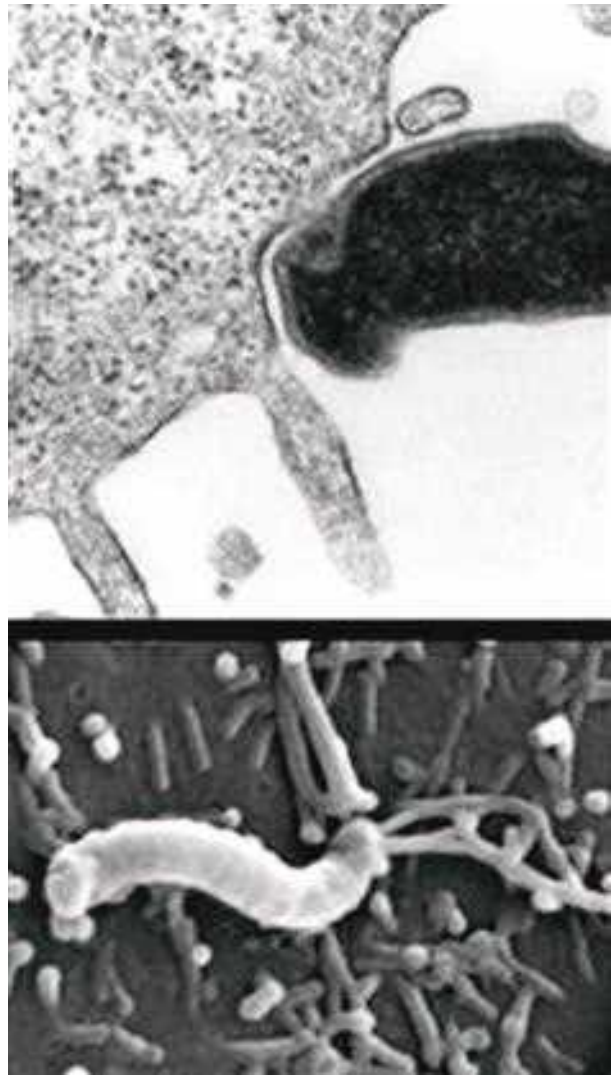

Figure 26-25. *Helicobacter pylori* closely adherent to the cell membrane (*top*), and spiral-shaped *H. pylori* attached to epithelial surface and surrounding microvilli (*bottom*). In the image on the bottom, the bacterial flagella can be seen arising from the upper pole of the bacterium. (*From Parsonnet J: Clinician-discoverers—Marshall, Warren, and* H. pylori. Figure 26-26. Model of *Helicobacter* effects on duodenal ulcer pathogenesis. (*Reproduced with permission from Peek RM Jr., Blaser MJ: Pathophysiology of* Helicobacter pylori*-induced gastritis and peptic ulcer disease.* Am J Med *102:200, 1997. Copyright Elsevier.*)

somatostatin messenger RNA production, and fewer somatostatin-producing D cells. These effects are probably mediated by *H. pylori*–induced local alkalinization of the antrum (antral acidification is the most potent antagonist to antral gastrin secretion), and *H. pylori*–mediated increases in other local mediators and cytokines. The result is hypergastrinemia and acid hypersecretion (Fig. 26-26).[49] This hypergastrinemia presumably leads to the parietal cell hyperplasia seen in many patients with duodenal ulcer. The acid hypersecretion and the antral gastritis are thought to lead to antral epithelial metaplasia in the postpyloric duodenum. This duodenal metaplasia allows *H. pylori* to colonize the duodenal mucosa and, in these patients, the risk of developing a duodenal ulcer increases 50-fold. When *H. pylori* colonizes the duodenum, there is a significant decrease in acid-stimulated duodenal bicarbonate release. When *H. pylori* infection is successfully treated, acid secretory physiology tends to normalize. Other mechanisms whereby *H. pylori* can induce gastroduodenal mucosal injury include the production of toxins (vacA and cagA), local elaboration of cytokines (particularly interleukin-8) by infected mucosa, recruitment of inflammatory cells and release of inflammatory mediators, recruitment and activation of local immune factors, and increased apoptosis (Fig. 26-27).[54,55] The net effect is a weakening of mucosal defenses.The mechanism by which the helicobacter organism avoids recognition and destruction by the mucosal immune system is a topic of interest and active research.[56]

The evidence supporting the central role of *H. pylori* in the pathophysiology of PUD is strong. Patients with *H. pylori* infection and antral gastritis are three and one-half times more likely to develop PUD than patients without *H. pylori* infection. Up to 90% of patients with duodenal ulcers, and 70% to 90% of patients with gastric ulcers, have *H. pylori* infection. It is clear from multiple randomized prospective studies that curing *H. pylori* infection dramatically alters the natural history of PUD, decreasing the recurrent ulcer rate from more than 75% in patients treated with a course of acid-suppressive therapy alone (in whom *H. pylori* is not eradicated) to less than 20% in patients treated with a course of antibacterial therapy (Fig. 26-28).[57]

Obviously, other factors are involved in the etiology of PUD because many patients colonized with *H. pylori* do not get peptic ulcer disease, and many patients with peptic ulcer disease do not have *H. pylori* infection. These observations notwithstanding, it is clear from a variety of well-designed laboratory, clinical, and epidemiologic studies that *H. pylori* is indubitably an important factor in the development and recurrence of PUD. *H. pylori* also plays an etiologic role in gastric cancer and lymphoma.[54]

Acid Secretion and Peptic Ulcer. A variety of abnormalities related to mucosal acid exposure have been described in patients with duodenal ulcer (Fig. 26-29).[58] Although duodenal ulcer patients as a group have a higher mean BAO and mean MAO compared to normal controls, many duodenal ulcer patients have basal and peak acid outputs in the normal range, and there is no correlation between acid secretion and the severity of the ulcer disease. As a group, duodenal ulcer patients produce more acid than normal controls in response to any known acid secretory stimulus. Although they usually have normal fasting serum gastrin levels, DU patients often produce more gastric acid at any given dose of gastrin than controls. Considering that many duodenal ulcer patients do produce excessive gastric acid, it has been argued that a "normal" fasting gastrin level in these patients is inappropriately high, and that there is an impaired feedback mechanism, especially in light of the apparently increased sensitivity of the parietal cell mass to gastrin. Many of these long-standing observations now seem reasonable in light of recently gained understanding of the perturbations in acid and gastrin secretion associated with *H. pylori* infection. Some patients with duodenal ulcer also have increased rates of gastric emptying that deliver an increased acid load per unit of time to the duodenum. Finally, the buffering capacity of the duodenum in many patients with duodenal ulcer is compromised due to decreased duodenal bicarbonate secretion.

In patients with gastric ulcer, acid secretion is variable. Currently, five types of gastric ulcer are described, although the original Johnson classification contained three types (Fig. 26-30).[59] The most common, Johnson type I gastric ulcer, is typically located near the angularis incisura on the lesser curvature, close to the border between antral and corpus mucosa. Patients with type I gastric ulcer usually have normal or decreased

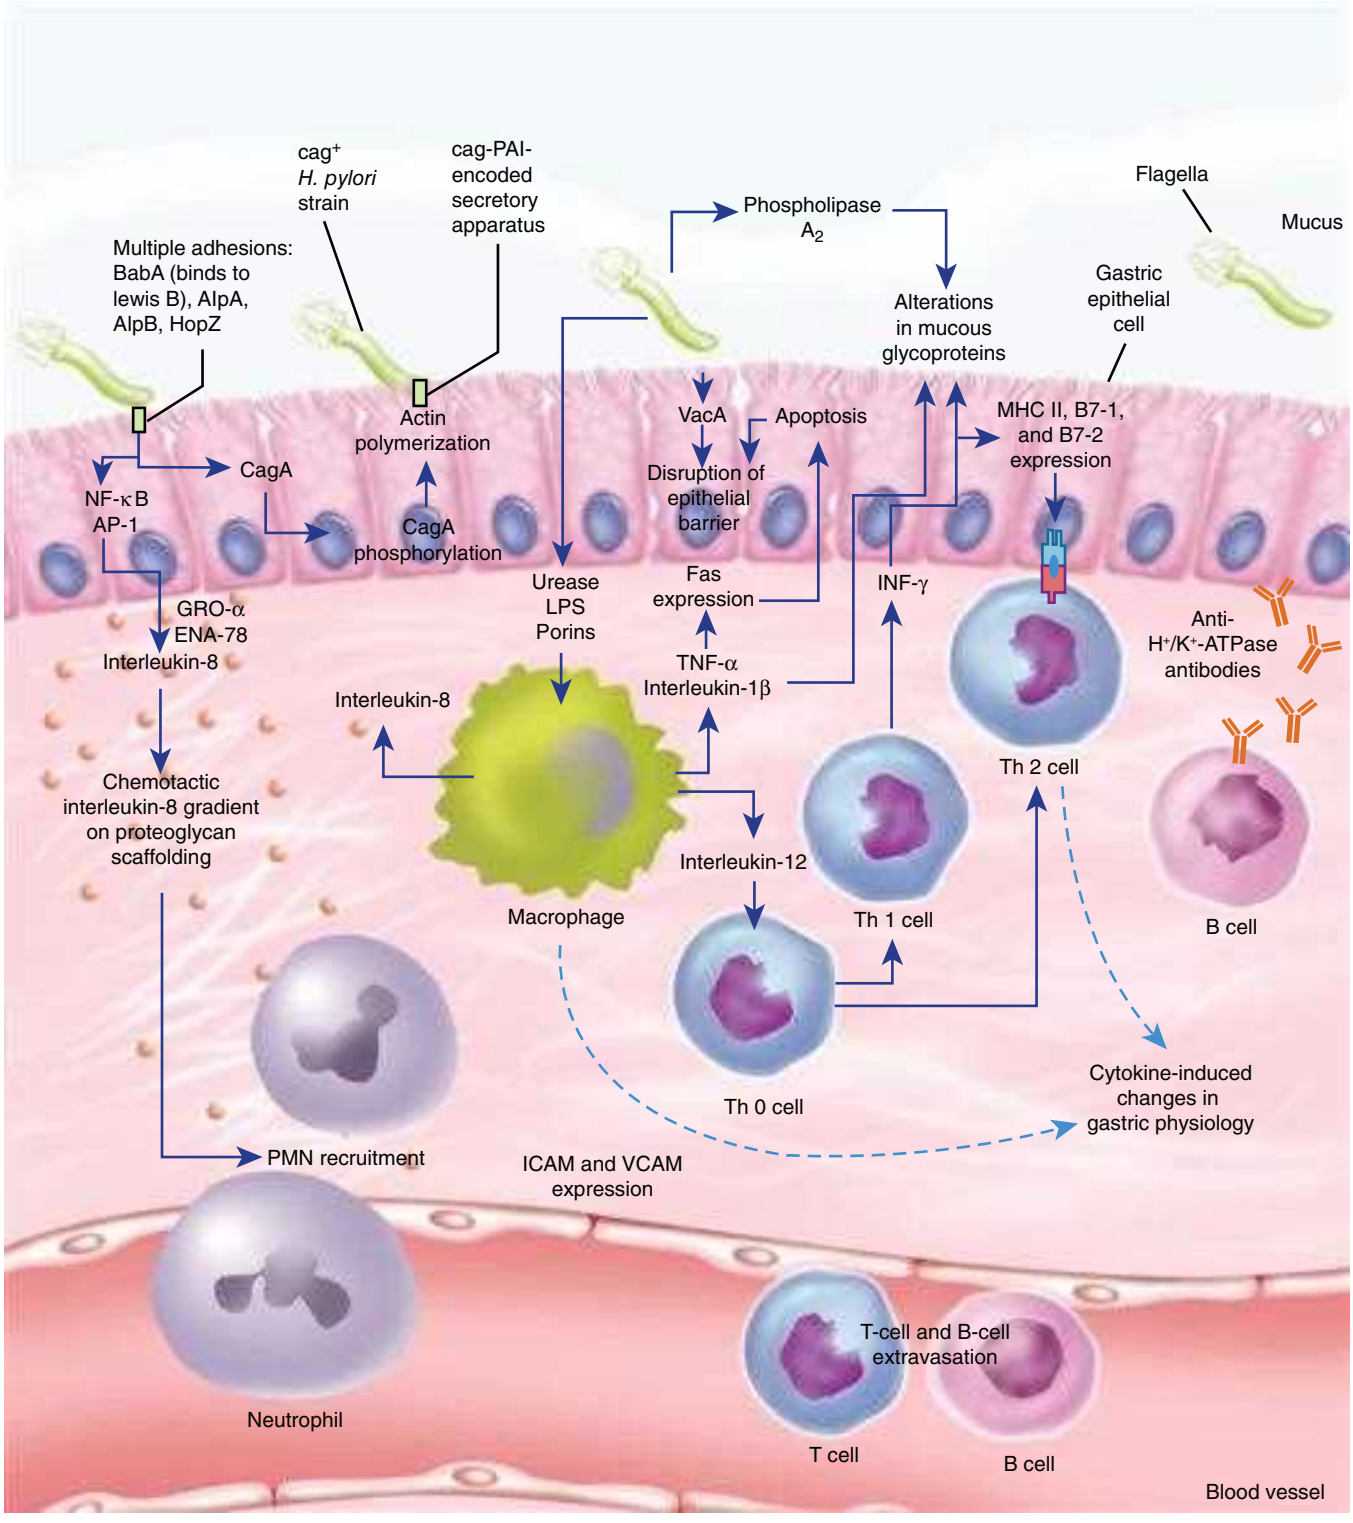

Figure 26-27. Pathogen-host interactions in the pathogenesis of *Helicobacter pylori* infection. acid secretion. Type II gastric ulcer is associated with active or quiescent duodenal ulcer disease, and type III gastric ulcer is prepyloric ulcer disease. Both type II and type III gastric ulcers are associated with normal or increased gastric acid secretion. Type IV gastric ulcers occur near the GE junction, and acid secretion is normal or below normal. Type V gastric ulcers are medication induced and may occur anywhere in the stomach. Patients with gastric ulcers may have weak mucosal defenses that permit an abnormal amount of injurious acid back-diffusion into the mucosa. Duodenogastric reflux may play a role in

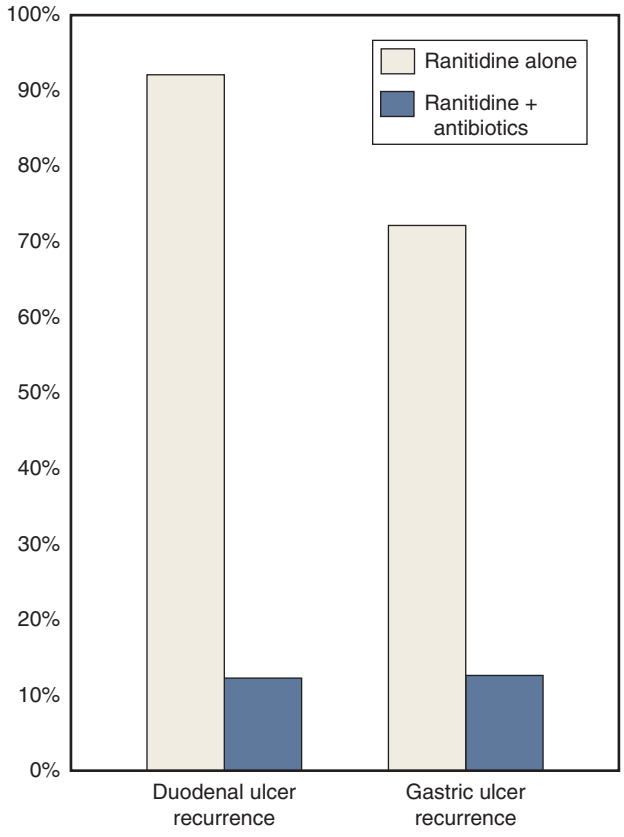

Figure 26-28. *Helicobacter* treatment dramatically decreases the recurrence rate of duodenal and gastric ulcer. Medication-induced (NSAID/acetylsalicylic acid), anywhere in stomach. *[Reproduced with permission from Fisher WE, Brunicardi FC: Benign gastric ulcer, in Cameron JL (ed):* Current Surgical Therapy, *9th ed. Philadelphia: Mosby Elsevier, 2008, p 81. Copyright Elsevier.]*

weakening the gastric mucosal defenses, and a variety of components in duodenal juice, including bile, lysolecithin, and pancreatic juice, have been shown to cause injury and inflammation in the gastric mucosa. NSAIDs and aspirin have similar effects. Although chronic gastric ulcer usually is associated with surrounding gastritis, it is unproven that the latter leads to the former.

Nonsteroidal Anti-Inflammatory Drugs in Peptic Ulcer Disease. Chronic use of NSAIDs (including aspirin) increases the risk of peptic ulcer disease about 5-fold and upper GI bleeding about 4-fold.[60,61] Complications of PUD (specifically hemorrhage and perforation) are much more common in patients

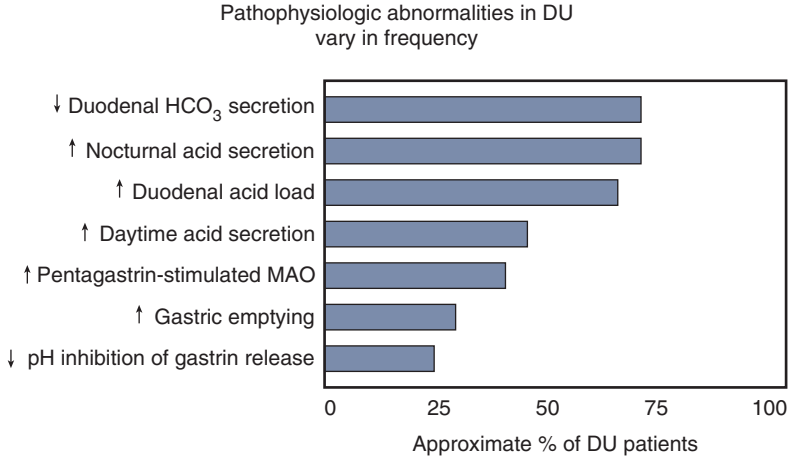

Figure 26-29. Frequency of physiologic abnormalities in patients with duodenal ulcer (DU). Table 26-6

Hospitalization rates for GI events with and without NSAID use in selected large populations

			ANNUALIZED INCIDENCE[b]			
	THERAPIES USED		CLINICAL UPPER GI EVENTS[c]		COMPLICATED UPPER GI EVENTS[d]	
STUDY[a]	NSAID CONTROL	STUDY DRUGS	CONTROL	STUDY DRUG	CONTROL	STUDY DRUG
MUCOSA	NSAIDs ($n = 4439$)	Misoprostol 200 µg qid + NSAID ($n = 4404$)	3.1%	1.6%	1.5%	0.7%
CLASS	Ibuprofen 800 mg tid, diclofenac 75 mg bid ($n = 3987$)	Celecoxib 400 mg bid ($n = 3995$)	3.5%	2.1%	1.5%	0.8%
			(No aspirin[e]: 2.9%)	1.4%	1.3%	0.4%
VIGOR	Naproxen 500 mg bid ($n = 4047$)	Rofecoxib 50 mg qd ($n = 4029$)	4.5%	2.1%	1.4%	0.6%

[a]MUCOSA and VIGOR trials included only rheumatoid arthritis patients; CLASS trial included osteoarthritis (73%) and rheumatoid arthritis (27%).
[b]Incidence for MUCOSA trial represents doubling of results provided at 6 months (although median follow-up was <6 months). Incidences for VIGOR and CLASS trials represent rates per 100 patient-years, although VIGOR median follow-up was 9 months and CLASS data include only the first 6 months of the study.
[c]Includes perforations, obstructions, bleeding, and uncomplicated ulcers discovered on clinically indicated work-up.
[d]Includes perforation, obstruction, bleeding (documented due to ulcer or erosions in MUCOSA and CLASS; major bleeding in VIGOR).
[e]21% of patients in CLASS study were taking low-dose aspirin.
Note: All differences between controls and study drugs were significant except clinical upper GI events in overall CLASS study ($P = .09$).

taking NSAIDs. More than half of patients who present with peptic ulcer hemorrhage or perforation report the recent use of NSAIDs, including aspirin. Many of these patients remain asymptomatic until they develop these life-threatening complications.

The overall risk of significant serious adverse GI events in patients taking NSAIDs is more than three times that of controls (Table 26-6). This risk increases to five times in patients more than age 60 years old. In elderly patients taking NSAIDs, the likelihood that they will require an operation related to a GI complication is 10 times that of the control group, and the risk that they will die from a GI cause is about four and one-half times higher. This problem is put into perspective when one realizes that approximately 20 million patients in the United States take NSAIDs on a regular basis; probably more regularly take aspirin. Persons who take NSAIDs also have a higher hospitalization rate for serious GI events than those who do not.

Factors that clearly put patients at increased risk for NSAID-induced GI complications include age >60, prior GI event, high NSAID dose, concurrent steroid intake, and concurrent anticoagulant intake. *ANY patient taking NSAIDs or aspirin who has one or more of these risk factors should receive concomitant acid suppressive medication*[62] (Table 26-7). High dose H2 blockers have been shown to be less effective than PPIs in preventing GI complications in these high risk patients on antiplatelet therapy, but clearly they are better than no acid suppression.

Smoking, Stress, and Other Factors. Epidemiologic studies suggest that smokers are about twice as likely to develop PUD as nonsmokers. Smoking increases gastric acid secretion and duodenogastric reflux. Smoking decreases both gastroduodenal prostaglandin production and pancreaticoduodenal bicarbonate production. These observations may be related, and any or all could explain the observed association between smoking and PUD.

Although difficult to measure, both physiologic and psychologic stress undoubtedly play a role in the development of peptic ulcer in some patients. In 1842, Curling described duodenal ulcer and/or duodenitis in burn patients. Decades later, Cushing described the appearance of acute peptic ulceration in patients with head trauma (Cushing's ulcer). Even the ancients recognized the undeniable links between PUD and stress. Patients still present with ulcer complications (bleeding, perforation, and obstruction) that are seemingly exacerbated by stressful life events. The use of crack cocaine has been linked to juxtapyloric peptic ulcers with a propensity to perforate. Alcohol is commonly mentioned as a risk factor for PUD, but confirmatory data are lacking.

Table 26-7

Patients taking NSAIDs or aspirin need concomitant acid suppressing medication if any of the following risk factors is present

- Age over 60
- History of acid/peptic disease
- Concurrent steroid intake
- Concurrent anticoagulant intake
- High-dose NSAID or acetylsalicylic acid

Clinical Manifestations

More than 90% of patients with PUD complain of abdominal pain. The pain is typically nonradiating, burning in quality, and located in the epigastrium. The mechanism of the pain is unclear. Patients with duodenal ulcer often experience pain 2 to 3 hours after a meal and at night. Two thirds of patients with duodenal ulcers will complain of pain that awakens them from sleep. The pain of gastric ulcer more commonly occurs with eating and is less likely to awaken the patient at night. A history of PUD, use of NSAIDs, over-the-counter antacids, or antisecretory drugs is suggestive of the diagnosis. Other signs and symptoms include nausea, bloating, weight loss, stool positive for occult blood, and anemia. Duodenal ulcer is about twice as common in men compared to women, but the incidence of gastric ulcer is similar in men and women. On average, gastric ulcer patients are older than duodenal ulcer patients, and the incidence is increasing in the elderly, perhaps because of increasing NSAID and aspirin.

Diagnosis

In the young patient with dyspepsia and/or epigastric pain, it may be appropriate to initiate empirical PPI therapy for PUD without confirmatory testing. In such cases, it is prudent to discuss with the patient the small possibility of an alternative diagnosis, including malignancy, even if symptoms improve with the initiation of therapy. All patients more than 45 years old with the above symptoms should have an upper endoscopy, and all patients, regardless of age, should have this study if any alarm symptoms (see Table 26-5) are present. A double-contrast upper GI X-ray study may be useful. Once an ulcer has been confirmed endoscopically or radiologically, obvious possible causes (*Helicobacter*, NSAIDs, gastrinoma, cancer) should always be considered. All gastric ulcers should be adequately biopsied, and any sites of gastritis should be biopsied to rule out *H. pylori*, and for histologic evaluation. Additional testing for *H. pylori* may be indicated. It is not unreasonable to test all peptic ulcer patients for *H. pylori* (Table 26-8) 63A baseline serum gastrin level is appropriate to rule out gastrinoma.

Table 26-8

Indications for diagnosis and treatment of *Helicobacter pylori*

Established
- Active peptic ulcer disease (gastric or duodenal ulcer)
- Confirmed history of peptic ulcer disease (not previously treated for *H. pylori*)
- Gastric mucosa-associated lymphoid tissue lymphoma (low grade)
- After endoscopic resection of early gastric cancer
- Uninvestigated dyspepsia (depending on *H. pylori* prevalence)

Controversial
- Nonulcer dyspepsia
- Gastroesophageal reflux disease
- Persons using NSAIDs
- Unexplained iron deficiency anemia
- Populations at higher risk for gastric cancer

Complications

The three most common complications of PUD, in decreasing order of frequency, are bleeding, perforation, and obstruction.[51,52,64] Most peptic ulcer–related deaths in the United States are due to bleeding. Bleeding peptic ulcers are by far the most common cause of upper GI bleeding in patients admitted to hospital (Fig. 26-31).[65] Patients with a bleeding peptic ulcer typically present with melena and/or hematemesis. Nasogastric aspiration is usually confirmatory of the upper GI bleeding. Abdominal pain is quite uncommon. Shock may be present, necessitating aggressive resuscitation and blood transfusion. Early endoscopy is important to diagnose the cause of the bleeding and to assess the need for hemostatic therapy.

Three-fourths of the patients who come to the hospital with bleeding peptic ulcer will stop bleeding if given acid suppression and nothing by mouth. However, one fourth will continue to bleed or will rebleed after an initial quiescent period, and virtually all the mortalities (and all the operations for bleeding) occur in this group. This group can be fairly well delineated based on clinical factors related to the magnitude of the hemorrhage, comorbidities, age, and endoscopic findings. Shock, hematemesis, transfusion requirement exceeding four units in 24 hours, and certain endoscopic stigmata (active bleeding or visible vessel) define this high-risk group. Two widely used risk stratification tools have proven useful in predicting rebleeding and death: the Blatchford and Rockall scores (Table 26-9).[66] High-risk patients benefit from endoscopic therapy to stop the bleeding. The most common endoscopic hemostatic modalities used are injection with epinephrine, and electrocautery. In a case with exposed vessel, mechanical hemostasis using a clip is useful to control the bleeding.[66A] Persistent bleeding or rebleeding after endoscopic therapy is an indication for operation, although repeat endoscopic treatment has been successful in treating rebleeding. Elderly patients and patients with multiple comorbidities do not tolerate repeated episodes of hemodynamically significant hemorrhage, and may benefit from early elective operation after initially successful endoscopic treatment, especially if they have a high-risk ulcer.

Planned surgery under controlled circumstances often yields better outcomes than emergent surgery. Deep bleeding ulcers on the posterior duodenal bulb or lesser gastric curvature are high-risk lesions, because they often erode large arteries not amenable to nonoperative treatment, and early operation should be considered.

Table 26-9

Risk-stratification tools for upper gastrointestinal hemorrhage[a]

A. BLATCHFORD SCORE

AT PRESENTATION	POINTS
Systolic blood pressure	
100–109 mmHg	1
90–99 mmHg	2
<90 mmHg	3
Blood urea nitrogen	
6.5–7.9 mmol/L	2
8.0–9.9 mmol/L	3
10.0–24.9 mmol/L	4
≥25 mmol/L	6
Hemoglobin for men	
12.0–12.9 g/dL	1
10.0–11.9 g/dL	3
<10.0 g/dL	6
Hemoglobin for women	
10.0–11.9 g/dL	1
<10.0 g/dL	6
Other variables at presentation	
Pulse ≥100 beats/min	1
Melena	1
Syncope	2
Hepatic disease	2
Cardiac failure	2

B. ROCKALL SCORE

COMPLETE ROCKALL SCORE

CLINICAL ROCKALL SCORE

VARIABLE	POINTS
Age	
<60 y	0
60–79 y	1
≥80 y	2
Shock	
Heart rate >100 beats/min	1
Systolic blood pressure <100 mmHg	2
Coexisting illness	
Ischemic heart disease, congestive heart failure, other major illness	2
Renal failure, hepatic failure, metastatic cancer	3
Endoscopic diagnosis	
No lesions observed, Mallory-Weiss syndrome	0
Peptic ulcer, erosive disease, esophagitis	1
Cancer of the upper GI tract	2
Endoscopic stigmata of recent hemorrhage	
Clean base ulcer, flat pigmented spot	0
Blood in upper GI tract, active bleeding, visible vessel, clot	2

[a]Panel A shows the values used in the Blatchford risk-stratification score, which ranges from 0 to 23, with higher scores indicating higher risk. Panel B shows the Rockall score, with point values assigned for each of three clinical variables (age and the presence of shock and coexisting illnesses) and two endoscopic variables (diagnosis and stigmata of recent hemorrhage). The complete Rockall score ranges from 0 to 11, with higher scores indicating higher risk. Patients with a clinical Rockall score (Age + Shock + Coexisting illness) of 0 or a complete Rockall score of 2 or less are considered to be at low risk for rebleeding or death.

Figure 26-32. Pneumoperitoneum on upright chest X-ray in patient with perforated ulcer.

Perforated peptic ulcer usually presents as an acute abdomen. The patient can often give the exact time of onset of the excruciating abdominal pain. Initially, a chemical peritonitis develops from the gastric and/or duodenal secretions, but within hours a bacterial peritonitis supervenes. The patient is in obvious distress, and the abdominal examination shows peritoneal signs. Usually, marked involuntary guarding and rebound tenderness is evoked by a gentle examination. Upright chest X-ray shows free air in about 80% of patients (Fig. 26-32). Once the diagnosis has been made, the patient is given analgesia and antibiotics, resuscitated with isotonic fluid, and taken to the operating room. Fluid sequestration into the third space of the inflamed peritoneum can be impressive, so preoperative fluid resuscitation is mandatory. Sometimes, the perforation has sealed spontaneously by the time of presentation, and surgery can be avoided if the patient is doing well. Nonoperative management is appropriate only if there is objective evidence that the leak has sealed (i.e., radiologic contrast study), and in the absence of clinical peritonitis.

Gastric outlet obstruction occurs in no more than 5% of patients with PUD. It is usually due to duodenal or prepyloric ulcer disease, and may be acute (from inflammatory swelling and peristaltic dysfunction) or chronic (from cicatrix). Patients typically present with nonbilious vomiting and may have a profound hypokalemic hypochloremic metabolic alkalosis. Pain or discomfort is common. Weight loss may be prominent, depending on the duration of symptoms. A succussion splash may be audible with stethoscope placed in the epigastrium. Initial treatment is nasogastric suction, IV hydration and electrolyte repletion, and acid suppression. The diagnosis is confirmed by endoscopy. Most patients admitted to the hospital nowadays with obstructing ulcer disease require intervention, either balloon dilation or operation. Cancer must be ruled out because most patients who present with the symptoms of gastric outlet obstruction will have a pancreatic, gastric, or duodenal malignancy.

Medical Treatment of Peptic Ulcer Disease

PPIs are the mainstay of medical therapy for PUD, but high dose H_2RAs and sucralfate are also quite effective. Patients hospitalized for ulcer complications should receive PPI by continuous IV infusion and, when discharged, should be considered for lifelong PPIs unless the definitive cause is eliminated or a definitive operation performed. Peptic ulcer patients should stop smoking and avoid alcohol and NSAIDs (including aspirin). Patients who require NSAIDs or aspirin to treat other medical conditions should always take concomitant PPIs or high dose H_2 receptor blockers. If *H. pylori* infection is documented, it should be treated with one of several acceptable regimens (Table 26-10).[63] Infectious disease consultation may be helpful in the compliant, symptomatic patient with persistent *H. pylori* infection following treatment, or another regimen could be tried (e.g., quadruple therapy). If initial *H. pylori* testing is negative and ulcer symptoms persist, an empirical trial of anti-*H. pylori* therapy is reasonable since false-negative *H. pylori* tests are common. Generally, acid suppression can be stopped after 3 months if the ulcerogenic stimulus (usually *H. pylori*, NSAIDs, or aspirin) has been removed. However, long-term maintenance PPI therapy should be considered in all patients admitted to hospital with ulcer complications, all high-risk patients on NSAIDs or aspirin (the elderly or debilitated), and all patients with a history of recurrent ulcer or bleeding. Consideration should also be given to maintenance PPI therapy in refractory smokers with a history of peptic ulcer. Sucralfate acts locally on mucosal defects and is well tolerated, and occasionally is useful as a supplement to acid suppression.

Surgical Treatment of Peptic Ulcer Disease

The indications for surgery in PUD are bleeding, perforation, obstruction, and intractability or nonhealing.[67,68] Gastric cancer must always be considered in patients with gastric ulcer or gastric outlet obstruction.

Today, most patients undergoing operation for PUD have simple oversewing of a bleeding ulcer or simple patch of a perforated ulcer.[51] Simultaneous performance of vagotomy either truncal or highly selective is increasingly uncommon,

Table 26-10

Treatment regimens for *Helicobacter pylori*

MEDICATIONS/DOSE/FREQUENCY	DURATION
PPI + clarithromycin 500 mg bid + amoxicillin 1000 mg bid	10–14 d
PPI + clarithromycin 500 bid + metronidazole 500 bid	10–14 d
PPI + amoxicillin 1000 mg bid, then	5 d
PPI + clarithromycin 500 mg bid + tinidazole 500 mg bid	5 d
Salvage regimens for patients who fail one of the above initial regimens:	
Bismuth subsalicylate 525 mg qid + metronidazole 250 mg qid + tetracycline 500 mg qid + PPI	10–14 d
PPI + amoxicillin 1000 mg bid + levofloxacin 500 mg daily	10 d

PPI = proton pump inhibitor.
Source: Data from Chey et al.[63]

probably due to surgeon unfamiliarity with the procedure and reliance on postoperative PPIs to decrease acid secretion.

Unfortunately, the data from many excellent randomized clinical trials evaluating elective operation for peptic ulcer over the last several decades may be irrelevant to most patients presenting for ulcer surgery today.[67] The large majority of these excellent studies were done in the pre-PPI, pre-*Helicobacter*, pre-NSAID era, and focused on elective operation for intractable disease, an unusual indication for operation nowadays. Thus, today's surgeon should take great care in applying this literature to inform surgical decision making.

Traditionally, the vast majority of peptic ulcers were treated by a variant of one of the three basic operations: parietal cell vagotomy also called highly selective vagotomy or proximal gastric vagotomy (HSV), vagotomy and drainage (V+D), and vagotomy and distal gastrectomy. Recurrence rates were lowest but morbidity highest with the latter procedure, while the opposite was true for HSV (Table 26-11).[67–69]

HSV severs the vagal nerve supply to the proximal two thirds of the stomach, where essentially all the parietal cells are located, and preserves the vagal innervation to the antrum and pylorus, and the remaining abdominal viscera (Fig. 26-33). Thus, the operation decreases total gastric acid secretion by about 75%, and GI side effects are rare. Elective HSV has largely been supplanted by long-term PPI treatment, but the operation, which has a learning curve, may still be useful in the patient (elective or emergent) who is noncompliant with, intolerant of, or cannot afford medical treatment. Historically, HSV has not performed particularly well for type II (gastric and duodenal) and III (prepyloric) gastric ulcer, perhaps because of hypergastrinemia caused by gastric outlet obstruction and persistent antral stasis. The Taylor procedure consists of a posterior truncal vagotomy and anterior seromyotomy (but anterior HSV is probably equivalent), and is an attractive and simple alternative to HSV with similar results.

Table 26-11

Clinical results of surgery for duodenal ulcer

	PARIETAL CELL VAGOTOMY	TRUNCAL VAGOTOMY AND PYLOROPLASTY	TRUNCAL VAGOTOMY AND ANTRECTOMY
Operative mortality rate (%)	0	<1	1
Ulcer recurrence rate (%)	5–15	5–15	<2
Dumping (%)			
Mild	<5	10	10–15
Severe	0	1	1–2
Diarrhea (%)			
Mild	<5	25	20
Severe	0	2	1–2

Truncal vagotomy and pyloroplasty, and truncal vagotomy and gastrojejunostomy are the paradigmatic *vagotomy and drainage procedures*. HSV may be substituted for truncal vagotomy. The advantage of V + D is that it can be performed safely and quickly by the experienced surgeon. The main disadvantages are the side effect profile (10% of patients have significant dumping and/or diarrhea). During truncal vagotomy (Fig. 26-34), care must be taken not to perforate the esophagus, a potentially lethal complication. Intraoperative frozen section confirmation of at least two vagal trunks is prudent; additional vagal trunks are common. Unlike HSV, V + D is widely accepted as a successful definitive operation for complicated PUD. It has been described as a useful part of the operative treatment for bleeding duodenal and gastric ulcer, perforated duodenal and gastric ulcer, and obstructing duodenal and gastric (type II and III) ulcer. When applied to gastric ulcer, the ulcer should be excised or biopsied.

Truncal vagotomy denervates the antropyloric mechanism, and therefore, some sort of procedure is necessary to ablate or bypass the pylorus. Gastrojejunostomy is a good choice in patients with gastric outlet obstruction or a severely diseased proximal duodenum. The anastomosis is done between the proximal jejunum and the most dependent portion of the greater gastric curvature, in either an antecolic or retrocolic fashion (Fig. 26-35). Marginal ulceration is a potential complication. Pyloroplasty is useful in patients who require a pyloroduodenotomy to deal with the ulcer complication (e.g., posterior bleeding duodenal ulcer), in those with limited or focal scarring in the pyloric region, or when gastrojejunostomy is technically difficult. The most commonly performed

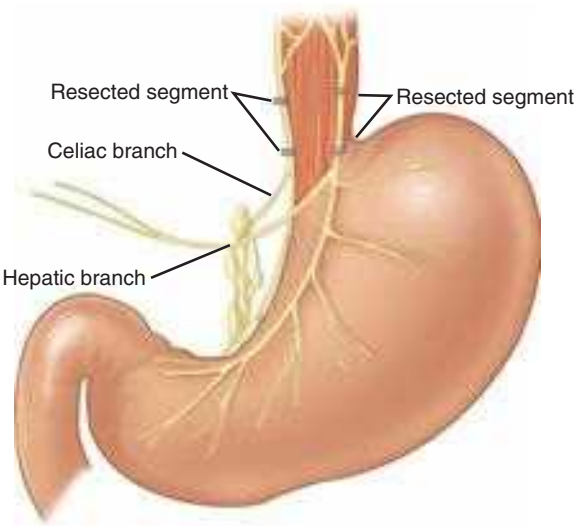

Figure 26-34. Truncal vagotomy. *[Reproduced with permission from Zollinger RM Jr., Zollinger RM Sr. (eds):* Zollinger's Atlas of Surgical Operations, *8th ed. New York: McGraw-Hill, 2003, p 45. Copyright © The McGraw-Hill Companies, Inc.]*

pyloroplasty is the Heineke-Mikulicz type (Fig. 26-36). Other occasionally useful techniques include the Finney (Fig. 26-37) and the Jaboulay pyloroplasties (Fig. 26-38). These more extensive pyloroplasty techniques may make subsequent distal gastric resection more difficult and/or hazardous.

Although *vagotomy and antrectomy* (V + A) is associated with a very low ulcer recurrence rate and is applicable to many patients with complicated PUD (e.g., bleeding duodenal and gastric ulcer, obstructing peptic ulcer, nonhealing gastric ulcer, and recurrent ulcer), V + A has a higher operative mortality risk (compared with HSV or V + D), and is irreversible. Following antrectomy, GI continuity may be reestablished with a Billroth I gastroduodenostomy (Fig. 26-39) or a Billroth II loop gastrojejunostomy (Fig. 26-40). Since antrectomy routinely leaves a 60% to 70% gastric remnant, routine reconstruction as a Roux-en-Y gastrojejunostomy should be avoided (Fig. 26-41). Although the Roux-en-Y operation is an excellent procedure for keeping duodenal contents out of the stomach and esophagus, in the presence of a large gastric remnant, this reconstruction will predispose to marginal ulceration and/or gastric stasis.

V + A should be avoided in hemodynamically unstable patients, and in patients with extensive inflammation and/or scarring of the proximal duodenum, because secure anastomosis (Billroth I) or duodenal closure (Billroth II) may be difficult.

Distal gastrectomy without vagotomy (usually about a 50% gastrectomy to include the ulcer) has traditionally been the procedure of choice for type I gastric ulcer. The addition of vagotomy should be considered for type II and III gastric ulcers (because the pathophysiology is more analogous to duodenal ulcer), or if the patient is believed to be at increased risk for recurrent ulcer, or perhaps even if Billroth II reconstruction is contemplated (to decrease the chance of marginal ulcer). Subtotal gastrectomy (75% distal gastrectomy) without vagotomy is rarely used to treat PUD today, although it was the most popular ulcer operation at the middle of the last century.

Pylorus preserving gastrectomy (PPG) was first reported as a surgical option for gastric ulcer which could minimize both dumping and duodenogastric reflux. Though not widely adopted for this indication, in some centers PPG is considered a good minimally invasive surgical option for early gastric cancer.[69A,69B]

Choice of Operation for Peptic Ulcer. The choice of operation for the individual patient with PUD depends on a variety of factors, including the type of ulcer (duodenal, gastric, recurrent, or marginal), the indication for operation, and the condition of the patient, among others. Other important considerations are intra-abdominal factors (duodenal scarring/inflammation, adhesions, or difficult exposure), the ulcer diathesis status of the patient, the surgeon's experience and personal preference, whether *H. pylori* infection is present, the need for NSAID therapy, previous treatment, and the likelihood of future compliance with treatment. Table 26-12 shows the surgical options for managing various aspects of PUD. In general, resective procedures have a lower ulcer recurrence rate, but a higher operative morbidity and mortality rate (see Table 26-11) compared to nonresective ulcer operations. Because ulcer recurrence often is related to *H. pylori*

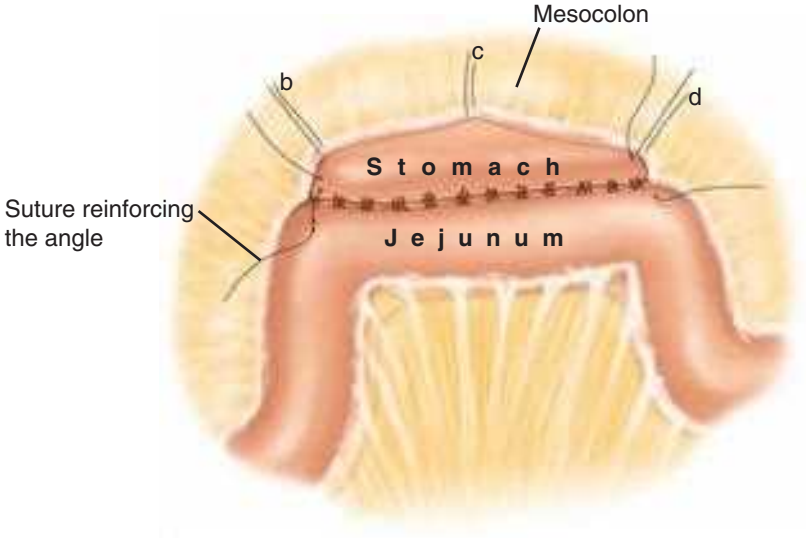

Figure 26-35. Retrocolic gastrojejunostomy. Figure 26-36. **A** through **D.** Heineke-Mikulicz pyloroplasty. *[Reproduced with permission from Zinner MJ (ed):* Atlas of Gastric Surgery. *New York: Churchill Livingstone, 1992, p 17. Copyright Elsevier.]*

and/or NSAIDs, it is usually managed adequately without reoperation. Thus, gastric resection to minimize recurrence in duodenal ulcer disease is often not justified today; resection for gastric ulcer remains the standard because of the risk of cancer. Clearly, the modern trend in peptic ulcer operation could be described as "less is more."[70,71] Vagotomy as a component of emergency ulcer operation is increasingly uncommon.

Bleeding Peptic Ulcer

Bleeding is the most common cause of ulcer-related death, but most patients admitted to hospital with bleeding gastric or duodenal ulcer today will not require an operation. In many hospitals, operation for ulcer perforation is much more common than operation for bleeding ulcer. The success of endoscopic treatment and medical therapy in treating and preventing bleeding PUD has resulted in the selection of a small subgroup of high-risk patients for today's surgeon. It is likely that patients currently coming to operation for bleeding PUD are at higher risk for a poor outcome than ever before. The surgical options for treating bleeding PUD include suture ligation of the bleeder; suture ligation and definitive nonresective ulcer operation (HSV or V + D); and gastric resection (usually, including vagotomy and ulcer excision). Gastric ulcer requires biopsy if not resected.

The management of bleeding peptic ulcer is summarized in the algorithm provided in Fig. 26-42. All patients admitted to hospital with bleeding peptic ulcer should be adequately resuscitated and started on continuous IV PPI.[72] Seventy-five percent of patients will stop bleeding with these measures alone, but 25% will continue to bleed or will rebleed in hospital. It is important to identify this high-risk group early with clinical

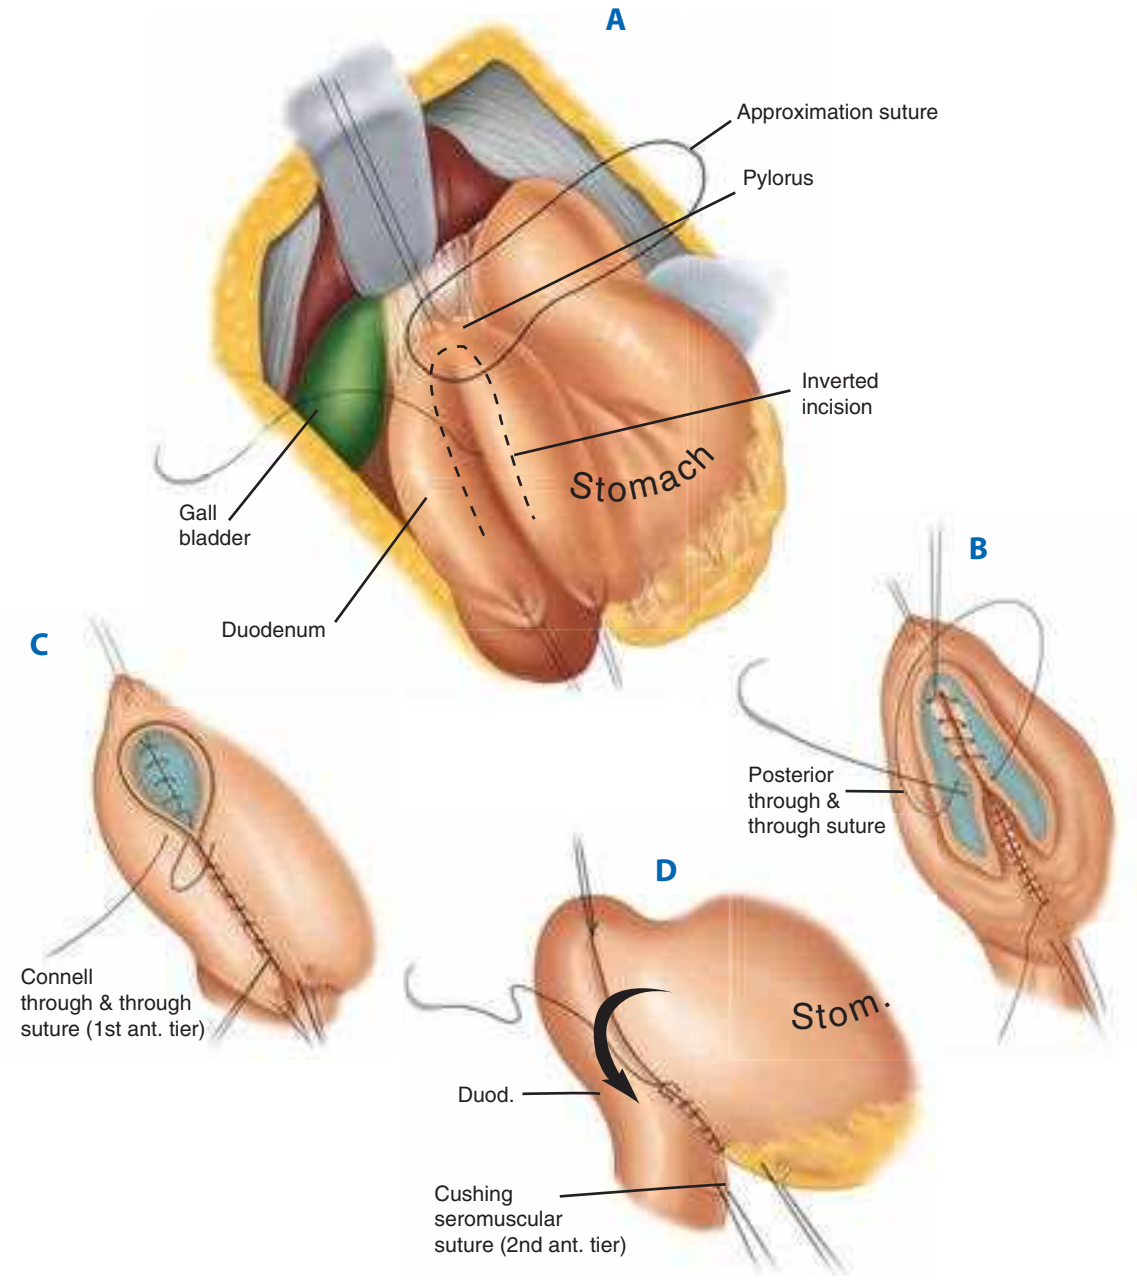

Figure 26-37. **A** through **D.** Finney pyloroplasty. ant. = anterior; Duod. = duodenum; Stom. = stomach. *[Reproduced with permission from Sawyers JL: Vagotomy and pyloroplasty, in Zuidema GD (ed):* Shackelford's Surgery of the Alimentary Tract, *4th ed. Philadelphia: Saunders, 1996, p 150. Copyright Elsevier.]*

and endoscopic parameters because, essentially, all the deaths from bleeding ulcer occur in this group. Surgical consultation is mandatory, and endoscopic hemostatic therapy (cautery, epinephrine injection, clipping) is indicated and usually successful in these high-risk patients.[73,74] Indications for operation include massive hemorrhage unresponsive to endoscopic control, and transfusion requirement of more than four to six units of blood, despite attempts at endoscopic control. Lack of availability of a therapeutic endoscopist, recurrent hemorrhage after one or more attempts at endoscopic control, lack of availability of blood for transfusion, repeat hospitalization for bleeding ulcer, and concurrent indications for surgery such as perforation or obstruction, are also indications for surgery. Patients with massive bleeding from high-risk lesions (e.g., posterior duodenal ulcer with erosion of gastroduodenalartery, or lesser curvature gastric ulcer with erosion of left gastric artery or branch) should be considered for early operation. Early operation should also be considered in patients more than 60 years of age, those presenting in shock, those requiring more than four units of blood in 24 hours or eight units of blood in 48 hours, those with rebleeding, and those with ulcers >2 cm in diameter. The mortality rate for surgery for bleeding peptic ulcer is around 20%. Angiography and embolization may be useful in some patients.

Operation for Bleeding Peptic Ulcer (Fig. 26-43)

The two operations most commonly used for bleeding duodenal ulcer are oversewing of the ulcer usually without vagotomy,[70] or V + A. Oversewing alone results in a higher rebleeding rate

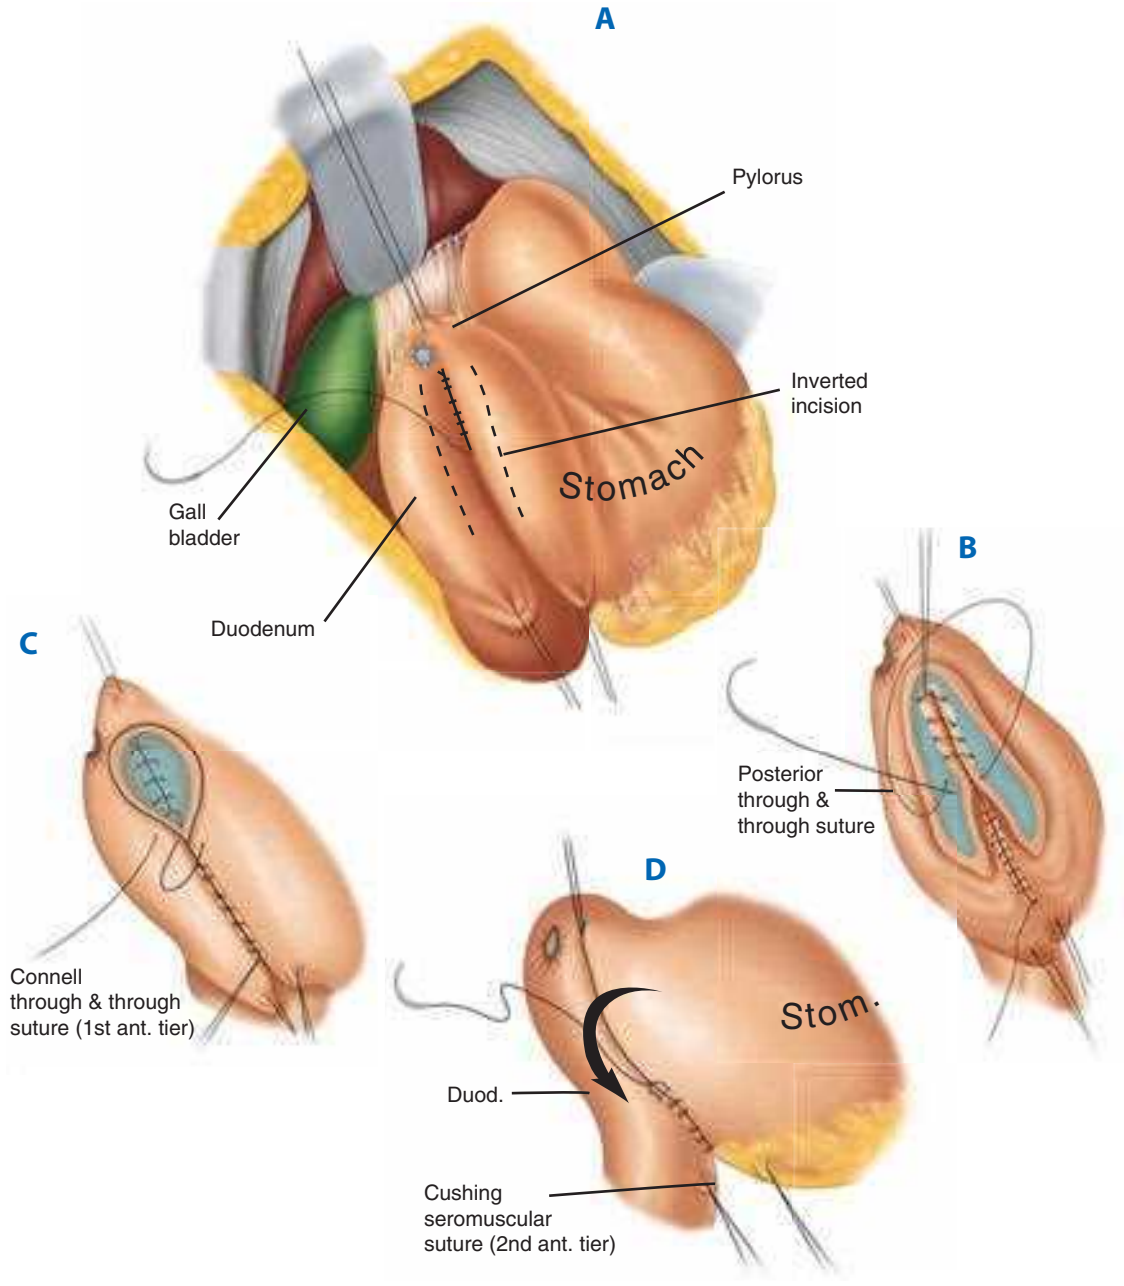

Figure 26-38. **A** through **D.** Jaboulay pyloroplasty. ant. = anterior; Duod. = duodenum; Stom. = stomach. *[Reproduced with permission from Sawyers JL: Vagotomy and pyloroplasty, in Zuidema GD (ed):* Shackelford's Surgery of the Alimentary Tract, *4th ed. Philadelphia: Saunders, 1996, p 150. Copyright Elsevier.]*

but a lower operative mortality rate. When the mortality for reoperation for rebleeding is considered, the overall mortality is probably comparable for the two approaches. Patients who are in shock or medically unstable should not have gastric resection.

An initial pyloromyotomy incision allows access to the bleeding posterior duodenal ulcer, and an expeditious Kocher maneuver allows the surgeon to control the hemorrhage with the left hand if necessary. Heavy suture material on a stout needle is used to place figure-of-eight sutures or a U-stitch to secure the bleeding vessel at the base of the posterior duodenal ulcer. Multiple sutures are usually necessary. Once the surgeon is unequivocally convinced that hemostasis is secure, a pyloroplasty can be performed. If the patient is stable, vagotomy may be considered if the surgeon is experienced and the vagotomy straightforward. If the patient is not a high operative risk and V + A is selected, smaller duodenal ulcers are resected with the specimen; larger bleeding duodenal ulcers must often be left behind in the duodenal stump. In this situation, suture hemostasis must be attained and a secure duodenal closure accomplished. The anterior wall of the open duodenum can be sutured to either the proximal or distal lip of the posterior ulcer once the bleeding vessel has been sutured. The duodenal closure can be buttressed with omentum and the duodenum should be

Table 26-12

Surgical options in the treatment of duodenal and gastric ulcer

INDICATION	DUODENAL	GASTRIC
Bleeding	1. Oversew[a] 2. Oversew, V + D 3. V + A	1. Oversew and biopsy[a] 2. Oversew, biopsy, V + D 3. Distal gastrectomy[b]
Perforation	1. Patch[a] 2. Patch, HSV 3. Patch, V + D	1. Biopsy and patch[a] 2. Wedge excision, V + D 3. Distal gastrectomy[b]
Obstruction	1. HSV + GJ 2. V + A	1. Biopsy; HSV + GJ 2. Distal gastrectomy[b]
Intractability/ nonhealing	1. HSV[b] 2. V + D 3. V + A	1. HSV and wedge excision 2. Distal gastrectomy

[a]Unless the patient is in shock or moribund, a definitive procedure should be considered.
[b]Operation of choice in low-risk patient.
GJ = gastrojejunostomy; HSV = highly selective vagotomy; V + A = vagotomy and antrectomy; V + D = vagotomy and drainage.

decompressed, either with a lateral duodenostomy or retrograde tube via the proximal jejunum or nasogastric tube secured with tip well into afferent limb. Right upper quadrant closed suction peritoneal drainage is important. Use of a feeding jejunostomy is also considered. A Billroth II anastomosis reestablishes gastrointestinal continuity.

The initial management of bleeding gastric ulcers and the indications for operation are similar to those for bleeding duodenal ulcer. These lesions tend to occur in older and/or medically complicated patients, and this fact may increase the operative risk. However, experience shows that planned surgery in a resuscitated patient results in a better operative survival rate than emergent operation in a patient who has rebled and is in shock. Distal gastric resection to include the bleeding ulcer is the procedure of choice for bleeding gastric ulcer. Second best is V + D with oversewing and biopsy of the ulcer to rule out cancer. Oversewing of the bleeder followed by long-term acid suppression is a reasonable alternative in high-risk or unstable patients.

Perforated Peptic Ulcer (Fig. 26-44)

Perforation is the second most common complication of peptic ulcer but nowadays a more common indication for operation than bleeding. As with bleeding ulcer, NSAID and/or aspirin use have been inextricably linked with perforated PUD, especially in the elderly population.[61] Surgery is almost always indicated for ulcer perforation, although occasionally nonsurgical treatment can be used in the stable patient without peritonitis in whom radiologic studies document a sealed perforation. Patients with acute perforation and GI blood loss (either chronic or acute) should be suspected of having a second ulcer or a GI cancer.

The options for surgical treatment of perforated duodenal ulcer are simple patch closure, patch closure and HSV, or patch closure and V + D. Simple patch closure, currently the most commonly performed operation for perforated peptic ulcer, should be done in patients with hemodynamic instability and/or exudative peritonitis signifying a perforation >24 hours old. In stable patients without longstanding perforation, the addition of HSV may be considered. However, in the United States and Western Europe, there is clearly a trend away from definitive operation for perforated duodenal ulcer, probably because of the ready availability of PPI, and surgeon unfamiliarity with definitive operation in this setting.[51,70]

In the stable patient without multiple operative risk factors, perforated gastric ulcers are best treated by distal gastric resection. Vagotomy is usually added for type II and III gastric ulcers. Patch closure with biopsy; or local excision and closure; or biopsy, closure, truncal vagotomy, and drainage are alternative operations in the unstable or high-risk patient, or in the patient with a perforation in an inopportune location. All perforated gastric ulcers, even those in the prepyloric position, should be biopsied if they are not removed at surgery.

Obstructing Peptic Ulcer

Acute ulcers associated with obstruction due to edema and/or motor dysfunction may respond to intensive antisecretory therapy and nasogastric suction. But most patients with significant obstruction from chronic ulceration will require some sort of more substantial intervention. Endoscopic balloon dilation can often transiently improve obstructive symptoms, but many of these patients ultimately fail and come to operation.[75]

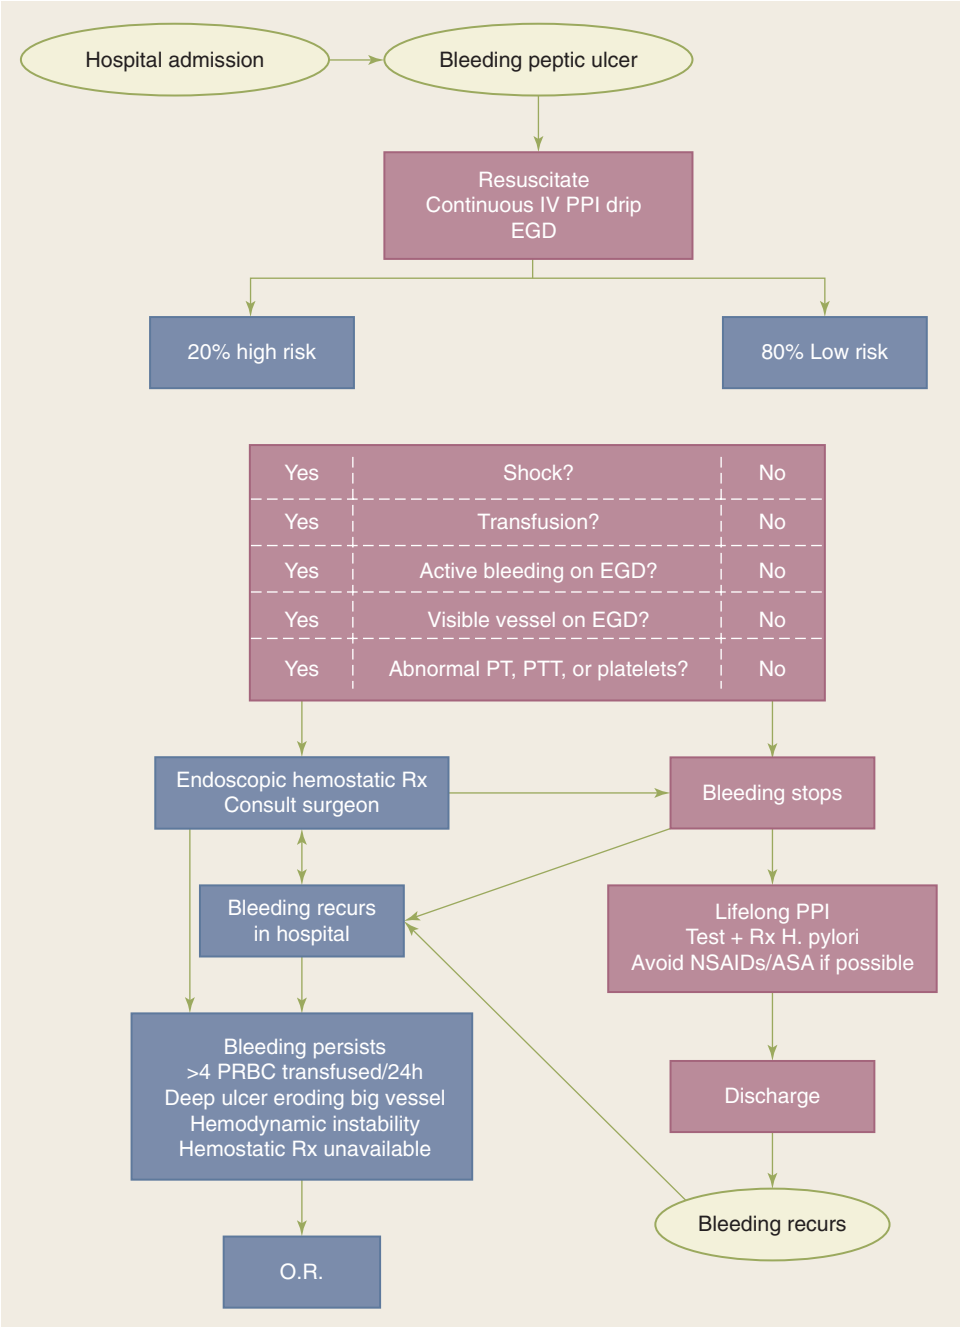

Figure 26-42. Algorithm for the treatment of bleeding peptic ulcer. ASA = acetylsalicylic acid; EGD = esophagogastroduodenoscopy; O.R. = operating room; PPI = proton pump inhibitor; PRBC = unit of packed red blood cells; PT = prothrombin time; PTT = partial thromboplastin time; Rx = treatment.

The standard operation for obstructing PUD is vagotomy and antrectomy. Alternatively vagotomy and gastrojejunostomy should be considered if a difficult duodenal stump is anticipated with resection. HSV and gastrojejunostomy may be comparable to V+A for obstructing ulcer disease,[76] and sometimes has appeal because it can be done laparoscopically, and because it does not complicate future resection, if needed. However, potentially curable gastric or duodenal cancers can be missed with this approach.

Intractable or Nonhealing Peptic Ulcer

Intractability should be an unusual indication for peptic ulcer operation nowadays. The patient referred for surgical evaluation because of intractable PUD should raise red flags for the surgeon: Maybe the patient has a missed cancer; maybe the patient is noncompliant (not taking prescribed PPI, still taking NSAIDs, still smoking); maybe the patient has *Helicobacter* despite the presence of a negative test or previous treatment. Because acid secretion can be totally blocked and *H. pylori* eradicated with modern medication, the question remains: "Why does the patient have a persistent ulcer diathesis?" The surgeon should review the differential diagnosis of nonhealing ulcer before any consideration of operative treatment (Table 26-13).

Surgical treatment should be considered in patients with nonhealing or intractable PUD who have multiple recurrences, large ulcers (>2 cm), complications (obstruction, perforation, or

Zollinger-Ellison syndrome

4▶ hemorrhage), or suspected malignancy. Definitive operation, particularly gastric resection, should be considered most cautiously in the thin or marginally nourished individual.

It is important that the surgeon not fall into the trap of performing a large, irreversible operation on these patients, based on the unproven theory that if all other methods have failed to heal the ulcer, a large operation is required. Although there is a large quantity of very good data in the surgical literature suggesting that the large majority of patients do well after the larger elective ulcer operations, these data may not be particularly relevant to the modern patient.[67] Candidates for ulcer operation today are different than those of 30 to 50 years ago. One might argue that current medical care has healed the minor ulcers, and that patients presenting with true intractability or nonhealing will be more difficult to treat and are likely to have chronic problems after a major ulcer operation.

If surgery is necessary, a lesser operation may be preferable. It is prudent to avoid truncal vagotomy and/or distal gastrectomy as the initial elective operation for intractable peptic ulcer in the thin or asthenic patient. Alternatives for intractable duodenal ulcer include HSV with or without gastrojejunostomy (reversible drainage operation). In patients with nonhealing gastric ulcer, wedge resection with HSV should be considered in thin or frail patients. Otherwise, distal gastrectomy (to include the ulcer) is recommended. It is unnecessary to add a vagotomy in patients with type I or type IV (juxta-esophageal) gastric ulcers because they are usually associated with acid hyposecretion. Type IV gastric ulcers may be difficult to resect as part of a distal gastrectomy, and a variety of surgical techniques have been described to treat these more proximal lesions (Fig. 26-45).

Zollinger-Ellison Syndrome[77–79]

ZES is caused by the uncontrolled secretion of abnormal amounts of gastrin by a duodenal or pancreatic neuroendocrine tumor (i.e., gastrinoma). Most cases (80%) are sporadic, but 20% are inherited. The inherited or familial form of gastrinoma is associated with multiple endocrine neoplasia type I (MEN I), which consists of parathyroid, pituitary, and pancreatic (or duodenal) tumors. Gastrinoma is the most common pancreatic tumor in patients with MEN I. Patients with MEN I usually have multiple gastrinoma tumors, and surgical cure is less common; sporadic gastrinomas are more often solitary and are more often amenable to surgical cure. Currently, about 50% to 60% of gastrinomas are malignant, with lymph node, liver, or other distant metastases at operation. Five-year survival in patients presenting with metastatic disease is approximately 40%. The larger the primary gastrinoma, the higher the likelihood of metastatic disease. More than 90% of patients with sporadically, completely resected gastrinoma will be cured.

The most common symptoms of ZES are epigastric pain, GERD, and diarrhea. More than 90% of patients with gastrinoma have peptic ulcer. Most ulcers are in the typical location (proximal duodenum), but atypical ulcer location (distal duodenum, jejunum, or multiple ulcers) should prompt an evaluation for gastrinoma. Gastrinoma also should be considered in

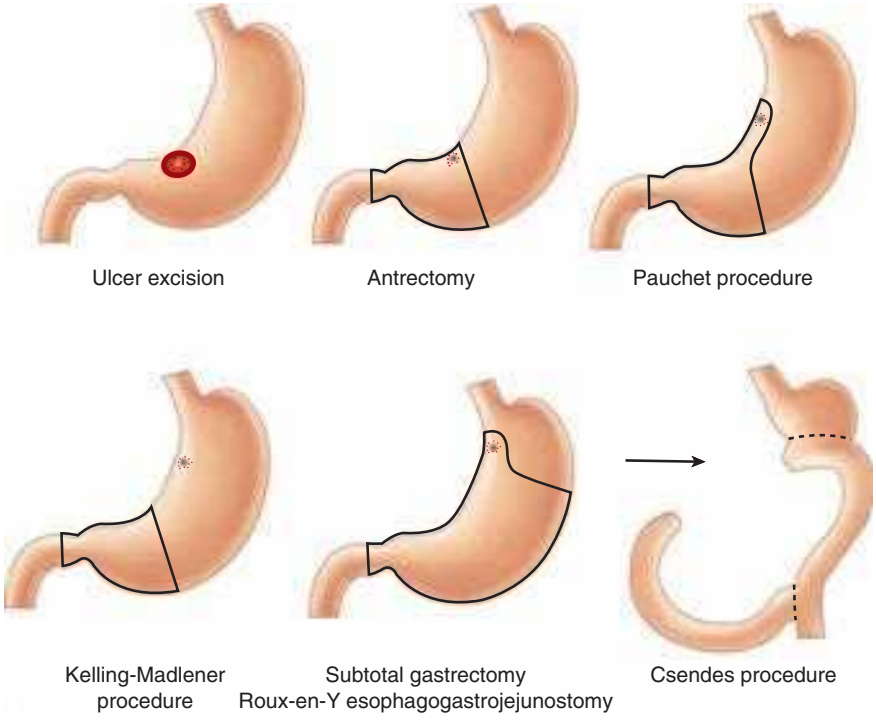

Figure 26-45. Operations for gastric ulcer. *[Reproduced with permission from Seymour NE: Operations for peptic ulcer and their complications, in Feldman M, Sharschmidt BF, Sleisenger MH (eds):* Gastrointestinal and Liver Disease, *6th ed. Philadelphia: Saunders, 1998, p 702. Copyright Elsevier.]*

the differential diagnosis of recurrent or refractory peptic ulcer, secretory diarrhea, gastric rugal hypertrophy, esophagitis with stricture, bleeding or perforated ulcer, familial ulcer, peptic ulcer with hypercalcemia, and gastric carcinoid. The majority of patients with ZES have been symptomatic for several years before definitive diagnosis and, in general, patients with ZES and MEN1 are diagnosed in their 20s and 30s, while those with sporadic ZES more typically are diagnosed in their 40s and 50s.

ZES is an important part of the differential diagnosis of hypergastrinemia (Fig. 26-46). All patients with gastrinoma have an elevated gastrin level, and hypergastrinemia in the presence of elevated BAO strongly suggests gastrinoma. Patients with gastrinoma usually have a BAO >15 mEq/h or >5 mEq/h if they have had a previous procedure for peptic ulcer. Acid secretory medications should be held for several days before gastrin measurement, because acid suppression may falsely elevate gastrin levels. Causes of hypergastrinemia can be divided into those associated with hyperacidity and those associated with hypoacidity (see Fig. 26-46). The diagnosis of ZES is confirmed by the secretin stimulation test. An IV bolus of secretin (2 U/kg) is given and gastrin levels are checked before and after injection. An increase in serum gastrin of 200 pg/mL or greater suggests the presence of gastrinoma. Patients with gastrinoma should have serum calcium and parathyroid hormone levels determined to rule out MEN1 and, if present, parathyroidectomy should be considered before resection of gastrinoma.

About 80% of primary tumors are found in the gastrinoma triangle (Fig. 26-47), and many tumors are small (<1 cm), making preoperative localization difficult. Transabdominal ultrasound is quite specific, but not very sensitive. CT will detect most lesions >2 cm in size and MRI is comparable. EUS is more sensitive than these other noninvasive imaging tests, but it still misses many of the smaller lesions, and may confuse normal lymph nodes for gastrinomas. Currently, the preoperative imaging study of choice for gastrinoma is somatostatin receptor scintigraphy (the octreotide scan). When the pretest probability of gastrinoma is high, the sensitivity and specificity of this modality approach 100%. Gastrinoma cells contain type II somatostatin

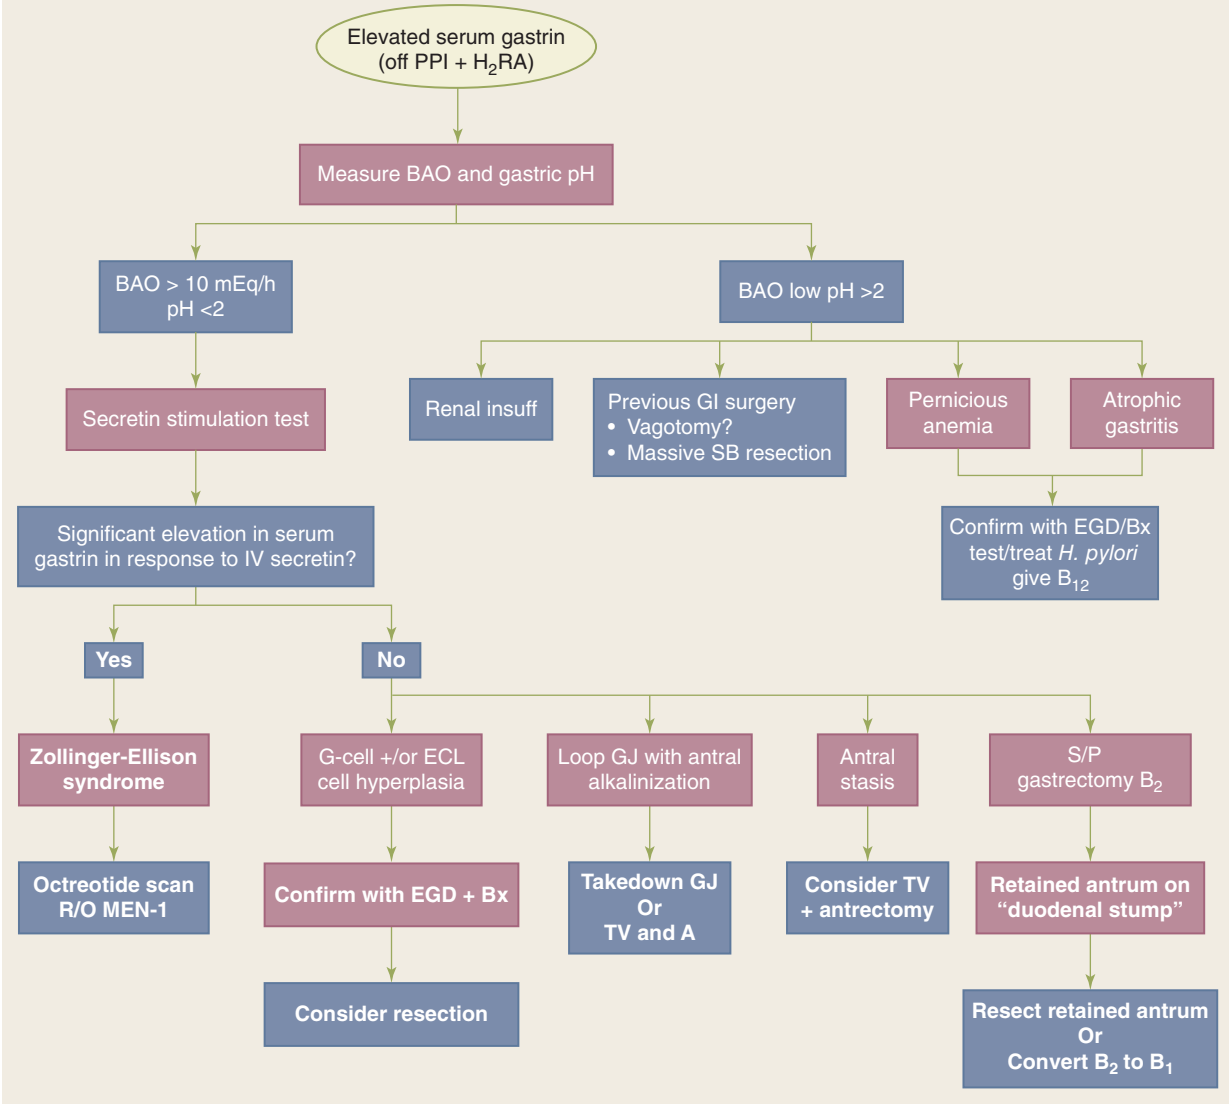

Figure 26-46. Algorithm for diagnosis and management of hypergastrinemia. Figure 26-48. Positive octreotide scan in patient with gastrinoma. (*Reproduced with permission from Alan Maurer, MD.*)

receptors that bind the indium-labeled somatostatin analogue (octreotide) with high affinity, making imaging with a gamma camera possible (Fig. 26-48). Currently, angiographic localization studies are infrequently performed for gastrinoma. Both diagnostic angiography and transhepatic selective venous sampling of the portal system have been supplanted by selective arterial secretin infusion, which helps to localize the tumor as inside or outside the gastrinoma triangle.

In this test, an arterial catheter is selectively placed in a named vessel supplying the pancreas (e.g., gastroduodenal or splenic), and a venous catheter is placed in a hepatic vein. Secretin is injected into the visceral artery and gastrin is sampled in the hepatic vein. A significant elevation in hepatic venous gastrin indicates that the tumor is supplied by the injected artery. This test should be performed if pancreaticoduodenectomy is contemplated. Probably the most important means of locating gastrinomas is intraoperative exploration.

All patients with sporadic (nonfamilial) gastrinoma should be considered for surgical resection and possible cure. The lesions should be located in 90% of patients, and the large majority is cured by extirpation of the gastrinoma(s). A thorough intraoperative exploration of the gastrinoma triangle and pancreas is essential, but other sites (i.e., liver, stomach, small bowel, mesentery, and pelvis) should be evaluated as part of a thorough intra-abdominal evaluation to find the primary tumor, which is usually solitary and often in the duodenal wall. The duodenum and pancreas should be extensively mobilized and intraoperative ultrasound should be used. Intraoperative EGD with transillumination may be considered. If the tumor can not be located, generous longitudinal duodenotomy with inspection and palpation of the duodenal wall is performed. Lymph nodes from the portal, peripancreatic, and celiac drainage basins should be sampled. Ablation or resection of hepatic metastases should be considered.

The management of gastrinoma in patients with MEN I is controversial because the patients are often not cured by operation, and the tumors tend to be small and multiple. If the tumor can be imaged preoperatively, operation by an experienced gastrinoma surgeon is reasonable.

Acid hypersecretion in patients with gastrinoma can always be managed with high-dose PPIs. Highly selective vagotomy may make management easier in some patients and should be considered in those with surgically untreatable or unresectable gastrinoma. Gastrectomy for ZES is no longer indicated.

GASTRITIS AND STRESS ULCER

Pathogenesis and Prevention

Gastritis is mucosal inflammation. The gross endoscopic diagnosis of gastritis correlates poorly with histologic findings, and is thus relatively useless as a diagnosis without confirmatory biopsy. Additionally, there is poor correlation between symptoms and histologic gastritis. The most common cause of gastritis is *H. pylori*. Other causes of gastritis include alcohol, NSAIDs, Crohn's disease, tuberculosis, and bile reflux (primary or secondary). These agents cause injury by a variety of different mechanisms. In general, the infectious and inflammatory causes result in immune cell infiltration and cytokine production which damage mucosal cells. The chemical agents (alcohol, aspirin, and bile) generally work to disrupt the mucosal barrier, allowing mucosal damage by back diffusion of luminal hydrogen ions.

Stress gastritis is a peculiar entity that has all but disappeared from the clinical (if not endoscopic) lexicon, largely due to better critical care and acid suppression or cytoprotective agents (e.g., sucralfate) in the intensive care unit (ICU). Stress gastritis and stress ulcer are probably due to inadequate gastric mucosal blood flow during periods of intense physiologic stress. Adequate mucosal blood flow is important to maintain the mucosal barrier, and to buffer any back-diffused hydrogen ions. When blood flow is inadequate, these processes fail and mucosal breakdown occurs. Modern intensive care, with emphasis on adequate tissue perfusion and oxygenation, has undoubtedly decreased the severity of gastric mucosal injury seen in the ICU today. Although it is still common to see small mucosal erosions when performing upper endoscopy in the ICU, it is rare for these lesions to coalesce into the larger bleeding erosions that plagued the ICU patient 30 to 50 years ago. The rationale for routine acid suppression in the ICU, supported by excellent data from clinical trials and the laboratory, is that less mucosal injury will be caused in the potentially weakened gastric mucosa if there is less luminal acid.[80,81] There are some studies suggesting that routine acid suppression leads to overgrowth of gastric bacteria, which increases the incidence and/or severity of aspiration pneumonia in the ICU. Nevertheless, acid suppression, particularly in the severely ill patient, remains an important part of clinical pathways in most ICUs.[82] In the extraordinarily rare patient requiring operation today for hemorrhagic stress gastritis, the surgical options include V + D with oversewing of the major bleeding lesions, or near total gastrectomy. Angiographic embolization and endoscopic hemostatic treatment should be considered as well.

MALIGNANT NEOPLASMS OF THE STOMACH

The three most common primary malignant gastric neoplasms are adenocarcinoma (95%), lymphoma (4%), and malignant GIST (1%) (Table 26-14). Other rare primary malignancies include carcinoid, angiosarcoma, carcinosarcoma, and squamous cell carcinoma. Occasionally the stomach is the site of hematogenous metastasis from other sites (e.g., melanoma or breast). More commonly, malignant tumors from adjacent organs invade the stomach by direct extension (e.g., colon or pancreas) or by peritoneal seeding (e.g., ovary).

Table 26-14

Frequency of gastric tumors

TUMOR TYPE	NO. OF CASES	PERCENT
Malignant tumors	4199	93.0
Carcinoma	3970	87.9
Lymphoma	136	3.0
Leiomyosarcoma	77	1.7
Carcinoid	11	0.3
Others	5	0.1
Benign tumors	315	7.0
Polyp	140	3.1
Leiomyoma	92	2.0
Inflammatory lesions	30	0.7
Heterotopic pancreas	20	0.4
Others	33	0.8

Adenocarcinoma

Epidemiology. Globally, gastric cancer is the fourth most common cancer type and the second leading cause of cancer death. Over the past several decades, there has been a dramatic decrease in the gastric cancer incidence and death rate in most Western industrialized countries (Fig. 26-49). This decrease has been largely in the so-called intestinal form rather than in the diffuse form of gastric cancer. In Asia and Eastern Europe, gastric cancer remains a leading cause of cancer death. In 2012 in the United States, there were approximately 21,320 new cases of stomach cancer (13,020 in men and 8300 in women), and 10,540 deaths from this disease (6190 men and 4350 women.[83] The estimated 5-year survival rate is 27%, up from about 15% in 1975.

In general, gastric cancer is a disease of the elderly, and it is twice as common in blacks as in whites. In younger patients, tumors are more often of the diffuse variety and tend to be large, aggressive, and more poorly differentiated, sometimes infiltrating the entire stomach (linitis plastic). Gastric cancer has a higher incidence in groups of lower socioeconomic status.

Etiology. Gastric cancer is more common in patients with pernicious anemia, blood group A, or a family history of gastric cancer. When patients migrate from a high-incidence region to a low-incidence region, the risk of gastric cancer decreases in the subsequent generations born in the new region. This strongly suggests an environmental influence on the development of gastric cancer. Environmental factors appear to be more related etiologically to the intestinal form of gastric cancer than the more aggressive diffuse form. The commonly accepted risk factors for gastric cancer are listed in Table 26-15.

Diet and Drugs Typically, a starchy diet high in pickled, salted, or smoked food is found in many regions of high gastric cancer risk. Dietary nitrates have been impugned as a possible cause of gastric cancer. Gastric bacteria (more common in the achlorhydric stomach of patients with atrophic gastritis, a risk factor for gastric cancer) convert nitrate into nitrite, a proven carcinogen. A diet high in fresh fruits and vegetables and rich in vitamin C and E has been shown to decrease the population's risk of gastric cancer. The reduced consumption of nitrate-rich preserved foods seen with the growth of refrigeration has been suggested as a cause of the dramatic decrease in gastric cancer seen in North America and Western Europe over the last century. Tobacco use probably increases the risk of stomach cancer, and alcohol use probably has no effect. Regular aspirin use may be protective.

Helicobacter pylori [54,84] The risk of gastric cancer in patients with chronic *H. pylori* infection is increased about threefold. Compared to uninfected patients, patients with a history of gastric ulcer are more likely to develop gastric cancer (incidence ratio 1.8, 95% confidence interval 1.6–2.0), and patients with a history of duodenal ulcer are at decreased risk for gastric cancer (incidence ratio 0.6, 95% confidence interval 0.4–0.7). As diagrammed in Fig. 26-50, this may be due to the fact that some patients develop antral-predominant disease (predisposing to duodenal ulcer and somehow protecting against

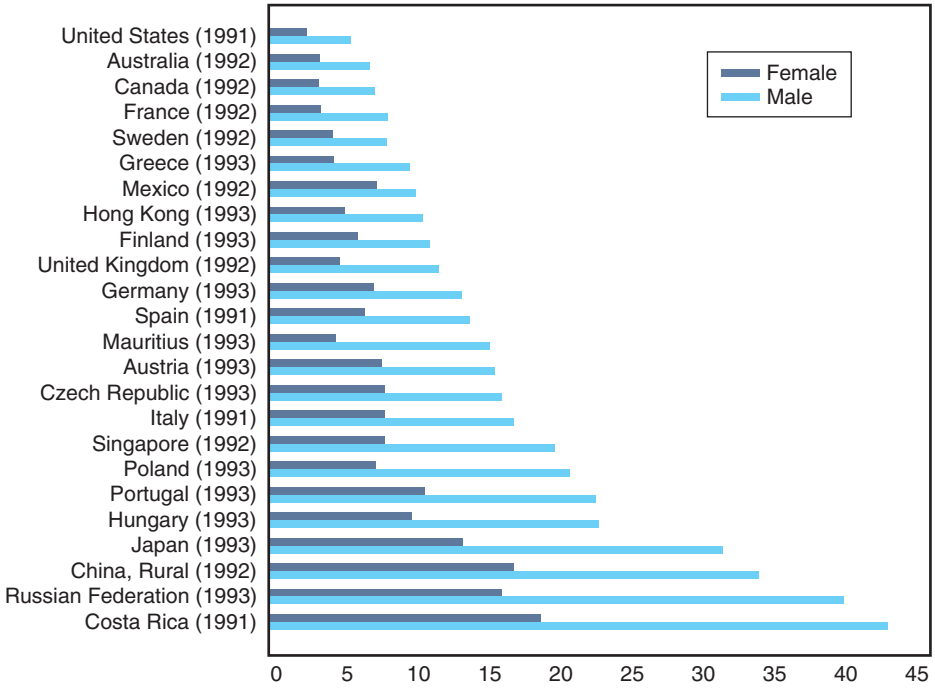

Figure 26-49. Death rates for gastric cancer in different countries. *[Reproduced with permission from Ming S-C, Hirota T: Malignant epithelial tumors of the stomach, in Ming S-C, Goldman H (eds):* Pathology of the Gastrointestinal Tract, *2nd ed. Baltimore: Williams & Wilkins, 1998, p 607.]*

gastric cancer), while other patients develop corpus-predominant gastritis, resulting in hypochlorhydria and somehow predisposing to gastric ulcer and gastric cancer.[85] The theoretical sequence for development of gastric adenocarcinoma is diagrammed in Fig. 26-51.[54,85] Recently, it has been demonstrated that bone marrow-derived stem cells play a key role in the pathogenesis of gastric adenocarcinoma in patients with chronic *H. pylori* infection.[54] However, it must be recognized that gastric adenocarcinoma is a multifactorial disease. Not all patients with gastric cancer have *H. pylori*, and there are some geographic areas with a high prevalence of chronic *H. pylori* infection and a low prevalence of gastric cancer (the "African enigma").

Table 26-15

Factors increasing or decreasing the risk of gastric cancer

Increase risk
Family history
Diet (high in nitrates, salt, fat)
Familial polyposis
Gastric adenomas
Hereditary nonpolyposis colorectal cancer
Helicobacter pylori infection
Atrophic gastritis, intestinal metaplasia, dysplasia
Previous gastrectomy or gastrojejunostomy (>10 y ago)
Tobacco use
Ménétrier's disease
Decrease risk
Aspirin
Diet (high fresh fruit and vegetable intake)
Vitamin C

Finally, *H. pylori*-infected patients seem to be at decreased risk for the development of adenocarcinoma of the distal esophagus and cardia region.[86] Perhaps the corporeal gastritis decreases acid secretion, creating a less damaging refluxate and thus reducing the risk for Barrett's esophagus, the precursor lesion for these tumors.

Epstein-Barr Virus About 10% of gastric adenocarcinomas carry the EBV virus. Recently it has been suggested that EBV infection is a rather late step in gastric carcinogenesis, since EBV transcripts are present in cancer cells but not in the metaplastic cells of precursor epithelium.[87]

Genetic Factors A variety of genetic abnormalities have been described in gastric cancer (Table 26-16). Most gastric cancers are aneuploid. The most common genetic abnormalities in sporadic gastric cancer affect the *p53* and *COX-2* genes. Over two thirds of gastric cancers have deletion or suppression of the important tumor-suppressor gene *p53*. Additionally, approximately the same proportion have overexpression of *COX-2*. In the colon, tumors with upregulation of this gene have suppressed apoptosis, more angiogenesis, and higher metastatic potential. Gastric tumors that overexpress *COX-2* are more aggressive tumors. Recently, a germline mutation in the CDH1 gene encoding E-cadherin was shown to be associated with hereditary diffuse gastric cancer. Prophylactic total gastrectomy should be considered in patients with these mutations.[88]

Recently the role of microRNA abnormalities in gastric cancer have received attention. These are small short sequence molecules (18 to 25 nucleotides) which inhibit the translation or promote the degradation of messenger RNA with complementary sequences. MicroRNAs are important regulators of gene expression, and abnormalities in microRNA have been identified in gastric cancer which effect the cell cycle, apoptosis, and cellular invasiveness and/or metastatic potential.[89] It is likely

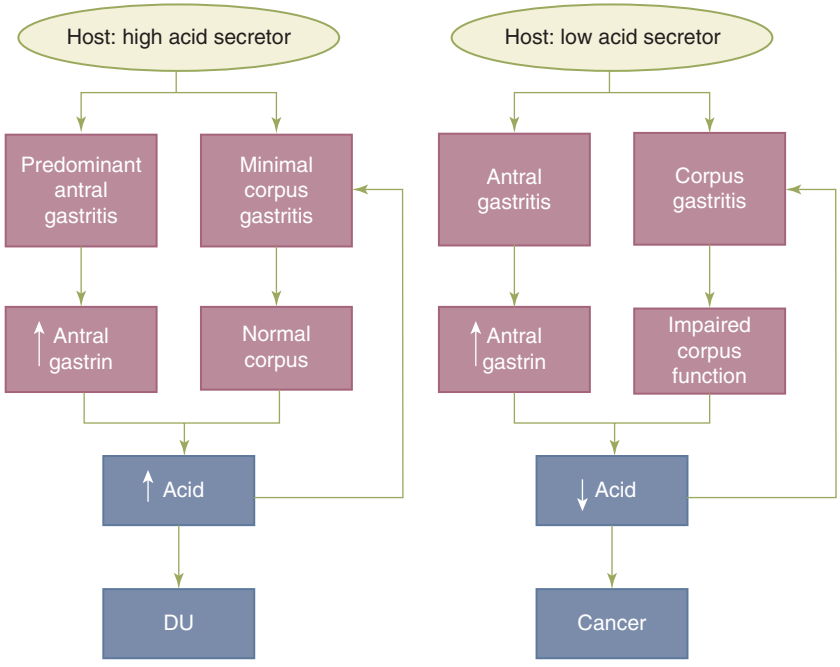

Figure 26-50. *Helicobacter* and gastritis, and the pathogenesis of duodenal ulcer (DU) or gastric cancer. *[Reproduced with permission from Leung WK, Ng EKW, Sung JJY: Tumors of the stomach, in Yamada T, et al (eds):* Textbook of Gastroenterology, *4th ed. Philadelphia: Lippincott, Williams & Wilkins, 2003, p 1416.]*

microRNA will have increasing diagnostic, therapeutic, and prognostic significance in gastric cancer as well as other tumors.

Premalignant Conditions of the Stomach Figure 26-52 shows the prevalence of some premalignant conditions associated with the development of early gastric cancer in a series of 1900 cases from Tokyo. By far the most common precancerous lesion is atrophic gastritis. There is a growing appreciation of the important influence of the chronic inflammatory milieu on the genome of mucosal cells. Chronic inflammation leads to both genetic and epigenetic changes in mucosal cells which in the stomach leads to the development of gastritis associated cancer.[90]

Polyps Benign gastric polyps are classified as neoplastic (adenoma and fundic gland polyps) or nonneoplastic (hyperplastic polyp, inflammatory polyp, hamartomatous polyp).[90A] In general, inflammatory and hamartomatous polyps have little or no malignant potential. Fundic gland polyps, commonly seen in patients on long term proton pump inhibitor therapy, are not premalignant but in patients with familial adenomatous polyposis, dysplasia in these lesions is not uncommon. Hyperplastic polyps usually occur in the setting of chronic inflammation. Large hyperplastic polyps (>2cm) may harbor dysplasia or carcinoma in situ, and gastric cancer may develop remote from the hyperplastic polyp in an area of associated chronic inflammation. Gastric adenomas are premalignant, similar to colon adenomas. Patients with familial adenomatous polyposis (FAP) have a high prevalence of gastric adenomatous polyps (about 50%), and are

Figure 26-52. Precancerous lesions of the stomach. *[Reproduced with permission from Ming S-C, Hirota T: Malignant epithelial tumors of the stomach, in Ming S-C, Goldman H (eds):* Pathology of the Gastrointestinal Tract, *2nd ed. Baltimore: Williams & Wilkins, 1998, p 607.]*

10 times more likely to develop adenocarcinoma of the stomach than the general population.[91] Screening EGD is indicated in these families. Patients with hereditary nonpolyposis colorectal cancer may also be at risk for gastric cancer.[92]

Gastric polyps greater than 1cm should be removed to confirm the diagnosis and to eliminate any risk of malignant degeneration. Patients with gastric adenomatous polyps and FAP should have periodic upper endoscopy, which may also be considered in selected patients with hyperplastic polyps and chronic gastric inflammation.

Atrophic Gastritis Chronic atrophic gastritis (Fig. 26-53) is by far the most common precursor for gastric cancer, particularly the intestinal subtype (see Fig. 26-52). The prevalence of atrophic gastritis is higher in older age groups, but it is also common in younger people in areas with a high incidence of gastric cancer. In many patients, it is likely that *H. pylori* is involved in the pathogenesis of atrophic gastritis. Correa described three distinct patterns of chronic atrophic gastritis: autoimmune (involves the acid-secreting proximal stomach), hypersecretory (involving the distal stomach), and environmental (involving multiple random areas at the junction of the oxyntic and antral mucosa).[84]

Intestinal Metaplasia Gastric carcinoma often occurs in an area of intestinal metaplasia. Furthermore, an individual's risk of gastric cancer is proportional to the extent of intestinal metaplasia of the gastric mucosa. These observations strongly suggest that intestinal metaplasia is a precursor lesion to gastric cancer. There are different pathologic subtypes of intestinal metaplasia in the stomach, based upon the histologic and biochemical characteristics of the changed mucosal glands. In the complete type of intestinal metaplasia, the glands are completely lined with goblet cells and intestinal absorptive cells (Fig. 26-54). These cells are indistinguishable histologically and biochemically from their small bowel counterparts, and are not seen in the normal stomach. There is evidence that eradication of *H. pylori* infection leads to significant regression of intestinal metaplasia and improvement in atrophic gastritis. Therefore, treatment of *H. pylori* infection is a reasonable recommendation for patients with these pathologic diagnoses and *H. pylori* infection.

Benign Gastric Ulcer Although once considered a premalignant condition, it is likely that the older literature was confounded by mistakenly labeling inadequately biopsied ulcers and healing ulcers as "benign," when, in fact, they were malignant to begin with. It is now generally recognized that all gastric ulcers are cancer until proven otherwise with adequate biopsy and follow-up. Even today, carcinomas are occasionally found when adequately biopsied "benign" ulcers are resected for nonhealing. It is more than likely that the factors previously discussed are more significant etiologically in the development of gastric cancer than the history of a benign gastric ulcer.

Gastric Remnant Cancer It has long been recognized that stomach cancer can develop in the gastric remnant, usually years following distal gastrectomy for PUD. The risk is controversial, but the phenomenon is real. Most tumors develop >10 years following the initial operation, and they usually arise in an area of chronic gastritis, metaplasia, and dysplasia. This is often near the stoma, but many of these tumors are quite large at presentation, and are equally divided between intestinal and diffuse subtypes. Most cases have been reported following Billroth II gastroenterostomy, but there also have been cases following Billroth I gastroduodenostomy. Whether simple loop gastrojejunostomy increases a patient's risk of gastric cancer, and whether a Roux-en-Y anastomosis following gastric resection lowers their risk of gastric cancer is unknown. Stage for stage, the prognosis for gastric stump cancer is similar to proximal gastric cancer.[93]

Other Premalignant States A mutated E-cadherin gene is associated with hereditary diffuse gastric cancer. Prophylactic total gastrectomy should be considered.[88] Obviously, a myriad of genetic and environmental factors will affect members of the same family, and up to 10% of gastric cancer cases appear to be familial without a clear-cut genetic diagnosis. First-degree relatives of patients with gastric cancer have a two- to threefold increased risk of developing the disease. Patients with hereditary nonpolyposis colorectal cancer have a 10% risk of developing gastric cancer, predominantly the intestinal subtype. The mucous cell hyperplasia of Ménétrier's disease is generally considered to carry a 5% to 10% risk of adenocarcinoma. Periodic surveillance EGD is prudent in all the above conditions. The glandular hyperplasia associated with gastrinoma is not premalignant, but ECL hyperplasia and/or carcinoid tumors can occur.

Pathology

Dysplasia It is generally accepted that gastric dysplasia is the universal precursor to gastric adenocarcinoma. Patients with severe dysplasia should be considered for gastric resection if the abnormality is widespread or multifocal, or EMR if the severe dysplasia is localized. Patients with mild dysplasia should be followed with endoscopic biopsy surveillance, and *Helicobacter* eradication.

Early Gastric Cancer Early gastric cancer is defined as adenocarcinoma limited to the mucosa and submucosa of the stomach, regardless of lymph node status. The entity is common in the Orient, where gastric cancer is a common cause of cancer death, and where aggressive surveillance programs have therefore been established. Approximately 10% of patients with early gastric cancer will have lymph node metastases. There are several types and subtypes of early gastric cancer (Table 26-17 and Fig. 26-55). Approximately 70% of early gastric cancers are well differentiated, and 30% are poorly differentiated. The overall cure rate with adequate gastric resection and lymphadenectomy is 95%. In some Japanese centers, 50% of the gastric cancers treated are early gastric cancer. In the United States, less than 20% of resected gastric adenocarcinomas are early gastric cancer. Small intramucosal lesions can be treated with EMR.[94]

Gross Morphology and Histologic Subtypes There are four gross forms of gastric cancer: polypoid, fungating, ulcerative, and scirrhous. In the first two, the bulk of the tumor mass is intraluminal. Polypoid tumors are not ulcerated; fungating tumors are elevated intraluminally, but also ulcerated. In the latter two gross subtypes, the bulk of the tumor mass is in the wall of the stomach. Ulcerative tumors are self-descriptive; scirrhous tumors infiltrate the entire thickness of the stomach and cover a very large surface area. Scirrhous tumors (linitis plastica) have a particularly poor prognosis, and commonly involve the entire stomach. Although these latter lesions may be technically resectable with total gastrectomy, it is common for both the esophageal and duodenal margins of resection to show microscopic evidence of tumor infiltration, and death from recurrent disease within 6 months is common. Palliative chemotherapy may prolong median survival[94A].

Table 26-17

Macroscopic types of superficial gastric cancer

Type 0-I (protruding)*	Polypoid tumors
Type 0-II (superficial)	Tumors with or without minimal elevation or depression relative to the surrounding mucosa.
Type 0-IIa	Slightly elevated tumors. (superficial elevated)
Type 0-IIb	Tumors without elevation or depression. (superficial flat)
Type 0-IIc	Slightly depressed tumors. (superficial depressed)
Type 0-III (excavated)	Tumors with deep depression

*Tumors with less than 3-mm elevation are usually classified as –IIa, with more elevated tumors being classified as 0-I.

The location of the primary tumor in the stomach is important in planning the operation. Several decades ago, the large majority of gastric cancers were in the distal stomach. Recently, there has been a proximal migration of tumors, so that currently, the distribution is closer to 40% distal, 30% middle, and 30% proximal.

Histology The most important prognostic indicators in gastric cancer are both histologic: lymph node involvement and depth of tumor invasion. Tumor grade (degree of differentiation: well, moderately, or poorly) is also important prognostically.

There are several histologic classifications of gastric cancer. The World Health Organization recognizes several histologic types (Table 26-18). The Japanese classification is similar but more detailed. The commonly used Lauren classification separates gastric cancers into intestinal type (53%), diffuse type (33%), and unclassified (14%). The intestinal type is associated with chronic atrophic gastritis, severe intestinal metaplasia, and dysplasia, and tends to be less aggressive than the diffuse type. The diffuse type of gastric cancer is more likely to be poorly differentiated and is associated with younger patients and proximal tumors. The Ming classification also is useful and easy to remember, with only two types—expanding (67%) and infiltrative (33%).

Recently, the significance of human epidermal growth factor receptor-2 (HER2) was reported in patients with gastric cancer. In breast cancer, overexpression of HER2 has been reported in 15% to 25% and is well recognized as one of the unfavorable prognostic factors. However, the development of molecular targeted agents such as trastuzumab has improved the survival of HER2 positive patients. Likewise, recently in gastric cancer, HER2 overexpression has been reported in 13% to 30% of patients. According to the result of large clinical trial, Immunohistochemistry (IHC) staining of HER2 has become the important examination for recurrent or metastatic gastric cancer to decide the treatment strategy.[94B]

Pathologic Staging Ultimately, prognosis is related to pathologic stage. The most widespread system for staging of gastric cancer is the tumor-node-metastasis (TNM) staging system based on depth of tumor invasion, extent of lymph node metastases, and presence of distant metastases. This system was developed by the American Joint Committee on Cancer and the International Union Against Cancer, and has under gone several modifications since it was originally conceived (Table 26-19).

Clinical Manifestations. Most patients who are diagnosed with gastric cancer in the United States have advanced stage III or IV disease at the time of diagnosis. The most common symptoms are weight loss and decreased food intake due to anorexia and early satiety. Abdominal pain (usually not severe and often ignored) also is common. Other symptoms include nausea, vomiting, and bloating. Acute GI bleeding is somewhat unusual (5%), but chronic occult blood loss is common and manifests as iron deficiency anemia and heme-positive stool. Dysphagia is common if the tumor involves the cardia of the stomach. Paraneoplastic syndromes such as Trousseau's syndrome (thrombophlebitis), acanthosis nigricans (hyperpigmentation of the axilla and groin), or peripheral neuropathy are rarely present.

Physical examination typically is normal. Other than signs of weight loss, specific physical findings usually indicate incurability. A focused examination in a patient in whom gastric cancer is a likely part of the differential diagnosis should include an examination of the neck, chest, abdomen, rectum, and pelvis. Cervical, supraclavicular (on the left referred to as Virchow's node), and axillary lymph nodes may be enlarged, and today can be sampled in the office with fine-needle aspiration cytology. There may be a metastatic pleural effusion, or aspiration pneumonitis in a patient with vomiting and/or obstruction. An abdominal mass could indicate a large (usually T4 incurable) primary tumor, liver metastases, or carcinomatosis (including Krukenberg's tumor of the ovary). A palpable umbilical nodule (Sister Joseph's nodule) is pathognomonic of advanced disease, or there may be evidence on exam of malignant ascites. Rectal exam may reveal heme-positive stool and hard nodularity

Table 26-19

TNM classification of tumors of the stomach

T: Primary tumor	
T0	No evidence of primary tumor
Tis	Carcinoma in situ; intraepithelial tumor without invasion of the lamina propria, high-grade dysplasia
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularispropria
T3	Tumor invades subserosa
T4	Tumor perforates serosa or invades adjacent structures
T4a	Tumor perforates serosa
T4b	Tumor invades adjacent structures
N: Regional lymph nodes	
N0	No regional lymph-node metastasis
N1	Metastasis in 1 to 2 regional lymph nodes
N2	Metastasis in 3 to 6 regional lymph nodes
N3	Metastasis in 7 or more regional lymph nodes
N3a	Metastasis in 7 to 15 regional lymph nodes
N3b	Metastasis in 16 or more regional lymph nodes
M: Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

extraluminally and anteriorly, indicating so-called *drop metastases*, or rectal shelf of Blumer in the pouch of Douglas.

Diagnostic Evaluation. Distinguishing between peptic ulcer and gastric cancer on clinical grounds alone is usually impossible. Patients over the age of 45 years old who have new-onset dyspepsia, as well as all patients with dyspepsia and alarm symptoms (weight loss, recurrent vomiting, dysphagia, evidence of GI bleeding, or anemia) or with a family history of gastric cancer should have prompt upper endoscopy and biopsy if a mucosal lesion is noted. Essentially, all patients in whom gastric cancer is part of the differential diagnosis should have endoscopy and biopsy. If suspicion for cancer is high and the biopsy is negative, the patient should be re-endoscoped and more aggressively biopsied. In some patients with gastric tumors, upper GI series can be helpful in planning treatment. Although a good double-contrast barium upper GI examination is sensitive for gastric tumors (up to 75% sensitive), in most centers, endoscopy has become the gold standard for the diagnosis of gastric malignancy.

In addition, recent advances in endoscopy have contributed to the earlier diagnosis of gastric cancer. Magnifying endoscopy with narrow-band imaging (NBI) has undergone technological improvements and can observe the microvascular architecture of the mucosa and microsurface pattern of the lesion. Magnifying endoscopy with NBI has been reported to be accurate and reliable in the diagnosis of early gastric cancer.[94C] Furthermore, endocytoscopy, a technique allowing microscopic visualization of the mucosal surface, has been developed and has the potential for pathological diagnosis.[94D] Another diagnostic innovation is virtual endoscopy which is an imaging examination of the gastrointestinal tract reconstructed by multidetector-row computed tomography. The image of virtual endoscopy is now quite similar to that of upper endoscopy. In the near future, this novel technology may play a role in the screening of the stomach.

Preoperative staging of gastric cancer is best accomplished with abdominal/pelvic CT scanning with IV and oral contrast. MRI is probably comparable. The best way to stage the tumor locally is via EUS, which gives fairly accurate (80%) information about the depth of tumor penetration into the gastric wall, and can usually show enlarged (>5 mm) perigastric and celiac lymph nodes. In some centers, if the tumor is transmural (T3) or involves lymph nodes (enlarged nodes can usually be needled under endoscopic ultrasound guidance), preoperative (neoadjuvant) chemotherapy is given. However, there are limitations to tumor staging with EUS. It largely is operator dependent and may underestimate lymph node involvement because normal-sized nodes (<5 mm) can harbor metastases. EUS is most accurate in distinguishing early gastric cancer (T1) from more advanced tumors.

Positron Emission Tomography Scanning Whole-body PET scanning uses the principle that tumor cells preferentially accumulate positron-emitting 18F-fluorodeoxy glucose. This modality is most useful in the evaluation of distant metastasis in gastric cancer but can also be useful in locoregional staging. PET scan is accurate when combined with spiral CT (PET-CT)[95] and should be considered before major surgery in patients with particularly high-risk tumors or multiple medical comorbidities.

Staging Laparoscopy and Peritoneal Cytology To some extent, the usefulness of these modalities depends on the individual patient's situation as well as the treatment philosophy of the cancer team. The fundamental question is "will it make a difference to this patient's management?" Patients with gastric cancer who undergo R0 resection (i.e., no gross residual

disease) and are found to have positive peritoneal cytology (no gross carcinomatosis) have a much worse prognosis than the cytology negative group (median survival 14.8 months vs. 98.5 months).[96] It is controversial how much this information adds prognostically to that of pathologic staging (TNM). Whether this poor prognosis can be improved postresection with aggressive adjuvant treatment (systemic, or local intraperitoneal hyperthermic chemotherapy) is unknown. Unfortunately, it is also unclear how much these patients benefit from gastric resection. Currently peritoneal cytology information is unlikely to change the treatment of patients with gastric cancer, and most patients without detectable distant metastases will have (and should have) gastric resection regardless of the peritoneal cytology results. A quick laparoscopic examination can occasionally reveal small peritoneal implants or liver metastases that were not detected on preoperative imaging studies and, in some patients (e.g., high risk for surgery or impressive carcinomatosis), this will change the operative plan and avoid a major but futile surgical procedure. Laparoscopy may be most useful in patients with proximal tumors or with adenopathy on spiral CT scan.[97] An extensive laparoscopic staging procedure, although quite accurate, has not been widely adopted.

Treatment. Surgical resection is the only curative treatment for gastric cancer[98,99] and most patients with clinically resectable locoregional disease should have gastric resection. Obvious exceptions include patients who cannot tolerate an abdominal operation, and patients with overwhelming metastatic disease.

The goal of curative surgical treatment is resection of all tumor (i.e., R0 resection). Thus, all margins (proximal, distal, and radial) should be negative and an adequate lymphadenectomy performed. Generally, the surgeon strives for a grossly negative margin of at least 5 cm. Some gastric tumors, particularly the diffuse variety, are quite infiltrative and tumor cells can extend well beyond the tumor mass; thus, gross margins beyond 5 cm may be desirable. Frozen section confirmation of negative margins is important when performing operation for cure, but it is less important in patients with nodal metastases beyond the N1 nodal basin. It should be strongly emphasized that many patients with positive lymph nodes are cured by adequate surgery. It should also be stressed that often lymph nodes that appear to be grossly involved with tumor turn out to be benign or reactive on pathologic examination. More than 15 resected lymph nodes are required for adequate staging.[100] Therapeutic nihilism should be avoided and, in the low-risk patient, an aggressive attempt to resect all tumor should be made. The primary tumor may be resected en bloc with adjacent involved organs (e.g., distal pancreas, transverse colon, or spleen) during the course of curative gastrectomy. Palliative gastrectomy may be indicated in some patients with obviously incurable disease, but most patients presenting with stage IV gastric cancer can be managed without major operation.[99,101]

Extent of Gastrectomy The standard operation for gastric cancer is radical subtotal gastrectomy. Unless required for R0 resection, total gastrectomy confers no additional survival benefit and may have adverse nutritional or quality-of-life consequences, and higher peri-operative morbidity and mortality.[98,99] Subtotal gastric resection typically entails ligation of the left and right gastric and gastroepiploic arteries at the origin, as well as the en bloc removal of the distal 75% of the stomach, including the pylorus and 2 cm of duodenum, the greater and lesser omentum, and all associated lymphatic tissue (Fig. 26-56). Reconstruction

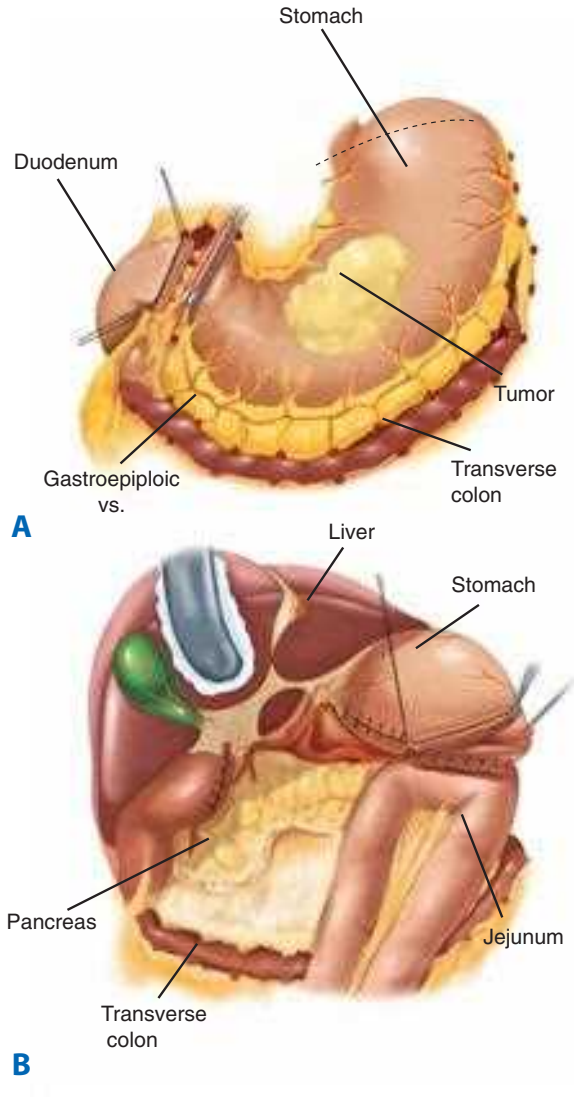

Figure 26-56. A and **B.** Radical subtotal gastrectomy. vs. = vessels. *[Reproduced with permission from Daly JM, Cady B, Low DW (eds): Atlas of Surgical Oncology. St. Louis: Mosby-Year Book, 1993, p 231. Copyright Elsevier.]*

is usually by Billroth II gastrojejunostomy, but if a small gastric remnant is left, a Roux-en-Y reconstruction is considered. In East Asia especially in Japan, Billroth-I gastroduodenostomy was usually performed after distal gastrectomy. Billroth-I gastroduodenostomy consists of one anastomosis (which is usually straightforward and keeps the duodenum in the food stream). In the United States, traditional surgical teaching eschews gastroduodenostomy following gastric cancer resection because of the possibility of anastomotic recurrence and obstruction. The operative mortality is around 2% to 5%. Radical subtotal gastrectomy is generally deemed to be an adequate cancer operation in most Western countries, provided that tumor-free margins are obtained, >15 lymph nodes are removed, and all gross tumor is resected. In the absence of involvement by direct extension, the spleen and pancreatic tail are not removed.

Total gastrectomy with Roux-en-Y esophagojejunostomy may be required for R0 resection (Fig. 26-57), and may be the best operation for patients with proximal gastric adenocarcinoma. The construction of a jejunal pouch can be beneficial nutritionally, particularly for those patients with a good prognosis.[102]

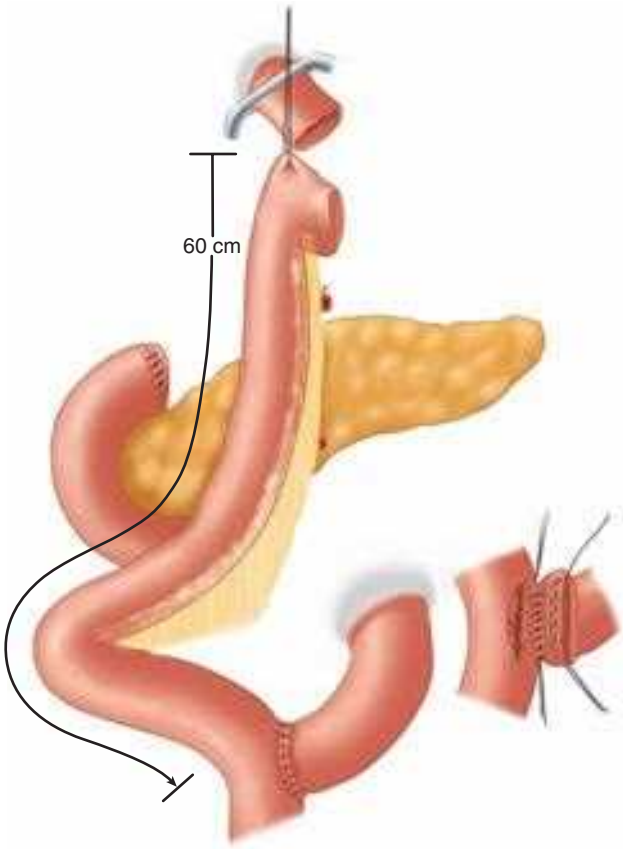

Figure 26-57. Reconstruction after total gastrectomy. Jejunal pouch (not shown here) should be considered. *[Reproduced with permission from Zinner MJ (ed):* Atlas of Gastric Surgery. *New York: Churchill Livingstone, 1992, p 167. Copyright Elsevier.]*

Proximal subtotal gastric resection, a technically feasible alternative to total gastrectomy for some proximal gastric tumors, requires an esophagogastrostomy to a vagotomized distal gastric remnant, and the functional outcome is poor. Pyloroplasty in this setting virtually guarantees bile esophagitis, and if the pylorus is left intact, gastric emptying may be problematic. An isoperistaltic jejunal interosition (Henley loop) between the esophagus and antrum could be considered an alternative reconstruction, but, all things considered, total gastrectomy usually results in superior functional, if not oncologic, results for most patients with proximal gastric cancer.

Extent of Lymphadenectomy According to the 3rd edition of Japanese classification of gastric carcinoma, lymph node stations are numbered by anatomical definition. Lymph node stations from 1 to 12, and 14V are classified as regional lymph nodes and metastasis of any other lymph node is classified as distant metastasis (M1) (see Fig. 26-4). According to the type of gastrectomy, the definition of extent of lymphadectomy is different. D1 lymphadenectomy in distal gastrectomy requires the dissection of the stations 1, 3, 4sb, 4d, 5, 6, 7. Furthermore, additional resection of stations 8a, 9, 11p and 12a is needed for D2 lymphadenectomy. D1 lymphadenectomy in total gastrectomy requires dissection of stations 1 through 7 and in D2, from 8a to 12a too. The operation described above (radical subtotal gastrectomy in the Extent of Gastrectomy section), which is by far the most commonly performed procedure in the United States for gastric cancer, is called a D1 resection because it removes the tumor and the perigastric D1 nodes. The standard operation for gastric cancer in Asia and specialized U.S. centers is the D2 gastrectomy, which involves a more extensive lymphadenectomy (removal of the D1 and D2 nodes). In addition to the tissue removed in a D1 resection, the standard D2 gastrectomy removes the peritoneal layer over the anterior mesocolon and selectively over the pancreas, along with nodes along the hepatic and splenic arteries, and the crural nodes. Splenectomy and distal pancreatectomy are not routinely performed, because this clearly has been shown to increase the morbidity of the operation. The purported survival advantage of D2 gastrectomy in gastric cancer is shown in Table 26-20, which shows the 5-year survival rates for gastric cancer stratified by pathologic stage for the United States and Japan. Unfortunately, the randomized prospective trials that have been performed have not confirmed this survival advantage, but the morbidity and mortality in the D2 group was higher (Table 26-21).[103,104,104A] This was mostly attributable to the splenectomy and distal pancreatectomy, which are no longer routinely done as part of the D2 gastrectomy in the United States. However, since D2 lymphadenectomy in total gastrectomy requires the dissection of station 10 which is splenic hilar lymph node as described above, splenectomy is recommended to fulfill the criteria of D2. In Japan, pancreas-preserving splenectomy is generally performed to avoid the severe postoperative complications such as pancreas fistula in patients with advanced upper gastric cancer who underwent total gastrectomy. Some experts have argued that the D2 operation is simply a better staging procedure, and that the apparent improved survival with this more extensive dissection is simply an epiphenomenon of improved pathologic staging. This stage shift suggests that many patients in the U.S. series treated with D1 gastrectomy really had metastatic nodes at the D2 level that went unresected and undetected. Therefore, in the U.S. series, there were patients classified as stage I, who, if they had undergone a D2 gastrectomy, would be classified as stage II; and there were patients classified as stage II, who, if they had undergone a D2 gastrectomy, would be classified as stage III. The stage I survival in the United States would then actually be closer to the (more accurately staged) stage II survival in Japan, because this group includes some patients who really *are* stage II, but the nodes were not found in the D1 resection. All experts would agree that to avoid understaging of gastric cancer, a minimum of 15 nodes should be resected with the gastrectomy specimen. Despite the lack of strong data from RCTs supporting a survival advantage of D_2 gastrectomy for gastric cancer, this

has become standard practice in Asia and has been adopted by an increasing number of large Western centers. Reasons for this are safety of operation in experienced hands as well as data from observational studies and subgroup analysis of RCTs suggesting a survival benefit.[104B]

Chemotherapy and Radiation for Gastric Cancer In general, the actuarial 5-year survival for resected gastric adenocarcinoma stages I, II, and III is about 75%, 50%, and 25%, respectively. Because most surgical patients have stage II disease or greater, it is common to refer gastric cancer patients postoperatively to a medical and/or radiation oncologist. Unfortunately, the existing data suggest that the incremental survival benefit attendant to adjuvant treatment is marginal, particularly in those patients who have had an adequate resection.[98,99] In one prospective randomized study, adjuvant treatment with chemotherapy (5-fluorouracil and leucovorin) and radiation (4500 cGy) has demonstrated a survival benefit in resected patients with stage II and III adenocarcinoma of the stomach.[105] Unfortunately, only 10% of patients entered in the study actually had D2 gastrectomy, and most (54%) had less than an adequate D1 gastrectomy. Because adequacy of lymphadenectomy has clearly been shown to impact survival, particularly in patients with stage III gastric cancer,[99,100] it has been suggested that the benefits of adjuvant chemoradiation shown in this study would be vitiated by an adequate operation. Recent clinical trials suggest the potential importance of adjuvant chemotherapy after D2 lymphadenectomy in patients with advanced gastric cancer. These trials compared surgery alone and surgery plus adjuvant chemotherapy including oral fluoropyrimidines for curatively resected advanced gastric cancer. After D2 lymphadenectomy, the benefit of adjuvant chemotherapy has also been established and further improvement in prognosis is expected.[105A,105B] A recently published study from the Japan Clinical Oncology Group showed a 69% overall 5-year survival rate in patients with clinically curable T2b, T3, and T4 gastric cancer, treated with D2 gastrectomy alone (no chemotherapy).[106] There was no incremental benefit from para-aortic lymph node dissection. There is no indication for the routine use of radiation alone in (D_3) the adjuvant setting, but in certain patients, it can be effective palliation for bleeding or pain. Although the prognosis of metastatic or recurrent gastric cancer is poor, systemic chemotherapy provides a significant survival benefit over the best supportive care.[106A] Agents that have shown activity against gastric cancer include 5-fluorouracil (5-FU), cisplatin, doxorubicin, methotrexate, taxanes, and camptothecin. Until recently, 5-FU based chemotherapy especially in combination with platinums played a key role in the treatment for the unresectable gastric cancer as well as several types of cancer, such as colon and lung. In the 1990s, the introduction of novel anticancer agents such as camptothecin, taxanes, third-generation platinums, and new oral fluoropyrimidines, improved the prognosis of unresectable gastric cancer. Recently, although the risk of the toxicities is increased, triple combination chemotherapy is associated with better prognosis than double agent therapy. In the United States, triple chemotherapy consists of 5-FU, cisplatin and docetaxel and is now recognized as a standard first-line regimen. In Europe, triple therapy is more often epirubicin, cisplatin, and 5-FU. Sometimes 5-FU may be replaced by capecitabine which is an oral fluoropyrimidine, and cisplatin can be replaced by oxaliplatin which does not require hydration, respectively. Neoadjuvant treatment of gastric adenocarcinoma is being evaluated, particularly in patients with clinical T3 or N1 disease.

It is likely that targeted molecular agents will have an increasing role in treating gastric cancer. Recently, Trastuzumab, a humanized molecular antibody reactive against the extracellular domain of HER2, increased the effectiveness of cytotoxic chemotherapy in patients with advanced gastric cancer.[94B] Other large trials are ongoing. Determination of HER2 gene amplification status may have prognostic significance.[106B]

Endoscopic Resection[106C] It has been demonstrated initially at numerous East Asian centers that some patients with early gastric cancer can be adequately treated by an endoscopic mucosal resection (EMR). EMR is a minimally invasive procedure that provides curative resection and has dramatically changed the treatment of early gastric cancer. EMR is indicated for patients in whom the probability of lymph node metastasis is low. According to the Japanese treatment guidelines for gastric cancer, EMR is a standard treatment for differentiated mucosal gastric cancer measuring less than 2 cm and without signs of ulceration, which has almost no risk of lymph node metastasis. En bloc resection is required to evaluate the surgical margin for confirmation of curative resection. Furthermore, the development of endoscopic submucosal dissection (ESD) allows en bloc resection of larger tumors. Therefore, the indications for endoscopic treatment of patients with gastric cancer may be broadened. New indications for minimally invasive treatment will require evaluation before implementation. Small tumors (<3 cm) confined to the mucosa have an extremely low chance of lymph node metastasis (3%), which approaches the operative mortality rate for gastrectomy. If the resected specimen demonstrates no ulceration, no penetration of the muscularis mucosae, no lymphatic invasion, and size <3 cm, then the risk of lymph node metastases is less than 1%. Thus, some patients with early gastric cancer might be better treated with the endoscopic technique. Currently, this should be limited

to patients with tumors <2 cm in size that are node negative and confined to the mucosa on EUS, in the absence of other gastric lesions. The addition of laparoscopic lymph node sampling may be considered in selected patients.

Prognosis. The 5-year survival for gastric adenocarcinoma has increased from 15% to 22% in the United States over the past 25 years. Survival is dependent on pathologic stage (TNM stage) and degree of tumor differentiation. Other important prognostic factors are sex, age, primary gastric tumor site, tumor size, and tumor depth.

Palliative gastrectomy may be indicated in some patients with obviously incurable disease, but most patients presenting with stage IV gastric cancer can be managed without major operation.[99,101]

Screening for Gastric Cancer. In Japan, it clearly has been shown that patients participating in gastric cancer screening programs have a significantly decreased risk of dying from gastric cancer. Thus, screening is effective in a high-risk population. Screening the general population in the United States (a low-risk country) does not make sense, but patients clearly at risk for gastric cancer probably should have periodic endoscopy and biopsy. This includes patients with familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, gastric adenomas, Ménétrier's disease, intestinal metaplasia or dysplasia, and remote gastrectomy or gastrojejunostomy.

Gastric Lymphoma

Gastric lymphomas generally account for about 4% of gastric malignancies. Over half of patients with non-Hodgkin's lymphoma have involvement of the GI tract. The stomach is the most common site of primary GI lymphoma, and over 95% are non-Hodgkin's type. Most are B-cell type, thought to arise in mucosa associated lymphoid tissue (MALT), although most high-grade gastric lymphomas are without any characteristics of the low-grade MALT neoplasm.[107] About half of gastric lymphomas are histologically low grade, and about half are high grade. Interestingly, the normal stomach is relatively devoid of lymphoid tissue. However, in the setting of chronic gastritis, the stomach acquires MALT, which can undergo malignant degeneration. Again, *H. pylori* is thought to be the culprit. In populations with a high incidence of gastric lymphoma, there is a high incidence of *H. pylori* infection; patients with gastric lymphoma also usually have *H. pylori* infection.[107A]

Low-grade MALT lymphoma, essentially a monoclonal proliferation of B cells, presumably arises from a background of chronic gastritis associated with *H. pylori*. These relatively innocuous tumors then undergo degeneration to high-grade lymphoma, which is the usual variety seen by the surgeon. Remarkably, when the *H. pylori* is eradicated and the gastritis improves, the low-grade MALT lymphoma often disappears. Thus, low-grade MALT lymphoma is not a surgical lesion. Careful follow-up is necessary particularly in those lesions with a t(11:18) translocation, thought to be a risk factor for a more aggressive MALT lesion. If low-grade lymphoma persists after *H. pylori* eradication, radiation should be considered for disease clinically confined to the stomach (stage I), while chemotherapy with or without radiation is used for more advanced lesions (Fig. 26-58).

Patients with high-grade gastric lymphoma require aggressive oncologic treatment for cure and present with many of the same symptoms as gastric cancer patients. However, systemic symptoms such as fever, weight loss, and night sweats occur in about 50% of patients with gastric lymphoma. The tumors may bleed and/or obstruct. Lymphadenopathy and/or organomegaly suggest systemic disease. Diagnosis is by endoscopy and biopsy. Much of the tumor may be submucosal, and an assiduous attempt at biopsy is necessary. Primary lymphoma is usually nodular with enlarged gastric folds. A diffusely infiltrative process akin to linitis plastica is more suggestive of secondary gastric involvement by lymphoma. A diligent search for extragastric disease is necessary before the diagnosis of localized primary gastric lymphoma is made. This includes EUS; CT scanning of the chest, abdomen, and pelvis; and bone marrow biopsy. Most patients with high-grade gastric lymphoma are currently treated with chemotherapy and radiation, without surgical resection. Treatment-related perforation or bleeding is unusual but recognized. For disease limited to the stomach and regional nodes, radical subtotal D2 gastrectomy may be performed, especially for bulky tumors with bleeding and/or obstruction. Palliative gastrectomy for tumor complications also has a role. Certainly, a multidisciplinary team should be involved with the treatment plan for patients with primary gastric lymphoma.

6▶

Gastrointestinal Stromal Tumor

GISTs arise from interstitial cells of Cajal (ICC) and are distinct from leiomyoma and leiomyosarcoma, which arise from smooth muscle.[108,109] Prognosis in patients with GIST tumors depends mostly on tumor size and mitotic count, and metastasis, when it occurs, is typically by the hematogenous route. Any lesion >1 cm can behave in a malignant fashion and may recur. Thus, all GISTs are best resected along with a margin of normal tissue. Almost all GISTs (and almost no smooth muscle tumors) express c-KIT (CD117) or the related PDGF receptor A, as well as CD34; almost all smooth muscle tumors (and almost no GISTs) express actin and desmin. These markers can often be detected on specimens obtained by fine-needle aspiration[110] and are useful in differentiating between GIST and smooth muscle tumor histopathologically. Lesions that are definitively leiomyoma by current histopathologic criteria are adequately treated by enucleation. Lesions that are definitively GIST or leiomyosarcoma are best treated by resection with negative margins. Most equivocal lesions should be resected provided that the patient is a reasonable operative risk.

Two-thirds of all GISTs occur in the stomach. Epithelial cell stromal GIST is the most common cell type arising in the stomach, and cellular spindle type is the next most common. The glomus tumor type is seen only in the stomach.

GISTs are submucosal tumors that are slow growing. Smaller lesions are usually found incidentally, although they occasionally may ulcerate and cause impressive bleeding. Larger lesions generally produce symptoms of weight loss, abdominal pain, fullness, early satiety, and bleeding. An abdominal mass may be palpable. Metastasis is by the hematogenous route, often to liver and/or lung, although positive lymph nodes are occasionally seen in resected specimens.

Diagnosis is by endoscopy and biopsy, although the interpretation of the latter may be problematic. EUS may be helpful, but symptomatic tumors and tumors >1 cm in size should be removed. Metastatic work-up entails CT of the chest, abdomen, and pelvis (chest X-ray may suffice in lieu of CT of the chest). Most gastric GISTs occur in the body of the stomach, but they also can occur in the fundus or antrum. They are almost always solitary. Wedge resection with clear margins is adequate surgical treatment. True invasion of adjacent structures by the primary tumor is evidence of malignancy. If safe, en bloc resection of involved surrounding organs is appropriate to remove all tumor when the primary is large and invasive. Five-year survival

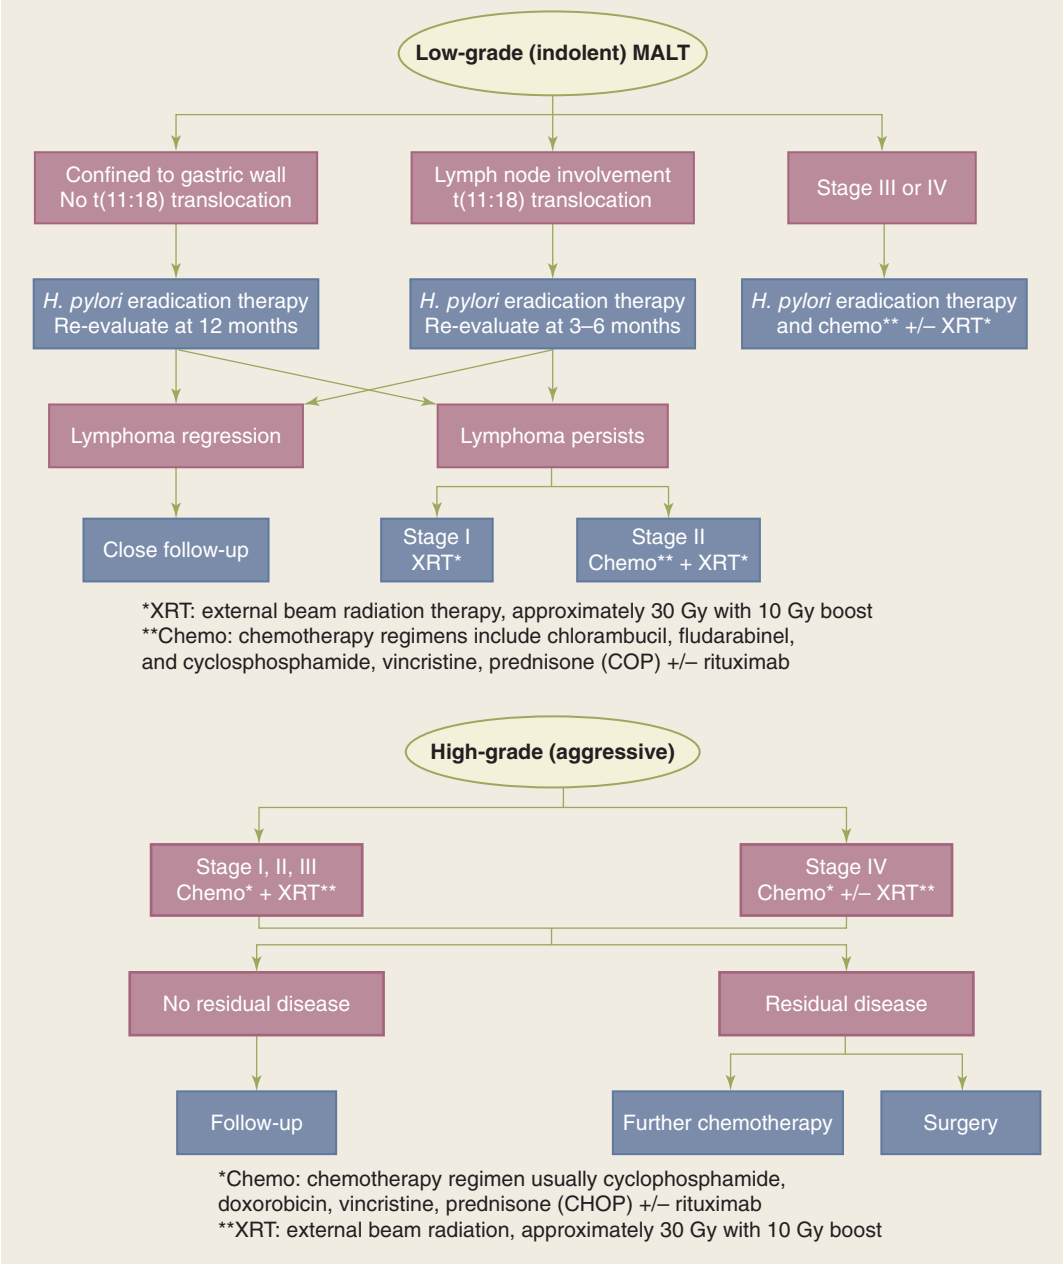

Figure 26-58. Algorithm for the treatment of gastric lymphoma. MALT = mucosa-associated lymphoid tissue. (*Reproduced with permission from Yoon SS, Coit DG, Portlock CS, et al: The diminishing role of surgery in the treatment of gastric lymphoma.* Ann Surg *240:28, 2004.*)

following resection for GIST is about 50%. Most patients with low-grade lesions are cured (80% 5-year survival), but most patients with high-grade lesions are not (30% 5-year survival).

According to the tumor size and mitotic count,[110A] the risk of aggressive behavior was classified into four groups. Very low risk was defined as <2 cm and <5/50 HPF (high-power field) and low risk was defined as 2 to 5cm and <5/50 cm. Intermediate risk was defined as <5 cm and 6 to 10/50 HPF or 5 to 10cm and >5/50 HPF. And high risk was defined as >5 cm and >5/50HPF, >10cm with any mitotic rate or >10/50/ HPF with any size. It was known that the risk of recurrence differs by the primary site of the tumor. Recently, new classification based on tumor location, size, and mitotic rate has been used to evaluate the risk of recurrence and metastasis.[110B]

GISTs are usually positive for the protooncogene, *c-kit*, a characteristic shared with the ICC. Imatinib (Gleevec), a chemotherapeutic agent that blocks the activity of the tyrosine kinase product of c-*kit*, yields excellent results in many patients with metastatic or unresectable GIST. Up to 50% of treated patients develop resistance to imatinib by 2 years, and several newer agents show promise for patients with refractory disease. The efficacy of imatinib as adjuvant therapy for high risk patients has been demonstrated in large clinical trials.[110C,110D] According to the NCCN guidelines for soft tissue sarcoma (version 2, 2012), the administration of imatinib was recommended in high risk groups as an adjuvant therapy.[110E] An algorithm for the treatment of patients with GIST is shown in Fig. 26-59.

Gastric Carcinoid Tumors[111–113]

Compared to midgut and hindgut locations, carcinoid tumors of the stomach are rather unusual. Gastric carcinoids comprise about 1% of all carcinoid tumors and less than 2% of gastric neoplasms. They arise from gastric enterochromaffin-like (ECL) cells and some have malignant potential. The apparent

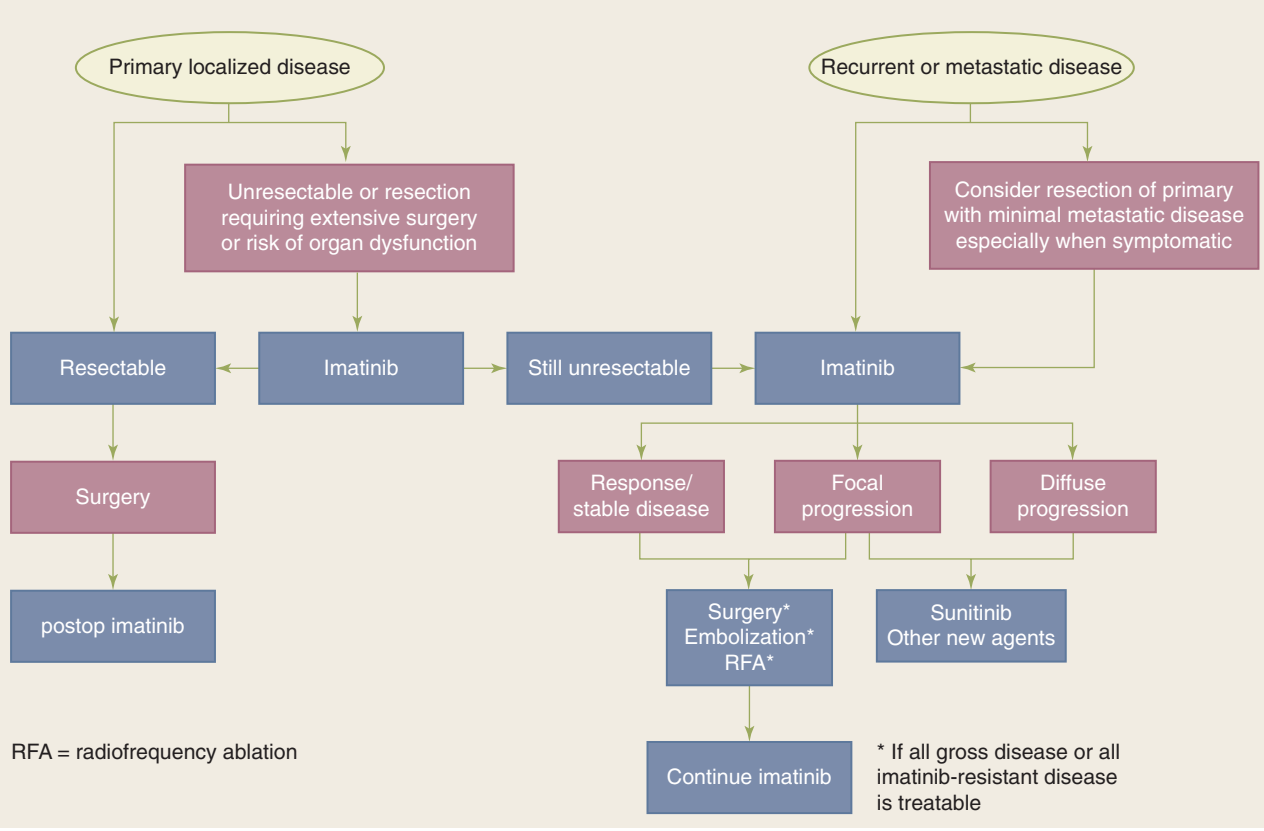

Figure 26-59. Algorithm for the treatment of gastrointestinal stromal tumor. (*Reproduced with permission from Gold JS, DeMatteo RP: Combined surgical and molecular therapy: The gastrointestinal stromal tumor model.* Ann Surg *244:176, 2006.*)

incidence of gastric carcinoids is increasing, perhaps related to the more common use of upper endoscopy and/or the increasing use of acid suppressive medication. The latter may cause hypergastrinemia, and gastrin has a recognized trophic effect on gastric ECL cells. Gastric carcinoid is equivalent to neuroendocrine tumor (NET) or well-differentiated neuroendocrine tumor/carcinoma according to WHO classification.

Gastric carcinoids are classified into one of three different types. Type I is the most common type of gastric carcinoid, accounting for about 75% of patients. Type I carcinoids occur in patients with chronic hypergastrinemia secondary to pernicious anemia or chronic atrophic gastritis. These lesions occur more frequently in women, are often multiple and small, and have low malignant potential (<5% metastasize). The role of long-term acid suppression with resultant hypergastrinemia in the pathogenesis of type I gastric carcinoids is unclear.

Type II gastric carcinoids are associated with MEN1 and ZES. These lesions also tend to be small and multiple, but have a somewhat higher malignant potential than type I lesions (10% metastasize). Type II gastric carcinoids are more strongly associated with MEN1; they are quite uncommon in patients with sporadic ZES without MEN1. Gastric acid hypersecretion, hypergastrinemia, and gastric carcinoid imply gastrinoma until proven otherwise.

Type III gastric carcinoids are sporadic tumors. They are most often solitary (usually >2 cm) and occur more commonly in men. They are not associated with hypergastrinemia and biopsy shows a heterogeneous cell population. Most patients have nodal or distant metastases at the time of diagnosis, and some present with symptoms of carcinoid syndrome.

Gastric carcinoids are usually diagnosed with endoscopy and biopsy. Some tumors are submucosal and may be quite small. They are often confused with heterotopic pancreas or small leiomyomas. Biopsy may be difficult because of the submucosal location, and EUS can be helpful in defining the size and depth of the lesion. Plasma chromogranin A levels are elevated in patients with gastric carcinoid. CT scan and octreotide scan are useful for staging.

Gastric carcinoids should be resected. Small lesions confined to the mucosa (typically type I or type II lesions) may be treated endoscopically with EMR if there are only a few lesions (<5) and if margins are histologically negative. Careful follow-up is necessary. Larger lesions should be removed by D1 or D2 gastrectomy. Survival is excellent for node-negative patients (>90% 5-year survival); node-positive patients have a 50% 5-year survival. Gastrinoma should be resected if located in patients with type II carcinoid. The 5-year survival for patients with type I gastric carcinoid is close to 100%; for patients with type III lesions, the 5-year survival is less than 50%. Somatostatin analogue treatment is useful in controlling the symptoms of carcinoid syndrome but apparently does not prolong survival in patients with metastatic gastric carcinoid. Surgical debulking may have a role in selected patients with metastatic disease. Because somatostatin has an antiproliferative effect on gastric ECL cells, there may be a possible primary treatment role for octreotide in poor-risk surgical patients with gastric carcinoid.

7▶

BENIGN GASTRIC NEOPLASMS

Leiomyoma

The typical leiomyoma is submucosal and firm. If ulcerated, it has an umbilicated appearance and may bleed. Histologically, these

lesions appear to be of smooth muscle origin. Lesions <2 cm are usually asymptomatic and benign. Larger lesions have greater malignant potential and a greater likelihood to cause symptoms such as bleeding, obstruction, or pain. Asymptomatic lesions <2 cm may be carefully observed or enucleated if fine-needle aspiration and immune markers confirm smooth muscle tumor; larger lesions and symptomatic lesions should be removed by wedge resection (often possible laparoscopically). When lesions thought to be leiomyoma are observed rather than resected, the patient should be made aware of their presence and the small possibility for malignancy.

Lipoma

Lipomas are benign submucosal fatty tumors that are usually asymptomatic, found incidentally on upper GI series or EGD. Endoscopically, they have a characteristic appearance; there also is a characteristic appearance on EUS. Excision is unnecessary unless the patient is symptomatic.

Gastric Motility Disorders

Gastric motility disorders include delayed gastric emptying (gastroparesis), rapid gastric emptying, and motor and sensory abnormalities (e.g., functional dyspepsia). Surgically relevant secondary disorders of gastric motility (e.g., dumping, gastric stasis, and Roux syndrome) are discussed under Postgastrectomy Problems. Gastroparesis is the most surgically relevant primary disorder of gastric motility.[114,115]

Most patients with primary gastroparesis present with nausea, vomiting, bloating, early satiety, and/or abdominal pain. Eighty percent of these patients are women; some are diabetic. Postprandial vomiting significantly complicates the management of blood glucose in the latter group, predisposing to hypoglycemia following preprandial insulin. In patients with gastroparesis, it is important to rule out mechanical gastric outlet obstruction, and small-bowel obstruction. An upper GI series may suggest slow gastric emptying and relative atony, or it may be normal. EGD may show bezoars or retained food but is frequently normal. Gastric emptying scintigraphy shows delayed solid emptying, and often delayed liquid emptying. Gastroparesis can be a manifestation of a variety of problems (Table 26-22). Medical treatment includes promotility agents, antiemetics, and, perhaps, botulinum injection into the pylorus.

If the diabetic gastroparetic patient is not a candidate for pancreas transplant, both gastrostomy (for decompression) and jejunostomy tubes (for feeding and prevention of hypoglycemia) can be effective. Other surgical options include implantation of a gastric pacemaker, and gastric resection.[115A] Generally, gastric resection should be done only after other therapeutic options have been exhausted.

Massive Upper Gastrointestinal Bleeding

Although there have been arbitrary definitions of "massive" upper GI bleeding put forth, perhaps the most practical definition in the current era would be acute bleeding proximal to the ligament of Treitz, which requires blood transfusion. In multiple series, the stomach and proximal duodenum is by far the most common source of pathology associated with this diagnosis.[65,116] The most common causes of acute GI bleeding in emergency room or hospitalized patients are peptic ulcer, gastritis, Mallory-Weiss syndrome, and esophagogastric varices. Less common causes include benign or malignant neoplasm, angiodysplasia, Dieulafoy's lesion, portal gastropathy, Ménétrier's disease, and watermelon stomach. Arterioenteric fistula should always be considered in the patient who has an aortic graft or who has undergone repair of a visceral artery aneurysm.

The most important issues in the early hospital management of patients with acute upper GI bleeding are resuscitation and risk stratification. Large-bore IV access and Foley catheterization is accomplished, and nasogastric intubation is considered. Risk stratification is essentially accomplished by answering the following questions:

a. What is the magnitude and acuity of the hemorrhage? Hypotension, tachycardia, oliguria, low hematocrit, pallor, altered mentation, and/or hematemesis suggest a large blood loss that has occurred over a short period of time. This is a high-risk situation.
b. Does the patient have significant chronic disease, particularly lung, liver, kidney, and/or heart disease, which compromises physiologic reserve? If yes, this is a high-risk situation.
c. Is the patient anticoagulated, or immunosuppressed? If yes, this is a high-risk situation.
d. On endoscopy, is the patient bleeding from varices, or is there active bleeding, or is there a visible vessel, or is there a deep ulcer overlying a large vessel (e.g., posterior duodenal ulcer overlying the gastroduodenal artery)? Could the patient be bleeding from an Arterio enteric fistula? If yes, this is a high-risk situation.

If judged to be low risk, most patients will stop bleeding with supportive treatment and IV PPI. Selected patients may be discharged from the emergency room and managed on an outpatient basis.

If the patient is judged to be high risk based on one or more of the questions previously listed, then the following should be done immediately:

1. Type and cross-match for transfusion of blood products.
2. Admit to ICU or monitored bed in specialized unit.
3. Consult surgeon.
4. Consult gastroenterologist.
5. Start continuous infusion of PPI.
6. Perform upper endoscopy within 12 hours, after resuscitation and correction of coagulopathy. Endoscopic hemostasis should be considered in most high-risk patients with acute upper GI bleeding.

Although the surgeon should be involved early in the hospital course of all high-risk patients with acute upper GI bleeding, most of these patients will be adequately managed without operation. Mucosal lesions can usually be controlled with endoscopic hemotherapy and medical management. Occasionally, arteriography can be helpful.[117] Operation for bleeding ulcer is discussed previously (see Operation for Bleeding Peptic Ulcer and Fig. 26-43).

Isolated Gastric Varices

Isolated gastric varices are those that occur in the absence of esophageal varices and are classified as type I (fundic) or type II (distal to fundus including proximal duodenum).[118] The presence of isolated gastric varices is usually associated with portal hyper-tension or splenic vein thrombosis. Although there is a significant bleeding risk from isolated gastric varices on long-term follow-up, there is no indication for the routine application of prophylactic measures.

Patients with acute upper GI bleeding from isolated gastric varices should be considered high risk. Although data are limited, octreotide and/or vasopressin infusion may decease bleeding, if tolerated. Balloon tamponade with a Sengstaken-Blakemore tube may provide temporary control of exsanguinating hemorrhage from type isolated gastric varices, but if this is used, endotracheal intubation for airway protection is prudent. Endoscopic treatment with sclerotherapy or varix ligation is less successful than in esophageal varices, but should be considered. Interventional radiology should be consulted and balloon occluded retrograde transvenous obliteration considered. A transjugular intrahepatic portosystemic shunt may be useful if there is nonsegmental portal hypertension. If the patient has splenic vein thrombosis and left-sided (sinistral) or segmental portal hypertension, splenectomy is quite effective in controlling bleeding from isolated gastric varices. The operative mortality is 5%. Liver transplantation should always be considered in the cirrhotic patient.

Hypertrophic Gastropathy (Ménétrier's Disease)

There are two clinical syndromes characterized by epithelial hyperplasia and giant gastric folds: ZES and Ménétrier's disease. The latter is characteristically associated with protein-losing gastropathy and hypochlorhydria. There are large rugal folds in the proximal stomach, and the antrum is usually spared. Mucosal biopsy shows diffuse hyperplasia of the surface mucus-secreting cells and usually decreased parietal cells (Fig. 26-60). It has recently been suggested that Ménétrier's disease is caused by local overexpression of transforming growth factor alpha in the gastric mucosa, which stimulates the epidermal growth factor receptor, a receptor tyrosine kinase, on gastric SECs. This results in the selective expansion of surface mucous cells in the gastric body and fundus. A few patients with this unusual disease have been successfully treated with the epidermal growth factor receptor blocking monoclonal antibody cetuximab.[119]

Most patients with Ménétrier's disease are middle-aged men who present with epigastric pain, weight loss, diarrhea, and hypoproteinemia. There may be an increased risk of gastric cancer. Sometimes, the disease regresses spontaneously. Gastric resection may be indicated for bleeding, severe hypoproteinemia, or cancer.

Watermelon Stomach (Gastric Antral Vascular Ectasia)

The parallel red stripes atop the mucosal folds of the distal stomach give this rare entity its sobriquet. Histologically, gastric antral vascular ectasia (GAVE) is characterized by dilated mucosal blood vessels that often contain thrombi, in the lamina propria. Mucosal fibromuscular hyperplasia and hyalinization often are present (Fig. 26-61). The histologic appearance can resemble portal hypertensive gastropathy, but the latter usually affects the proximal stomach, whereas watermelon stomach predominantly affects the distal stomach. Beta blockers and nitrates, useful in the treatment of portal hypertensive gastropathy, are ineffective in patients with gastric antral vascular ectasia. Patients with GAVE are usually elderly women with chronic GI blood loss requiring transfusion. Most have an associated autoimmune connective tissue disorder, and at least 25% have chronic liver disease. Nonsurgical treatment options include estrogen and progesterone, and endoscopic treatment with the neodymium yttrium-aluminum garnet (Nd:YAG) laser or argon plasma coagulator.[120] Antrectomy may be required to control blood loss, and this operation is quite effective but carries increased morbidity in this elderly patient group. Patients with portal hyper-tension and antral vascular ectasia should be considered for transjugular intrahepatic portosystemic shunt (TIPSS).

Dieulafoy's Lesion

Dieulafoy's lesion is a congenital arteriovenous malformation characterized by an unusually large tortuous submucosal artery. If this artery is eroded, impressive pulsatile bleeding may occur. To the endoscopist or surgeon, this appears as a stream of arterial blood emanating from what appears grossly to be a normal gastric mucosa. The lesion typically occurs in middle-aged or elderly men and may be more common in patients with liver disease.[121] Patients typically present with upper GI bleeding, which may be intermittent, and endoscopy can miss the lesion if it is not actively bleeding. Treatment options include endoscopic hemostatic therapy, angiographic embolization, or operation. At surgery, the lesion may be oversewn or resected.

Bezoars/Diverticula

Bezoars are concretions of indigestible matter that accumulate in the stomach. Trichobezoars, composed of hair, occur most commonly in young women who swallow their hair (Fig. 26-62). Phytobezoars are composed of vegetable matter and, in the United States, are usually seen in association with gastroparesis or gastric outlet obstruction. They also are associated with persimmon ingestion. Most commonly, bezoars produce obstructive symptoms, but they may cause ulceration and bleeding. Diagnosis is suggested by upper GI series and confirmed by endoscopy. Treatment options include enzyme therapy (papain, cellulase, or acetylcysteine), endoscopic disruption and removal, or surgical removal.

Gastric diverticula are usually solitary and may be congenital or acquired. Congenital diverticula are true diverticula and contain a full coat of muscularis propria, whereas acquired diverticula (perhaps caused by pulsion) usually have a negligible outer muscle layer. Most gastric diverticula occur in the posterior cardia or fundus (Fig. 26-63) and are usually asymptomatic. However, they can become inflamed and may produce pain or bleeding. Perforation is rare. Asymptomatic diverticula do not require treatment, but symptomatic lesions should be removed. This can often be done laparoscopically.

Foreign Bodies

Ingested foreign bodies are usually asymptomatic. Removal of sharp or large objects should be considered. This can usually be done endoscopically, with an overtube technique.

Recognized dangers include aspiration of the foreign body during removal, and rupture of drug-containing bags in "body packers." Both complications can be fatal. Surgical removal is recommended in body packers, and in patients with large jagged objects. Corrosive objects (e.g., watch batteries) should be removed promptly.

Mallory-Weiss Syndrome

The Mallory-Weiss lesion is a longitudinal tear in the mucosa of the GE junction.[122] It is presumably caused by forceful vomiting and/or retching, and is commonly seen in alcoholics. It presents with upper GI bleeding, often with hematemesis. Endoscopy confirms the diagnosis and may be useful in controlling the bleeding, but 90% of patients stop bleeding spontaneously. Other options to control the bleeding include balloon tamponade, angiographic embolization, or selective infusion of vasopressin, systemic vasopressin, and operation. Surgical treatment consists of oversewing the bleeding lesion through a long gastrostomy.

Volvulus

Gastric volvulus is a twist of the stomach that usually occurs in association with a large hiatal hernia. It also can occur in patients with an unusually mobile stomach without hiatal hernia. Typically, the stomach twists along its long axis (organoaxial volvulus), and the greater curvature flips up (Fig. 26-64C). If the stomach twists around the transverse axis, it is called *mesentero-axial rotation* (Fig. 26-64A and Fig. 26-64B). Often, volvulus is a chronic condition that can be surprisingly asymptomatic. In these instances, expectant nonoperative management is typically advised, especially in the elderly. The risk of strangulation and infarction has been overestimated in asymptomatic patients. Symptomatic patients should be considered for operation, especially if the symptoms are severe and/or progressive. Patients may present with symptoms of pain and pressure related to the intermittently distending and poorly emptying twisted stomach. Pressure on the lung may produce dyspnea, pressure on the pericardium may produce palpitations, and pressure on the esophagus may produce dysphagia. Symptoms are often relieved with vomiting or passage of a nasogastric tube. Gastric infarction is a surgical emergency, and the patient can be moribund. Gastric necrosis may be extensive or focal. With or without gastropexy, elective operation for gastric volvulus usually involves reduction of the stomach and repair of hiatal hernia. Gastropexy alone may be considered for high-risk patients since it can nearly always be performed laparoscopically and may be surprisingly effective in relieving mechanical symptoms.

GASTROSTOMY

A gastrostomy is performed either for alimentation or for gastric drainage/decompression. Gastrostomy may be done percutaneously, laparoscopically, or via open technique.[123,124] Currently, percutaneous endoscopic gastrostomy is the most common method used. The open techniques include the Stamm method (Fig. 26-65), the Witzel method (Fig. 26-66), and the Janeway method (Fig. 26-67). The last method is meant to create a permanent stoma that can be intubated as needed, but does not drain spontaneously. The Janeway gastrostomy is more complicated than the other open techniques, and is rarely necessary. By far the most common surgical technique is the Stamm gastrostomy, which can be performed open or laparoscopically.

Complications of gastrostomy include infection, dislodgment, leakage with peritonitis, and aspiration pneumonia. Although gastrostomy tubes usually do prevent tense gastric dilatation, they may not adequately drain the stomach, especially when the patient is bedridden.

POSTGASTRECTOMY PROBLEMS[125,126]

Dumping Syndrome

Dumping is a phenomenon caused by the destruction or bypass of the pyloric sphincter.[127] However, other factors undoubtedly play a role because dumping can occur after operations that

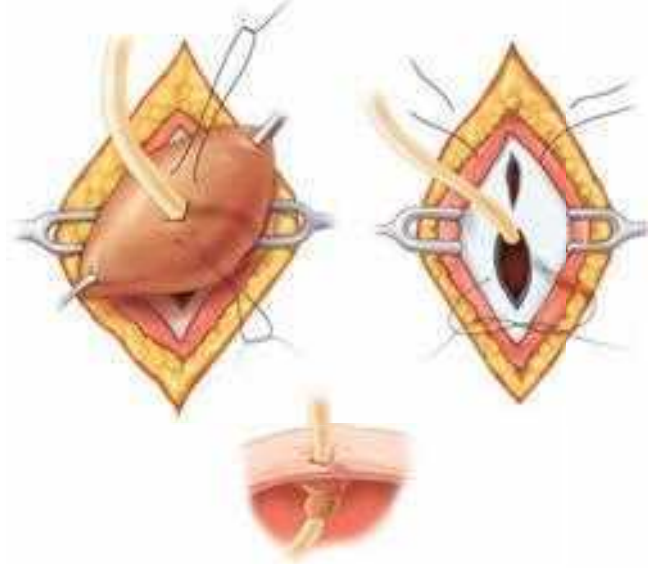

Figure 26-65. Stamm gastrostomy. *[Reproduced with permission from Tatum RP, Joehl RJ: Intubation of the stomach and small intestine, in Zuidema GD, Yeo CJ (eds):* Shackelford's Surgery of the Alimentary Tract, *5th ed., Vol. II. Philadelphia: Saunders, 2002, p 46.]*

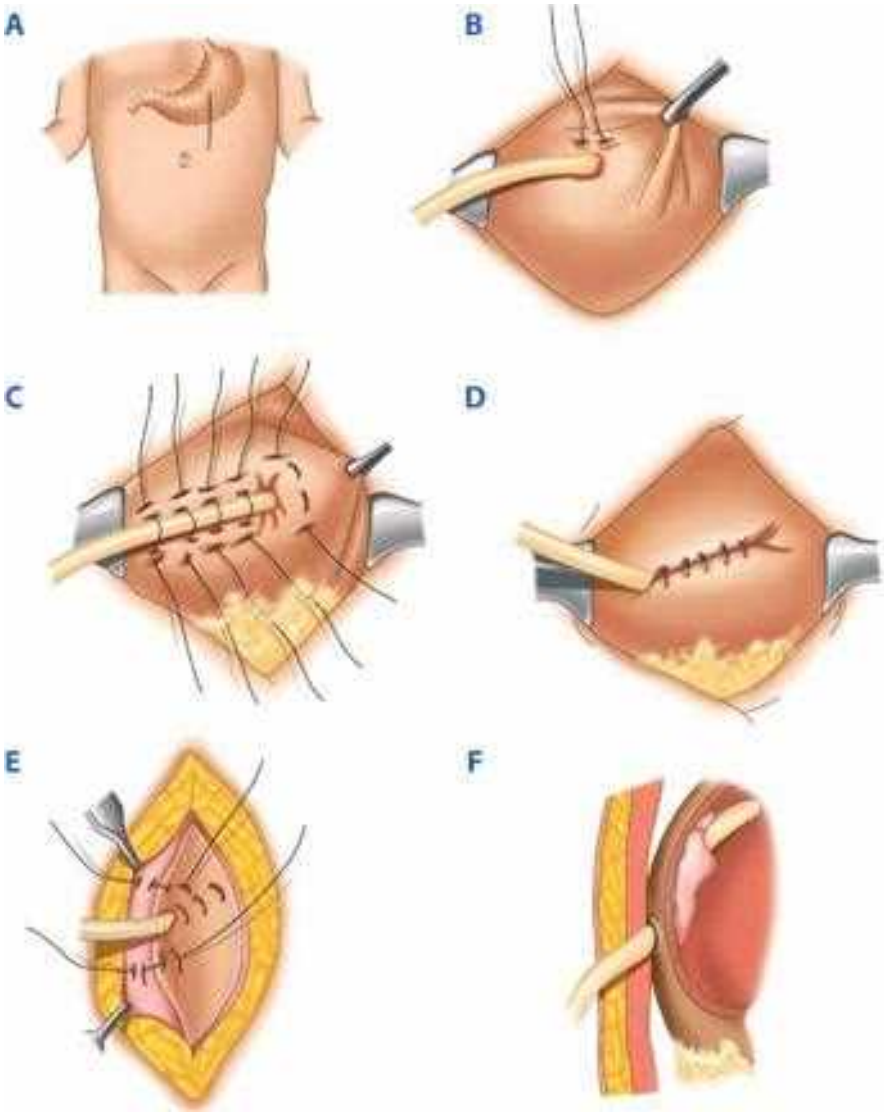

Figure 26-66. **A** through **F.** Witzel gastrostomy. *[Reproduced with permission from Tatum RP, Joehl RJ: Intubation of the stomach and small intestine, in Zuidema GD, Yeo CJ* (*eds*)*:* Shackelford's Surgery of the Alimentary Tract, *5th ed., Vol. II. Philadelphia: Saunders, 2002, p 46.]*

preserve the pylorus, such as parietal cell vagotomy. The appropriate stimulus can provoke dumping symptoms, even in some patients who have not undergone surgery. Clinically significant dumping occurs in 5% to 10% of patients after pyloroplasty, pyloromyotomy, or distal gastrectomy, and consists of a constellation of postprandial symptoms ranging in severity from annoying to disabling. The symptoms are thought to be the result of the abrupt delivery of a hyperosmolar load into the small bowel due to ablation of the pylorus or decreased gastric compliance. Typically, 15 to 30 minutes after a meal, the patient becomes diaphoretic, weak, light-headed, and tachycardic. These symptoms may be ameliorated by recumbence or saline infusion. Crampy abdominal pain is not uncommon and diarrhea often follows. This is referred to as *early dumping*, and should be distinguished from postprandial (reactive) hypoglycemia, also called *late dumping*, which usually occurs later (2–3 hours following a meal), and is relieved by the administration of sugar. A variety of hormonal aberrations have been observed in early dumping, including increased VIP, CCK, neurotensin, peripheral hormone peptide YY, renin-angiotensin-aldosterone, and decreased atrial natriuretic peptide. Late dumping is associated with hypoglycemia and hyperinsulinemia.

The medical therapy for the dumping syndrome consists of dietary management and somatostatin analogue (octreotide). Often, symptoms improve if the patient avoids liquids during meals. Hyperosmolar liquids (e.g., milk shakes) may be particularly troublesome. There is some evidence that adding dietary fiber compounds at mealtime may improve the syndrome. If dietary manipulation fails, the patient is started on octreotide, 100 µg subcutaneously twice daily. This can be increased up to 500 µg twice daily if necessary. The long-acting depot octreotide preparation is useful. Octreotide not only ameliorates the abnormal hormonal pattern seen in patients with dumping symptoms, but also promotes restoration of a fasting motility pattern in the small intestine (i.e., restoration of the MMC). The α-glucosidase inhibitor acarbose may be particularly helpful in ameliorating the symptoms of late dumping.

Only a very small percentage of patients with dumping symptoms ultimately require surgery. Most patients improve with time (months and even years), dietary management, and medication.

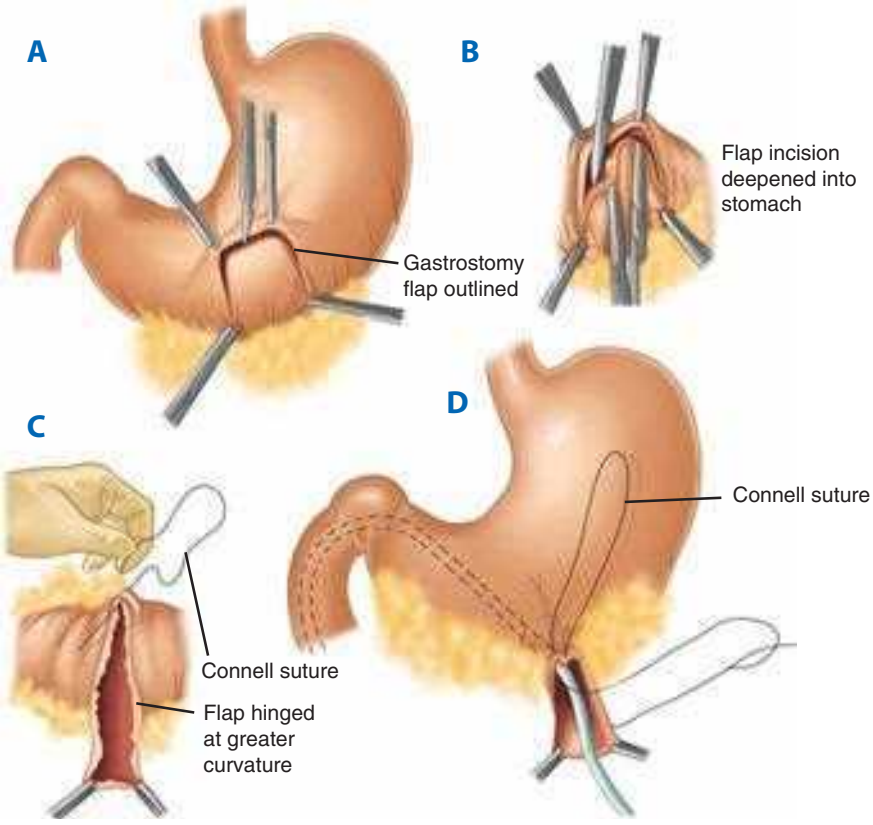

Figure 26-67. A through **D.** Janeway gastrostomy. *[Reproduced with permission from Tatum RP, Joehl RJ: Intubation of the stomach and small intestine, in Zuidema GD, Yeo CJ (eds):* Shackelford's Surgery of the Alimentary Tract, *5th ed., Vol. II. Philadelphia: Saunders, 2002, p 46.]*

Therefore, the surgeon should not rush to reoperate on the patient with dumping symptoms. Multidisciplinary nonsurgical management must be optimized first. Before reoperation, a period of inhospital observation is useful to define the severity of the patient's symptoms, and patient compliance with prescribed dietary and medical therapy.

The results of remedial operation for dumping are variable and unpredictable. There are a variety of surgical approaches, none of which work consistently well. Additionally, there is not a great deal of experience reported in the literature with any of these methods. Long-term follow-up is rare. Patients with disabling refractory dumping after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that the pyloric channel is open endoscopically. The reversed intestinal segment is rarely used today—and rightly so. This operation interposes a 10-cm reversed segment of intestine between the stomach and the proximal small bowel. This slows gastric emptying, but often leads to obstruction, requiring reoperation. Isoperistaltic interposition (Henley loop) has not been successful in ameliorating severe dumping over the long term. The Roux-en-Y gastrojejunostomy is associated with delayed gastric emptying, probably on the basis of disordered motility in the Roux limb. Taking advantage of this disordered physiology, surgeons have used this operation successfully in the management of the dumping syndrome. Although this is probably the procedure of choice in the small group of patients requiring operation for severe dumping following gastric resection, gastric stasis may result, particularly if a large gastric remnant is left. In the presence of significant gastric acid secretion, marginal ulceration is common after both jejunal interposition and Roux-en-Y procedures; thus concomitant vagotomy and hemigastrectomy should be considered. The theoretical possibility of treating postpyloroplasty dumping with a Roux-en-Y to the proximal duodenum (the duodenal switch, a potentially reversible operation) has not yet been reported (Fig. 26-68). Because pyloric ablation seems to be the dominant factor in the etiology of dumping, it is not surprising that conversion of Billroth II to Billroth I anastomosis has not been successful in the treatment of dumping.

Diarrhea

Diarrhea following gastric surgery may be the result of truncal vagotomy, dumping, or malabsorption. Truncal vagotomy is associated with clinically significant diarrhea in 5% to 10% of patients. It occurs soon after surgery and usually is not associated with other symptoms, a fact that helps to distinguish it from dumping. The diarrhea may be a daily occurrence, or there may be significant periods of relatively normal bowel function. The symptoms tend to improve over the months and years after the index operation. The cause of postvagotomy diarrhea is unclear. Possible mechanisms include intestinal dysmotility and accelerated transit, bile acid malabsorption, rapid gastric emptying, and bacterial overgrowth. The latter problem is facilitated by decreased gastric acid secretion and (even small) blind loops. Although bacterial overgrowth can be confirmed with the hydrogen breath test, a simpler test is an empirical trial of oral antibiotics. Some patients with postvagotomy diarrhea respond to cholestyramine, while in others codeine or loperamide may be useful. Octreotide should also be tried. Another theoretical cause of diarrhea following gastric surgery is fat malabsorption due to acid inactivation of pancreatic enzymes or poorly coordinated mixing of food and digestive juices. This can be confirmed with a qualitative test for fecal fat and treated with acid suppression. Postvagotomy diarrhea usually does not respond to treatment with pancreatic enzymes. In the rare patient who is debilitated by postvagotomy diarrhea unresponsive to medical management, operation might be considered but outcomes can be problematic. The operation of choice is probably a 10-cm reversed jejunal interposition placed in continuity 100 cm distal to the ligament of Treitz. Another option is the onlay antiperistaltic distal ileal graft. Both operations can cause obstructive symptoms and/or bacterial overgrowth.[127B]

Gastric Stasis[128,129]

Gastric stasis following surgery on the stomach may be due to a problem with gastric motor function or caused by an obstruction. The gastric motility abnormality could have been preexisting and unrecognized by the operating surgeon. Alternatively, it may be secondary to deliberate or unintentional vagotomy, or resection of the dominant gastric pacemaker. An obstruction may be mechanical (e.g., anastomotic stricture, efferent limb kink from adhesions or constricting mesocolon, or a proximal small-bowel obstruction) or functional (e.g., retrograde peristalsis in a Roux limb). Gastric stasis presents with vomiting (often of undigested food), bloating, epigastric pain, and weight loss.

The evaluation of a patient with suspected postoperative gastric stasis includes EGD, upper GI and small bowel series, gastric emptying scan, and gastric motor testing. Endoscopy shows gastritis and retained food or bezoar. The anastomosis and efferent limb should be evaluated for stricture or narrowing. A dilated efferent limb suggests chronic stasis, either from a motor abnormality (e.g., Roux syndrome) or mechanical small bowel obstruction (e.g., chronic adhesion). If the problem is thought to be primarily a disorder of intrinsic motor function, newer techniques such as EGG and GI manometry should be considered, but chronic distal mechanical obstruction may result in disordered motility in the proximal organ confounding interpretation.

Once mechanical obstruction has been ruled out, medical treatment is successful in most cases of motor dysfunction following previous gastric surgery. This consists of dietary modification and promotility agents. Intermittent oral antibiotic therapy may be helpful in treating bacterial overgrowth, with its attendant symptoms of bloating, flatulence, and diarrhea.

Gastroparesis following V + D may be treated with subtotal gastrectomy but simple loop gastrojejunoctomy (GJ) should be tried if previous drainage was pyloroplasty. Billroth II anastomosis with Braun enteroenterostomy may be preferable to Roux-en-Y reconstruction after subtotal gastrectomy for gastric stasis but bile reflux can still occur. Regeneration of gastric stasis is often associated with persistent emptying problems that may subsequently require near-total or total gastrectomy, a nutritionally unattractive option. Delayed gastric emptying following ulcer surgery (V + D or V + A) may represent an anastomotic stricture (often due to recurrent ulcer), or proximal small bowel obstruction. The latter should be dealt with at reoperation. Recurrent ulcer usually responds to medical therapy with PPI and abstinence from NSAIDs, aspirin, and smoking. Endoscopic dilation is occasionally helpful. Gastroparesis following subtotal gastric resection is best treated with near-total (95%) or total gastric resection and Roux-en-Y reconstruction. If total gastrectomy is performed, a jejunal reservoir should be fashioned. Gastric pacing is promising, but it has not achieved widespread clinical usefulness in the treatment of postoperative gastric atony.

Bile Reflux Gastritis and Esophagitis

Most patients who have undergone ablation or resection of the pylorus have bile in the stomach on endoscopic examination, along with some degree of gross or microscopic gastric inflammation. Therefore, attributing postoperative symptoms to bile reflux is problematic because most asymptomatic patients have bile reflux as well. However, it is generally accepted that a small subset of patients have bile reflux gastritis, and present with nausea, bilious vomiting, and epigastric pain, and quantitative evidence of excess enterogastric reflux. Curiously, symptoms often develop months or years after the index operation. The differential diagnosis includes afferent or efferent loop obstruction, gastric stasis, and small-bowel obstruction. Plain abdominal X-rays, upper endoscopy, upper GI series, abdominal CT scan, and gastric emptying scans are helpful in evaluating these possibilities.

Dysfunction of the cardia is one of the causes of bile reflux esophagitis in patients after gastrectomy, Proximal subtotal gastrectomy with esophagoantral anastomosis should be avoided, and if limited resection of the GE junction is performed, the pylorus should be left intact.

Bile reflux may be quantified with gastric analysis or esophageal impedance testing or with scintigraphy (bile reflux scan). Typically, enterogastric reflux is greatest after Billroth II gastrectomy or gastrojejunostomy, and least after vagotomy and pyloroplasty, with Billroth I gastrectomy giving intermediate values. Patients who are well into the abnormal range of bile reflux may be considered for remedial surgery if symptoms are severe. Remedial surgery will eliminate the bile from the vomitus and may improve the patient's pain, but it is quite unusual to render these patients completely asymptomatic, especially if they are narcotic dependent.

Bile reflux gastritis after distal gastric resection may be treated by one of the following options: Roux-en-Y gastro jejunostomy; interposition of a 40-cm isoperistaltic jejunal loop between the gastric remnant and the duodenum (Henley loop); Billroth II gastro jejunostomy with Braun enteroenterostomy; total gastrectomy with Roux esophagojejunostomy. To avoid bile reflux into the stomach or the esophagus the Roux limb should be at least 45 cm long (preferably 60 cm). The Braun

enteroenterostomy should be placed a similar distance from the stomach. Excessively long limbs may be associated with obstruction or malabsorption. All operations can result in marginal ulceration on the jejunal side of the gastrojejunostomy, and thus are combined with a generous distal gastrectomy. If this has already been done at a previous operation, the Roux or Braun operations may be attractively simple. Whether truncal vagotomy is necessary is controversial in the current era of excellent acid-suppressing medications. The benefits of decreased acid secretion following vagotomy may be outweighed by problems with vagotomy-associated dysmotility in the gastric remnant. The Roux operation may be associated with an increased risk of emptying problems compared to the other two options, but controlled data are lacking. Patients with debilitating bile reflux after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that the pyloric channel is open.

Primary bile reflux gastritis (i.e., no previous operation) is rare, and may be treated with the duodenal switch operation, essentially an end-to-end Roux-en-Y to the proximal duodenum (see Fig. 26-68). The Achilles' heel of this operation is, not surprisingly, marginal ulceration. Thus, it should be combined with highly selective vagotomy, and/or long term acid suppressive medication.

Roux Syndrome

A subset of patients who have had distal gastrectomy and Roux-en-Y gastrojejunostomy will have great difficulty with gastric emptying in the absence of mechanical obstruction. These patients present with vomiting, epigastric pain, and weight loss. This clinical scenario has been labeled the *Roux syndrome*. Endoscopy may show retained food or bezoars, dilation of the gastric remnant, and/or dilation of the Roux limb. Anastomotic inflammation and stricture from marginal ulceration is a confounding finding. An upper GI series confirms these findings and may show delayed gastric emptying. This is better quantified by a gastric emptying scan, which always shows delayed solid emptying, and may show delayed liquid emptying as well.

GI motility testing shows abnormal motility in the Roux limb, with propulsive activity toward, rather than away from, the stomach.[130] Gastric motility also may be abnormal. Presumably, the disordered motility in the Roux limb occurs in all patients with this operation. Why only a subset develops the Roux syndrome is unclear. Perhaps those patients with disordered gastric motility are at most risk. The disorder seems to be more common in patients with a generous gastric remnant. Truncal vagotomy also has been implicated.

Medical treatment consists of promotility agents. Surgical treatment consists of paring down the gastric remnant. Care should be taken to preserve adequate blood supply to the new gastric pouch. If the left gastric artery is intact, a vertically oriented lesser curvature based pouch (similar to gastric bypass) with excision of the fundus can be considered. If gastric motility is severely disordered, 95% gastrectomy or total gastrectomy should be done. The Roux limb should be resected if it is dilated and flaccid, unless doing so puts the patient at risk for short bowel problems.

Gallstones

Gallstone formation following gastric surgery generally is thought to be secondary to vagal denervation of the gallbladder with attendant gallbladder dysmotility and stasis. Although prophylactic cholecystectomy is not justified with most gastric surgery, it should be considered if the gallbladder appears abnormal, especially if subsequent cholecystectomy is likely to be difficult. If preoperative evaluation reveals sludge or gallstones, or if intraoperative evaluation reveals stones, incidental cholecystectomy should be considered if it appears straightforward and the gastric operation has gone well.

Weight Loss

Weight loss is common in patients who have had a vagotomy and/or gastric resection. The degree of weight loss tends to parallel the magnitude of the operation. It may be insignificant in the large person, or devastating in the asthenic female. The surgeon should always consider the possible nutritional consequences before performing a gastric resection for benign disease in a thin patient. The causes of weight loss after gastric surgery generally fall into one of two categories: altered dietary intake or malabsorption. If a stool stain for fecal fat is negative, it is likely that decreased caloric intake is the cause. This is the most common cause of weight loss after gastric surgery, and may be due to small stomach syndrome, postoperative gastroparesis, anorexia due to loss of ghrelin, or self-imposed dietary modification because of dumping and/or diarrhea. Consultation with an experienced dietitian may prove invaluable.

Anemia

Iron absorption takes place primarily in the proximal GI tract, and is facilitated by an acidic environment. Intrinsic factor, essential for the enteric absorption of vitamin B_{12}, is made by the parietal cells of the stomach. Vitamin B_{12} bioavailability also is facilitated by an acidic environment.

With this as background, it is easy to understand why patients who have had a gastric operation are at risk for anemia. Anemia is the most common metabolic side effect in patients who have had a gastric bypass for morbid obesity. It also occurs in up to one third of patients who have had a vagotomy and/or gastric resection. Iron deficiency is the most common cause, but vitamin B_{12} or folate deficiency also occurs, even in patients who have not had total gastrectomy. Of course, patients who have had a total gastrectomy will all develop B_{12} deficiency without parenteral vitamin B_{12}. Gastric bypass patients should be given oral iron supplements, and monitored for iron, B_{12}, and folate deficiency. Patients who have had a vagotomy and/or gastrectomy should be similarly monitored with periodic determination of hematocrit, red blood cell indices, iron and transferrin levels, B_{12}, and folate levels. Marginal nutrient status should be corrected with oral and/or parenteral supplementation.

Bone Disease

Gastric surgery sometimes disturbs calcium and vitamin D metabolism. Calcium absorption occurs primarily in the duodenum, which is bypassed with gastrojejunostomy. Fat malabsorption may occur because of blind loop syndrome and bacterial overgrowth, or because of inefficient mixing of food and digestive enzymes. This can significantly affect the absorption of vitamin D, a fat-soluble vitamin. Both abnormalities of calcium and vitamin D metabolism can contribute to metabolic bone disease in patients following gastric surgery. The problems usually manifest as pain and/or fractures years after the index operation. Musculoskeletal symptoms should prompt a study of bone density. Dietary supplementation of calcium and vitamin D may be useful in preventing these complications. Routine skeletal monitoring of patients at high-risk (e.g., elderly males and females and postmenopausal females) may prove useful

in identifying skeletal deterioration that may be stopped with appropriate treatment.

LAPAROSCOPIC GASTRIC OPERATIONS

The most common laparoscopic gastric operations performed today are for GERD and obesity (see Chapter 27, The Surgical Management of Obesity). However, all of the gastric operations described here can be performed with minimally invasive techniques.[131] Some are technically difficult (e.g., partial or total gastric resection) or are of debatable merit. The operations described in this chapter that lend themselves most readily to minimally invasive techniques are highly selective vagotomy, vagotomy and gastrojejunostomy, and gastrostomy. Laparoscopic wedge resection often is possible for GI stromal tumors, lipomas, or gastric diverticula. Combined endoscopic and laparoscopic techniques occasionally are useful. Robotic gastric operations have been described, but have not yet been widely adopted.[132] Recently laparoscopic resection has been applied increasingly to patients with gastric cancer[133] with promising early results. Advances of laparoscopic instruments particularly energy sources have rendered extended lymph node dissection, including suprapancreatic lymph node dissection feasible. The ratio of D2 lymph node dissection has been increased gradually due to these advances and surgeon's experiences. Laparoscopy surgery has been widely performed in reconstruction in which the intestine is pulled out of the body through a small laparotomy wound.[133A] Recently, based on the improvement in anastomosis devices, pure laparoscopic surgery has also been used in which a series of procedures (lymphadenectomy, resection, and reconstruction) is completely performed intra-abdominally. Finally, diagnostic laparoscopy may prevent a futile laparotomy in some patients with gastric cancer.

While transgastric appendectomy and transgastric pancreatic necrosectomy appears safe and effective in selected patients in experienced centers, [134,135] the role of transgastric natural orifice endoscopic surgery has yet to be defined.

chapter 27

The Surgical Management of Obesity

Philip R. Schauer and Bruce Schirmer

INTRODUCTION

The surgical treatment of obesity has evolved to focus more specifically on the treatment of medical comorbidities associated with obesity than simply obesity itself. While bariatric surgery remains the overriding name of the field, the importance of treatment of the metabolic aspects of obesity has caused the primary society of surgeons treating these problems to rename the society the American Society for Metabolic and Bariatric Surgery (ASMBS). The nomenclature reflects the new emphasis of treating the metabolic consequences of obesity surgically. For the first time in the history of bariatric surgery, considerable effort is being devoted to scientifically study the physiologic mechanisms that help promote weight loss and, more importantly, resolution of comorbid medical problems associated with obesity.

Other major changes in the field of bariatric surgery in the United States since the last edition of this text include the introduction and rapid adoption worldwide of the laparoscopic sleeve gastrectomy and the simultaneous decreasing popularity of the laparoscopic adjustable gastric banding procedure.

The bariatric surgery community also has focused on improvement of outcomes and treatment for patients. The Centers of Excellence (COE) concept is an obvious example in the United States, but internationally, greater attention to outcomes and optimal results has been uniform. Improved outcomes have been documented in the literature, as have notable prospective randomized trials of medical versus surgical therapy. In the United States, a very recent study has challenged the concept that improved outcomes arise in COEs, citing data that Medicare patients had similar complication rates after surgery before and after the institution of a policy of surgery approval only at COEs.[1]

Extension of the indication for metabolic surgery to patients with class 1 obesity (body mass index, 30–35 kg/m^2) has been another development during the past few years.[2] The regulatory and scientific communities have been more willing to acknowledge the efficacy of metabolic surgery for treating comorbid medical problems, such as diabetes, than have the payors. Insurance coverage for appropriately qualified patients remains one of the biggest barriers to the access of appropriate care for patients suffering from morbid obesity.

Acknowledgement of morbid obesity as a disease has recently been adopted by the American Medical Association.[3] This comes years after the recognition by the Centers for Medicare and Medicaid Services (CMS) of obesity as a disease,[4] a reversal of the usual situation in which medical organizations are ahead of payors in recognition of such issues. Despite CMS recognition, regional administrators of CMS still raise unnecessary barriers and make access to care for morbidly obese patients difficult. Long waiting periods, denials for arbitrary issues, and mandatory 6- to 12-month "diet" plans with no requirement for actually losing weight continue to dominate the landscape of the patient seeking metabolic and bariatric surgery. What is also becoming as big an issue for other patients who have had bariatric surgery is denial of subsequent coverage for any emergency complications of the original operation if the patient's new insurance plan does not cover bariatric surgery. Although the new Affordable Care Act will potentially eliminate the inability to obtain insurance because of pre-existing conditions, there is no guarantee that patients who have had bariatric surgery will be afforded the same rights to payment for emergent and needed surgery should a subsequent complication arise.

Key Points

1. Surgical therapy is the only effective and proven therapy for patients with severe obesity (body mass index >40 kg/m^2). Bariatric operations prolong survival and resolve comorbid medical conditions associated with severe obesity.
2. During the years 1999 to 2003, called the Bariatric Revolution in the United States, the availability of a laparoscopic approach for bariatric operations caused major changes in the field, including a massive increase in the number of procedures performed as well as an increased publc and professional awareness and understanding of the field.
3. Bariatric operations involve either restriction of caloric intake or malabsorption of nutrients, or both. Long-term follow-up is essential before the merits of an operation can be confirmed.
4. Patients who develop a bowel obstruction after laparoscopic gastric bypass require surgical and not conservative therapy due to the high incidence of internal hernias and the potential for bowel infarction.
5. Malabsorptive operations are highly effective in producing durable weight loss but have considerable nutritional side effects. Patients undergoing such procedures require complete follow-up and must take appropriate nutritional supplements.
6. The Roux-en-Y gastric bypass is the most commonly performed bariatric procedure, whereas the sleeve gastrectomy is the most rapidly increasing procedure worldwide.
7. All bariatric operations are tools that serve to allow the patient to lose weight, become healthier, and improve their quality of life. These changes are only maintained long-term if the patient permanently adopts the new eating patterns and exercise habits that are taught and expected in the early year(s) after surgery.
8. Bariatric surgery is also metabolic surgery, treating the varied metabolic consequences of the comorbid diseases arising from severe obesity. Some operations are particularly effective treatments for such metabolic consequences, such as gastric bypass for type 2 diabetes.

The merger of the COE systems of the ASMBS and the American College of Surgeons (ACS) has been a major positive event in recent years as well. Thanks to the leadership of Robin Blackwell, M.D., ASMBS President from 2011 to 2012, supported by the ASMBS Executive Council, the ASMBS took the initiative to merge with the ACS to create a single uniform system acceptable to both groups and clearly more authoritative due to its singular position. The ACS, to its credit, provided large fiscal and human resources to support the merger and adoption of a single COE system. Since the merger, the incorporation of virtually all the centers in the two systems has occurred under one new system. Outcomes, as reported for review by the oversight committee, are better than ever. Our patients have thus been well served.

THE DISEASE OF OBESITY

Obesity is the second leading cause of preventable death in the United States, currently outdone only by smoking. However, obesity as a separate disease entity is still underappreciated and certainly misunderstood. The fact that the American Medical Association waited until the summer of 2013 to acknowledge obesity as a disease entity illustrates this statement.

Obesity *is* a disease and is likely multifactorial in its origin. We may come to a simpler and direct understanding of its pathogenesis in the future with increased understanding of molecular genetics, but for now, it remains a complex issue. The components of the disease likely include a combination of environmental and genetic factors. The recent rapid rise in the incidence of obesity in less than a generational time suggests that genetic etiologies alone cannot be responsible for the disease. Nevertheless, the numerous factors contributing to the disease increase the difficulty in understanding its causes.

The degrees of obesity are defined by body mass index (BMI = weight [kg]/height [m]^2), which correlates body weight with height. Controversy exists as to the most accurate system by which to classify obesity. BMI has its inaccuracies, especially for the heavily muscled individual who may weigh more but have a low amount of body fat. However, BMI is the clinically easiest system to use, employing the simply measured parameters of height and weight. The World Health Organization classification of obesity is given in Table 27-1. It should be noted that for Asian populations, classifications remain the same as the international classification, but the public health action points for interventions are set at 23, 27.5, 32.5, and 37.5 kg/m^2.

Table 27-1

World Health Organization classification of obesity by body mass index (BMI)*

	BMI (KG/M^2)	
CLASSIFICATION	PRINCIPAL CUT-OFF POINTS	CUT-OFF POINTS FOR ASIANS*
Normal range	18.5–24.9	18.5–22.9 23.0–24.9
Pre-obese	25.0–29.9	25.0–27.4 27.5–29.9
Obese class I	30.0–34.9	30.0–32.4 32.5–34.9
Obese class II	35.0–39.9	35.0–37.4 37.5–39.9
Obese class III	≥40.0	≥40.0

*For Asian populations, classifications remain the same as the international classification, but that public health action points for interventions are set at 23, 27.5, 32.5 and 37.5 kg/m^2 [204].

Prevalence and Contributing Factors

Severe obesity is reaching epidemic proportions in the United States and dramatically increasing throughout the rest of the world. Since 1960, surveys of the prevalence of obesity have been conducted every decade by the National Center for Health Statistics. Data on obesity statistics have been updated annually since 1985. The latest figures for obesity incidence in the United States are that 35.7% of U.S. adults are obese (class 1 or higher).[5]

Genetic and environmental factors contribute to the development of obesity. While children of parents of normal weight have a 10% chance of becoming obese, the children of two obese parents have an 80% to 90% chance of developing obesity by adulthood. The weight of adopted children correlates strongly with the weight of their birth parents. Furthermore, concordance rates for obesity in monozygotic twins are doubled compared to others.[6] Diet and culture are important factors as well; these environmental factors contribute significantly to the epidemic of obesity in the United States since the rapid increase in obesity during the past two decades cannot be explained by any genetic etiology.

Other factors appear to contribute significantly to severe obesity. Intermittent or consistent excessive caloric intake occurs. The lack of satiety, on a consistent or intermittent basis, appears to be strongly correlated to such episodes of excessive caloric ingestion. As yet, the physiologic basis for the explanation of such lack of satiety is not understood. Other factors commonly suggested to play a role in the disease of obesity include decreased energy expenditure from reduced metabolic activity, reduction in the thermogenic response to meals, an abnormally high set-point for body weight, or a decrease in the loss of heat energy. Another factor that may influence absorption of ingested food is intraluminal bacterial composition of the intestinal tract. Studies have documented a difference in the composition of the intestinal flora of obese versus normal-weight individuals.[7]

Obese individuals have excessive adipose cells, both in size and number. The number of such cells often is determined early in life; adult-onset obesity is largely a product of increase in adipose cell size. Weight gain results from increase in both adipose cell size and number. Adipose tissue may be deposited in large quantities in the subcutaneous layer of the abdominal wall or the viscera. Males tend to have central visceral fat distribution, whereas females more often have a peripheral or gluteal fat distribution. Central or visceral fat distribution is associated with metabolic diseases such as diabetes, hypertension, and the metabolic syndrome.[8]

Concurrent Medical and Social Problems

The severely obese patient often presents with chronic weight-related problems, detailed below. However, the single most difficult aspect of the disease of severe obesity for those suffering from it is the discrimination they face from the rest of the population with respect to social stigmatization. This prejudice against obesity remains the last unlegislated discrimination in existence. Obese individuals are routinely discriminated against in terms of employment. Public facilities often do not allow them to participate in activities. Examples include the size of airline seats and bathrooms, the availability of appropriate clothing options, and the size of automobile cabins. Severely obese individuals are thought of by much of the public as being lazy or gluttonous and lacking self-discipline. They often endure not only discrimination and prejudice, but outright ridicule and disrespect. Consequently, the stigma of severe obesity has a major impact on social function and emotional well-being. Thus, psychological disorders such as depression are found in an extraordinarily high incidence in this population versus the general public. Poor self-image is almost universal among obese individuals.

Significant comorbidities, defined as medical problems associated with or caused by obesity, are numerous. The most prevalent and acknowledged of these include degenerative joint disease, low back pain, hypertension, obstructive sleep apnea, gastroesophageal reflux disease (GERD), cholelithiasis, type 2 diabetes, hyperlipidemia, hypercholesterolemia, asthma, hypoventilation syndrome of obesity, fatal cardiac arrhythmias, right-sided heart failure, migraine headaches, pseudotumor cerebri, venous stasis ulcers, deep venous thrombosis, fungal skin rashes, skin abscesses, stress urinary incontinence, infertility, dysmenorrhea, depression, abdominal wall hernias, and an increased incidence of various cancers such as those of the uterus, breast, colon, and prostate.[9]

Prognosis

Obesity has a profound effect on overall health and life expectancy, largely secondary to weight-related comorbidities. It is estimated that a severely obese male at age 21 will live 12 years less and a woman 9 years less than a nonobese individual. The incidence of severe obesity in the population is comparable for females below and above the age of 50 years, whereas for men, it is decreased above age 50. This is due to the fact that the severely obese man often is dead of comorbid medical conditions, especially cardiac arrhythmias and coronary artery disease, by age 50. A study carried out by the Veterans Administration showed a 12-fold increase in mortality among 200 morbidly obese men age 25 to 34 years and a six-fold increase in mortality among those age 35 to 44 years over a 7-year follow-up period.[10] Decreased quality of life also results due to severe obesity. Most patients seeking surgical treatment of severe obesity do so because of the medical issues they face from comorbid conditions or the decreased quality of life they are experiencing as a result of severe obesity. Bariatric surgery

1▶ can significantly prolong the lifespan of a severely obese individual, as well as improve the quality of that life.

MEDICAL MANAGEMENT

Medical treatment for severe obesity is aimed at reducing body weight with a combination of decreased caloric intake and accompanying increases in energy expended from moderate exercise. This method of weight loss is the safest possible and may work well for obese individuals who have modest amounts of weight to lose to regain normal body weight or return to being simply overweight instead of obese. However, for the severely obese individual, who usually must lose at least 75 or more pounds to achieve elimination of obesity, this daunting task is extremely difficult. The success rate for the severely obese patient population that tries dieting and exercise as a means of losing enough weight to no longer be obese and maintaining that weight loss is only approximately 3%.

Although the success rate is limited with diet and exercise alone, all severely obese individuals are asked to attempt this route of weight loss prior to undertaking any surgical therapy.

There are two main reasons for this. The first is to allow those who can achieve such weight loss through the safest possible means to do so. The second, and by far the most practical, is to have the severely obese individual begin to appreciate and practice the lifestyle changes that must ultimately become routine for them once weight loss is achieved, by whatever means. Thus the dieting and exercise of conservative weight loss plans are important preparation for the incorporation of such habits into the patient's lifestyle postoperatively after bariatric surgery. The adjustment of the patient's lifestyle to include these measures is the key to long-term success with any bariatric operation. Failure to do so usually results in regain of weight and sacrifice of any health benefits initially gained by the immediate postoperative weight loss.

The treatment of severe obesity should be initiated with simple lifestyle changes, including moderate reduction of caloric intake and beginning an exercise plan. Walking is the most common choice for this patient population, who may be unable to perform extremely vigorous exercise initially. Medical comorbidities must be identified and treated. Usually the patient's primary care physician will have already accomplished this, but we do at times identify bariatric-related comorbidities on initial history and physical examination in our clinic.

The severely obese patient will usually have been given dietary counseling by his or her primary care physician and often placed on a medically supervised diet. Most patients also have attempted commercially sponsored diets and diet plans. Success following these is not uncommon, but sustained weight loss for more than a year after stopping the program is uncommon. While primary care physicians usually do an outstanding job of identifying and treating comorbid medical problems, their offices usually do not have the related support staff in terms of nutritionists and psychologists, who are often very helpful in providing services to the severely obese patient undergoing significant lifestyle changes.

Lifestyle changes of diet, exercise, and behavior modification constitute the first tier of therapy for obesity. Dietary restriction and exercise can each independently create a caloric deficit. A daily energy deficit of 500 kcal/d, resulting in a weekly deficit of 3500 kcal, results in the loss of 1 lb of fat weekly. It has been shown that low-calorie diets (800–1500 kcal/d) are as effective as very-low-calorie diets at 1 year, but result in a lower rate of nutritional deficiencies.[11] Such diets may produce an average of 8% body weight loss over a 6-month period. Longer follow-up shows recidivism. Physical activity of a moderate daily nature can produce a 2% to 3% body weight loss.[12]

A behavioral modification program, which provides desirable rewards for meeting short-term dietary or exercise requirements, was shown in combination with diet and exercise to produce as much as a 10% weight loss at 6 months in one study. This weight loss was only sustained in 60% of patients at 40 weeks,[13] and at 1 year, the average sustained weight loss was decreased to 8.6%.[14]

Dietary, exercise, or behavior modification therapy is appropriate treatment for patients who are overweight (BMI <30 kg/m^2) and highly recommended for patients with a BMI between 30 and 35 kg/m^2. Most of the studies looking at dietary therapy do not include a patient population that is largely obese (BMI >30 kg/m^2). Dietary therapy can be effective in producing improvements in comorbid conditions such as diabetes mellitus, with weight loss of 2.3% to 3.7% influencing the disease.[15] Thus, lifestyle changes can be effective in improving the health of the nonobese, but less so for the obese population.

Pharmacologic therapy is also an option for patients attempting to lose weight. Unfortunately, the number of effective pharmacologic agents is small compared to the number of products sold with allegations that they will promote or support weight loss. Pharmacotherapy is normally used only after lifestyle changes and dietary therapies have failed. It is used either as primary therapy alone or in conjunction with simultaneous diet and exercise therapy.

Orlistat inhibits gastric and pancreatic lipase enzymes that promote lipid absorption in the intestine.[16] It produces a weight loss of between 6% and 10% of body weight after 1 year, but cessation of the drug usually results in prompt regain of lost weight.[16] Pharmacotherapy is recommended as an adjunctive or supplementary therapy to lifestyle changes including diet and exercise or behavioral therapy by the National Institutes of Health (NIH) consensus guidelines for treatment of obesity.[17] Two new medications have been approved by the Food and Drug Administration (FDA) within the past few years for weight loss. Qsymia, a combination of phentermine and topiramate, produced a 5% weight loss in over 70% of patients after 1 year.[18] Lorcaserin (Belviq), a central serotonin agonist, produced a 5% weight loss in 47% of patients taking the medication.[19]

Since medical therapies are almost uniformly ineffective long-term for patients with severe obesity, the severely obese patient tends to continue to gain weight over time. The number and strength of prescribed medications slowly increase as the medical comorbidities become increasingly worse. Unfortunately, for the majority of severely obese patients, this process continues unabated until death results eventually from the comorbidities. Until recently, less than 1% of severely obese patients underwent surgical treatment for obesity annually. That number has now increased, but still is not over 2% of individuals. Even accounting for patients referred for surgery and felt to be poor candidates, it is likely that less than 5% of patients with severe obesity are referred on an annual basis. Part of this issue may be patient aversion to surgical therapy. Primary care physician awareness, patient reticence, and economic concerns about potentially losing employment due to time off required for surgery or its complications have been the primary reasons cited for the lack of increased performance of bariatric and metabolic surgery. Lack of insurance coverage by many patients is also a primary reason for not seeking surgical therapy for the medical problems associated with severe obesity. Disincentives posed by insurance companies, such as required dietary periods that clearly have no scientific or clinical basis of merit, are still used to discourage patients from pursuing surgical therapy. The lack of efficacy and potential harm to patients of such policies has been clearly demonstrated in the literature.[20,21]

OVERVIEW OF BARIATRIC SURGERY

Bariatric operations produce weight loss through at least two mechanisms and probably many more that are not known. The most common is restriction of intake. Malabsorption of ingested food is the second mechanism. Restrictive operations may include no or only a modest malabsorptive component. Malabsorptive operations may have some restrictive component, but it is secondary to the malabsorptive aspect of the operation.

Table 27-2

Types of commonly performed bariatric operations by mechanism of action

Primarily Restrictive
Laparoscopic adjustable gastric banding (LAGB)
Sleeve gastrectomy (SG)
Primarily Malabsorptive
Biliopancreatic diversion (BPD)
Duodenal switch (DS)
Combination
Roux-en-Y gastric bypass (RYGB)

Table 27-2 describes the common currently performed operations listed by mechanism of action.

This chapter focuses on the operations listed in Table 27-2, whether they are done via a laparoscopic or an open incision approach. Any other procedures to produce weight loss are so infrequently done that they will not be discussed in detail. Vertical banded gastroplasty (VBG), although still one of the approved operations for the surgical treatment of severe obesity based on the NIH Consensus Conference of 1991,[22] is now so infrequently performed and has such poor long-term follow-up results[23] that it is of historic interest only.

Evolution of Bariatric Surgery

During the 1950s, operations were first performed to treat severe hyperlipidemia with associated obesity.[24] These were ileocolic bypass operations to limit absorption and were associated with severe nutritional complications and liver failure postoperatively. The jejunoileal bypass was then devised and popularized in the mid-1970s.[25] It was also a malabsorptive operation, but bypassed only a portion of the small intestine. Complications after this procedure included severe diarrhea, electrolyte disturbances, protein-calorie malnutrition, renal stones, and liver failure.

In 1969, Mason and Ito performed the first gastric bypass, describing a loop of jejunum connected to a transverse proximal gastric pouch.[26] Bile reflux esophagitis was severe postoperatively, causing Griffin and colleagues to describe the Roux-en-Y modification of the gastric bypass in 1977.[27] The gastric pouch was altered from transverse to vertical using the upper lesser curvature as well.

During the 1970s, the dismal failure of the jejunoileal bypass resulted in a very bad reputation in general for bariatric surgery among general surgeons who had performed the procedure or cared for patients suffering from its complications. The reputation was not enhanced by the many variations of gastric stapling that then became common during the 1970s and early 1980s. Such operations often consisted of a few rows of staples partially across the upper stomach for restrictive purposes. Since the procedure was easily done, some surgeons performed it in prolific numbers. Staple breakdown predictably occurred months to years later, with subsequent weight regain. These procedures added to the string of failures of bariatric operations.[28]

In 1980, Mason[29] first performed the VBG, which was a restrictive procedure using a stapled proximal gastric pouch of the upper lesser curvature of the stomach with a restrictive band for its outlet to the rest of the stomach. This operation produced excellent initial weight loss (50% of excess weight or more) with low morbidity and mortality. It rapidly became the most commonly performed bariatric operation in the United States during the 1980s. However, by the early 1990s, it became clear that patients who underwent VBG tended to adopt a diet of high-calorie liquids and regained weight.[30] A significant incidence of stenosis at the band was also a problem.[31] Long-term weight loss was poor,[23] and by the 1990s in the United States, Roux-en-Y gastric bypass (RYGB) became the procedure of choice for bariatric surgery.

In Italy, in the meantime, Scopinaro had developed and popularized the biliopancreatic diversion (BPD) in the early 1980s.[32] This procedure, described in more detail later, has been, along with its modification to include duodenal switch (DS),[33] the only major malabsorptive operation to enjoy long-term success. BPD and DS are both still used by a fairly select few surgeons throughout the world and have traditionally represented and continue to represent less than 5% of operations performed in the United States.

Fixed banding of the stomach, besides the VBG, was also described by other surgeons in the 1980s and 1990s. Kuzmak is credited with describing the fixed gastric band procedure, which later led to the development of the adjustable gastric banding operation.[34]

The laparoscopic alternative to bariatric surgery became available in the 1990s. Belachew performed the first laparoscopic adjustable gastric banding (LAGB) operation in 1994.[35] Wittgrove and Clark performed the first laparoscopic RYGB the same year.[36] Since the former operation is technically much easier than the latter, it was not surprising that it became very popular and frequently performed in Europe and Australia during the late 1990s. In 2001, LAGB was approved for use in the United States. Its popularity increased annually until 2009, but since then, it has decreased in popularity. Sleeve gastrectomy (SG) has enjoyed a rapid increase in popularity both in the United States and internationally since 2008. Buchwald and Oien[37] have recently described the international trends in the performance of bariatric operations.

The Bariatric Revolution

The Bariatric Revolution is a term applied to the 5-year stretch from 1998 to 2003 during which the number of gastric bypass operations performed in the United States, membership in ASMBS, and public recognition and interest and professional respect for the field dramatically increased. Few medical centers in the United States offered a laparoscopic approach to bariatric surgery prior to 1998. Several centers, most notably Schauer and colleagues at Pittsburgh, then began numerous programs to teach many bariatric surgeons the procedure. Simultaneous improvement in the laparoscopic instruments for bariatric procedures combined with these programs to allow the performance of laparoscopic Roux-en-Y gastric bypass (LRYGB) in numerous centers over the next few years. The field then literally exploded in terms of growth in the United States. Figure 27-1 illustrates the volume of LRYGBs performed during the years prior to and during the Bariatric Revolution. Operative procedures increased nearly eight-fold. Membership in the American Society for Bariatric Surgery (the name of the ASMBS at that time) tripled during these years. The number of minimally invasive fellowships offered to graduating residents, most of whom included bariatric surgical procedures as a major component of the case load, increased from about 25 to 125 during these years.

2▶

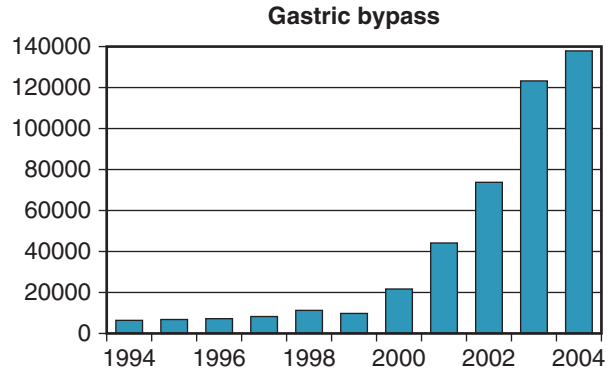

Figure 27-1. Number of Roux-en-Y gastric bypass operations performed in the United States by year. *(Data from the Nationwide Inpatient Sample Database.)*

Public recognition of the procedure markedly increased due to public figures in the media undergoing bariatric surgery. The widespread availability of the Internet to prospective patients allowed much more information to be relayed. Patients who had or were contemplating surgery were able to communicate via the Internet. Videos of bariatric operations became available via several media outlets including television and the Internet. Many U.S. surgical departments that had previously shunned the field of bariatric surgery recruited bariatric surgeons and established programs. Hospitals without programs recruited surgeons so they could offer the service. Bariatric surgery presentations at national surgical meetings became common instead of rare.

Indications

The indications for performing bariatric surgery remain as described in the NIH Consensus Conference of 1991.[22] The only major difference is the procedures that are now recognized as standard procedures. These were defined by the CMS in 2005 as those listed in Table 27-2, with the exception of SG. SG did not receive approval until 2012, when after a controversial initial rejection of coverage, the CMS decided to allow coverage based on the discretion of regional carriers. The standard and somewhat conservative indications for performing bariatric surgery are summarized in Table 27-3.

Contraindications

Of all the reasons a patient who desires bariatric surgery cannot have an operation, insurance coverage, or lack thereof, is the most common reason. This factor, however, is normally beyond surgeon control. Assuming the patient does have coverage or financial means to qualify for surgery, then application of the NIH criteria is the next consideration. Once a patient qualifies according to those criteria, then consideration of medical, social, and psychological issues can determine reasons to avoid surgical therapy.

The NIH criteria do not set limits for age, and surgeon opinion on this issue varies widely. Surgeons have variable practice patterns as to performance of surgery in the older patient. The philosophy for age restriction is two-fold: A large number of younger patients are interested in and eligible for bariatric surgery, and there is a greater likelihood that a longer period of postoperative benefit in terms of improved quality of life and longevity will occur with a younger patient population. Alternatively, older patients are more likely to have debilitating comorbid conditions and thus have immediate benefit in quality of life but not necessarily enhanced longevity.

Medical issues that preclude patients from being good surgical candidates include American Society of Anesthesiologists class IV disease of a nature that makes surgical therapy extraordinarily high risk. Psychological instability or the inability to understand the implications of the proposed operation and what changes will result from it in terms of the patient's lifestyle are also contraindications. Known and documented drug or alcohol addiction is a contraindication to surgery. Smoking is a relative contraindication, and requirement of cessation of smoking varies by surgical practice. A poorly controlled eating disorder, especially bulimia, is also a contraindication to surgery. Nonambulatory status is a relative contraindication to surgery, especially if the obesity is so severe that the patient cannot normally do self-care or would not likely be able to do so after surgery. Such patients have excessive morbidity in our experience, and placement in care facilities postoperatively after recovery from surgery is often impossible due to their size and limitations of physical ability. Although hard to determine on a single visit, an accumulation of evidence that suggests the patient views the operation as a "magic bullet" for which they must only show up and after which they will not be required to make any substantive changes in eating or lifestyle is a potential valid reason to deny surgery. Finally, lack of sufficient social support, an extremely poor or unsupportive home environment, or hostile spouse or relatives can be contraindications to surgical care, since such supportive environmental factors are important to optimize outcomes once discharged from the hospital. Table 27-4 summarizes potential contraindications for surgery.

Table 27-3

Indications for bariatric surgery

Patient must have:

1. Body mass index ≥40 kg/m^2 with or without comorbid medical conditions associated with obesity
2. Body mass index 35–40 kg/m^2 with comorbid medical conditions

In addition, it is expected that the patient:

3. Has failed attempt at medically supervised diet
4. Be psychiatrically stable

Table 27-4

Potential contraindications for bariatric surgery

1. Severe medical disease making anesthesia or surgery prohibitively risky (American Society of Anesthesiologists class IV)
2. Mentally incompetent to understand procedure
3. Inability or unwillingness to change lifestyle postoperatively
4. Drug, alcohol, or other addiction
5. Active problem of bulimia or other eating disorder
6. Psychologically unstable
7. Nonambulatory status
8. Unsupportive home environment

PREOPERATIVE ISSUES

Patient Selection

Patient selection for surgery should be based on a multidisciplinary team evaluation. The patient has usually been screened by his or her primary care physician prior to referral, with major medical issues addressed prior to referral. Qualification by NIH criteria and availability of insurance coverage can be handled by office administrators to document and confirm prior to the first appointment.

The preoperative assessment of the patient for bariatric surgery must include input from the nutritionist as an important independent evaluation. Careful assessment of the patient's eating habits, knowledge, self-awareness, and insight are important. An estimation of the patient's motivation to change eating habits is important. The nutritionist should have at least one assessment session with the patient and an educational session preoperatively once the decision to proceed with surgery has been determined. The operation to be performed requires specific nutritional counseling and education.

Psychological assessment is required by most insurance carriers. One major benefit of the psychological assessment is to determine the patient's understanding of the operation and whether he or she has a realistic understanding of the changes that are needed in lifestyle for optimal outcomes. The psychologist or psychiatrist often may diagnose previously unappreciated depression, which is prevalent in nearly 40% of our preoperative patients when carefully screened. Its treatment is felt to improve postoperative outcomes.

Most of the patients referred for surgery who have been screened for qualification by NIH standards will be appropriate candidates for bariatric surgery. Some will decide against the procedure after thorough educational and counseling sessions. Such sessions are imperative for improving outcomes. Providing both written detailed information and a verbal presentation by the multidisciplinary team to educate patients preoperatively regarding bariatric surgical procedures and expected outcomes and potential complications is recommended. Informed and prepared patients will likely be much more compliant with perioperative and postoperative requested behavioral and eating changes. Some patients who decide against the procedure will return in the future after their obesity comorbidities worsen. Reevaluation for continued appropriateness as a good surgical candidate is equally indicated at such time.

Preoperative Preparation

Preoperatively, current comorbid and other medical problems and their optimal therapy are confirmed. Potentially undiagnosed medical problems are sought. Screening for "hidden" diseases such as coronary artery disease in those patients over age 50 is important. For such patients, or those with known cardiovascular disease, a preoperative cardiology consultation is recommended. Such consultation usually then involves electrocardiogram (ECG), echocardiogram, and stress test, with the results of these at times suggesting need for cardiac catheterization. Another condition often underdiagnosed preoperatively in the severely obese patient population is obstructive sleep apnea (OSA). The Epworth Sleepiness Scale, a standard set of questions evaluating daytime sleepiness, is often used as a screening tool for OSA.[38] Many institutions are routinely employing it for all surgical patients, given the recognition that OSA increases postoperative morbidity after all operations. Patients who give a history of loud snoring, morning tiredness on waking, and falling asleep easily while driving or sitting likely have OSA. A diagnostic sleep study is indicated for these individuals. One report suggests that the incidence of sleep apnea in severely obese patients, when all are routinely subjected to sleep studies, may approach 80%.[39] Once diagnosed with sleep apnea, patients should use their positive airway pressure appliance as treatment. Use of this system in the immediate postoperative period is especially important to prevent episodes of hypoxia and potentially resulting cardiac arrhythmias. Asthma and hypoventilation syndrome of obesity are other significant pulmonary diseases often requiring preoperative management. Hypoventilation syndrome of obesity is defined as resting arterial partial pressure of oxygen less than 55 mmHg and partial pressure of carbon dioxide greater than 47 mmHg, with accompanying pulmonary hypertension and polycythemia. Pulmonary consultation is indicated for patients with hypoventilation syndrome. Postoperative intensive care unit hospitalization, rarely used after bariatric surgery, may be indicated for these patients.

For patients with active GERD on medication, a preoperative screening upper endoscopy to rule out Barrett's esophagus and to rule out intrinsic lesions of the stomach or duodenum is recommended. This is especially true for patients planning LRYGB, where the distal stomach and duodenum will be precluded from easy inspection postoperatively. Several studies have documented the considerable incidence of preoperative pathology on flexible upper endoscopy for this patient population, as well as a small but not insignificant incidence of pathology resulting in alteration of the originally planned surgical procedure.[40,41] At Virginia, our experience was that such pathology was present in 4.6% of examinations.[42] The presence of a hiatal hernia detected on preoperative esophagogastroduodenoscopy will alert the surgeon for the need to perform intraoperative repair.

Patients who are on anticoagulation medication for prosthetic cardiac valves or history of recent venous thromboembolism must have their anticoagulation managed perioperatively. Options include total cessation of oral warfarin therapy 5 days prior to surgery, bridging this time with subcutaneous low-molecular-weight heparin, or, more rarely, preoperative admission for intravenous heparin anticoagulation, which is then stopped 6 hours prior to surgery.

Patients with a strong history of previous venous thromboembolism or who are felt to have multiple risk factors for postoperative venous thromboembolism are potential candidates for preoperative placement of a temporary inferior vena cava filter. Such filters are placed the day prior to surgery by our interventional radiology colleagues and removed 3 to 6 weeks postoperatively. However, a report on a large experience of collected hospitals has shown this procedure has potential complications and morbidity, which may outweigh its use in all but the most high-risk patients.[43]

Some surgeons routinely perform screening ultrasound of the abdomen for patients planning to undergo LRYGB with an intact gallbladder to rule out the potential presence of gallstones. Should gallstones be discovered, simultaneous laparoscopic cholecystectomy is one option, whereas deferring until after weight loss is another reasonable option. Recent analysis of our experience with simultaneous cholecystectomy at the University of Virginia has shown the average increase in operative time to be approximately 30 minutes for both LRYGB and RYGB with no increase in hospitalization or morbidity.[44] An earlier study at

Pittsburgh did demonstrate an increased length of hospitalization for patients having simultaneous cholecystectomy.[45] When a patient does not have gallstones on preoperative ultrasound, use of prophylactic ursodiol in a dose of 300 mg twice a day will decrease the incidence of gallstone formation after RYGB to approximately 4%.[46] Controversy currently exists as to the proper role of simultaneous laparoscopic cholecystectomy at the time of LAGB. The conservative approach is to not perform such an operation, given the small potential for gallbladder bile spillage resulting in an infection of the prosthesis. However, some reports have shown that this risk may be very low.[47]

Another value of a preoperative ultrasound of the abdomen is the assessment of liver size and composition. An ultrasound that reveals a large fatty liver in a patient planning to undergo either LAGB or LRYGB should alert the surgeon to the high potential for technical difficulty in liver retraction and exposure. We have converted to an open incision and even deferred persisting with the operation altogether when confronted with an excessively large or a tremendously large liver, respectively. Knowledge of this prior to surgery allows the patient to follow a low-calorie diet to shrink the liver preoperatively.

Some surgeons require patients to follow a low-calorie diet in the immediate preoperative period, requiring weight loss prior to proceeding with surgery. Some data exist indicating that preoperative weight loss by patients may improve outcomes.[48] Such studies suffer from the fact that the patients who are most compliant and lose weight preoperatively may be the most compliant postoperatively, accounting for the improved outcomes. Preoperative weight loss is not necessary to achieve good outcomes from surgery. Requiring preoperative weight loss raises the dilemma of whether patients who do not achieve weight loss should be then denied the benefit of surgical therapy.

Another controversial area is the requirement for cessation of smoking by patients prior to undergoing surgery. Some surgeons make this an absolute requirement, while others do not. Certainly the risk of marginal ulcer after RYGB, which is more difficult to treat and has a higher recurrence rate in smokers,[49] should be considered as a factor in whether to offer the smoking patient this operation.

Other preparation for bariatric surgery includes the performance of a baseline arterial blood gas measurement. This is especially important in any patients with significant pulmonary disease or hypoventilation syndrome of obesity, since a baseline value of "normal" *for the patient* must be appreciated if ventilator management postoperatively is necessary.

Baseline evaluation of thyroid function is indicated preoperatively, since hypothyroidism is not uncommon in this patient population. Serum chemistries, liver function tests, and usual screening blood tests are done. Blood tests to determine baseline nutritional parameters are not uncommonly abnormal for low iron and vitamin D levels. The former finding is common in the menstruating female population, obese or not, while the latter has been reported for the population in general but especially for the obese patient population.[50] The necessity to treat low vitamin D levels preoperatively is unclear in terms of its influence on clinical outcomes. However, the primary reason to correct low vitamin D is improved long-term bone disease health.

Preoperative education is important to reemphasize important points of likely events of the perioperative period, expected postoperative course, and instructions for postoperative activity and diet. Expectations for patients include ambulation on the day of surgery, following postoperative dietary instructions, taking recommended vitamin and mineral supplements, and following a regular exercise plan.

Anesthesiology Issues

A preoperative anesthesiology assessment is indicated for all patients undergoing bariatric surgery. This assessment confirms the optimal assessment and management of ongoing comorbid medical problems. It also includes the aforementioned cardiopulmonary evaluation to determine any underlying pathology that requires preoperative treatment to decrease perioperative morbidity from cardiopulmonary complications.

It is important that the anesthesiologist be experienced in performing general anesthesia management for the bariatric patient. There is no question that the consistent participation of a few selected and experienced anesthesiologists who specialize in the care of the bariatric patient will minimize morbidity of surgical outcomes. Perioperative and intraoperative communication between the anesthesiology team and the surgical team is particularly important during bariatric operations to facilitate the smooth flow of the operation and avoid complications from the procedure.

Two major difficulties that the anesthesiologist faces when performing a general anesthetic for the severely obese patient are vascular access and airway management. Both are significantly more difficult in the obese patient population than the normal-weight population. Central venous access is at times the only available route for establishment of a reliable intravenous access. Access to both arms during the procedure is standard in our operating rooms; this allows for additional larger bore intravenous access should an episode of intra-abdominal hemorrhage occur. Jugular cannulation is often very difficult due to neck adipose tissue. However, ultrasound guidance can facilitate this procedure. Subclavian access is performed when other central access routes are not feasible.

Management of the severely obese patient airway is often a major challenge for the anesthesiologist and must be done well to avoid potentially significant morbidity. Videotelescopic intubation systems are successfully used in some institutions to manage difficult airway intubation. Fiberoptic laryngoscopy is more commonly used for the difficult airway should standard laryngoscopy provide an inadequate view. For the most difficult class IV or even class III airways, a fiberoptic guided intubation is used. Experience is key in performing smooth intubation of this patient population. Significant preoxygenation for 3 minutes or longer prior to intubation is used for the severely obese patient to provide a longer safe duration for intubation should difficulties be encountered. However, desaturation must be immediately addressed with reestablishment of oxygenated ventilation because this patient group does not tolerate any prolonged desaturation without potential adverse cardiopulmonary consequences.

The anesthesiologist must be adept at understanding and managing alterations in cardiopulmonary function from the use of a pneumoperitoneum during laparoscopic bariatric procedures. These alterations include the effects of carbon dioxide absorption on required minute ventilation, the potential for bradyarrhythmias, and the potential for decreased systemic pH with longer procedures in patients with preexisting cardiopulmonary disease. Arterial monitoring of the latter group of patients may be necessary by the anesthesiology team, and a radial arterial line is standard for such patients.[51]

Drug pharmacokinetics differ in severely obese patients as well. Changes in volume of distribution include smaller-than-normal fraction of total body water, greater adipose tissue content, altered protein binding, and increased blood volume. Possible changes in renal function and hepatic function must be considered when administering drugs.

Specific anesthetic drug metabolic alterations in the severely obese include a larger volume distribution of thiopentone, resulting in a prolonged effect of the drug.

Calculation of the dosage should be done by lean body weight. Benzodiazepines also exhibit a prolonged elimination phase, causing persistence of their effects. Increased pseudocholinesterase activity is present in the severely obese patient, requiring increased dosages of pancuronium. Enflurane metabolism is increased over the average-sized person, requiring a lower dosage of this agent.

BARIATRIC SURGICAL PROCEDURES

Laparoscopic versus Open Procedures

The procedures in this section will be described using a laparoscopic approach as the default or typical approach. RYGB, BPD, and DS may still be performed by some surgeons using an open approach, but this has now become the exception. Minimization of the morbidity of the open incision, especially incisional hernias and wound complications, as well as earlier hospital discharge and lower 30-day complication rates have all been clearly shown to favor using a laparoscopic approach when feasible.[52-54] In addition, the logical assumption that avoiding the major tissue trauma associated with a lengthy abdominal wall incision is beneficial to patient recovery has been confirmed. Most importantly, patient interest in bariatric surgery increased dramatically once a laparoscopic approach was available for these procedures, especially RYGB.[55] In the twenty-first century, most prospective bariatric patients are informed enough about the options for surgery that they seek out a surgeon who does laparoscopic bariatric surgery.

When an open surgical approach is used for any of these procedures, an upper midline incision is the most commonly used approach. Some surgeons have had excellent success with a left subcostal incision for performing RYGB.[56] Mechanical retractors afford additional exposure for open surgery and are indicated. Wound closure for midline incisions usually is performed using heavy monofilament suture for the midline fascia, but surgeon preferences vary. Any concerning drainage from a postoperative open surgical incision line requires opening of the wound in that area and confirmation that a more severe deep-seated fascial tissue infection does not exist.

Laparoscopic surgery requires a basic core set of knowledge and skills that have now become a standard part of surgical training. Successful completion of the Fundamentals of Laparoscopic Surgery (FLS) unit developed by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES)[57] is now mandatory for all surgical residents in the United States.

Laparoscopy begins with the safe creation of a pneumoperitoneum, often a difficult step in the bariatric patient. We have found the use of a tracheostomy hook inserted through a trocar-sized incision to elevate the fascia in the left subcostal region to be of great assistance in facilitating the insertion of a Veress needle into an appropriate location for pneumoperitoneum creation. In general, the use of a Hasson approach for creating a pneumoperitoneum in the bariatric population is limited by the thick body wall. In the patient with an extremely thick body wall, extra long trocar ports can be used for laparoscopic surgery.

The pneumoperitoneum pressure that is used when performing bariatric surgical procedures is generally in the 15 to 18 mmHg range. A high-flow insufflator is mandatory to maintain the pneumoperitoneum for adequate and safe visualization. An angled telescope is quite helpful. Instrumentation for performing laparoscopic bariatric surgery has dramatically improved in the past 15 years and continues to improve. We now favor using certain laparoscopic instruments, such as the staplers and harmonic scalpel, even if conversion to an open approach occurs.

Conversion to an open incision is appropriate in circumstances where patient safety would potentially be compromised by persisting with a laparoscopic approach. Table 27-5 lists appropriate reasons for conversion to an open incision as well as consideration for beginning with open surgery if certain conditions are known, such as an existing large upper abdominal incisional hernia or known severe intra-abdominal adhesions. Conversion to an open incision should not be viewed as a failure by the surgeon, nor should such an attitude bias the surgeon in favor of persisting with a laparoscopic approach if the operation is not progressing or if a complication is worsening when it could be corrected more quickly using an open approach. Patient safety is the gold standard for determining the timing and appropriateness of conversion. Usually, if conversion is needed, it is best to do so as early in the course of the operation as possible.

Postoperative Follow-Up

Short-term follow-up is defined as follow-up of up to 2 years. Unfortunately, even in the best of practices in the United States, because of the lack of a centralized health system or registry, 1-year follow-up of 90% or greater is a laudable achievement and rarely reported in most case series. Recommendations for bariatric centers wishing to be COEs are that 75% of patients are followed for 5 years with restrictive operations, and 90% are followed if they have malabsorptive operations. Those recommendations, however, are based on having a system that attempts maximum possible follow-up that should yield such results. Although a system may be in place that generates multiple attempts at having the patient return for postoperative check-ups, without patient compliance, all such systems are fallible.

The goals of short-term follow-up are to maximize care of the patient in the postoperative period; assist in adjustment to

Table 27-5

Indications for conversion from laparoscopic to open surgery

1. Failure to establish an adequate pneumoperitoneum
2. Hemodynamic adverse reaction to pneumoperitoneum
3. Intra-abdominal adhesions precluding safe access or presenting excessive difficulty to access abdomen
4. Hepatomegaly such that retraction is not feasible or, even with retraction, organ visualization is obscured
5. Intraoperative complications such as hemorrhage that are best managed with an open approach
6. Exceedingly thick body wall precluding adequate trocar access or manipulation
7. Existing large upper abdominal wall hernia that optimally can be repaired simultaneously using the same incision

new eating, exercise, and lifestyle patterns; be on the alert for and treat postoperative complications; and recommend measures to limit such complications. Objective data that should be obtained after all bariatric operations include weight loss, change in BMI, resolution or improvement in medical comorbidities, and any adverse events or complications that occur. Optimally, assessment of quality of life can help gauge efficacy as well, with the Short Form-36 (SF36) questionnaire being one standard, frequently used example. Short-term follow-up data do give a good reflection of the safety of the procedure, but only an estimate of the efficacy regarding weight loss and effect on resolution of medical comorbidities.

Medium-term follow-up is defined as that from 2 to 5 years. Medium- and long-term follow-up, defined as greater than 5 years, are the only means by which the true long-term efficacy of bariatric surgical operations can be assessed. Operations that initially appear quite promising, such as the VBG or even the jejunoileal bypass, were shown with long- and medium-term follow-up, respectively, to have significant deficiencies in efficacy for the VBG[23] and safety[25] for the jejunoileal bypass. Other stapled gastroplasties similarly did not demonstrate efficacy on medium-term follow-up.[25]

Unfortunately, to date, there has been no conventional method of reporting outcomes after bariatric surgery. The ideal publication includes quantitation of number of patients, a description of the operative technique, incidence of conversion to open if applicable, number of patients included in follow-up data per year, percentage of patients lost to follow-up, weight loss usually expressed as percentage of excess weight, initial and subsequent BMI, complications, mortality, resolution of medical comorbidities, and any quality of life data. Few publications have met these criteria. There are also only a few studies in which a prospective randomized comparison either between bariatric surgery and medical management or between different bariatric surgical operations or approaches (laparoscopic vs. open) have been performed. Improvement in study design and more complete data in future publications are indicated.

A multidisciplinary team approach to follow-up is as essential, if not more so, postoperatively than preoperatively. Regular counseling sessions with the nutritionist are always helpful. Psychological support should be available as needed to assist the patient in adjustment to major life changes. All programs should offer a frequent support group forum for patients to discuss issues on a less formal basis and receive encouragement from other patients as well as staff.

Experience of performing bariatric surgery for several decades between the co-authors has led us to conclude that *whatever the operation performed, its long-term success is only achieved by patients if they embrace the eating and lifestyle changes the operation allows them to adopt.* Continuation of exercise as part of the daily lifestyle is associated with a high incidence of preservation of weight loss. Diligence to avoid snacking and returning to other poor eating habits is also important. The majority of patients do embrace the metamorphosis their bariatric operation produces such that they maintain their new eating, lifestyle, and exercise habits to the benefit of their continued improved health, self-image, and well-being.

Laparoscopic Adjustable Gastric Banding

Background. LAGB involves placement of an inflatable silicone band around the proximal stomach. The band is attached to a reservoir system that allows adjustment of the tightness of the band. This reservoir system is accessed through a subcutaneously placed port, similar in concept to ports used for chemotherapy via central venous catheters. Figure 27-2 shows the LAGB apparatus in place.

Two major types of bands have been used for this procedure. The original Lap-Band, most recently marketed by Apollo Endosurgery, has been used most frequently. The Swedish Band, now remarketed as the Realize Band by Ethicon, is slightly wider than the Lap-Band.[58] The port systems have differences as to profile and methods of attachment to the fascia.

Technique. Port placement for LAGB has varied among surgeons. Figure 27-2 shows a common configuration used. Usually some combination of two ports for the surgeon's hands, one or two for the assistant, a port for the telescope, and a liver retractor site are needed.

With the patient placed in reverse Trendelenburg position, the procedure begins with division of the peritoneum at the angle of His and then division of the gastrohepatic ligament in its avascular area (the *pars flaccida*) to expose the base of the right crus of the diaphragm. If a hiatal hernia is present, it must be repaired at this point, using a standard posterior esophageal dissection to expose the crura and perform suture repair. A grasper (Lap-Band) or specially devised instrument (Realize Band) is inserted along the base of the anterior surface of the diaphragmatic crura, from right to left, emerging at the angle of

Figure 27-2. Laparoscopic adjustable band overall scheme. *(From Schauer PR, et al, eds.* Minimally Invasive Bariatric Surgery*, 1st ed. New York: Springer; 2007. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All rights reserved.)*

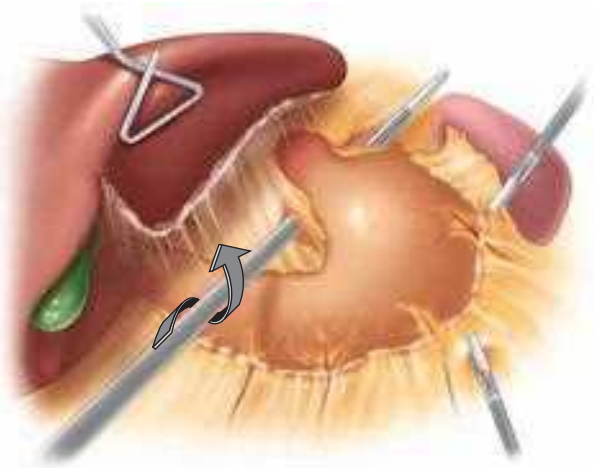

Figure 27-3. Grasper being passed through under stomach to grasp tubing during placement. *(From Schauer PR, et al, eds. Minimally* Invasive Bariatric Surgery*, 1st ed. New York: Springer; 2007. His in the area of the divided peritoneum (Fig. 27-3). The device is then used to pull the band underneath the posterior surface of the gastroesophageal junction. This technique, by passing the band through some fibrous tissue in this plane, serves to anchor the band more securely posteriorly. During the initial years of band placement, a retrogastric location of the posterior half of the band in the free space of the lesser sac caused an unacceptably high incidence of slippage and prolapse of the band. The adoption of the *pars flaccida* technique decreased the incidence of such slippage.[59]

Once the band is passed around the proximal stomach, it is locked into its ring configuration through its own self-locking mechanism. This involves the tubing end being passed through the orifice of the buckle for the Lap-Band and the suture on the end of the flanged end of the band site being passed through for the Realize Band. Once the band is securely locked in place, the buckle portion of the band is located on the lesser curvature of the stomach (Fig. 27-4A,B). Now the anterior surface of the fundus and proximal stomach is imbricated over the band using several sutures (Fig. 27-5).

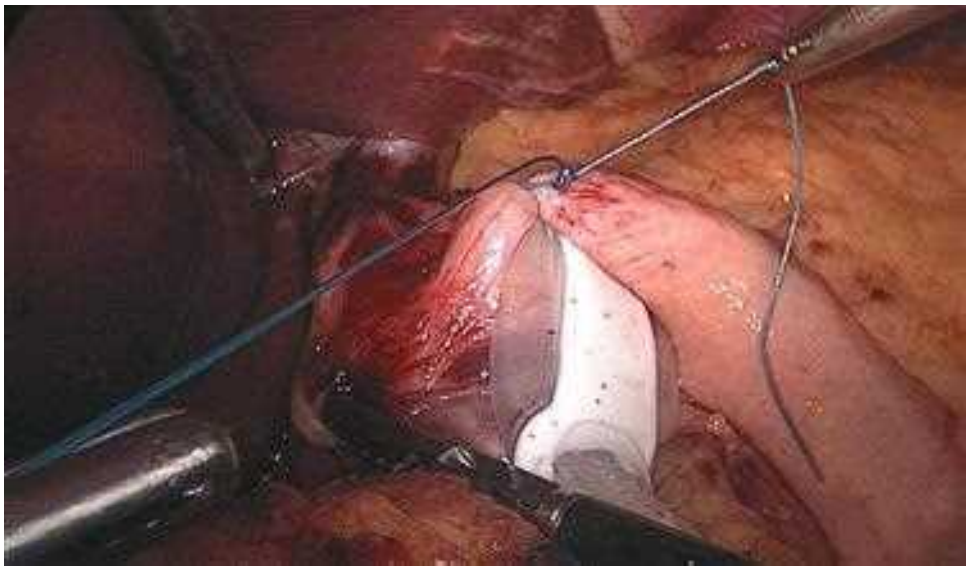

Figure 27-5. Stomach imbricated over band.

The tubing of the band system is brought out through the desired site for placement of the port portion of the system. Usually this is a trocar site near the upper abdomen or xiphoid region to place the port most superficially such that it can be palpated postoperatively. The port is secured to the anterior abdominal wall fascia. Access to the port for subsequent addition of fluid to the band system is percutaneously achieved using a Huber or noncutting type needle. The band is initially placed empty of fluid in most circumstances.

Patient Selection and Preparation. Most LAGB procedures are done on an outpatient basis. Technically the operation is not as difficult as the other operations described later. Because the gastrointestinal tract is not violated, the relative risk of the procedure is lower than most other bariatric operations, making this procedure more amenable to offer to older, more medically ill, or higher risk patient populations. However, efficacy of the operation in the superobese (BMI >50 kg/m^2) is less impressive, with average BMI remaining over 40 kg/m^2 after 5 to 8 years of follow-up.[60] It has been our impression that optimal results occur with this operation in a patient population who is motivated, needs to lose less than 50 kg to achieve a BMI less than 30 kg/m^2, is willing and able to exercise regularly, is amenable to changing eating patterns as recommended, and is within a geographically close enough area for ease of follow-up. Patients who are impatient to lose weight, immobile, unable or unwilling to exercise, or confirmed "grazers" or "nibblers" on high-calorie sweets who expect to be able to continue their dietary habits without great alteration are not good candidates for this operation. Similarly, patients who have had previous upper gastric surgery, such as a Nissen fundoplication, are relatively poor candidates for LAGB due to the potential tissue compromise in taking down the wrap to place the band.

Important points of preoperative preparation specific to the procedure include being nil per os (NPO), receiving preoperative appropriate venous thromboembolism prophylaxis, appropriate broad-spectrum intravenous antibiotics, and having appropriate intravenous access and monitoring. An orogastric tube is inserted into the stomach. These preoperative measures are recommended in all the procedures described later as well.

Postoperative Care and Follow-Up. The majority of LAGB procedures are performed on an outpatient basis. Insurance requirement and pre-existing medical issues are usually the only reason for overnight hospitalization. Diet instructions, wound care, pain medications, and instructions on time schedule of resuming other preoperative medications should all be explained to the patient as well as to a family member (who has not just undergone general anesthesia) prior to discharge. Arrangements for a postoperative follow-up visit, phone numbers to call for emergencies, and indications to call should all be explained as well.

The first postoperative evaluation after LAGB generally occurs 2 to 3 weeks after surgery. By this time, patients have begun to tire of the blenderized diet recommended, are often eager to return to work if they have not done so, and are amenable to discussions of an exercise plan and diet progression plan. Wounds are assessed, as are medical problems, oral intake, and adherence to diet. Since LAGB does not preclude absorption of any specific nutrients, we only recommend a multivitamin for patients whose preoperative lab values are normal. Use of ursodiol (300 mg twice a day) for gallstone prophylaxis after LAGB is variable from surgeon to surgeon. Weight loss after LAGB often does not occur as rapidly as after gastric bypass, and data regarding gallstone formation after LAGB are lacking. However, rapid weight loss after LAGB will occur in some patients justifying prophylaxis with ursodiol.

Band adjustments and postoperative support group sessions are extremely important for good outcomes after LAGB.[61] Band adjustments are paramount as part of the operation. The actual performance of the LAGB procedure is really only a small part of the care of the patient. Frequent postoperative visits, band adjustments as necessary, and participation in an appropriate exercise program are all important for postoperative success for these patients. Recommendations for timing of band adjustments vary from practice to practice. In general, there is agreement that losing less than 2 lb per week is an indication to increase the restriction of the band by adding fluid. Patients who can easily eat most solid foods and have little satiety and a fairly pronounced appetite need additional restriction from the band.

Band fills usually are accomplished in the outpatient clinic setting. Occasionally fluoroscopic radiology is needed to assist in accessing the port, based on the depth of the port from the skin and its ease of palpation. Experience by the person doing the band fill is an important factor in increasing the percentage

of patients able to be accessed in clinic without radiology assistance. A careful record should be maintained of the amount of fluid in each patient's band. Some surgeons will withdraw all the fluid at each fill, reinserting the desired amount. Many will just add additional fluid as indicated. The amount of fluid added is based on hunger, weight loss, and ability to eat meat or bread. Figure 27-6 shows an in-office algorithm adjustment scheme used by Ren and colleagues at New York University.[62] Ideally, adjustments are performed over approximately a 2-year period after surgery. However, changing life and clinical circumstances can require adjustments at any time thereafter.

An optimal situation for LAGB success is a program whose patients all live within an easy drive of the center, will and do participate in frequently available support groups and use exercise facilities supplied by the program, have access to band adjustment visits as needed, and are carefully selected for appropriateness and motivation for the procedure preoperatively.

Outcomes. Medium- to long-term (8-year follow-up) outcomes have been reported for LAGB from Weiner et al.[63] At 5 and 7 years after LAGB, an average of published studies in the literature showed that patients lost 60% and 58% of excess weight, respectively.[64] Resolution of comorbidities after LAGB has been reported as overall very good, with hypertension resolving in 55% at 1 year,[64] observed sleep apnea decreasing from 33% to 2%,[65] GERD improving in over 50% of cases,[66] and asthma,[67] depression,[68] and quality of life[69] improving for patients after LAGB. Dixon and colleagues[70] published a landmark article describing the vastly superior results of managing patients with diabetes using LAGB versus optimal medical management. Resolution of diabetes was 13% in the medical group versus 73% in the surgical group after a 2-year follow-up.

Large institutional series of LAGB results have been published from centers in Europe and Australia, with good results[71,72] for the Lap-Band. Similarly excellent results have been published for the Swedish adjustable band.[73] Buchwald and colleagues[74] performed a meta-analysis of all bariatric surgical papers published from 1990 to 2003. Overall mortality for LAGB was given as 0.1%. Table 27-6 shows the data from this paper and another meta-analysis[75] for weight loss,

Table 27-6
Outcomes for bariatric operations

	LAGB	RYGB	BPD/DS
% Excess weight loss	47.5	61.6	70.1
% Mortality	0.1	0.5	1.1
% Morbidity	10–25	13–38	27–33
% Nutritional morbidity	0–10	15–25	40–77

Source: Buchwald and colleagues.[74]

morbidity, and mortality for LAGB compared with RYGB and the malabsorptive procedures. Table 27-7 also shows data also from Buchwald and colleagues[74] regarding the percentage of resolution of four major comorbidities associated with obesity after the most common types of bariatric operations, including LAGB.

Specific complications that may occur after LAGB include prolapse, slippage, erosion, and port and tubing complications. In addition, just plain failure to lose weight is more commonly seen with this procedure than with other common bariatric procedures.

Prolapse is perhaps the most common emergent complication that requires reoperation after LAGB. The incidence of reoperation is generally around 3%. Postoperative vomiting predisposes to this problem. The lower stomach is pushed upward and trapped within the lumen of the band. Typical patient symptoms include immediate dysphagia, vomiting, and inability to take oral food or liquid. Either anterior or posterior prolapse may occur.[76] The initial evaluation for prolapse involves obtaining a plain film radiograph. If the band is in a horizontal position, prolapse must be strongly suspected. This orientation differs from the normal angulation of the band in the 1 to 2 o'clock and 7 to 8 o'clock positions of the two ends of the band on plain radiograph. Initial treatment for a prolapse is to remove all the fluid from the system. This often allows reduction of the prolapse and resolution of symptoms. If symptoms resolve, the necessity of performing an upper gastrointestinal series is lessened. If they do not, an upper gastrointestinal series is indicated, and if prolapse persists, then reoperation laparoscopically to reduce the prolapse and resuture the band in place is indicated.

Slippage has been greatly reduced by the *pars flaccida* technique, and operative need for repair now occurs in about 3% of cases in most series of short-term follow-up. Longer-term follow-up rates may show higher rates of prolapse. In our experience, a symptom-related need for band deflation, with suspected prolapse, occurs in 10% of patients.

Band erosion is uncommon, reported in 1% to 2% of most series. The patient usually becomes ill but not floridly ill, developing either a port site infection or systemic fever and a low-grade abdominal inflammatory sepsis. Endoscopy can be diagnostic. The presence of otherwise unexplained free air on computed tomography (CT) scan should alert the surgeon to this diagnosis as well. Laparoscopic removal of the band is indicated, with repair of any gastric perforation. Often the perforation is already sealed by an inflammatory process, but if not, appropriate management of a gastric perforation must be followed.[76]

Port and tubing problems occur in approximately 5% of patients undergoing LAGB. These require revision of the port/tubing system due to perforation, leaking, or kinking of the tubing or turning of the port such that access to the surface of the port for adding fluid is precluded. Usually a procedure under local anesthesia is all that is required to repair or realign the tubing or port.

The incidence of band removal for patient dissatisfaction or lack of weight loss is difficult to assess, since this number is increasing annually at a not small rate. The figure also is likely related to patient follow-up and may be artificially low if the patient seeks a second surgeon to remove a band. The true incidence probably varies widely. Angrisani et al[77] reported a 40.9% incidence of band removal after 10-year follow-up.

One of the positive outcomes of LAGB is the safety of the procedure. While complications are not rare, most of them involve non–life-threatening events. Nutritional complications are uncommon and easily treated. Based on worldwide data, the results appear to be optimal in those practices and centers where continued optimal follow-up and encouragement of appropriate behavioral lifestyle changes occur.

The Lap-Band also has its limitations, which may be the cause of its reduced popularity. It is often ineffective in producing adequate weight loss. Restriction of high-caloric liquids, easily digested snacks, and other foods that tend to negate dietary efforts is not adequately achieved with the Lap-Band. Patients must have enough willpower to avoid such foods. If weight loss remains poor, patient frustration and dissatisfaction increase as time passes postoperatively. In centers where suboptimal conditions exist for support and follow-up, the rate of band failure in terms of poor overall weight loss is significant. Reports in the literature tend to only include patients who still have their bands in place and exclude patients who have had bands removed for failure to lose weight. While the latter group of patients probably varies widely from center to center, the trend in many centers to now perform more LRYGB or SG and less LAGB than 5 years ago suggests that LAGB outcomes may rest as much on the postoperative support setting as the operation itself. Centers should reassess their ability to provide optimal follow-up and should do so if possible for optimal long-term results after LAGB.

Laparoscopic Roux-en-Y Gastric Bypass

Background. LRYGB was first described in 1994,[25] but by 1998, only a few centers had accumulated any significant experience with the procedure. The University of Pittsburgh was one of those centers, with Schauer and colleagues performing the procedure, and instituted a large number of training courses from 1998 to 2001, which trained many of the bariatric surgeons who adopted the laparoscopic approach. By 2003, over 130,000 gastric

bypasses were done in the United States, with more than half of them being done laparoscopically. Currently over 90% of gastric bypass operations nationally are performed laparoscopically.

Figure 27-7 depicts the configuration of the LRYGB. The major feature of the operation is a proximal gastric pouch of small size (often <20 mL) that is totally separated from the distal stomach. A Roux limb of proximal jejunum is brought up and anastomosed to the pouch. The pathway of that limb can be anterior to the colon and stomach, posterior to both, or posterior to the colon and anterior to the stomach. The length of the biliopancreatic limb from the ligament of Treitz to the distal enteroenterostomy is 20 to 50 cm, and the length of the Roux limb is 75 to 150 cm. Longer Roux limb lengths are performed but considered to have more malabsorption than the standard gastric bypass.

Experience has resolved several controversies about gastric bypass, but others are still debated. It is clear that creating the proximal gastric pouch by totally dividing it from the distal stomach is superior to simply stapling the stomach, since the latter is associated with a high incidence of staple breakdown.[78] The size of the proximal gastric pouch must be small to create adequate restriction and should be based on the lesser curvature of the stomach to prevent dilation over time. Length of the Roux limb is associated with higher short-term weight loss for longer length limbs,[79] but this difference becomes less on long-term follow-up.[80] Some surgeons doing LRYGB will create a longer (150 cm) Roux limb for patients with a BMI over 60 or even 50 kg/m^2. Antecolic position of the Roux limb is associated with a lower incidence of internal hernias leading to obstruction in most series with short-term follow-up.[81] However, reports with longer follow-up suggest later internal hernia incidence may increase with an antecolic approach.[82] Despite the plethora of enthusiasm for reoperative endoscopic narrowing of the gastrojejunostomy opening,[83-85] good long-term data do not yet exist to confirm that size of the gastrojejunostomy can be related to weight loss. The gastrojejunal anastomosis can be constructed in a variety of ways. Smaller diameter circular staplers are associated with a higher incidence of postoperative stenosis, and linear stapling is associated with a lower incidence of stenosis compared to circular stapling.[86,87]

Technique. The operation generally is performed using five ports plus a liver retractor. Both the surgeon, who stands on the patient's right, and the first assistant, who stands on the patient's left, have two ports for instruments. The telescope requires a port, usually in the supraumbilical region. The assistant's ports are in the left subcostal and flank areas, while the surgeon may have both ports in the right upper quadrant (Cleveland approach) or one on each side of the camera (Virginia approach, Fig. 27-8). Division of the proximal jejunum at 40 to 50 cm distal to the ligament of Treitz is performed with the linear stapler, using the

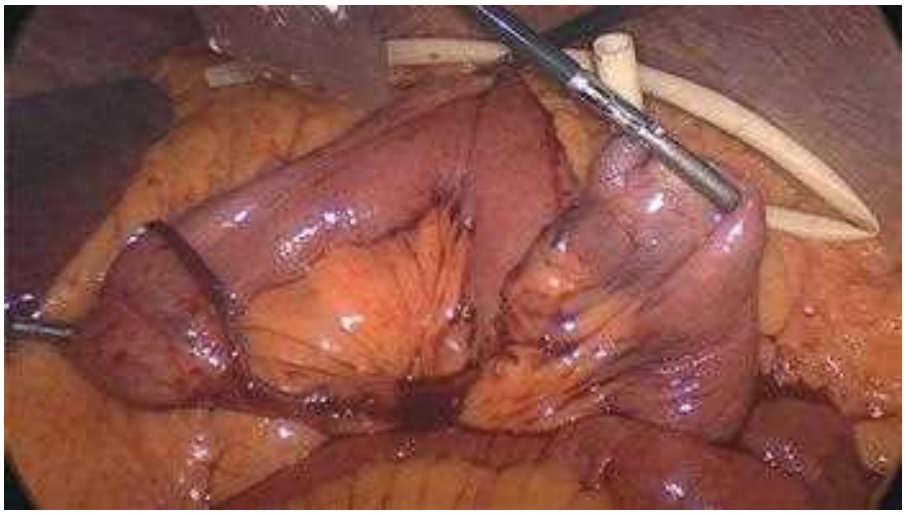

Figure 27-9. Creating Roux limb during laparoscopic gastric bypass.

white stapler cartridge. Further division of the mesentery at that location is performed either with the stapler or harmonic scalpel, such that adequate mobilization of the Roux limb is achieved. A Penrose drain or suture is sutured to the proximal Roux limb (Fig. 27-9) for identification and facilitation of advancement to the gastric pouch.

The length of the Roux limb (usually 100–150 cm) to be created is now measured. A jejunojejunostomy is then created to the proximal end of the biliopancreatic limb at the above-determined location along the Roux limb. A side-to-side stapled anastomosis is performed (Fig. 27-10). Either single- or double-fired staple technique (the latter using a stapler fired in each direction) is used. The stapler defect is optimally closed with sutures but can be closed with a stapler if great care is taken not to narrow the lumen of the alimentary tract at this location. Once the stapler defect is closed, the mesenteric defect is then also closed with running permanent suture.

Passage of the Roux limb toward the stomach is now performed. If an antecolic route is to be used, the end of the Roux limb is brought up so as to confirm its ability to reach the stomach. If a retrocolic route is to be used, a defect is made in the transverse colon mesentery just to the left and slightly above the ligament of Treitz. The Penrose drain and the proximal end of the Roux limb are placed into the retrogastric space (Fig. 27-11).

The left lobe of the liver is now retracted using any one of several retractor types. The patient is moved to a reverse Trendelenburg position. The harmonic scalpel divides the peritoneum in the area of the angle of His. Then it is used to open an area along the lesser curvature of the stomach approximately 3 cm down from the gastroesophageal junction. Another approach for creating access to the lesser curvature of the stomach is to use a white or gray load (vascular load) of the stapler and divide the lesser curvature vessels up to the surface of the stomach. Then a blue load of the stapler is fired one time transversely from the lesser curvature side partially across the stomach, followed by multiple subsequent firings of the stapler upward in the direction of the angle of His, to completely separate the proximal gastric pouch from the remainder of the stomach (Fig. 27-12). Use of an Ewald tube passed by the anesthesiologist and maneuvered to lie against the lesser curvature of the proximal stomach can help calibrate the pouch size.

Once the pouch is created, the Roux limb is brought up to the proximal gastric pouch. For the linear stapled anastomosis, the proximal end of the Roux limb is aligned with the distal gastric pouch end, and the sides of the organs are sutured together to maintain their side-by-side position. A blue load of the stapler is introduced through a gastrotomy and an enterotomy for the two legs of the stapler, and the anastomosis is created (Fig. 27-13).

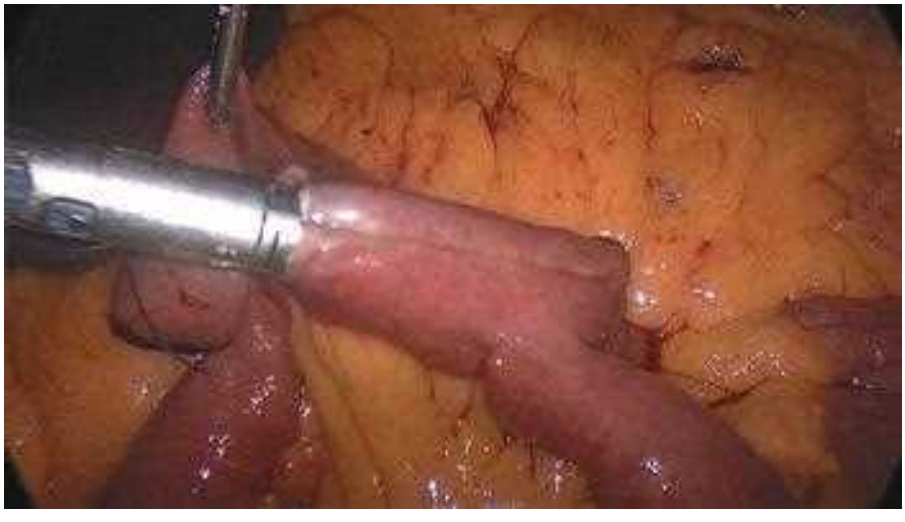

Figure 27-10. Enteroenterostomy of laparoscopic Roux-en-Y gastric bypass.

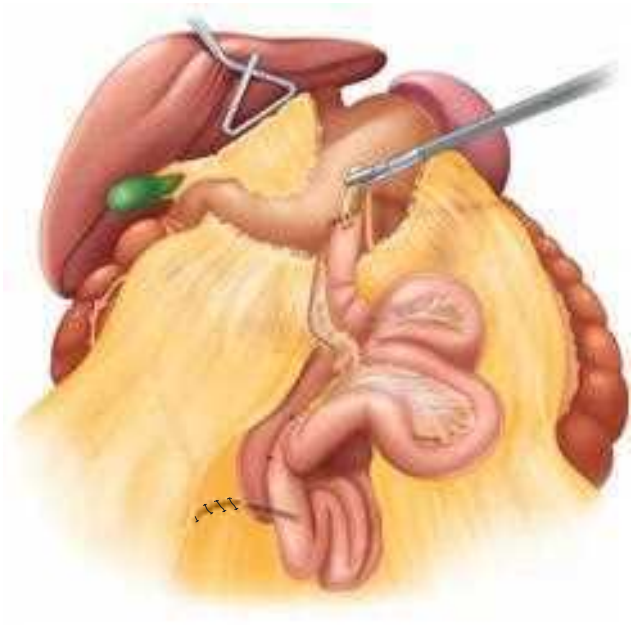

Figure 27-11. Passage of Roux limb. *(From Schauer PR, et al, eds.* Minimally Invasive Bariatric Surgery, *1st ed. New York: Springer; 2007. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All rights reserved.)*

The stapler defect is closed with sutures and often reinforced with a second layer of sutures. At this point, the gastrojejunostomy is tested for security by using either methylene blue injected under pressure through the Ewald tube or a flexible upper endoscopy intraoperatively to test for air leakage from the anastomosis. The latter technique has been shown to decrease the incidence and seriousness of anastomotic leaks postoperatively.[88] The final step of the operation involves suture closure of all mesenteric defects using permanent suture.

Circular anastomosis for the gastrojejunostomy is accomplished through placement of the anvil of the stapler through the anterior wall of the proximal gastric pouch. This is accomplished by pulling the anvil transorally via an endoscopically placed

guidewire (Fig. 27-14), making a gastrotomy in the pouch that is later closed, or making a gastrotomy in the lower stomach before completing gastric division to create the pouch, allowing the anvil to be placed into the lumen of the stomach and then be brought through the anterior stomach in an area that is subsequently included in the proximal gastric pouch (Fig. 27-15).

Hand-sewn gastrojejunostomy is usually created using two layers of absorbable suture to anastomose an approximately 1-cm gastrotomy and enterotomy.

Patient Selection and Preparation. LRYGB is an appropriate operation for consideration for most patients eligible for bariatric surgery. Relative contraindications to LRYGB include previous gastric surgery, previous antireflux surgery, severe iron deficiency anemia, distal gastric or duodenal lesions that require ongoing future surveillance, and Barrett's esophagus with severe dysplasia. Contraindications to a laparoscopic approach to RYGB should cause the surgeon to choose an open RYGB or other open procedure instead.

Preoperative flexible upper endoscopy is indicated in all patients contemplating undergoing RYGB to rule out lesions of the stomach or duodenum noted earlier.[42] Preoperative low-calorie diet for patients with hepatomegaly can decrease liver size and thus improve the chances of completing the operation laparoscopically. We use a mechanical bowel prep to decrease bowel weight and the chance of an inadvertent tear with handling using the laparoscopic graspers.

Postoperative Care and Follow-Up. LRYGB patients are usually hospitalized for 2 to 3 days. Major concerns on the night of surgery include adequate analgesia, adequate fluid resuscitation to provide adequate urine output, and early ambulation. We still routinely employ a postoperative oral contrast study

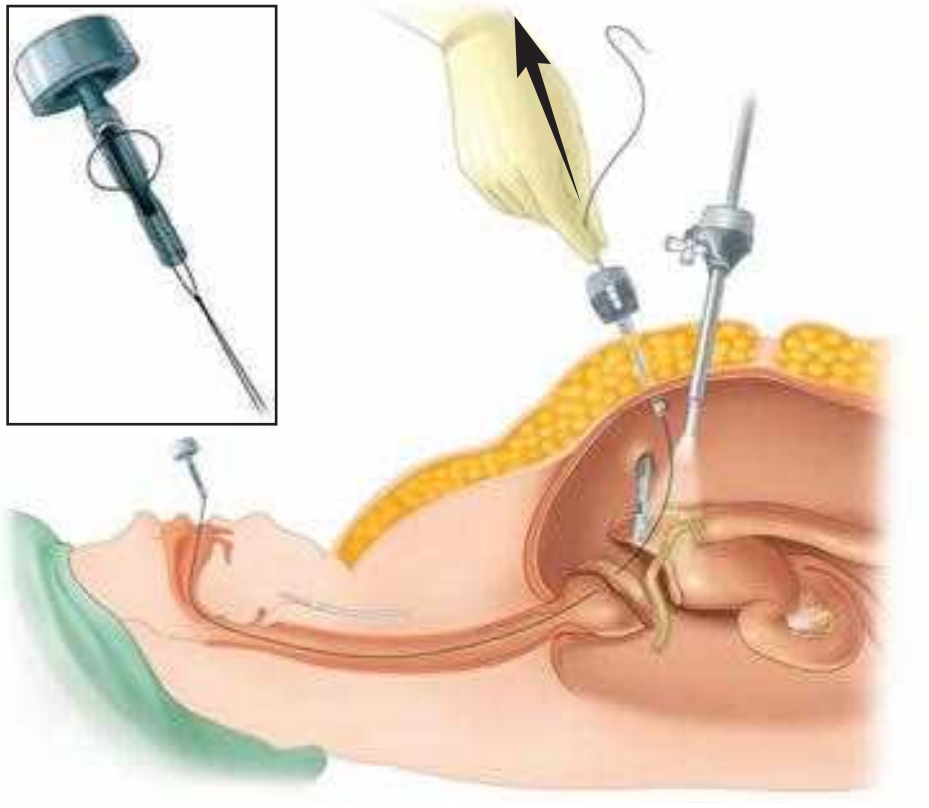

Figure 27-14. Oral passage of EEA circular stapler to create gastrojejunostomy for laparoscopic Roux-en-Y gastric bypass. *(From Schauer PR, et al, eds.* Minimally Invasive Bariatric Surgery, *1st ed. on the first postoperative day. Numerous studies have advocated abandoning this practice due to its lack of accuracy and cost-effectiveness.[89,90] The study's value to us has been to alert us to edema or stenosis of the enteroenterostomy or any other obstructive pattern of the proximal bowel. Obstruction of the enteroenterostomy or beyond can result in distal gastric dilatation over just a period of several hours, which, if untreated, can cause distal gastric staple line rupture with fatal consequences.

Aside from early ambulation, postoperative prophylaxis against venous thromboembolism includes compression shoes and low-molecular-weight subcutaneous heparin. Discharge on a blenderized diet is standard for our practice.

Diet advancement occurs after the first clinic visit, usually approximately 3 weeks after surgery. At that time, an exercise plan is initiated if not already started.

Patients on insulin for type 2 diabetes and on antihypertensive medications should be monitored to determine whether reduction of their medication is indicated. Subsequent follow-up visits are usually scheduled for 3 months, 6 months, and 1 year after surgery, and then annually thereafter. The focus of later postoperative visits is documentation of outcomes and testing for postoperative nutritional deficiencies.

Outcomes. Patients undergoing LRYGB usually lose between 60% and 70% of excess body weight during the first year after surgery. This has held true since the earliest large series of this operation was reported.[91] Resolution of comorbidities varies, but is over 90% for GERD and venous stasis ulcers and over 80% for patients with type 2 diabetes of less than 5 years in duration. Hyperlipidemias are almost always improved and resolve totally in about 70% of cases. Hypertension resolves in 50% to 65% of cases (see Table 27-7). Even superobese patients who do not achieve an ultimate BMI of less than 35 kg/m^2 can experience significant improvements in comorbidities after LRYGB or open RYGB.[92]

Mortality after LRYGB is now consistently less than 0.5% in most large reported series. Recent data from centers applying to be centers of bariatric surgery excellence showed a mortality rate of approximately 0.3% overall. The Bariatric Surgery Center Network (BSCN) of the ACS database showed a mortality of 0.14% at 30 days.[93]

Overall morbidity after LRYGB has been acceptably low. In the BOLD database of the ASMBS, it was 14.87% for 30,864 gastric bypass procedures.[94] In the BSCN database, the 30-day

Table 27-8

Complications for which laparoscopic Roux-en-Y gastric bypass patients require urgent surgical intervention

Small bowel obstruction

Early postoperative hematemesis with obstructive picture
Intestinal leak
Bleeding

morbidity rate was 5.91% for 14,491 LRYGB procedures.[93] LRYGB avoids most wound and incisional hernia problems. Complications that do occur include a 0.3% incidence of anastomotic leak,[95] 0.33% incidence of venous thromboembolism,[96] a 3% to 5% incidence of wound infections or problems,[93] a 3% to 15% incidence of marginal ulcers,[97] an approximately 7% incidence of bowel obstruction,[98] a 4% incidence of postoperative transfusion,[99] and a 1% to 19% incidence of anastomotic stenosis,[87] based on the type of anastomosis created.

Postoperative nutritional complications after LRYGB include a 66% incidence of iron deficiency, a 5% incidence of iron deficiency anemia, a 50% incidence of vitamin B_{12} deficiency,[100] and an at least 15% incidence of vitamin D deficiency,[101] which usually is present preoperatively.

Several complications that are specific to LRYGB must be emphasized. One of the most important is small bowel obstruction. This complication must be treated differently than in the average general surgery patient, whose complication is usually from adhesions and often will resolve with conservative, nonoperative therapy. Patients who have had LRYGB who present with obstructive symptoms generally **require surgical therapy on an emergent basis (Table 27-8).** This is because the etiology of the bowel obstruction after LRYGB is often an internal hernia from inadequate or nonclosure of the mesenteric defects by the surgeon at the time of operation. Thus, treatment for these patients differs from most patients with small bowel obstruction. One of the **most important points** of this chapter is to emphasize to general surgeons to be aware of the need to emergently operate on patients after LRYGB who present with small bowel obstruction. Currently, centers that perform small bowel transplantation are seeing patient referral for that procedure after small bowel obstruction after LRYGB, where patients developed infarction of most of the bowel from an internal hernia and have short gut syndrome.[102] Other patients, for whom surgery is delayed and the bowel infarcts, do not survive. When the surgeon does encounter bowel obstruction after LRYGB, he or she can expect to see proximally dilated bowel. Cutoff of passage of contrast on CT scan at the enteroenterostomy is particularly suggestive of this diagnosis (Fig. 27-16). The surgical treatment of this particular problem can, if addressed early in the course of the obstruction, be treated laparoscopically. The surgeon must place a trocar for the telescope low enough in the abdomen to adequately survey most of the small intestine. The cecum and terminal ileum are identified, and the bowel is followed retrograde from the terminal ileum to determine the anatomy. Often much of the small bowel is herniated through a mesenteric defect, and only this technique allows the surgeon to reliably identify the bowel and decompress it appropriately. If the bowel is viable, suturing the mesenteric defect is all that is needed for treatment. It should be emphasized that either an antecolic or retrocolic placement of the Roux limb can result in this complication, as internal hernias can arise from either approach.

Marginal ulcers are another complication relatively specific to RYGB, either LRYGB or open RYGB. The patient presents with pain in the epigastric region that is not altered by eating. Diagnosis is by endoscopy. Treatment is medical with proton pump inhibitors, which are effective in 90% of cases. Only those with a gastrogastric fistula to the distal stomach, severe stenosis of the lumen of the gastrojejunostomy, or acute perforation require surgical therapy.

Stenosis of the gastrojejunostomy has been remarkably reduced by the use of a linear stapling technique in our experience.[86] Stenosis symptoms usually appear from 6 to 12 weeks postoperatively, but less commonly can occur later. Diagnosis is by upper endoscopy. Treatment is balloon dilatation. Resolution normally occurs with one or two treatments. Less than 10% of patients require reoperation, and those are almost always associated with concurrent marginal ulcers.[103]

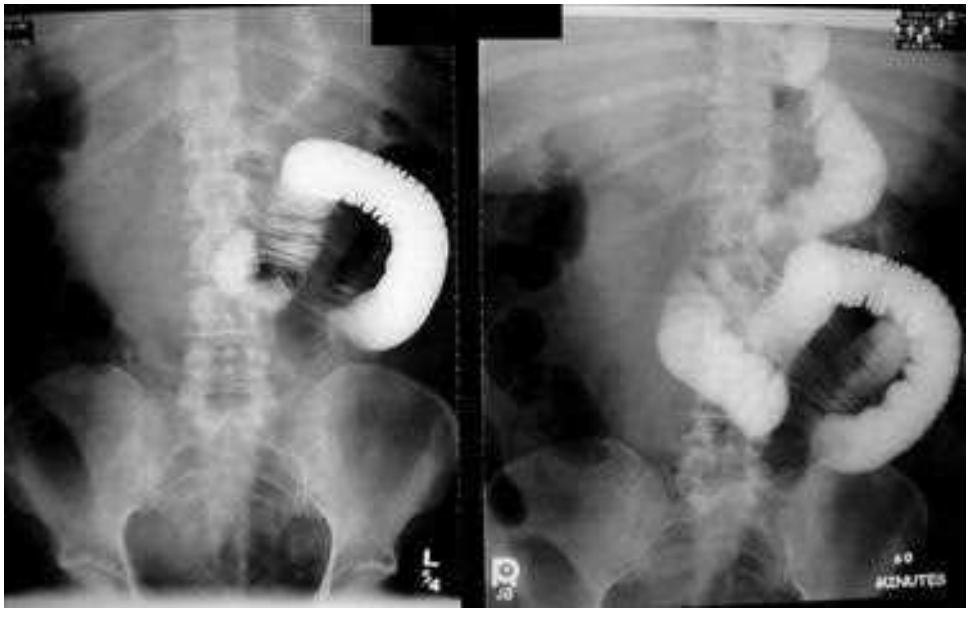

Figure 27-16. Obstruction of contrast at enteroenterostomy with small bowel obstruction from internal hernia after laparoscopic Roux-en-Y gastric bypass.

In the immediate postoperative period, anastomotic leak is the single most feared complication after RYGB, either open or laparoscopic. Careful vigilance and a high index of suspicion for this problem are the only appropriate approach, since its presentation may be insidious and the patient's demise, if untreated, sudden and complete. Tachycardia, tachypnea, fever, and oliguria are the most common symptoms that arouse suspicion for this problem. The treatment is surgical except in rare circumstances where a drain is already in place, no hemodynamic or clinical deterioration is present, and the leak is contained.[104] Usual surgical treatment involves repair as feasible, drainage, and creation of a reliable feeding access through a distal Stamm gastrostomy.

In the first few hours or day after surgery, hematemesis indicates bleeding from the gastrojejunostomy unless proven otherwise. The dangers to the patient include aspiration, life-threatening hemorrhage, or more commonly intraluminal hematoma of the Roux limb and enteroenterostomy, which then causes an obstruction of the biliopancreatic limb leading to distal gastric staple line rupture. In fact, any obstructive symptoms in the first few weeks after surgery or any signs of obstruction of the biliopancreatic limb on postoperative swallow studies due to stenosis of the enteroenterostomy require immediate surgical intervention to prevent rupture of the distal gastric staple line. Some reports show that percutaneous decompression of the distal stomach can ameliorate the danger.[105] Alternatively, operative therapy to decompress the stomach and treat the obstructive problem is also a reasonable option.

Overall, LRYGB has the significant advantages over open RYGB of avoiding incisional hernias and severe wound infections. Table 27-9 shows the data on these problems, comparing outcomes for laparoscopic versus open procedures at the University of Virginia. Compared with other bariatric surgical procedures, the LRYGB offers a reliable and powerful operation to allow the severely obese patient to lose weight. Although more reliable and greater, this weight loss does come at a slightly higher complication rate compared with LAGB and SG. However, these complication rates, as well as mortality, have been steadily decreasing for LRYGB in the past decade.

Open Roux-en-Y Gastric Bypass

Background. As described earlier in the chapter, Mason and Itoh[26] first described gastric bypass, and Griffin and colleagues[27] first described its Roux limb modification. It has been the most time-tested and proven of all bariatric operations. The procedure is now done virtually the same as LRYGB, with the only difference being the access route to perform it. Experienced bariatric surgeons who do not perform laparoscopic surgery still perform this operation with excellent overall outcomes,[56] but their numbers are diminishing. RYGB was the most popular operation performed in the United States in the 1990s, but is now far exceeded by LRYGB and LAGB in terms of volume due to the preference of patients to undergo a laparoscopic rather than open procedure. However, for the patient for whom a laparoscopic approach fails, RYGB must be an operation that the bariatric surgeon can perform with skill.

Technique. RYGB is performed essentially the same as LRYGB. Some surgeons who use an open approach prefer to perform creation of the gastric pouch as the first part of the procedure, but in essence, the net procedure is the same. Access for open RYGB is usually through an upper midline incision, although a left subcostal incision has been reported to furnish adequate access as well. Closure of the midline wound is performed using a running monofilament suture. Subcutaneous tissues are thoroughly irrigated, and skin is closed with a skin stapler.

Patient Selection and Preparation. Patient selection is essentially the same as for LRYGB, since the operation is the same. Extraordinarily large patients or those with multiple previous abdominal operations, particularly previous gastric surgery, left colectomy, and splenectomy, often require an open incision to perform RYGB. Abdominal wall thickness and liver size are other factors that may require an open incision approach. Patients who have an existing large midline incisional hernia are also candidates for an open approach.

Preparation for open RYGB is identical to LRYGB.

Postoperative Care and Follow-Up. The postoperative care of the patient undergoing open RYGB is very similar to that of the patient undergoing LRYGB. Larger volumes of fluid resuscitation and often more narcotic analgesics are required the day of surgery and often the next as well. Greater attention must be paid to the incision site for potential infection, since an inadequately treated wound infection in these patients can extend easily to the fascial level and cause significant tissue loss before it is fully diagnosed. The perioperative care of open RYGB patients is usually more intense, often because such patients are very large, and concurrently have severe comorbidities, making them higher risk overall for complications of all types. It is interesting, though, that since the era of LRYGB,

Table 27-9

Outcomes for laparoscopic versus open Roux-en-Y gastric bypass (University of Virginia 1994–2004)

CHARACTERISTICS	LRYGB	ORYGB	*P* VALUE
Preoperative body mass index (kg/m^2)	50.9 ± 0.3	57.5 ± 0.5	<.001
Number of comorbidities	2.7 ± 0.1	3.6 ± 0.1	<.001
30-day mortality	2 (0.3%)	6 (1.7%)	<.02
Overall complications	111 (14.5 %)	208 (57.3%)	<.001
Reoperation	67 (8.8%)	150 (41.3%)	<.001
Incisional hernia	13 (1.7%)	123 (33.9%)	<.001
Wound infection	14 (1.8%)	27 (7.4%)	<.001

LRYGB = laparoscopic Roux-en-Y gastric bypass; ORYGB = open Roux-en-Y gastric bypass.

patients who still undergo open RYGB (usually due to intraoperative conversion) in our practice often are discharged within 1 day of the laparoscopic patients. Our overall length of stay has decreased for RYGB patients based on postoperative pathways geared toward LRYGB.

Postoperative follow-up visits are similar to those of LRYGB patients, with the first visit being timed to appropriately remove skin staples. Other visits, follow-up schedule, and blood testing are identical to LRYGB.

Outcomes. The weight loss statistics and patterns for RYGB are comparable to those of LRYGB, as would be expected. Postoperative deaths are slightly higher for RYGB, but this is almost certainly due to the patient population, which is often among the most severely medically compromised preoperatively. Flum and Dellinger[106] showed that for a patient population on Medicare insurance, and hence largely disabled, RYGB had an across-the-board mortality rate of 2.0%. This rate is considerably higher than the 0.3% to 0.4% incidence that was reported for programs applying at that time as bariatric COEs and is in large part due to the patient population. Interestingly, in the report by Flum and Dellinger, surgeons with the most experience had a mortality rate of less than 1.0% for this patient population, suggesting that surgeon experience and patient selection by experienced surgeons influence mortality for RYGB.

One of the most important population studies showing the benefit of bariatric surgery was done in patients undergoing RYGB. Christou and colleagues[107] showed a lower incidence of mortality (0.68% vs. 6.17%) in the 5-year follow-up of over 1000 patients undergoing RYGB versus over 5000 severely obese individuals who did not have surgery. This was a reduction of 89% in the death rate.

The incidence of postoperative complications for RYGB is higher than that of LRYGB, due largely to increased morbidity from incisional hernias and other wound-related problems (see Table 27-9). Other than incisional hernias, the long-term results of patients undergoing RYGB are similar to those undergoing LRYGB, including nutritional issues, weight loss, and overall resolution of comorbidities.

Biliopancreatic Diversion and Duodenal Switch

Background. BPD was first described by, and remains championed by, Scopinaro in Italy.[32] The operation, which is shown in Fig. 27-17, involves resection of the distal half to two-thirds of the stomach and creation of an alimentary tract of the most distal 200 cm of ileum, which is anastomosed to the stomach. The biliopancreatic limb is anastomosed to the alimentary tract either 75 or 100 cm proximal to the ileocecal valve, depending on the protein content of the patient's diet. This operation met with limited international popularity, due to the technical difficulty to perform it combined with the significant percentage of nutritional complications that arise postoperatively. However, the procedure did develop a devoted following among a few bariatric surgeons.

One complication that plagued the BPD was the development of a high incidence of marginal ulcers postoperatively. Hess and Hess[33] and Marceau and colleagues[108] separately described the adaptation of the DS operation, originally proposed by DeMeester and colleagues[109] for treatment of bile reflux gastritis, to replace the gastric portion of the BPD. This new procedure was originally called BPD with DS. For ease of description, we now simply use the term *duodenal switch (DS)* to describe this procedure. It is illustrated in Fig. 27-18.

Figure 27-17. Diagram of biliopancreatic diversion. *(From Schauer PR, et al, eds.* Minimally Invasive Bariatric Surgery, *1st ed. New York: Springer; 2007. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All rights reserved.)*

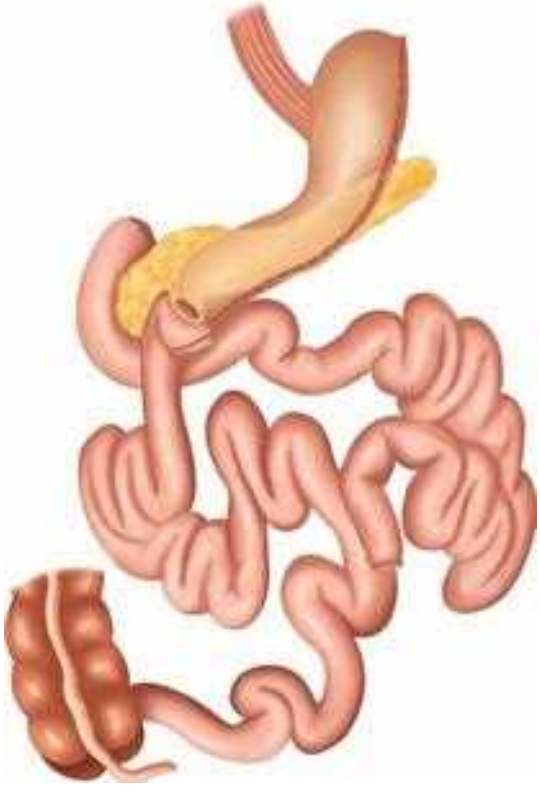

Figure 27-18. Diagram of duodenal switch. *(From Schauer PR, et al, eds.* Minimally Invasive Bariatric Surgery, *1st ed. New York: Springer; 2007. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All rights reserved.)*

Currently BPD and DS represent together less than 3% of bariatric operations performed in the United States, and this rate could be as low as 1% to 2%. The lack of a significant number of surgeons offering the operation, especially via a laparoscopic approach, probably has a great deal to do with that statistic. BPD and DS are, however, recognized as standard bariatric operations and approved for coverage by most insurance companies at this time.

Technique. The technique for BPD will be described for the open approach, but the laparoscopic approach essentially reproduces what is done with the open approach, using different access. Laparoscopic BPD and DS are very technically challenging operations, perhaps another contributing factor to the relatively low numbers of surgeons offering these operations.[110]

The BPD operation begins with performance of a distal subtotal gastrectomy. A residual 200-mL gastric pouch is created for superobese patients, or a slightly larger pouch is created for patients with a BMI under 50 kg/m^2. The terminal ileum is identified and divided 250 cm proximal to the ileocecal valve. The distal end of that divided ileum is then anastomosed to the stomach, creating a 2- to 3-cm stoma. The proximal end of the ileum is then anastomosed side-to-side to the terminal ileum approximately 100 cm proximal to the ileocecal valve. Some surgeons perform the anastomosis only 50 cm proximal to the valve, but in these patients, the likelihood of good protein intake postoperatively should be high. Prophylactic cholecystectomy is performed due to the high incidence of gallstone formation with the malabsorption of bile salts.

The DS procedure differs from the BPD only in the proximal gut portion of the operation. Instead of a distal gastrectomy, resection of all the stomach except for a narrow lesser curvature tube of the stomach is performed. The diameter of this tube is calibrated with a dilator and, if limited to a 32- to 40-French diameter, produces the optimal amount of weight loss while still allowing adequate oral intake. The duodenum is now divided in its first portion, leaving an approximately 2-cm length of duodenum intact beyond the pylorus. This end of the duodenum is then anastomosed to the distal 250 cm of ileum. This anastomosis is often done in an end-to-end fashion with a circular stapler. It is the most difficult portion of the DS procedure, and leak rates are slightly higher than with other anastomoses. The distal bowel configuration and cholecystectomy are similar to BPD.

Patient Selection and Preparation. Patients who undergo either BPD or DS must be prepared for the consequences of a malabsorptive operation. Frequent and large-quantity bowel movement after any large amount of oral intake is common. Patients who have this procedure must be willing to accept frequent, voluminous bowel movements and will also usually modify their eating pattern to restrict intake if access to a bathroom will prove difficult. Patients who undergo either operation must agree to close follow-up preferably *by the surgeon.* Internists and family physicians may not appreciate the issues related to protein-calorie malabsorption if they occur and treat the patients instead for congestive heart failure. Disastrous results may then occur. Patients must also have the financial means to afford the large number of vitamin and mineral supplements that must be taken to avoid nutritional problems in this patient population.

Given the increased incidence of postoperative nutritional and other complications relative to any of the restrictive operations, BPD and DS usually are recommended only for patients who have superobesity or for whom it is reasonable to believe they will not succeed with the diet and exercise requirements that form the basis for long-term success with restrictive operations. Patients who have failed a restrictive operation and are considering reoperation are candidates for these procedures.

Contraindications to the procedure include geographic distance from the surgeon, lack of financial means to afford supplements, and preexisting calcium, iron, or other nutrient deficiencies.

Postoperative Care and Follow-Up. Patients undergoing BPD or DS must be followed closely and with absolute completeness for nutritional issues long term. Postoperatively, BPD and DS patients face the same potential complications as seen after RYGB. Anastomotic leaks, pulmonary compromise and complications, gastrointestinal bleeding, anastomotic stenosis or obstruction, and infections are all potential concerns during the index hospitalization. The long gastric staple line and the duodenoileostomy of the DS and the duodenal stump and gastroileostomy of the BPD are all areas of anatomic concern postoperatively. Distal anastomotic problems can occur with either procedure as well. Thorough preoperative and postoperative counseling by a nutritionist versed in the operation and potential nutritional deficiencies is essential. Vitamin and mineral supplements must be taken regularly on follow-up, including oral supplements for iron, calcium, and vitamin B_{12} and a multivitamin. Fat-soluble vitamins must be supplemented in parenteral form. Careful monitoring of protein intake and serum albumin is necessary. More frequent follow-up than with RYGB is needed; checkups at 2-month intervals for the first year and semi-annual or more frequent visits thereafter are appropriate.

Outcomes. Weight loss results with BPD or DS are both excellent and comparable. They also are very durable. One 18-year follow-up study after BPD showed a mean excess weight loss of 70% persisting for that duration of time.[111]

Although most of the results of BPD or DS are after open operations, one report of laparoscopic DS showed that for 40 patients with an average BMI of 60 kg/m^2 the mean hospital stay was 4 days, average operation room time was 3.5 hours, and mean excess weight loss at 9 months was 58%.[112]

Buchwald and colleagues[74] showed that the average weight loss after BPD and DS in the literature was over 70%, with mortality rate of 1.1%, complication rate of 27% to 33%, and nutritional complication rate of 40% to 77% (see Table 27-6).

Complications that occur after the BPD include those seen after RYGB, where intestinal anastomoses and gastric division create potential problems. Scopinaro and colleagues[111] reported obstruction in 1.2%, wound infections in a similar rate, and marginal ulcer in 2.8% of patients. However, others found the incidence of marginal ulcer to be higher after BPD, causing the adoption of the DS. Preservation of the pylorus drastically reduces the significant incidence of dumping (poorly quantitated in most series) after BPD. The duodenoileostomy of DS also has a very low rate of stomal ulcer, unlike the gastroileostomy of BPD.

Nutritional complications are by far the most frequent and concerning after both of these operations, particularly on long-term follow up. Scopinaro and colleagues[111] reported a protein malnutrition rate of 7%, iron deficiency anemia rate of less than 5%, and bone demineralization at 5 years of 53%. Other problems that may arise include alopecia from inadequate protein absorption, night blindness from a lack of vitamin A, and

gallstones if the gallbladder is not removed. However, of all these nutritional complications, protein-calorie malnutrition is the most severe and life-threatening. When it is diagnosed, the treatment is parenteral nutrition. Two episodes of required parenteral nutrition are usually considered adequate indication to lengthen the "common channel" of ileum—the ileum between the ileoileostomy of the biliopancreatic limb to the alimentary tract and the ileocecal valve. The amount that the surgeon should lengthen it is poorly documented, but most surgeons will favor making it long enough to be certain to avoid recurrence of the problem, such as doubling the length of the common channel, even if it decreases weight loss somewhat.

It cannot be emphasized enough that patients who undergo either BPD or DS should be impressed with the fact that lifetime nutritional supplements and lifetime follow-up are essential to preserve good health after these operations.

Laparoscopic Sleeve Gastrectomy

Laparoscopic sleeve gastrectomy has taken the bariatric surgical scene by storm over the past 5 to 10 years. It is rapidly increasing in popularity, and by the time this book is published, it may be, in some countries and areas, the most popular bariatric and metabolic operation performed. Its rapid rise in popularity coupled with good initial results suggest that it will be a major component of patient care for the treatment of morbid obesity and its comorbid medical problems for years to come in the future.

Since sleeve gastrectomy is performed almost exclusively using a laparoscopic approach, the remainder of this text will use the simple term sleeve gastrectomy (SG) to describe the procedure, with the understanding that it is routinely performed using a laparoscopic approach. SG had its origins in the early days of laparoscopic bariatric surgery. The procedure represents the gastric portion of the DS procedure.[33] Ren and colleagues[112] reported an initial experience of performing DS using a laparoscopic approach that had relatively higher mortality than seen with gastric bypass or other treatment options being performed laparoscopically. This was in part due to the fact that patients selected to receive DS often were significantly larger and had more numerous and more severe comorbid medical problems. Gagner began to perform the gastric resection portion of the DS operation as a first-stage procedure. After patients had lost weight, the malabsorptive component of the procedure was then performed. However, many of the patients had such good results after the first stage of the procedure that they refused to proceed to the second portion.[113] Thus, the concept of performing SG as a primary procedure was born.

Until 2009, SG was considered an "experimental" procedure by insurance carriers. That year, the ASMBS reviewed the data on the procedure and published a statement in January of 2010 recognizing the procedure had adequate data and results to support its use as a primary bariatric operation for carefully selected patients.[114] Shortly thereafter, SG received a designated Common Procedural Terminology (CPT) code. Since that time, insurance carriers have recognized the procedure as being appropriate for treating severe obesity and its comorbid problems. The final carrier, Medicare and Medicaid in the United States, issued a statement in April 2012 that left the determination of coverage of this procedure to the regional insurance carriers administering Medicare. This happened only after a hearing to determine coverage in which a great deal of data was presented in favor of the procedure. The initial conclusion of that panel was that SG should be reimbursed if performed in the setting of a prospective randomized trial. However, subsequent public opinion and data caused CMS to revise its decision to allow regional carriers to determine coverage.

SG has the advantage of being a technically easier operation to perform than gastric bypass, while achieving better efficacy in treating comorbid medical problems and producing superior weight loss than LAGB. Once the results of the procedure began to be published, understood, and accepted, its popularity rose dramatically. In the United States, the incidence of performing SG has risen rapidly since 2008, as shown in Fig. 27-19. The incidence of SG is increasing at a rate that suggests that within the next 2 years it may pass LRYGB as the most popular bariatric operation performed in the United States.

6▶

Throughout the rest of the world, the popularity of SG has also risen dramatically in the past 5 to 8 years. In Asia, where there is a high incidence of gastric cancer in countries such as Japan, SG makes more sense anatomically as an appropriate treatment for severe obesity. In India, where the high incidence of diabetes in the obese population makes metabolic and bariatric surgery a desirable option, SG has gained popularity once its effectiveness in treating diabetes was shown. Figure 27-20 shows the trend in performance of several bariatric operations in Asia from 2003 to 2011, during which the totals of those procedures from surgeons surveyed increased over 500%.[37] This rise in bariatric and metabolic surgery was comparable to the same increase in percentage of cases performed seen in the United States from 1998 to 2003. In Europe, the past few years have seen a clear trend away from performing LAGB and a higher incidence of performing both SG and LRYGB.[37]

Indications. Patient selection for SG is comparable to that for other bariatric and metabolic operations with a few notable exceptions. SG was originally introduced as the first of a two-stage operative treatment for patients with super obesity (BMI >60 kg/m^2).[115] It remains an effective first- or second-stage treatment for such patients. Whether a second stage is indicated depends on the effectiveness of the SG. SG has been shown to be safe and effective in adolescent obese patients.[116] It has also been shown to be an acceptable procedure for the elderly obese patient.[117] SG effectively treats most of the comorbid medical problems associated with obesity. The one exception is GERD. Patients with GERD experience less resolution of their symptoms after SG than do patients with LAGB, even when the LABG patients lost less weight overall.[93] Patients who have longstanding severe GERD may not be good candidates for SG. Barrett's esophagus is considered a relative contraindication for performing SG, since the potential for future esophagectomy and the need for an available intact stomach for reconstruction outweigh the potential advantages of the procedure.

Technique. The patient is positioned supine, with foot support to allow reverse Trendelenburg positioning. The surgeon stands to the patient's right along with the camera driver, while the assistant stands to the patient's left. Port placement may vary from institution to institution, but our recommended port placement is shown in Fig. 27-21. The 15-mm port, helpful for removal of the stomach, is located in either the camera (just to the patient's left of the umbilicus) or surgeon's right hand (right upper quadrant near the midline) location. The other of these ports is a 12-mm port. The assistant has two 5-mm ports available in the left upper quadrant laterally, and the surgeon's left hand port is a 5-mm port more lateral and superior in the right upper quadrant. A liver retractor is placed in the epigastric region. This can be a Nathanson or T-Boone retractor.

The operation begins by devascularizing the greater curvature of the stomach, beginning 3 to 5 cm proximal to the pylorus. The harmonic scalpel works nicely to perform this tissue division. The division of all vessels adjacent to the greater curvature is continued up to the left crus of the diaphragm. A complete mobilization of the fundus in this area and division of posterior

Figure 27-21. Port scheme for Laparoscopic sleeve gastrectomy.

fibrous attachments to the antrum and body of the stomach are then performed such that the stomach is attached solely by the lesser curvature blood supply and the pyloric and esophageal regions. Stapled division of the stomach now follows. The first firing of the stapler occurs from the point of devascularization of the greater curvature at an angle pointing toward a point about 2 cm lateral to the incisura. The antrum of the stomach is at its thickest here, and so it is important to be certain the stapler load used is sufficiently large enough to allow good approximation and closure of the divided stomach. We have favored use of the black load (2.5-mm staple height) in all males with a BMI over 45 kg/m^2, females with a BMI over 55 kg/m^2, or anyone whose stomach looks particularly thick. A green load (staple height of 2 mm when closed) is used for less thick stomachs or smaller individuals. We continue the use of this color load for the first two firings, which takes the gastric division to past the incisura. After the first staple firing, some surgeons will engage the anesthesiologist to pass a 32- to 36-French bougie and position it along the lesser curvature of the stomach. This bougie then serves as a guide for further gastric division. Alternatively, some surgeons will insert the endoscope instead of the bougie as a guide for gastric division. It can also be used to test for air

leaks, bleeding, or obstruction as it is withdrawn after gastric division. Dividing the stomach adjacent to the bougie or endoscope will produce the desired diameter of the gastric sleeve. It is most important **not to narrow the stomach lumen at the incisura**. During the second and third firing of the stapler to divide the stomach, it is critical to confirm by visualization of both the anterior and posterior surfaces of the stomach that the incisura area is not narrowed. By the third firing of the stapler, usually the angle of the gastric division is now pointed directly toward the angle of His, parallel to the bougie (Fig. 27-22). At this point, changing staple loads to lower staple height is advisable. We usually switch to gold then blue staple loads as we progress proximally in dividing the stomach. It is essential that with each firing of the stapler, adequate time (10–20 seconds) is allowed for tissue compression to allow optimal staple closure and security of the divided tissue.

Once the stomach is completely divided up to the angle of His, the staple line is inspected for hemostasis and integrity. Some surgeons will reinforce the staple line with a buttress material, while others will invaginate the staple line with a running serosa to serosa suture. Some surgeons will exchange the bougie at this point for a 32-French Ewald tube and perform a methylene blue leak test. Alternatively, if an endoscope is used, it is withdrawn with insufflation, and the staple line is inspected for air leaks while submerged in saline. The specimen is removed through the 15-mm trocar site, usually with only slight enlargement of the site. Figure 27-23 shows the completed operation.

Controversy still exists as to the optimal size of the bougie used during the procedure. One summary of the literature shows that the stenosis rate is lower if a 40-French bougie is used, and the leak rate may also be lower without compromising weight loss.[118] However, individual institutional experiences with smaller-sized bougies have shown the potential for exceptionally good weight loss and no increased incidence of stenosis.[119] Another controversial area is that of staple line reinforcement

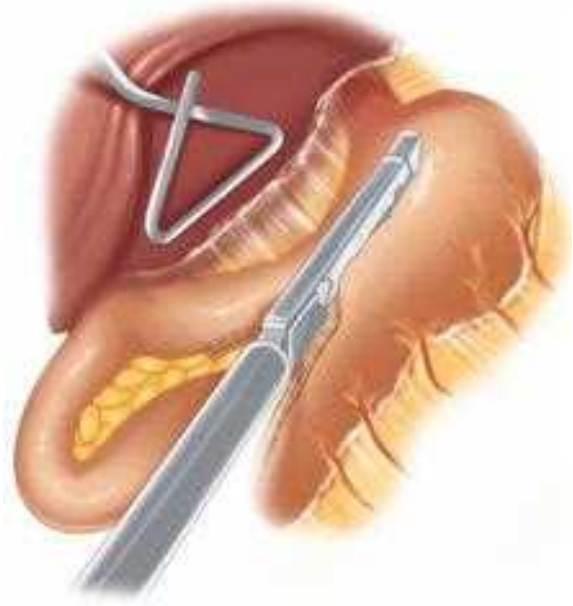

Figure 27-22. Performing sleeve gastrectomy. *(From Schauer PR, et al, eds.* Minimally Invasive Bariatric Surgery, *1st ed. New York: Springer; 2007. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All rights reserved.)*

with staple buttressing material. Some surgeons advocate routine staple line reinforcement, whereas others advocate none. Still others advocate oversewing of the staple line in areas of bleeding or in selected cases that show a predilection for bleeding intraoperatively. Other experts advocate routine oversewing of the entire staple line.[120] At this time, there is no preponderance of data to support one approach as being superior to others.

Postoperative Care and Follow-Up. SG usually is performed with an overnight stay of 2 nights after surgery. Longer hospitalizations are indicated for patients with more severe medical problems. Absence of signs of bleeding and a documented intact staple line with good gastric emptying are required prior to discharge. Routine Gastrografin swallow on the first day after surgery is used by many surgeons, but its efficacy and cost-effectiveness have yet to be clearly documented. Follow-up is similar to that after LRYGB. Few nutritional complications occur unless the patient has difficulty taking in enough nutrients or protein or vitamins due to edema or tightness of the sleeve lumen. Most surgeons advocate routine vitamin B_{12}. Iron supplementation may be required as well since iron in the diet is usually drastically restricted by elimination of many foods rich in iron. It is unclear whether the same need for vitamin D supplementation seen after LRYGB is also needed after SG, since there is a high incidence of low 25-hydroxyvitamin D levels preoperatively in patients undergoing SG.[121] Routine multivitamins are usually prescribed to avert any potential other shortages from dietary vagaries.

The other aspect of weight loss that must be considered in the nutritional aspects of postoperative care and follow-up after SG is that patients are at risk of losing significant lean body

mass while they are also losing weight. Damms-Machado and colleagues[121] showed that SG patients' lean body mass decreased from 74.8 kg to 62.3 kg at 1 year after SG. This emphasizes the need for high protein content in the postoperative diet of SG patients to maintain lean body mass.

Outcomes and Complications. Reports in the literature of the success and excellent weight loss after SG have been accumulating since 2006.[122,123] The first very large series from a single institution reported 750 patients undergoing SG as a primary weight loss procedure. Five-year follow-up of some patients was available, and a hospital stay averaging 1.7 days, a major complication rate under 5%, an operative time under 80 minutes, and no conversions or mortality were reported.[124]

Brethauer and colleagues[125] published an excellent review of the early data on SG through 2009. For the collected number of patients treated with SG (2750 patients), the excess weight loss rate was 55.4%. Studies with 5-year follow-up for SG are not yet common. One highly successful series was recently reported by Rawlins and colleagues[119] for 49 patients followed for 5 years after SG with an average weight loss of 86% of excess weight and a decrease in average BMI from 65 to 35 kg/m^2. One of the longest follow-up studies for SG by Eid and colleagues[126] demonstrated an average excess weight loss of 48% and BMI decrease from 66 to 46 kg/m^2 in 74 superobese patients with 6- to 8-year follow-up.

Prospective randomized trials comparing SG with other procedures have shown that SG is superior to LAGB for excess weight loss at 3 years (66% vs. 48%).[127] One study reported that SG achieved a superior excess weight loss compared with LRYGB (69.7% vs. 60.5%) at 1 year after surgery. This study also found greater appetite suppression and a lower serum ghrelin level for SG.[128]

SG has been included in the results of large databases showing outcomes after bariatric surgery. Data from the ACS BSCN showed that SG was positioned between LAGB and LRYGB for efficacy of weight loss and resolution of comorbid medical problems and for morbidity and mortality.[93]

As noted earlier, controversy exists as to whether the use of buttress materials with the stapling of the stomach improves outcomes. The overall bleeding rate for the staple line after SG is generally cited as about 2% in collected series.[125] There have been no studies that have shown a definitive decrease in this bleeding rate with the use of buttress materials; however, a panel of experts has voiced support for a decreased incidence of bleeding from the staple line if buttress material is used.[120]

Measures to prevent staple line leakage are similarly controversial with respect to buttress materials and other measures. It is certain that appropriate stapling technique in dividing the stomach is important. Using an adequately high staple height for the tissue to be divided and allowing an adequate amount of time for tissue decompression within the stapler jaws before firing are essential to minimize the likelihood of a staple line leak. Failure to perform gastric division appropriately in this fashion will lead to an early staple line leak after surgery. Whether buttress materials do decrease the leak rate with SG is very controversial. One meta-analysis did show that there is evidence to suggest buttress materials may decrease this rate.[129] Other prospective randomized studies have failed to show a benefit of buttress materials.[130] To date, the literature has not clearly shown a benefit for using buttress materials in terms of leak prevention.

Perhaps the major factor that is different in SG than other gastric stapling procedures is that SG creates a high-pressure gastric tube. This increased intraluminal pressure places the staple line at risk for leakage. If there is a relative obstruction or stenosis of the sleeve, which most often may occur at the incisura due to narrowing there during formation of the sleeve, pressure above the level of the obstruction will be even more elevated and create an increased risk for staple line leak. Leaks of the proximal staple line are the most frequent type seen after SG and often are felt to be related to increased intraluminal pressure distally. They may also be related to stapling too close to the angle of His, with resultant instability of the tissue directly adjacent to the esophagus in this area. It is important not to staple too close to the angle of His during the final stapling division portion of the stomach so as to not further weaken the staple line in this area. Proximal staple line leaks may also present as late leaks. Late leaks are generally felt to be those that occur 6 weeks or longer after surgery. Late leaks are rare in other bariatric procedures, but are seen with SG. The increased pressure of the system may be a reason SG is associated with late leaks. Confirmation and treatment of stenosis symptoms early after SG may prevent such leaks.

Distal staple line leaks are different than proximal staple line leaks, and are usually associated with earlier presentation and related to mechanical failure of the staple line to securely approximate the thicker distal gastric tissue. These leaks are more amenable to successful repair with a reoperation, whereas proximal leaks may not improve with oversewing at a reoperation unless the mechanics of the relative distal obstruction and high intraluminal pressure of the sleeve are also treated. Endoscopic intervention to dilate stenotic areas as well may be beneficial in the setting of a stenosis with or without a proximal leak. Care must be taken by the endoscopist to not excessively dilate the tract beyond the original size of the bougie used. Another factor that may influence stenosis at the incisura is that there may be a relative twisting of the stomach at this location, with the antrum being partially twisted away from the upper portion of the sleeve. Endoscopic treatment can help straighten and markedly alleviate the obstruction in such cases. Thus relatively early endoscopic intervention is appropriate in the patient with a stenosis at the incisura. One study has shown that endoscopic dilation is usually successful in treating stenosis after SG, with a mean of 1.6 dilatations being done an average of 48 days postoperatively.[131]

The patient with the proximal gastric staple line leak due to mechanical factors may experience a persistence of the leak for months. Such cases are now only recently being published and discussed in the literature. It is unclear how long one should optimally treat such a leak conservatively with the likelihood it will close. Reports of such leaks persisting for multiple months postoperatively exist. Our own experience has been that eventual closure of such a leak is possible even 4 months postoperatively. However, longer duration leaks are less likely to close. Some experts have now advocated conversion of the patient with a longstanding leak after SG to a RYGB to provide a low-pressure anastomosis above the site of the stenosis. Similarly, persistent stenosis of the sleeve despite conservative therapy and endoscopic dilatation also is an indication for conversion to LRYGB.

Physiology of Weight Loss. SG is a fairly simple technical operation, amenable to performance by many surgeons. The results of the operation for weight loss have been excellent

and dramatic. However, the mechanisms of the resolution of comorbidities, such as diabetes, are still not totally clear. While weight loss alone may provide the majority of the physiologic changes that improve comorbid problems such as diabetes and hypertension, it is also possible that other factors may be involved. Certainly SG, through gastric resection, eliminates much of the ghrelin-producing portion of the stomach. The resolution of type 2 diabetes after SG is remarkable, although not as good as that seen after RYGB. The reasons for this are as yet unclear, since lap RYGB has been shown to have independent factors influencing glucose metabolism separate from weight loss alone. The hormonal and peptidergic changes produced by SG in terms of appetite suppression, glucose metabolism, and other metabolic pathways have yet to be clarified. A recent hypothesis summarized by Ed Mason[132] is that the rapid emptying of the stomach after SG creates a similar exaggerated release of GLP-1 as seen after LRYGB, and this results in the improved carbohydrate metabolism and improvement of type 2 diabetes seen after SG, as after LRYGB.[133]

There is some concern among the bariatric surgical community that SG, because it is technically not that difficult, could become a procedure performed by surgeons without a full support system and follow-up mechanism for bariatric patients. The bariatric surgery community feels strongly that this procedure should remain a procedure done within the confines of the COE framework. This will ensure optimal patient outcomes.

SPECIAL ISSUES RELATING TO THE BARIATRIC PATIENT

Bariatric Procedures in Adolescent and Elderly Patients

The incidence of obesity in the U.S. population has risen dramatically during the past two decades. This increase has included children and adolescents as well. The incidence of obesity (BMI >30 kg/m^2) is estimated to exceed 25% in the adolescent population. Factors felt to contribute to this include decreased participation in physical sports and activities, increased time playing computer and screen games, and increased consumption of fast food and processed foods.

Obese adolescents have a high likelihood of being obese adults. In one study, 75% of adolescents above the 85th percentile were obese as adults.[134] The social stigmatization of the severely obese adolescent is often brutal. Comorbid medical problems may already be present in severely obese adolescents, including hypertension and type 2 diabetes. The overwhelming likelihood of a severely obese adolescent facing a lifetime of severe obesity as an adult also implies that an average of 12 years of life for males and 9 years of life for females will be lost due to this medical problem.

The major controversy with regard to adolescents undergoing bariatric surgery includes the general aversion of subjecting an adolescent to surgery as well as the concern of the secondary side effects of bariatric surgery on remaining growth and development. Clearly the younger the patient, the more relevant the latter concern becomes.

The literature to date on the results of outcomes from bariatric surgery on adolescents is generally quite favorable. However, it is still limited. Sugerman and colleagues[135] reported on results for 33 adolescents, 30 of whom had RYGB (mostly open RYGB). There were two late deaths at 2 and 6 years of follow-up unrelated to surgery. There were 20 early and late complications, including six incisional hernias and five wound infections. Significant weight loss was maintained in the majority of patients for up to 14 years after surgery. Most comorbidities resolved at 1 year after surgery. Self-image was greatly enhanced and social stigmatization greatly decreased. Capella and Capella[136] reported on 19 adolescent patients treated with a modified version of open RYGB in which a vertical band was added to the pouch. After an average 5.5-year follow-up, average BMI for the group was 28 kg/m^2. No deaths occurred, but two patients required revisional surgery. No mortality or morbidity was reported, and all comorbidities resolved. Abu-Abeid and colleagues[137] treated 11 adolescents with LAGB. No late complications occurred, and after a 4-year follow-up, BMI average went from 46.4 to 32.1 kg/m^2.

A meta-analysis involving 131 adolescents undergoing bariatric surgery demonstrated a 17.8 to 22.3 kg/m^2 decrease in BMI after RYGB.[138] They also observed improvement of hypertension in more than half the patients and sleep apnea resolution in all 131 patients. There were four mortalities in this cohort, but only one of them was potentially associated with the procedure (*Clostridium difficile* colitis 9 months after operation). Morbidity in the adolescent literature ranges from 0% to 38% and tends to be minor in most cases. The most common complication in the meta-analysis was nutrient deficiencies. The weight of the evidence supports adolescent bariatric surgery as a safe and effective treatment of severe obesity in adolescents. The ASMBS pediatric guidelines suggest using BMI criteria similar to the adult population but with some modifications to comorbidity thresholds.[139] They recommend considering surgery in patients with a BMI of 35 kg/m^2 or greater with major comorbidities (e.g., type 2 diabetes, severe nonalcoholic fatty liver disease, OSA) or a BMI of 40 kg/m^2 or greater with minor comorbidities (e.g., hypertension, dyslipidemia, insulin resistance).

The elderly patient population certainly suffers from severe obesity. However, data on the effect of nonsurgical therapies in treating this patient population are lacking. Similarly, it is likely that the patient who becomes obese late in life has a significantly different prognosis than the individual who has been severely obese and does manage to survive to an older age despite the resulting comorbidities.

There has been an increasing tendency to offer bariatric surgery to patients over the age of 60. Studies have documented that this patient population can have the same good outcomes and resolution of comorbidities as younger patients.[140] Nehoda and colleagues[141] reported equally excellent results for LAGB in patients over age 50 compared with those under age 50. Excess weight loss of 68%, reoperation rate of 10%, and 97% improvement in comorbidities were reported for this age group. A recent retrospective review of 42 carefully selected bariatric surgery patients over 70 years old looked at the outcomes up to 1 year after surgery. Of these patients, 22 patients (52.4%) underwent laparoscopic gastric banding, 12 patients (28.6%) underwent laparoscopic SG, and 8 patients (19%) underwent LRYGB. They safely achieved a mean weight loss of 47.7% with no mortality and modest improvement in obesity-associated comorbidities.[142] SG for elderly patients is also gaining popularity. In 35 patients ≥60 years of age, Soto and colleagues[143] demonstrated greater than 60% excess weight loss at 48 months with low morbidity (8.4%) and no mortality with SG.

Although these data show that in selected older patients excellent results can be obtained, surgeons must be cautious to

determine which patients have been severely obese for decades and therefore have essentially end-stage organ function in many cases as a result of the comorbid medical conditions that have been present for decades. Flum and Dellinger[106] showed that the older patient population, especially those few patients older than age 70 undergoing bariatric surgery, did have an increased incidence of mortality and morbidity after RYGB.

The concept that bariatric surgery confers an improved quality of life, a longer life, and a life without as many associated medical problems leads to the logical conclusion that the benefits of an operation will be more fully realized in the younger patient. This philosophy, in view of the large number of unserved patients, does justify age limits for individual surgeon practices. While some surgeons do have such limits, patients near or just over the age limit are often reviewed on an individual basis to determine their appropriateness for surgery. However, some surgeons will base their decision on "physiologic" age rather than chronologic age because many elderly patients may be reasonably low risk for major complications. Accumulation of data may also change these limits in the future.

The Female Patient: Pregnancy and Gynecologic Issues in the Bariatric Surgery Patient

Hormonal levels in female patients are related to body weight. Obesity alters the levels of estrogen and progesterone available for normal ovulation, resulting in abnormal ovulation patterns, amenorrhea, and difficulty conceiving. Should an obese woman become pregnant, the increased chances of gestational diabetes and hypertension make the pregnancy high risk. Macrosomia is increased. There is a two- to three-fold increase in the rate of cesarean sections, with more complications. Fetal mortality does not appear to be changed when maternal weight gain is limited.[144] With obesity, there is an increased risk for breast and endometrial cancer in the postpartum mother.

Infertility compounds the difficulties of the obese woman who wishes to have an uncomplicated pregnancy and delivery. The same hormonal alterations that cause an increased incidence of cancer (i.e., increased circulating estrogen levels) also cause infertility. If a severely obese woman becomes pregnant, the pregnancy management is made more difficult by the body habitus and the need for more frequent ultrasounds as opposed to physical examination, which yields limited information.

Women who become pregnant soon after undergoing bariatric surgery can be at risk due to the ongoing weight loss produced by the operation. However, if the pregnancy is quickly recognized and appropriately managed, patients after bariatric surgery may actually have a better prognosis than if they had not had surgery. Wittgrove and colleagues[145] showed that patients who had undergone RYGB had a decreased incidence of diabetes, macrosomia, and cesarean section than those who had not had surgery. However, iron replacement was cited as a critical need for these pregnant women. Despite these good results, there are issues for the female patient who undergoes RYGB and becomes pregnant during the rapid weight loss phase after surgery. Special attention is needed to assure adequate intake of vitamins and essential nutrients during what otherwise would be a period of rapid weight loss. Although no clear consensus exists regarding management of pregnancy after bariatric surgery, Beard and colleagues[146] provide the following sound advice: (a) promotion of reliable contraception for 12 to 18 months after surgery; (b) close nutritional and weight monitoring during and after pregnancy; (c) supplementation to include daily prenatal vitamin, folate 400 μg, iron 50 to 100 mg, calcium 1000 mg, and protein 60 g; and (d) collaboration with high-risk obstetrical colleagues as needed.

Patients who become pregnant after LAGB would seem to have even less likelihood of significant risk to their pregnancy, since the band can be adjusted to allow more food intake during the pregnancy but similarly limit weight gain to a healthy amount. Dixon and colleagues[147] wrote that morbidly obese women do have higher risks during pregnancy, but LAGB allows weight loss, which reduces such risk. The adjustability of the band provides a potential advantage for the pregnant woman.

Weight loss after bariatric surgery can correct the high incidence of gynecologic problems that may exist as a result of severe obesity. Deitel and colleagues[148] found menstrual irregularities in over 40% of patients preoperatively, which became normal in over 95% of patients postoperatively. Infertility problems were present preoperatively in 29% of patients, and medical problems were frequent during previous pregnancies including hypertension in 26.7%, preeclampsia in 12.8%, diabetes in 7%, and deep vein thrombosis in 7%. These problems were virtually eliminated after weight loss. Stress urinary incontinence in the female patients in that study decreased from 61.2% to 11.6% after bariatric surgery.

Polycystic ovary syndrome (PCOS) is another common hormonal dysfunction associated with severe obesity. It is associated with obesity, infertility, hyperandrogenism, dyslipidemia, anovulation, insulin resistance, and abnormal menses.[149] Bariatric surgery improves not only metabolic disease but also menstrual irregularity, hirsutism, and infertility associated with PCOS.[150,151]

Stress urinary incontinence is a frequent problem of the severely obese woman, which must be specifically solicited on history. The increased intra-abdominal pressure from severe obesity contributes to the high incidence of this problem in the severely obese population. Obesity may also alter the neuromuscular function of the genitourinary tract, contributing to incontinence. Studies have confirmed the increased incidence of obesity in patients with both true stress incontinence and detrusor instability.[152] Weight loss alone relieves symptoms in many patients with obesity. A recent study involving 72 patients who had bariatric surgery (90% RYGB) showed a nearly 50% reduction in prevalence and severity of urinary incontinence after surgery based on objective urodynamic testing.[153] A significant improvement in subjective quality of life and sexual function was also achieved.

Metabolic Surgery

Advances in the role of metabolic surgery to treat type 2 diabetes mellitus (T2DM) and increases in the understanding of how surgery improves or resolves T2DM continue to represent the single most prominent change in the field of bariatric surgery since the last edition of this text. Nearly all international bariatric surgery societies have added "metabolic" to their name, including the American Society for Metabolic and Bariatric Surgery (ASMBS), which was formerly the American Society for Bariatric Surgery (ASBS). International meetings on the topic of bariatric surgery and its effects on diabetes have convened during the last 5 years to establish new guidelines regarding indications for metabolic surgery for T2DM as well as research priorities.[154] The entire field of bariatric surgery is now much more focused on the metabolic effects and benefits of bariatric surgery.

Although many comorbidities are improved by bariatric surgery and its resultant weight loss, the metabolic diseases that are most particularly affected are T2DM and the hyperlipidemias and metabolic syndrome. Hypertension and cardiovascular disease are also improved indirectly through metabolic benefits as well as directly through weight loss effects.

Type 2 Diabetes. There has been a dramatic increase in the potential application of surgical therapy to treat T2DM. Much of this stems from the original observations of surgeons performing RYGB concerning the improvement or near resolution of T2DM well before patients who had undergone the operation had achieved maximum weight loss. Pories and colleagues[155] championed these observations in a landmark paper that confirmed RYGB as an effective treatment for T2DM, resolving the condition in 85% of patients who had developed it within the 5 years prior to surgery. MacDonald and colleagues,[156] also from the same institution, showed that treatment with RYGB of patients with T2DM resulted in longer life span. Schauer and colleagues[157] showed that improvement in T2DM after LRYGB is comparable to that seen in Pories' original work, with fasting insulin levels and glycosylated hemoglobin levels returned to normal levels in 83% of patients and markedly improved in 17% of patients. RYGB has been shown to decrease overall long-term mortality related to diabetes in several large population studies.[158,159]

These results and studies, as well as the observation that T2DM resolved quickly after RYGB, led to the general belief that there is an important contribution of the enteric hormonal component of glucose metabolism influencing the disease. Rubino and Marescaux[160] reported the resolution of diabetes in the obese rat model with surgical diversion of the food stream from the duodenum and proximal jejunum. Reversal of the operation led to return of the disease state. The extension of the findings of Rubino and Marescaux to humans has occurred; a duodenojejunal exclusion operation has been performed and shows initial safety and efficacy in a small group of patients.[161] Although the majority of patients who have T2DM are obese, approximately 10% of patients with T2DM are not obese, and these data from Brazil may confirm that the resolution of the disease through enteric diversion is not based on associated weight loss.[162]

Surgical therapy that does produce weight loss without diversion of the enteric stream also can be quite effective in resolving T2DM. Dixon and colleagues[70] reported, in the first randomized controlled trial comparing surgical versus medical treatment of diabetes, that 73% of patients undergoing LAGB and followed for 2 years achieved resolution of T2DM versus 13% of medically treated patients in the control group. An accompanying editorial to Dixon's article advocated that the treatment for diabetes be reshaped to include consideration of surgical therapy as an option for patients, especially severely obese patients.[163]

Despite these data in the literature, there has been resistance from endocrinologists and internists specializing in the medical treatment of diabetes to accept the use of surgical therapy as an optimal treatment for the disease.[164] One major criticism pertaining to the quality of outcome studies for diabetes surgery has been that except for the Dixon study, none have been randomized controlled trials. In the last few years, however, three additional randomized controlled trials have been published in high-impact medical journals. Schauer and colleagues (n = 150) showed superior glycemic control (defined as hemoglobin A1c [HbA1c] <6% with or without medications) after RYGB (42%) and SG (37%) compared to intense medical therapy (12%) at 1 year ($P < .001$) in patients with mild to moderate obesity (BMI 27–43 kg/m^2) and poorly controlled T2DM (average HbA1c 9%).[165] Gastric bypass and SG resulted in greater improvement in other cardiovascular risk factors such as BMI, triglycerides, high-density lipoprotein, and C-reactive protein compared with intense medical therapy. The surgical patients also significantly reduced their dependency on diabetes medications, while medical patients had increased dependency on diabetes medications. Mingrone and colleagues (n = 60) demonstrated that diabetes remission rates (HbA1c <6.5% without medications) were superior after BPD (95%) and RYGB (75%) compared to conventional medical therapy (0%) at 2 years ($P < .001$) in patients with severe obesity (average BMI 45 kg/m^2) and poorly controlled T2DM (average HbA1c 9%).[166] Ikramuddin and colleagues (n = 120) found that RYGB (49%) was superior ($P < .001$) to intense medical therapy (19%) in achieving the American Diabetes Association goal of therapy (HbA1c <7%, low-density lipoprotein cholesterol <100 mg/dL, systolic blood pressure <130 mmHg) in patients with obesity (BMI 30 to 40 kg/m^2) and poorly controlled T2DM (average HbA1c 9.6%).[167] All four randomized controlled trials to date have shown that surgery in the short term (1–2 years) was well tolerated, with few major complications (two serious cases of sepsis), no cardiovascular events, and no operative mortality, and that surgery resulted in both superior glycemic control and greater improvements in cardiovascular risk factors compared to medical treatment alone.

Adoption of metabolic surgery by endocrinologists, internists, and primary care physicians as a treatment of T2DM has gradually increased over the last 5 years. The Diabetes Surgery Summit in 2007 published the first consensus guidelines for the use and study of metabolic surgery.[154] Since 2009, the American Diabetes Association has included bariatric surgery in their position statement on standards of medical care in T2DM. The guideline indicates that "bariatric surgery should be considered for adults with BMI ≥35 kg/m^2 and T2DM, especially if the diabetes is difficult to control with lifestyle and pharmacological therapy."[168] In 2011, the International Diabetes Federation (IDF) released its position statement on the role of surgery and other gastrointestinal interventions in the management of T2DM.[169] At this time, the IDF guidelines are the most useful summaries, from the evidence available, for healthcare providers who manage patients with T2DM. The IDF guidelines are the first to recommend that metabolic surgery be considered for patients with a BMI as low as 30 kg/m^2 if they are not in good glycemic control on optimal medical therapy.

Metabolic Syndrome. The metabolic syndrome is characterized by central obesity, glucose intolerance, dyslipidemia, and hypertension. This is a common finding in patients with severe obesity, occurring in 52% of individuals in one report.[170] All the associated metabolic problems of the metabolic syndrome respond to surgical therapy to produce weight loss. Basic scientists attribute the occurrence of this associated array of diseases to an enhanced inflammatory state in the body resulting from the increased production of cytokines by the adipocyte. These cytokines in turn produce a mild inflammatory reaction that promotes the production of these diseases.

Diabetes and glucose tolerance are effectively treated by bariatric operations as discussed earlier. These operations also are effective in treating the other components of metabolic syndrome.

RYGB produced a 98% resolution of the metabolic syndrome in patients 1 year after surgery.[171]

Dyslipidemias improve in over 70% of patients undergoing RYGB. Improvement is 100% and resolution is greater than 90% after any of the malabsorptive operations (see Table 27-7). Overall lipid profiles are improved, and the degree to which this occurs is in part related to exercise levels of the individual as well as genetic components of the disease.

Cardiovascular Disease. Hypertension, a component of the metabolic syndrome, is one of the cardiovascular diseases that are increased in the setting of obesity. Elevated arterial pressure in patients with obesity-related hypertension is associated with increased cardiac output and total peripheral resistance. The elevated output is related to expanded intravascular volume that increases cardiopulmonary volume, venous return, and left ventricular preload; the elevated pressure and total peripheral resistance increase afterload. This dual ventricular overload promotes a dimorphic, concentric, and eccentric hypertrophy in response to the volume and pressure overload. Increased myocardial oxygen demand results from the elevated tension in the left ventricular wall, reflecting its increased diameter and pressure, and provides a physiologic rationale for the greater potential of coronary arterial insufficiency and cardiac failure. There is greater renal blood flow and lower renal vascular resistance in patients with obesity-related hypertension at any level of arterial pressure. This may be offset by an increased renal filtration fraction that may favor protein deposition and glomerulosclerosis.[170]

Weight loss results in decreased intravascular volume, decreased cardiac output, and decreased arterial pressure. These manifestations occur after all the various bariatric operations that produce weight loss.

Heart failure also is increased in the setting of severe obesity. Much of the risk is secondary to the processes mentioned earlier, which produce hypertension and cardiac hypertrophy. Hypertension and obesity have significant independent associations with left ventricular hypertrophy and cardiac wall thickness. Obesity is particularly strongly associated with left ventricular internal diameter.[172]

Much data now exists regarding the effect of bariatric surgery on cardiovascular disease. A recent systematic review of long-term cardiovascular risk factor reduction after bariatric surgery involved 73 studies and 19,543 subjects with a mean age of 42 years; 76% of subjects were female, and 44%, 24%, and 44% had a baseline hypertension, diabetes, and hyperlipidemia, respectively.[173] At a mean follow-up of 57.8 months, the average excess weight loss for all bariatric procedures was 54%, and remission/improvement was 63% for hypertension, 73% for T2DM, and 65% for hyperlipidemia. Echocardiographic results from 713 subjects showed statistically significant improvements in left ventricular mass, E/A ratio, and isovolumic relaxation time postoperatively.

Thus far, there are no long-term randomized controlled trials comparing bariatric surgery with nonsurgical medical treatment of obesity that evaluate cardiovascular endpoints and mortality. However, 12 cohort-matched studies comparing bariatric surgery with nonsurgical controls have recently been reviewed.[174] Collectively, all but two of these studies support a reduced cardiovascular event rate and all-cause mortality rate conferred by bariatric surgery. Of these studies, the Swedish Obesity Subjects (SOS) study has the longest outcomes follow-up at a median of 14.7 years.[158] Cardiovascular mortality in the surgical group was significantly lower than for control subjects (adjusted hazard ratio, 0.47; 95% confidence interval, 0.29–0.76; $P = .002$) despite the greater prevalence of smoking and higher baseline weights and blood pressures in the surgical cohort. The SOS study has formed the basis of much of our current understanding of medium- and long-term outcomes after bariatric surgery despite the fact that the majority of their surgical cohort received vertical-banded gastroplasty (>70%), a gastric volume reduction procedure that is now rarely performed in the United States.

Resolution of Other Comorbid Medical Problems

Bariatric surgery can produce resolution of many, if not all, of the comorbid medical problems associated with obesity and present at the time of surgery. This is true to some extent for all bariatric procedures, although some are more efficient at reversing specific comorbid problems than others.

GERD is symptomatically present in approximately half of patients with severe obesity and has been objectively proven to be present in 21%.[92] Unfortunately, obese patients with GERD have a higher chance of failing to obtain symptomatic relief from standard antireflux surgery. The recurrence of symptoms is higher, likely due to a higher incidence of wrap herniation into the mediastinum and other mechanical failure of the fundoplication, which in turn is likely affected by the increased intra-abdominal pressure of the obese condition. The patient with a BMI over 35 kg/m^2 who has GERD has a better chance of elimination of symptoms by undergoing LRYGB, which is >90% effective in the elimination of GERD.[175] LRYGB creates such a small gastric pouch that it has a very limited volume for acid production. LAGB improves GERD but to a considerably lesser extent than RYGB. A recent prospective analysis of 558 consecutive laparoscopic SG (n = 200) and LRYGB (n = 358) patients demonstrated significantly improved subjective GERD symptoms in the bypass cohort when compared to the SG patients at 1 year ($P < .001$).[176] In fact, some studies suggest that SG can increase GERD symptoms postoperatively. Zhang and colleagues[177] reported new reflux seen on upper gastrointestinal series in 18% of their 28 patients after SG.

OSA is a disturbance of sleep associated with obesity. It is a measurable problem, quantitated by polysomnography. In one recent study of 349 patients considering bariatric surgery who were referred and tested, only 17% had no sleep apnea, whereas 32% had mild, 18% moderate, and 33% severe sleep apnea.[178] At a mean time of 11 months after RYGB, the mean Respiratory Disturbance Index for all patients decreased from 51 to 15 ($P < 0.01$). Of 83 patients using continuous positive airway pressure or bilevel positive airway pressure preoperatively, only 31 still required it, and they had decreased setting requirements. A recent systematic review of 13,900 patients (69 studies) showed significant improvement or resolution of sleep apnea in more than 75% of bariatric surgery patients.[179] Comparison of outcomes between procedures demonstrated the most benefit with BPD and gastric bypass and the least with LAGB. However, a recent randomized control trial comparing the effect of medical and surgical weight loss (LAGB) on sleep apnea found no significant difference in apnea events despite major differences in weight loss. The findings suggested that much of the improvement achieved was in the mild to moderate weight loss range, with little benefit of further weight loss.[180]

Another pulmonary symptom that commonly occurs in severely obese patients is asthma. Dixon and colleagues[181] studied 23 asthmatic patients who underwent bariatric surgery and found a significant improvement in asthma control (e.g., forced expiratory

volume in 1 second, forced vital capacity), asthma-related quality of life, and responsiveness to methacholine. Boulet and colleagues[182] found similar results in their cohort of 12 patients with asthma who experienced significant weight loss after bariatric surgery.

Nonalcoholic fatty liver disease (NAFLD) is a metabolically related problem associated with obesity. The disease is a spectrum of liver abnormalities including steatosis, steatohepatitis, fibrosis, and cirrhosis of the liver. It is estimated that 20% of U.S. adults have NAFLD, largely because of the high incidence of obesity. NAFLD is present in an estimated 85% of patients with severe obesity.[183] Due to the high incidence of this disease, some authorities have advocated routine liver biopsy at the time of bariatric operations. However, since the treatment of the disease is weight loss, patients with mild forms of the disease need no further treatment or follow-up. Biopsy reports showing any degree of fibrosis should be further followed up by a hepatologist. Weight loss after RYGB decreases metabolic disease, hepatic steatosis, inflammation, and in some cases even fibrosis.[184] Although further research is needed to accurately assess the role of bariatric surgery as a potential treatment for NAFLD, there are numerous reports that support its use. A recent systematic review of the available literature found many retrospective and prospective observational cohort studies, but no randomized control trials or case-control series.[185] There did appear to be significant histologic regression of NAFLD in most of these studies; however, steatohepatitis and fibrosis were also observed in rare cases postoperatively. In one prospective study with before and after liver biopsies, residual steatohepatitis did not appear to be associated with the various bariatric approaches; rather, it was related to higher baseline BMI, degree of previous steatosis/fibrosis, NAFLD activity score, ballooning, degree of inflammation, and insulin resistance.[186] The role of bariatric surgery in the treatment in NAFLD remains to be seen.

Musculoskeletal problems, especially degenerative joint disease and low back pain, are among the most common complaints and associated comorbid problems of the severely obese population. Quantitation of their severity, however, is often difficult, making resolution or improvement equally difficult. Symptoms often resolve and usually improve in patients who experience significant weight loss. This is likely a combined effect of the direct lessened work load as well as some secondary resolution of the inflammatory process of the joints brought on directly and indirectly by obesity. A prospective cohort of 50 obese females age 20 to 74 years were followed for 1 year after RYGB using the timed-get-up-and-go (TGUG) and health survey Short Form-36 (SF-36).[187] The results showed a significant improvement in musculoskeletal function and likely enhanced ability to progress in rehabilitation. Patients with osteoarthritis of the neck, shoulder, spine, hip, knee, ankle, wrist, and hand have been shown to have improved or resolved joint pain after bariatric surgery. Reduction in BMI values of 6.2 to 14.7 kg/m^2 has corresponded with back and knee pain resolution in 5% to 100% of patients, whereas pain severity was reduced in 31% to 94% of patients depending on the joint and study.[188]

Plastic Surgery after Weight Loss

Patients who have undergone bariatric surgery are often left with large amounts of hanging skin or rolls of skin and subcutaneous tissue as a result of the weight loss. Additional problems include skin rashes; maceration under folds in the pannus, thighs, and breasts; body odor; and poorly fitting clothes. Excess skin can be a limiting factor in exercise and sexual activity.

Many patients desire to be rid of the extra skin and its associated problems. The major problem they face, however, in accomplishing this is obtaining insurance approval for surgical removal of the excess skin. Most insurance companies consider this "cosmetic" surgery and will not authorize coverage. A few, with appropriate documentation of the conditions and problems from excess skin, do provide coverage for surgery. Plastic surgeons who are experienced in abdominoplasty and body contouring can offer these patients an excellent surgical treatment for the problems of excessive skin.

Reconstructive surgery requires careful preoperative planning and is based on the patient's deformities and priorities. Excess tissue of the lower torso is the most common deformed area for which patients undergo surgical intervention. A standard abdominoplasty to remove this excessive tissue is performed. More radical body contouring can include a circumferential abdominoplasty and lower body lift.[189] This procedure involves excision of tissue from the buttocks and lateral thighs, with skin undermining down the thighs. Circumferential abdominoplasty removes redundant skin of the lower abdomen, flattens the abdomen, and incorporates the lower body lift. It requires central undermining to the xiphoid and minimal lateral undermining of the superior flap. The central abdominal fascia often requires imbrication. If simultaneous abdominal hernia repair is performed, this performs the function of fascial imbrication by creating a repair with some degree of fascial tension. The closure of the superior flap to the inferior skin edge incorporates lateral tension to narrow the waist and advance the anterolateral thighs. Medial thighplasty also may be needed for patients with significant excess medial thigh skin. This is done transversely.

Excess skin redundancy distal to the mid-thighs requires long vertical medial excision of skin. Mid-back and epigastric rolls, along with sagging breasts, are corrected with an upper body lift. The upper body lift is a reverse abdominoplasty, removal of mid-torso excessive skin, and reshaping of the breasts. For highly selected individuals, and with a well-organized team, a single-stage total body lift, which includes a circumferential abdominoplasty, lower body lift, medial thighplasty, an upper body lift, and breast reshaping, can be performed safely in under 8 hours (Figs. 27-24 and 27-25).[190] While many bariatric surgery programs do not have the accompanying volume, experience, and interest to offer such an extensive single-stage operation, most programs do offer availability of plastic surgery expertise for abdominoplasty and removal of excess skin of the extremities as separate procedures. Increasing numbers of patients undergoing bariatric surgery have provided an increased flow of patients requesting such services, which in turn should lead to improved outcomes with increasing experience for surgeons performing these procedures. One matched control study suggests that plastic surgery after bariatric surgery may actually improve long-term weight loss.[191]

Endoscopic, Electric, and Other Experimental Procedures

Bariatric surgery has been a field of constant succession of procedures in an attempt to improve safety, minimize invasiveness, and offer better outcomes. Recent experimental procedures in electrical stimulation of the stomach and vagus nerves have been performed to produce weight loss.

The implantable gastric stimulation device, initially marketed by Trasneuronix, Inc., in the early part of the twenty-first century, was a dual-lead implantable gastric electrical

Figure 27-24. Preoperative frontal, right lateral, and left anterior oblique views of a 36-year-old, 150-lb, 5'6" woman who lost 120 lb 2 years after laparoscopic Roux-en-Y bypass procedure. She desired a one-stage total body lift and bilateral brachioplasties, which were performed in the manner described in the text. *(Courtesy of Dennis Hurwitz, MD, Clinical Professor of Plastic Surgery, University of Pittsburgh.)*

stimulator that theoretically interfered with the stomach's innate myoelectric pattern, causing decreased gastric emptying and nausea. A mean excess weight loss of 23% was reported at 16-month follow-up for the second U.S. trial.[192] Longer-term follow-up for the first European study showed a 25% excess weight loss in 91 patients over a 2-year follow-up.[193] The disappointing aspect of this treatment is that a significant number of the patients lose little weight, whereas a smaller group seem to respond well to the treatment. The ability to select patients who will respond remains a challenge for this technology, which is still in the status of only a proposed potential operation for weight loss.

Figure 27-25. Frontal, right lateral, and left anterior oblique views 6 weeks after surgery for the woman in Fig. 27-24. The scars indicate the circumferential abdominoplasty, lower body lift, upper body lift, breast reshaping, and autoaugmentation through a keyhole pattern and bilateral brachioplasties. All redundant skin has been removed, leaving well-positioned scars and feminine features. *(Courtesy of Dennis Hurwitz, MD, Clinical Professor of Plastic Surgery, University of Pittsburgh.)*

Vagal stimulation/blockade has recently been proposed as a means of stimulating the neural input to the stomach to achieve decrease in appetite, early satiety, at times nausea, and weight loss. Data to date have been sparse and very preliminary in showing any merits of the potential efficacy of this approach.[194]

Endoscopic procedures to decrease gastric pouch size and to limit gastrojejunostomy anastomotic size are currently being performed at several medical centers.[84,195] These are currently reoperative procedures, not initial procedures for weight loss. Long-term weight loss of significant magnitude has yet to be demonstrated by these revisional endoscopic procedures.

Intragastric balloon placement has resurfaced on the bariatric scene in the past few years. The Garren-Edwards bubble of the late 1980s era[196] was prone to migration and bowel obstruction, which led to its early demise. Now this concept has resurfaced as a short-term bridge to weight loss to be followed by a more definitive procedure. While there may be some limited application of this device for such purposes,[197] its ability to produce durable weight loss is unproven. It may have potential use only as a preliminary procedure prior to a more definitive one.

Prototype procedures undergoing trial include one that uses an endoscopically placed sleeve to limit absorption. A small randomized control study out of the Netherlands compared an endoscopically placed intraluminal sleeve extending from the duodenum to the jejunum (EndoBarrier) to a diet modification control group.[198] They successfully placed 26 devices, but were unable to do so in 4 cases. Four implants had to be removed before the end of the study due to migration, obstruction, and continuous epigastric pain. Mean weight loss at 3 months was 19.0% in the study group and 6.9% in the control group. HbA1c was significantly improved after EndoBarrier placement in seven of eight patients with T2DM. An FDA trial is currently under way to determine the long-term safety and efficacy of this experimental gastrointestinal liner.

The eventual ability to endoscopically create a stapled or sutured gastric pouch and hence a completely endoscopically performed restrictive operation is being envisioned. While these proposed procedures speak to the energy and innovation of today's bariatric surgery community, their implementation into clinical practice has yet to occur. Endoscopic procedures and devices such as the transoral gastroplasty (TOGA) and the transoral endoscopic restrictive implant system (TERIS) did not initially achieve sufficient weight loss to satisfy FDA requirements and thus have been withheld from further development at this time.[199,200]

Other investigational procedures under development and performed laparoscopically include the duodenal-jejunal bypass and ileal transposition. These procedures are intended to improve T2DM without intentional weight loss.[201,202] Gastric plication is also a new laparoscopic procedure intended to mimic results of SG but without requiring stapling or stomach removal.[203] Further studies with long-term safety and efficacy data are required before these investigational procedures can be considered for routine clinical use.

chapter 28

Small Intestine

Ali Tavakkoli, Stanley W. Ashley, and Michael J. Zinner

INTRODUCTION

The small intestine is the raison d'être of the gastrointestinal tract as it is the principle site of nutrient digestion and absorption.[1] The small intestine is also the body's largest reservoir of immunologically active and hormone-producing cells and hence can be conceptualized as the largest organ of the immune and endocrine systems, respectively. It achieves this diversity of action through unique anatomic features, which provide it with a massive surface area, a diversity of cell types, and a complex neural network to coordinate these functions.

1▶

Despite its size and importance, diseases of the small intestine are relatively infrequent and present diagnostic and therapeutic challenges. Treatments for common conditions such as postoperative ileus are hardly more effective than those used at the dawn of the last century. Mortality rates associated with acute mesenteric ischemia have not improved during the past 50 years.

Despite introduction of novel imaging techniques such as capsule endoscopy and double balloon endoscopy, diagnostic tests lack sufficient predictive power to definitively guide clinical decision making for individual patients. Furthermore, few high-quality, controlled data on the efficacy of surgical therapies for small bowel diseases are available.

Therefore, sound clinical judgment and a thorough understanding of anatomy, physiology, and pathophysiology remain essential to the care of patients with intestinal disorders.

GROSS ANATOMY

The small intestine is a tubular structure that extends from the pylorus to the cecum. The estimated length of this structure varies depending on whether radiologic, surgical, or autopsy measurements are made. In the living, it is thought to measure 4 to 6 m.[2] The small intestine consists of three segments lying in series: the duodenum, the jejunum, and the ileum.

Key Points

1. The small intestine performs a diverse set of functions.
2. Small bowel obstruction is one of the most common surgical diagnoses.
3. Most cases of small bowel obstruction are due to adhesions from previous surgery and resolve with conservative management.
4. Tumors and malignancies of the small bowel are rare and difficult to diagnose.
5. Small bowel may be the source of gastrointestinal bleeding, which may be difficult to diagnose.
6. If following surgical resection, less than 200 cm of small bowel remains, patients are at risk of developing short bowel syndrome.

The duodenum, the most proximal segment, lies in the retroperitoneum immediately adjacent to the head and inferior border of the body of the pancreas. The duodenum is demarcated from the stomach by the pylorus and from the jejunum by the ligament of Treitz. The jejunum and ileum lie within the peritoneal cavity and are tethered to the retroperitoneum by a broad-based mesentery. No distinct anatomic landmark demarcates the jejunum from the ileum; the proximal 40% of the jejunoileal segment is arbitrarily defined as the jejunum and the distal 60% as the ileum. The ileum is demarcated from the cecum by the ileocecal valve.

The small intestine contains internal mucosal folds known as *plicae circulares* or *valvulae conniventes* that are visible upon gross inspection. These folds are also visible radiographically and help in the distinction between small intestine and colon, which does not contain them, on abdominal radiographs. These folds are more prominent in the proximal intestine than in the distal small intestine. Other features evident on gross inspection that are more characteristic of the proximal than distal small intestine include larger circumference, thicker wall, less fatty mesentery, and longer vasa recta (Fig. 28-1). Gross examination of the small-intestinal mucosa also reveals aggregates of lymphoid follicles. Those follicles, located in the ileum, are the most prominent and are designated *Peyer's patches*.

Most of the duodenum derives its arterial blood from branches of both the celiac and the superior mesenteric arteries. The distal duodenum, the jejunum, and the ileum derive their arterial blood from the superior mesenteric artery. Their venous drainage occurs via the superior mesenteric vein. Lymph drainage occurs through lymphatic vessels coursing parallel to corresponding arteries. This lymph drains through mesenteric lymph nodes to the cisterna chyli, then through the thoracic duct, and ultimately into the left subclavian vein. The parasympathetic and sympathetic innervation of the small intestine is derived from the vagus and splanchnic nerves, respectively.

HISTOLOGY

The wall of the small intestine consists of four distinct layers: mucosa, submucosa, muscularis propria, and serosa (Fig. 28-2).

The mucosa is the innermost layer, and it consists of three layers: epithelium, lamina propria, and muscularis mucosae. The epithelium is exposed to the intestinal lumen and is the surface through which absorption from and secretion into the lumen occurs. The lamina propria is located immediately external to the epithelium and consists of connective tissue and a heterogeneous population of cells. It is demarcated from the more external submucosa by the muscularis mucosae, a thin sheet of smooth muscle cells.

The mucosa is organized into villi and crypts (crypts of Lieberkuhn). *Villi* are finger-like projections of epithelium and underlying lamina propria that contain blood and lymphatic (lacteals) vessels that extend into the intestinal lumen. Intestinal, epithelial cellular proliferation is confined to the *crypts*, each of which carries 250 to 300 cells. All epithelial cells in each crypt are derived from an unknown number of multipotent stem cells located at or near the crypt's base. Our understanding of these crypt cells is rapidly expanding. It appears that there are two subgroups of intestinal stem cells, with specific cell markers. Bmi1-positive cells are usually quiescent, radiation-resistant cells that are induced by injury, whereas LGR5-positive cells facilitate homeostatic vs. injury-induced regeneration and are radiation sensitive.[3]

The stem cells can differentiate along one of four pathways that ultimately yield *enterocytes* and *goblet*, *enteroendocrine*, and *Paneth* cells. With the exception of Paneth cells, these lineages complete their terminal differentiation during an upward migration from each crypt to adjacent villi. The journey from the crypt to the villus tip is completed in 2 to 5 days and terminates with cells being removed by apoptosis and/or exfoliation. Thus, the small-intestinal epithelium undergoes

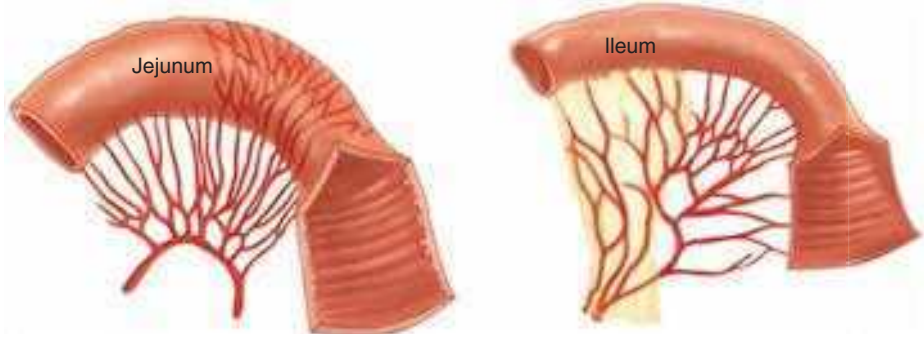

Figure 28-1. Gross features of jejunum contrasted with those of ileum. Relative to the ileum, the jejunum has a larger diameter, a thicker wall, more prominent plicae circulares, a less fatty mesentery, and longer vasa recta.

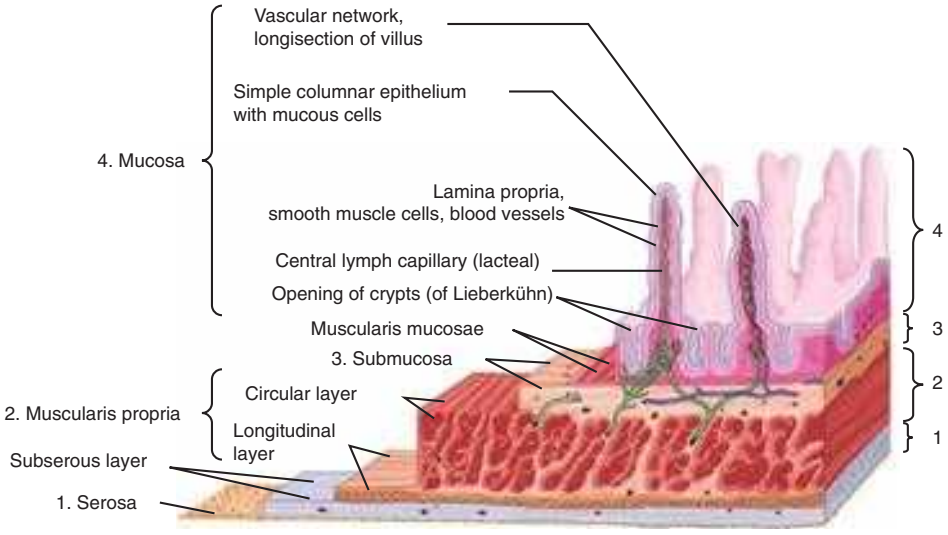

Figure 28-2. Layers of wall of the small intestine. The individual layers and their prominent features are represented schematically.

continuous renewal, making it one of the body's most dynamic tissues. The high cellular turnover rate contributes to mucosal resiliency but also makes the intestine uniquely susceptible to certain forms of injury such as that induced by radiation and chemotherapy.

Enterocytes are the predominant absorptive cell of the intestinal epithelium. Their apical (lumen-facing) cell membrane contains specialized digestive enzymes, transporter mechanisms, and microvilli that are estimated to increase the absorptive surface area of the small intestine by up to 40-fold. *Goblet cells* produce mucin believed to play a role in mucosal defense against pathogens. *Enteroendocrine cells* are characterized by secretory granules containing regulatory agents and are discussed in greater detail later in the Endocrine Function section. *Paneth cells* are located at the base of the crypt and contain secretory granules containing growth factors, digestive enzymes, and antimicrobial peptides. In addition, the intestinal epithelium contains M cells and intraepithelial lymphocytes. These two components of the immune system are discussed later.

The submucosa consists of dense connective tissue and a heterogeneous population of cells, including leukocytes and fibroblasts. The submucosa also contains an extensive network of vascular and lymphatic vessels, nerve fibers, and ganglion cells of the submucosal (Meissner's) plexus.

The muscularis propria consists of an outer, longitudinally oriented layer and an inner, circularly oriented layer of smooth muscle fibers. Located at the interface between these two layers are ganglion cells of the myenteric (Auerbach's) plexus.

The serosa consists of a single layer of mesothelial cells and is a component of the visceral peritoneum.

DEVELOPMENT

The first recognizable precursor of the small intestine is the embryonic gut tube, formed from the endoderm during the fourth week of gestation. The gut tube is divided into forgut, midgut, and hindgut. Other than duodenum, which is a foregut structure, the rest of the small intestine is derived from the midgut. The gut tube initially communicates with the yolk sac; however, the communication between these two structures narrows by the sixth week to form the vitelline duct. The yolk sac and vitelline duct usually undergo obliteration by the end of gestation. Incomplete obliteration of the vitelline duct results in the spectrum of defects associated with Meckel's diverticulum.

Also during the fourth week of gestation, the mesoderm of the embryo splits. The portion of mesoderm that adheres to the endoderm forms the visceral peritoneum, while the portion that adheres to the ectoderm forms the parietal peritoneum. This mesodermal division results in the formation of a coelomic cavity that is the precursor of the peritoneal cavity.

At approximately the fifth week of gestation, the bowel begins to lengthen to an extent greater than that which can be accommodated by the developing abdominal cavity, resulting in the extracoelomic herniation of the developing bowel. The bowel continues to lengthen during the subsequent weeks and is retracted back into the abdominal cavity during the tenth week of gestation. Subsequently, the duodenum becomes a retroperitoneal structure. Coincident with extrusion and retraction, the bowel undergoes a 270° counterclockwise rotation relative to the posterior abdominal wall. This rotation accounts for the usual locations of the cecum in the right lower quadrant and the duodenojejunal junction to the left of midline (Fig. 28-3).

The celiac and superior mesenteric arteries and veins are derived from the vitelline vascular system, which in turn is derived from blood vessels formed within the splanchnopleuric mesoderm during the third week of gestation. Neurons found in the small intestine are derived from neural crest cells that begin to migrate away from the neural tube during the third week of gestation. These neural crest cells enter the mesenchyme of the primitive foregut and subsequently migrate to the remainder of the bowel.

During the sixth week of gestation, the lumen of the developing bowel becomes obliterated as bowel epithelial proliferation accelerates. Vacuoles form within the bowel substance during the subsequent weeks and coalesce to form the intestinal lumen by the ninth week of gestation. Errors in this recanalization may account for defects such as intestinal webs and stenoses. Most intestinal atresias, however, are believed to be related to ischemic episodes occurring after organogenesis has been completed rather than to errors in recanalization.

During the ninth week of gestation, the intestinal epithelium develops intestine-specific features such as crypt-villus architecture. Organogenesis is complete by approximately the twelfth week of gestation.

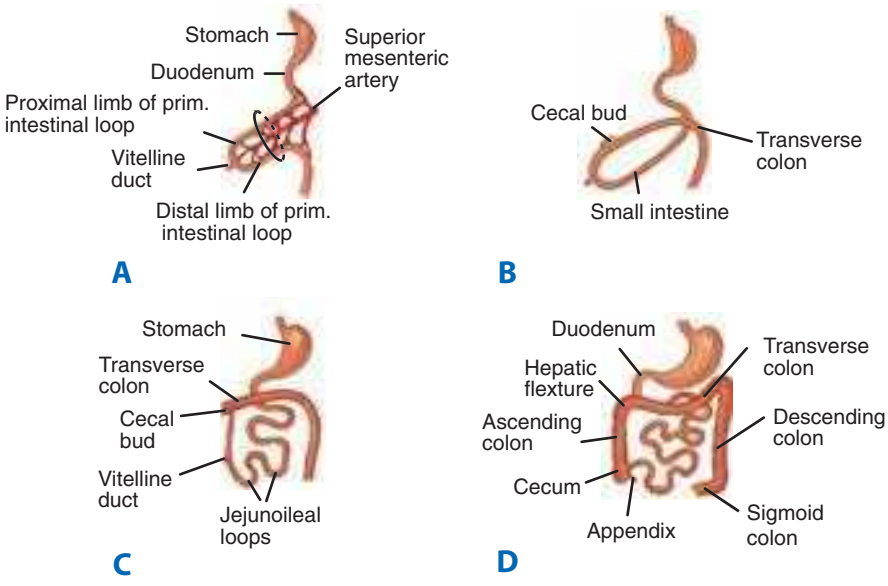

Figure 28-3. Developmental rotation of the intestine. **A.** During the fifth week of gestation, the developing intestine herniates out of the coelomic cavity and begins to undergo a counterclockwise rotation about the axis of the superior mesenteric artery. **B** and **C.** Intestinal rotation continues, as the developing transverse colon passes anterior to the developing duodenum. **D.** Final positions of the small intestine and colon resulting from a 270° counterclockwise rotation of the developing intestine and its return into the abdominal cavity.

PHYSIOLOGY

Digestion and Absorption

The intestinal epithelium is the interface through which absorption and secretion occur. It has features characteristic of absorptive epithelia in general including epithelial cells with cellular membranes possessing distinct apical (luminal) and basolateral (serosal) domains demarcated by intercellular tight junctions and an asymmetric distribution of transmembrane transporter mechanisms that promotes vectorial transport of solutes across the epithelium.

Solutes can traverse the epithelium by active or passive transport. Passive transport of solutes occurs through diffusion or convection and is driven by existing electrochemical gradients. *Active transport* is the energy-dependent net transfer of solutes in the absence of or against an electrochemical gradient.

Active transport occurs through transcellular pathways (through the cell), whereas passive transport can occur through either transcellular or paracellular pathways (between cells through the tight junctions). Transcellular transport requires solutes to traverse the cell membranes through specialized membrane proteins, such as channels, carriers, and pumps. The molecular characterization of transporter proteins is evolving rapidly, with different transporter families, each containing many individual genes encoding specific transporters, now identified. Similarly, understanding of the paracellular pathway is evolving. In contrast to what was once believed, it is becoming apparent that paracellular permeability is substrate-specific, dynamic, and subject to regulation by specific tight junction proteins.

Water and Electrolyte Absorption and Secretion. Eight to nine L of fluid enters the small intestine daily. Most of this volume consists of salivary, gastric, biliary, pancreatic, and intestinal secretions. Under normal conditions, the small intestine absorbs over 80% of this fluid, leaving approximately 1.5 L that enters the colon (Fig. 28-4). Small-intestinal absorption and secretion are tightly regulated; derangements in water and electrolyte homeostasis characteristic of many of the disorders discussed in this chapter play an important role in contributing to their associated clinical features.

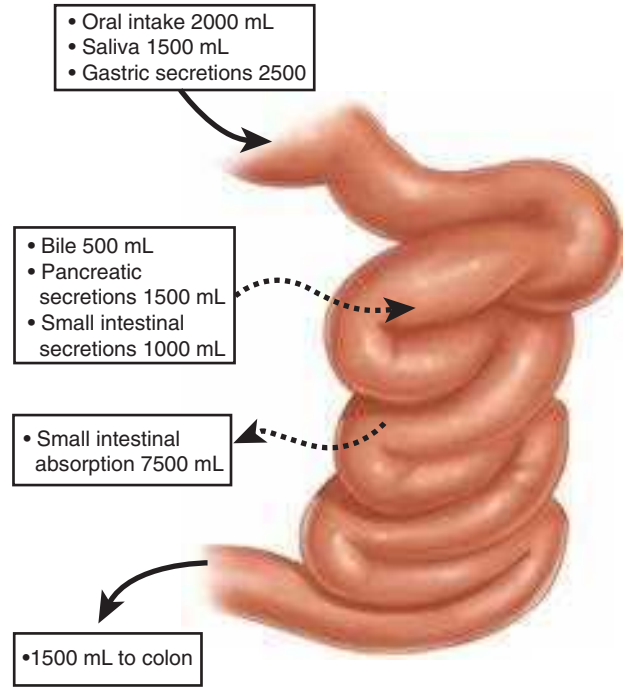

Figure 28-4. Small intestinal fluid fluxes. Typical quantities (in volume per day) of fluid entering and leaving the small intestinal lumen in a healthy adult are shown.

Gut epithelia have two pathways for water transport: (a) the paracellular route, which involves transport through the spaces between cells, and (b) the transcellular route, through apical and basolateral cell membranes. Although most water absorption was thought to occur through the paracellular pathway, it is now well documented that most intestinal water transport occurs through the transcellular pathway.[4] The specific transport mechanisms mediating this transcellular transport are not completely characterized and may involve passive diffusion through the phospholipid bilayer, cotransport with other ions and nutrients, or diffusion through water channels called aquaporins. Many different types of aquaporins have been identified;

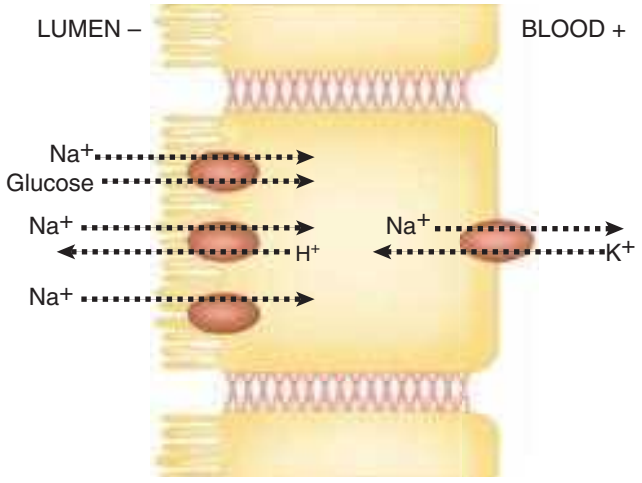

Figure 28-5. Model of transepithelial sodium (Na^+) absorption. Na^+ traverses the apical membrane of enterocytes through a variety mechanisms, including nutrient-coupled Na^+ transport, Na^+/H^+ exchange, and Na^+ channels. Activity of the Na^+/K^+ ATPase located on the basolateral membrane generates the electrochemical gradient that provides the driving force for Na^+ absorption.

however, their contribution to overall intestinal water absorption appears to be relatively minor.[5]

The prevailing model for intestinal epithelial Na^+ absorption is shown in Fig. 28-5. Activity of the Na^+/K^+ ATPase enzyme, which is located in the basolateral membrane and exchanges three intracellular Na^+ for every two extracellular K^+ in an energy-dependent process, generates the electrochemical gradient that drives the transport of Na^+ from the intestinal lumen into the cytoplasm of enterocytes. Na^+ ions traverse the apical membrane through several distinct transporter mechanisms including nutrient-coupled sodium transport (e.g., sodium glucose cotransporter-1 [SGLT1]), sodium channels, and sodium-hydrogen exchangers (NHEs). Absorbed Na^+ ions are then extruded from enterocytes through the Na^+/K^+ ATPase located in the basolateral membrane. Similar mechanistic models that account for the transport of other common ions such as K^+ and HCO_3^- also exist.

Substantial heterogeneity, with respect to both crypt-villus and craniocaudal axes, exists for intestinal epithelial transport mechanisms. This spatial distribution pattern is consistent with a model in which absorptive function resides primarily in the villus and secretory function in the crypt.

Intestinal absorption and secretion are subject to modulation under physiologic and pathophysiologic conditions by a wide array of hormonal, neural, and immune regulatory mediators (Table 28-1).

Carbohydrate Digestion and Absorption. Approximately 45% of energy consumption in the average Western diet consists of carbohydrates, approximately one half of which is in the form of starch (linear or branched polymers of glucose) derived from cereals and plants. Other major sources of dietary carbohydrates include sugars derived from milk (lactose), fruits and vegetables (fructose, glucose, and sucrose), or purified from sugar cane or beets (sucrose). Processed foods contain a variety of sugars including fructose, oligosaccharides, and polysaccharides. Glycogen derived from meat contributes only a small fraction of dietary carbohydrate.

Table 28-1

Regulation of intestinal absorption and secretion

Agents that stimulate absorption or inhibit secretion of water
Aldosterone
Glucocorticoids
Angiotensin
Norepineprhine
Epinephrine
Dopamine
Somatostatin
Neuropeptide Y
Peptide YY
Enkephalin
Agents that simulate secretion or inhibit absorption of water
Secretin
Bradykinin
Prostaglandins
Acetylcholine
Atrial natriuretic factor
Vasopressin
Vasoactive intestinal peptide
Bombesin
Substance P
Serotonin
Neurotensin
Histamine

Pancreatic amylase is the major enzyme of starch digestion, although salivary amylase initiates the process. The terminal products of amylase-mediated starch digestion are oligosaccharides, maltotriose, maltose, and α-limit dextrins (Fig. 28-6). These products, as well as the major disaccharides in the diet (sucrose and lactose), are unable to undergo absorption in this form. They must first undergo hydrolytic cleavage into their constituent monosaccharides; these hydrolytic reactions are catalyzed by specific brush border membrane hydrolases that are expressed most abundantly in the villi of the duodenum and jejunum. The three major monosaccharides that represent the terminal products of carbohydrate digestion are glucose, galactose, and fructose.

Under physiologic conditions, most of these sugars are absorbed through the epithelium via the transcellular route. Glucose and galactose are transported through the enterocyte brush border membrane via intestinal Na^+-glucose cotransporter, SGLT1 (Fig. 28-7). Fructose is transported through the brush border membrane by facilitated diffusion via GLUT5 (a member of the facilitative glucose transporter family). All three monosaccharides are extruded through the basolateral membrane by facilitated diffusion using GLUT2 and GLUT5 transporters. Extruded monosaccharides diffuse into venules and ultimately enter the portal venous system.

There is evidence of overexpression of hexose transporters, specifically SGLT1, in disease states such as diabetes.[6] Several approaches aimed at downregulation of intestinal glucose transporter are being investigated as a novel therapy for disease states such as diabetes and obesity.[7]

Protein Digestion and Absorption. Ten to fifteen percent of energy consumption in the average Western diet consists of proteins. In addition to dietary proteins, approximately one half of the protein load that enters the small intestine is derived from

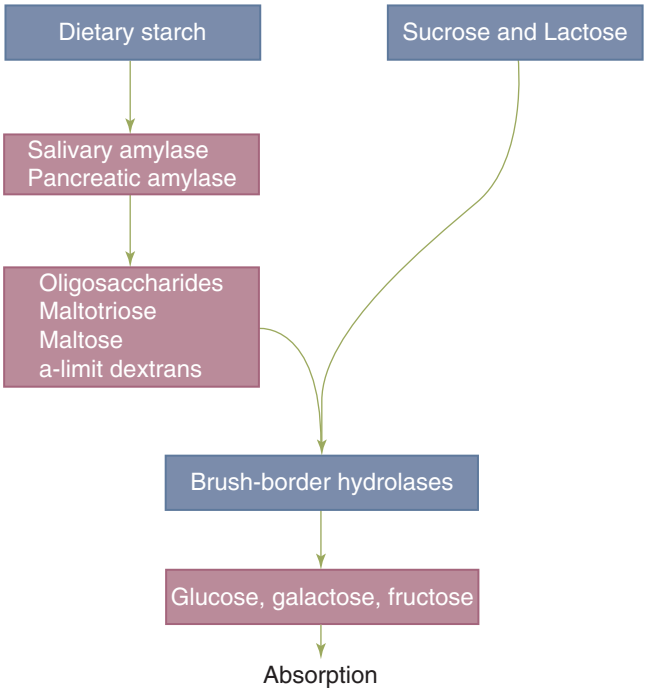

Figure 28-6. Carbohydrate digestion. Dietary carbohydrates, including starch and the disaccharides sucrose and lactose, must undergo hydrolysis into constituent monosaccharides glucose, galactose, and fructose before being absorbed by the intestinal epithelium. These hydrolytic reactions are catalyzed by salivary and pancreatic amylase and by enterocyte brush border hydrolases.

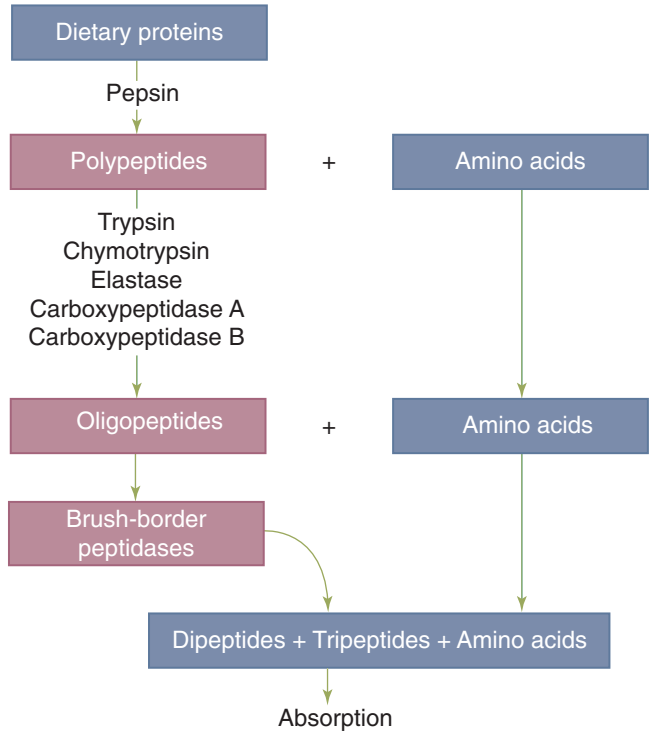

Figure 28-8. Protein digestion. Dietary proteins must undergo hydrolysis into constituent single amino acids and di- and tripeptides before being absorbed by the intestinal epithelium. These hydrolytic reactions are catalyzed by pancreatic peptidases (e.g., trypsin) and by enterocyte brush border peptidases.

endogenous sources including salivary and gastrointestinal secretions and desquamated intestinal epithelial cells. Protein digestion begins in the stomach with action of pepsins. This is not, however, an essential step, since surgical patients who are acholorhydric or who have lost part or all their stomach are still able to successfully digest proteins. Digestion continues in the duodenum with the actions of a variety of pancreatic peptidases.

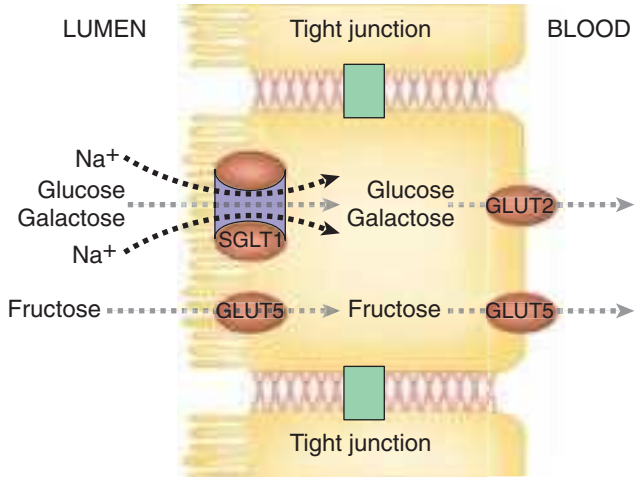

Figure 28-7. Hexose transporters. Glucose and galactose enter the enterocyte through secondary active transport via the sodium-glucose cotransporter (SGLT1) located on the apical (brush border) membrane. Fructose enters through facilitated diffusion via glucose transporter 5 (GLUT5). Glucose and galactose are extruded basolaterally through facilitated diffusion via glucose transporter 2 (GLUT2). Fructose is extruded basolaterally via GLUT5.

These enzymes are secreted as inactive proenzymes. This is in contrast to pancreatic amylase and lipase, which are secreted in their active forms. In response to the presence of bile acids, enterokinase is liberated from the intestinal brush border membrane to catalyze the conversion of trypsinogen to active trypsin; trypsin in turn activates itself and other proteases. The final products of intraluminal protein digestion consist of neutral and basic amino acids and peptides two to six amino acids in length (Fig. 28-8). Additional digestion occurs through the actions of peptidases that exist in the enterocyte brush border and cytoplasm. Epithelial absorption occurs for both single amino acids and di- or tripeptides via specific membrane-bound transporters. Absorbed amino acids and peptides then enter the portal venous circulation.

Of all amino acids, glutamine appears to be a unique, major source of energy for enterocytes. Active glutamine uptake into enterocytes occurs through both apical and basolateral transport mechanisms.

Fat Digestion and Absorption. Approximately 40% of the average Western diet consists of fat. Over 95% of dietary fat is in the form of long-chain triglycerides; the remainder includes phospholipids such as lecithin, fatty acids, cholesterol, and fat-soluble vitamins. Over 94% of the ingested fats are absorbed in the proximal jejunum.

Since fats are normally water insoluble, key to successful digestion of ingested fats is solubalization of them into an emulsion by the mechanical actions of mastication and antral peristalsis. Although lipolysis of triglycerides to form fatty acids and monoglyciderides is initiated in the stomach by gastric lipase, its principal site is the proximal intestine, where pancreatic lipase is the catalyst (Fig. 28-9).

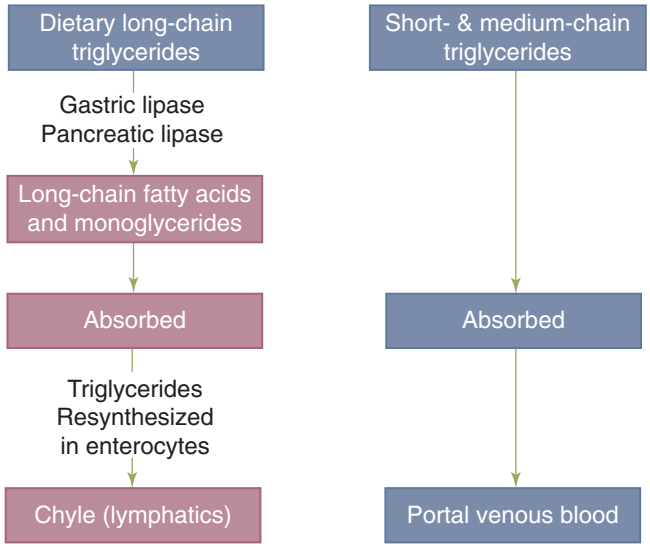

Figure 28-9. Fat digestion. Long-chain triglycerides, which constitute the majority of dietary fats, must undergo lipolysis into constituent log-chain fatty acids and monoglycerides before being absorbed by the intestinal epithelium. These reactions are catalyzed by gastric and pancreatic lipases. The products of lipolysis are transported in the form of mixed micelles to enterocytes, where they are resynthesized into triglycerides, which are then packaged in the form of chylomicrons that are secreted into the intestinal lymph (chyle). Triglycerides composed of short- and medium-chain fatty acids are absorbed by the intestinal epithelium directly, without undergoing lipolysis, and are secreted into the portal venous circulation.

Bile acids act as detergents that help in solubalization of the lipolysis by forming mixed micelles. These micelles are polymolecular aggregates with a hydrophobic core of fat and a hydrophilic surface that act as shuttles, delivering the products of lipolysis to the enterocyte brush border membrane, where they are absorbed. The bile salts, however, remain in the bowel lumen and travel to the terminal ileum, where they are actively resorbed. They enter the portal circulation and are resecreted into bile, thus completing the enterohepatic circulation.

Dissociation of lipids from the micelles occurs in a thin layer of water (50–500 µm thick) with an acidic microenvironment immediately adjacent to the brush border called the *unstirred water layer*. Most lipids are absorbed in the proximal jejunum, whereas bile salts are absorbed in the distal ileum through an active process. Fatty acid binding proteins (FABPs) are a family of proteins located on the brush border membrane, facilitating diffusion of long-chain fatty acids across the brush border membrane. Cholesterol crosses the brush border membrane through an active process that is yet to be completely characterized. Within the enterocytes, triglycerides are resynthesized and incorporated into chylomicrons that are secreted into the intestinal lymphatics and ultimately enter the thoracic duct. In these chylomicrons, lipoproteins serve a detergent-like role similar to that served by bile salts in the mixed micelles.

The steps described above are required for the digestion and absorption of triglycerides containing long-chain fatty acids. However, triglycerides containing short- and medium-chain fatty acids are more hydrophilic and are absorbed without undergoing intraluminal hydrolysis, micellular solubilization, mucosal re-esterification, and chylomicron formation. Instead, they are directly absorbed and enter the portal venous circulation rather than the lymphatics. This information provides the rationale for administering nutritional supplements containing medium-chain triglycerides to patients with gastrointestinal diseases associated with impaired digestion and/or malabsorption of long-chain triglycerides.

Vitamin and Mineral Absorption. Vitamin B_{12} (cobalamin) malabsorption can result from a variety of surgical manipulations. The vitamin is initially bound by saliva-derived R protein. In the duodenum, R protein is hydrolyzed by pancreatic enzymes, allowing free cobalamin to bind to gastric parietal cell–derived intrinsic factor. The cobalamin-intrinsic factor complex is able to escape hydrolysis by pancreatic enzymes, allowing it to reach the terminal ileum, which expresses specific receptors for intrinsic factor. Subsequent events in cobalamin absorption are poorly characterized, but the intact complex probably enters enterocytes through translocation. Because each of these steps is necessary for cobalamin assimilation, gastric resection, gastric bypass, and ileal resection can each result in vitamin B_{12} insufficiency.

Other water-soluble vitamins for which specific carrier-mediated transport processes have been characterized include ascorbic acid, folate, thiamine, riboflavin, pantothenic acid, and biotin. Fat-soluble vitamins A, D, and E appear to be absorbed through passive diffusion. Vitamin K appears to be absorbed through both passive diffusion and carrier-mediated uptake.

Calcium is absorbed through both transcellular transport and paracellular diffusion. The duodenum is the major site for transcellular transport; paracellular transport occurs throughout the small intestine. A key step in transcellular calcium transport is mediated by calbindin, a calcium-binding protein located in the cytoplasm of enterocytes. Regulation of calbindin synthesis is the principle mechanism by which vitamin D regulates intestinal calcium absorption. Abnormal calcium levels are increasingly seen in surgical patients who have undergone a gastric bypass. Although usual calcium supplementation is often in the form of calcium carbonate, which is cheap, in such patients with low acid exposure, calcium citrate is a better formulation for supplemental therapy.

Iron and magnesium are each absorbed through both transcellular and paracellular routes. A divalent metal transporter capable of transporting Fe^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Cd^{2+}, Cu^{2+}, Ni^{2+}, and Pb^{2+} that has recently been localized to the intestinal brush border may account for at least a portion of the transcellular absorption of these ions.[8]

Barrier and Immune Function

Although the intestinal epithelium allows for the efficient absorption of dietary nutrients, it must discriminate between pathogens and harmless antigens such as food proteins and commensal bacteria, and it must resist invasion by pathogens. Factors contributing to epithelial defense include immunoglobulin A (IgA), mucins, and the relative impermeability of the brush border membrane and tight junctions to macromolecules and bacteria. Recently described factors likely to play important roles in intestinal mucosal defense include antimicrobial peptides such as the defensins.[9] The intestinal component of the immune system, known as the gut-associated lymphoid tissue (GALT), contains over 70% of the body's immune cells.

The GALT is conceptually divided into inductive and effector sites.[10] Inductive sites include Peyer's patches, mesenteric lymph nodes, and smaller isolated lymphoid follicles scattered throughout the small intestine (Fig. 28-10).

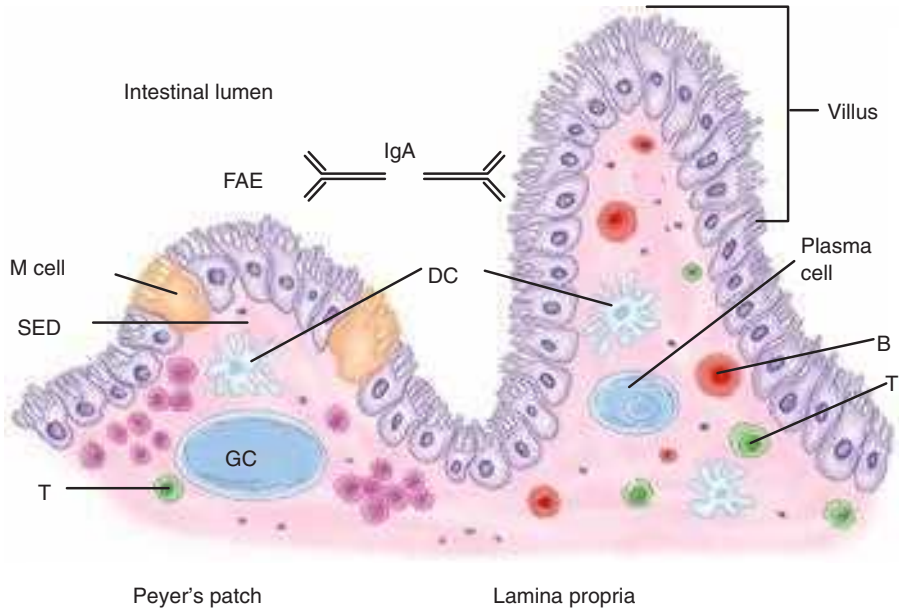

Figure 28-10. Gut-associated lymphoid tissue. Select components of the gut-associated lymphoid tissue (GALT) are schematically represented. Peyer's patches consist of a specialized follicle-associated epithelium (FAE) containing M cells, a subepithelial dome (SED) rich in dendritic cells, and B-cell follicle-containing germinal centers (GC). Plasma cells in the lamina propria produce immunoglobulin A (IgA), which is transported to the intestinal lumen where it serves as the first line of defense against pathogens. Other components of GALT include isolated lymphoid follicles, mesenteric lymph nodes, and regulatory and effector lymphocytes.
