# Postoperative Care of Cardiac Surgery Patients

Farhang Yazdchi • James D. Rawn

Mortality and morbidity in cardiac surgery have continued to decline despite increases in patient age, comorbid conditions, and procedure complexity. Much of this success can be attributed to advances in critical care. This chapter will outline some strategies and principles of modern postoperative care.

## CARDIOVASCULAR CARE

### Hemodynamic Assessment

Assessment and optimization of hemodynamics is a principle focus of care following cardiac surgery. Appropriate management requires knowledge of preoperative cardiac function and an appreciation of the impact of intraoperative events. The goal of postoperative hemodynamic management is the maintenance of adequate oxygen delivery to vital tissues in a way that avoids unnecessary demands on a heart recovering from the stress of cardiopulmonary bypass (CPB), ischemia, and surgery.

A basic initial hemodynamic assessment includes a review of current medications, heart rate and rhythm, mean arterial pressure (MAP), central venous pressure (CVP), and an ECG analysis to exclude ischemia and conduction abnormalities. The presence of a pulmonary artery catheter enables the measurement of pulmonary artery pressures, left-sided filling pressures (pulmonary capillary wedge pressure (PCWP)), and mixed venous oxygen saturation ( $MVO_2$ ). Cardiac output (CO), as well as pulmonary and systemic vascular resistances (SVRs) can also be calculated when a PA catheter is present. CO is determined utilizing thermodilution or by using the Fick equation. CO, blood pressure (BP), and SVR are related to each other using Ohm's law (Table 17-1). Reasonable minimum goals for most patients include an  $MVO_2$  of about 60%, MAP > 65 mm Hg, and a cardiac index (CI) > 2 L/min/m<sup>2</sup>. Goals should be individualized. Patients with a history of hypertension or significant peripheral vascular disease will benefit from higher BP; patients who are bleeding or who have suture lines in fragile tissue are best served with tighter control. Strategies designed to produce a supra-normal CI or  $MVO_2$  have failed to demonstrate a survival advantage.<sup>1</sup>

Failure to achieve adequate CO and end-organ oxygen delivery can be caused by many co-dependent factors. These include volume status (preload), peripheral vascular tone (afterload), cardiac pump function, heart rate and rhythm, and blood oxygen carrying capacity.

Volume status can be estimated using invasive monitoring. CVP, unless it is very low, is an unreliable indicator of left ventricular end-diastolic volume. An elevated CVP can be seen in volume overload, right heart failure, tricuspid and mitral regurgitation, pulmonary hypertension, cardiac tamponade, tension pneumothorax, and pulmonary embolism. Pulmonary artery diastolic pressure correlates with left-sided filling pressures when pulmonary vascular resistance (PVR) is normal (low). PCWP (or left atrial pressure if this is being directly measured) provides the most accurate assessment of left-sided filling pressures in the absence of significant mitral stenosis, and its correlation with pulmonary artery diastolic pressure should be noted to enable a more continuous assessment of left-sided pressures. Determination of optimum filling pressures is generally empiric. A wedge pressure of 15 mm Hg is generally adequate, but many patients can require higher pressures. Most patients arrive from the operating room with a significant net fluid gain, but much of this excess volume is extravascular due to third space and pleural cavity accumulation. Consequently, many patients are intravascularly underfilled and have on going volume requirements in the immediate postoperative period. Postoperative vasoplegia is common. Contributors include a systemic inflammatory response to CPB and the stress of surgery in addition to preoperative and perioperative medications including ACE inhibitors, calcium channel blockers, and sedatives. Urine output and bleeding are common sources of ongoing fluid loss. Hypothermia promotes vasoconstriction. As patients rewarm, changes in peripheral vascular tone contribute to labile hemodynamics which are often best treated with volume replacement.

Peripheral vascular tone needs to be sufficient to provide the patient with adequate BP; excess vasoconstriction can increase SVR and create dangerous levels of hypertension and decreased CO. Increases in afterload can be caused by medications, hypothermia, increased sympathetic output

**TABLE 17-1: Common Intensive Care Values and Formulae**

Early postoperative hemodynamic parameters	Expected values
Mean arterial pressure (MAP)	60-90 mm Hg
Systolic blood pressure (sBP)	90-140 mm Hg
Right arterial pressure (RAP)	5-15 mm Hg
Cardiac index (CI)	2.2-4.4 L/min/m <sup>2</sup>
Pulmonary artery wedge pressure (PAWP)	10-15 mm Hg
Systemic vascular resistance (SVR)	1400-2800 dyn-s/cm <sup>5</sup>
Common hemodynamic formulae	Normal values
CO = SV × HR	4-8 L/min
CI = CO/BSA	2.2-4.0 L/min/m <sup>2</sup>
CO = cardiac output; HR = heart rate; SV = stroke volume; BSA = body surface area	
$SV = \frac{CO \text{ (L/min)} \times 1000 \text{ (mL/L)}}{HR}$	60-100 mL/beat (1 mL/kg/beat)
SVI = SV ÷ BSA	33-47 mL/beat/m <sup>2</sup>
SVI = stroke volume index	
$MAP = \frac{DP + (SP - DP)}{3}$	70-100 mm Hg
$SVR = \frac{MAP - CVP}{CO} \times 80$	800-1200 dyn-s/cm <sup>5</sup>
CVP = central venous pressure; Ohm's law: Voltage (V) = Current (I) × Resistance (R); Resistance is directly proportional to viscosity (hematocrit) and inversely proportional to the radius to the 4th power	
$PVR = \frac{PAP - PCWP}{CO} \times 80$	50-250 dyn-s/cm <sup>5</sup>
PVR = pulmonary vascular resistance, PAP = mean pulmonary arterial pressure, PCWP = pulmonary capillary wedge pressure	
LVSWI = SVI × (MAP - PCWP) × 0.0136	45-75 mg-M/beat/m <sup>2</sup>
(LVSWI = left ventricular stroke work index)	
O <sub>2</sub> delivery = CO (Hb × %sat)(1.39) + (PaO <sub>2</sub> )(0.0031)	60-80%
1.39 is milliliters of oxygen transported per gram of serum hemoglobin (Hb); 0.0032 is solubility coefficient of oxygen dissolved in solution (mL/torr of PaO <sub>2</sub> )	
A-V O <sub>2</sub> Difference = (1.34)(Hb) × (SaO <sub>2</sub> - SvO <sub>2</sub> )	Normal Pvo <sub>2</sub> = 40 torr and SvO <sub>2</sub> = 75%
Fick Cardiac Output = $\frac{\text{Estimated O}_2 \text{ consumption}}{\text{A-V O}_2 \text{ difference}}$	Normal Pao <sub>2</sub> = 100 torr and SaO <sub>2</sub> = 99%
A-V = arterio-venous oxygen difference. Oxygen consumption is measured from a nomogram based on age, sex, height, height; Hb = serum hemoglobin (g/dL), SaO <sub>2</sub> = arterial oxygen saturation (%) in arterial blood, SvO <sub>2</sub> = mixed venous oxygen saturation (%) from the pulmonary artery in the absence of a shunt or calculated MvO <sub>2</sub> = (3 × SVC saturation + IVC saturation) ÷ 4, if a left-right shunt is present; 1.34 = m O <sub>2</sub> per gram of Hb, 10 dL/L	
Shunt Fraction = $\frac{Q_p}{Q_s} = \frac{(SaO_2 - Mvo_2)}{(Pvo_2 - Pao_2)}$	Normal, <5%
Q <sub>s</sub> = systemic flow (L/min); Q <sub>p</sub> = pulmonary flow (L/min)	
EF (%) = $\frac{\text{end-diastolic volume} - \text{end-systolic volume}}{\text{end-diastolic volume}}$	60-70%
EF = ejection fraction (an index of ventricular activity)

Prosthetic heart valves: current anticoagulation regimens (adapted from Ref. 129)	Coumadin target INR/aspirin 81 mg
AVR mechanical	2.5-3.0/yes, if high risk
AVR bioprosthetic (tissue)	2.5-3.0 (3 months) or none if aspirin used/yes
MVR mechanical	2.5-3.5 (indefinitely)/yes, if high risk
MVR bioprosthetic or MV repair	2.5-3.0 (3 months; continue 1 year if history of embolism; indefinitely if AF and LA thrombus at time of surgery)/yes, after 3 months
AVR and MVR mechanical	2.5-3.0 (indefinitely)/yes
AVR and MVT bioprosthetic (tissue)	2.5-3.0 (3 months)/yes, after 3 months
Atrial fibrillation (with any of the above)	2.5-3.0 (indefinitely)/yes

AF = atrial fibrillation; AVR = aortic valve replacement; MVR = mitral valve replacement; high risk = AF, myocardial infarction, enlarged left atrium (LA), endocardial damage, low EF, history of systemic embolism despite adequate anticoagulation.

(including pain and anxiety) or may be secondary to hypovolemia or pump failure.

Left ventricular pump function can be influenced by levels of exogenous or endogenous inotropes, postoperative ischemic stunning or infarction, valve function, acidosis, electrolyte abnormalities, hypoxia or cardiac tamponade. Bradycardia, arrhythmias, and conduction defects can also adversely affect CO.

The oxygen carrying capacity of blood is a function of hematocrit and oxygenation. A hematocrit of 21% and oxygen saturation greater than 90% is adequate for a stable postoperative patient.

It is important not to allow the evaluation of the patient to become obscured by too many numbers or theories, and an overall assessment of the patient is always more important than any single parameter. Trends in hemodynamic parameters are usually more important than isolated values. Patients generally do well if they have warm, well-perfused extremities, a normal mental status and good urine output (>0.5 cc/kg/min). Acute changes in hemodynamic status are common postoperatively, and vigilant monitoring should enable care to be more preemptive than reactive.

## Hemodynamic Management

### FLUID MANAGEMENT

As emphasized previously, the goal of postoperative hemodynamic management is the maintenance of adequate end-organ perfusion without taxing the heart unnecessarily. Assessment and optimization of intravascular volume status are generally the first steps in this process. Most patients have ongoing fluid requirements in the immediate postoperative period that can be caused by persistent third spacing, warming, diuresis, vasodilation, and bleeding. Careful monitoring of fluid balance and filling pressures should guide volume resuscitation. Starling curves are highly variable; it is helpful to correlate CO and  $MVO_2$

with changes in volume status. Patients with ventricular hypertrophy (eg, those with a history of hypertension or aortic stenosis) diastolic dysfunction or systolic anterior motion of the mitral valve usually need higher filling pressures. Patients with persistently low filling pressures despite aggressive fluid administration are usually either bleeding or vasodilated. Calculation of CO and SVR can often help sort this out. Monitoring devices that measure respiratory variation in the pulse arterial waveform have been shown to successfully predict the ability to improve CO with volume administration. In the case of significant vasodilation, judicious use of a pressor agent can help to decrease fluid requirements. Inotropic agents should not be administered for the treatment of hypovolemia. Fluid requirements can often be reduced following extubation; as decreased intrathoracic pressures will improve venous return.

The choice of an optimal resuscitation fluid has been controversial. In the acute setting, colloid infusions achieve comparable hemodynamic effects with less volume when compared to crystalloid solutions. After one hour, 80% of 1000 cc of 5% albumin solution is retained intravascularly. In situations characterized by loss of vascular endothelial integrity (ie, following CPB) albumin will redistribute into the interstitial space and increase third space fluid accumulation. One study has shown that the accumulation of extravascular pulmonary water is unaffected by the prime type or the type of fluid administered postoperatively.<sup>2</sup> The largest prospective randomized controlled study comparing colloid to crystalloid has been unable to demonstrate a difference in outcomes, although a subsequent subgroup analysis found increased mortality in patients who suffered brain injury who were randomized to receive colloid.<sup>3</sup> Albumin and hetastarch provide comparable hemodynamic benefits, although hetastarch should be avoided in bleeding or coagulopathic patients or in those with renal impairment.

Although unusual in the immediate postoperative period, volume overload is a common problem in the days following surgery. If patients have normal cardiac function they often diuresis appropriately without intervention. Conversely, volume overload is a common cause of postoperative heart failure. Diuretics and vasodilators are frequently required in patients with impaired pump function before or following surgery, or in those who receive large volumes of fluid perioperatively. Patients with impaired renal function may require renal replacement therapy (ultrafiltration, continuous veno-venous hemofiltration, or hemodialysis) to become euvolemic. Rapid diuresis accompanied by inadequate electrolyte repletion is frequently arrhythmogenic.

**PHARMACOLOGIC SUPPORT**

Medications are used perioperatively to provide vasoconstriction, venous and arterial vasodilation, inotropic support and treatment of arrhythmias. As summarized in Table 17-2, many of the medications commonly used have multiple actions. Selection of appropriate agents depends on accurate hemodynamic assessment.

Pressors are indicated for vasodilated patients who have normal pump function and are unresponsive to volume. These agents include  $\alpha$ -agents (neosynephrine) and vasopressin. Methylene blue has demonstrated efficacy in vasopressor-resistant hypotension. Pressors can contribute to peripheral ischemia and vasospasm of coronary arteries and arterial conduits. Careful monitoring of extremity perfusion and

electrocardiographic changes is required when using these agents.

Vasodilators are indicated for hypertensive patients and for patients who are normotensive with poor pump function. Nitroglycerin and sodium nitroprusside are commonly used in the immediate postoperative period. Both have the advantage of being short acting and easy to titrate. Both can cause hypoxia by inhibiting pulmonary arterial hypoxic vasoconstriction and increasing blood flow through poorly oxygenated lung. Nitroglycerin is a stronger venodilator than an arterial dilator, and

can increase intercoronary collateral blood flow, but patients can quickly become tachyphylactic. Prolonged nitroprusside use can lead to cyanide toxicity, and methemoglobin levels must be monitored. Nicardipine is a calcium channel blocker with minimal effects on contractility or atrioventricular (AV) nodal conduction; it appears to have the efficacy of nifedipine without its toxicity. Nicardipine has been shown to control BP with less variability than nitroglycerin or nitroprusside and this has been found to correlate with improved outcomes. Nesiritide, or brain natriuretic peptide, promotes diuresis in addition

to vasodilation and may have beneficial lusitropic effects in patients with diastolic dysfunction.

Hypertension can also be treated with beta blockers. These agents work by decreasing heart rate and contractility. Esmolol is useful in the presence of labile BP because of its short half-life. Labetolol combines beta and alpha adrenergic blockade. Patients whose pump function is inotrope dependent should not receive beta blockers.

Inotropic agents are indicated when low CO persists despite optimization of fluid status (preload), vascular tone (afterload), and heart rate and rhythm. These agents include beta adrenergic agents (dobutamine) and cyclic nucleotide phosphodiesterase inhibitors (milrinone). Both of these agents increase CO by increasing myocardial contractility and by reducing afterload through peripheral vasodilation. Dobutamine is shorter acting and easier to titrate; milrinone achieves increases in CO with lower myocardial oxygen consumption. Both are arrhythmogenic and can exacerbate coronary ischemia. Both epinephrine and norepinephrine combine  $\beta$  and  $\alpha$  adrenergic agonist effects; they are pressors in addition to positive inotropes. Relative  $\alpha$  effects increase with dose. Dopamine in low doses causes splanchnic and renal vasodilation;  $\alpha$  and  $\beta$  effects dominate at higher doses. Since perioperative beta blockade has been shown to improve mortality and morbidity following cardiac surgery, it seems reasonable to avoid the gratuitous use of inotropes, and efforts should be made to rapidly wean these agents when they are no longer required.

## Heart Rate and Rhythm Management

Deviations from normal sinus rhythm can cause significant clinical deterioration and optimization of heart rate and rhythm is frequently an effective way to improve hemodynamic status.

### PACING (SEE TABLE 17-2)

Within normal rate ranges, CO increases linearly with heart rate, and pacing is often very helpful. However, it is important to carefully monitor the response to pacing. For example, sinus bradycardia is often more effective than ventricular pacing at a more normal rate. Ventricular pacing can cause ventricular dysfunction and dys-synchrony and the loss of consistent filling from atrial contraction; ventricular pacing is often useful in acutely decreasing BP while waiting to initiate a vasodilator. If possible atrial pacing is preferred to AV pacing which is preferred to ventricular pacing. Pacing too rapidly can adversely affect cardiac performance by decreasing filling time, exacerbating ischemia or inducing heart block. Ensure that pacemakers in patients undergoing ventricular pacing can sense appropriately in order to avoid R on T and subsequent ventricular fibrillation. Internal pacemakers can often be reprogrammed to improve output.

Heart block can occur following aortic, mitral and tricuspid valve surgery. It is also associated with inferior myocardial infarction and can be secondary to medications (eg, digoxin, amiodarone, calcium channel blockers, and beta blockers). If a bi-atrial trans-septal approach to the mitral valve is

employed, sinus rhythm can be lost due to the division of the sinoatrial node.<sup>4</sup> Heart block is frequently transient. If the ventricular escape rate is absent or insufficient, pacing wire thresholds need to be carefully monitored and backup pacing methods employed (by transvenous wire, pacing pulmonary artery catheter, or external pacing pads) if needed while waiting for placement of a permanent pacemaker.

### VENTRICULAR ARRHYTHMIAS

Nonsustained ventricular tachycardia (VT) is common following cardiac surgery and typically a reflection of perioperative ischemia/reperfusion injury, electrolyte abnormalities (typically hypokalemia and hypomagnesemia) or an increase in exogenous or endogenous sympathetic stimulation. Generally, nonsustained VT is more important as a symptom of an underlying cause requiring diagnosis and correction than as a cause of hemodynamic instability.

Sustained VT persisting for more than 30 seconds or associated with significant hemodynamic compromise, requires more aggressive treatment. Ongoing ischemia should be ruled out (coronary angiography may be necessary), electrolytes should be replaced and inotropes should be minimized. Beta blockers, amiodarone, and lidocaine can be useful therapies. Electrocardioversion should be employed if sustained VT causes significant compromise.

### ATRIAL FIBRILLATION AND FLUTTER

**Background.** The incidence of postoperative atrial fibrillation (POAF) following cardiothoracic surgery is 30 to 50%,<sup>5</sup> and has been shown to be higher in the elderly and patients with renal impairment or chronic obstructive pulmonary disease (COPD).<sup>6</sup> This is associated with an increased risk of stroke, longer hospitalization, higher cost, and greater risk of long-term mortality.<sup>7</sup>

**Prophylaxis.** The incidence of POAF is 20 to 40% in coronary artery bypass graft (CABG) patients but it is generally more common in patients undergoing valve and combined procedures. POAF is typically a transient phenomenon. Use of beta blockers for the prevention of POAF is supported by the highest level of evidence. Therefore, beta blockers should be started or resumed as soon as they can be safely tolerated following cardiac surgery. Inotropic support, hemodynamic compromise, and AV block (PR interval > 0.24 ms, second or third degree block) are contraindications. Beta blockers appear to provide more effective prophylaxis when they are dosed with high frequency and titrated to produce an effect on heart rate and BP. Sotalol and amiodarone are also effective for prophylaxis but not superior. Sotalol, like other type II agents, can promote ventricular arrhythmias. Beta blockers also confer benefits other than atrial fibrillation prophylaxis, are easy to titrate, and do not have the toxicities associated with amiodarone. The postinflammatory milieu following cardiothoracic surgery may contribute to the pathogenesis of postoperative arrhythmias. For example, IL6 and C-reactive protein elevation postoperatively and atrial fibrillation (AF)

have been linked. In the only randomized clinical trial in this arena atorvastatin started 7 days before cardiac surgery was associated with a >60% reduction in the incidence of postoperative AF among 200 patients undergoing CABG surgery. However, the high AF rate (~60%) in the control group of this study was not representative of the experience at most centers; this may reflect the fact that beta blockers were not administered routinely after surgery.

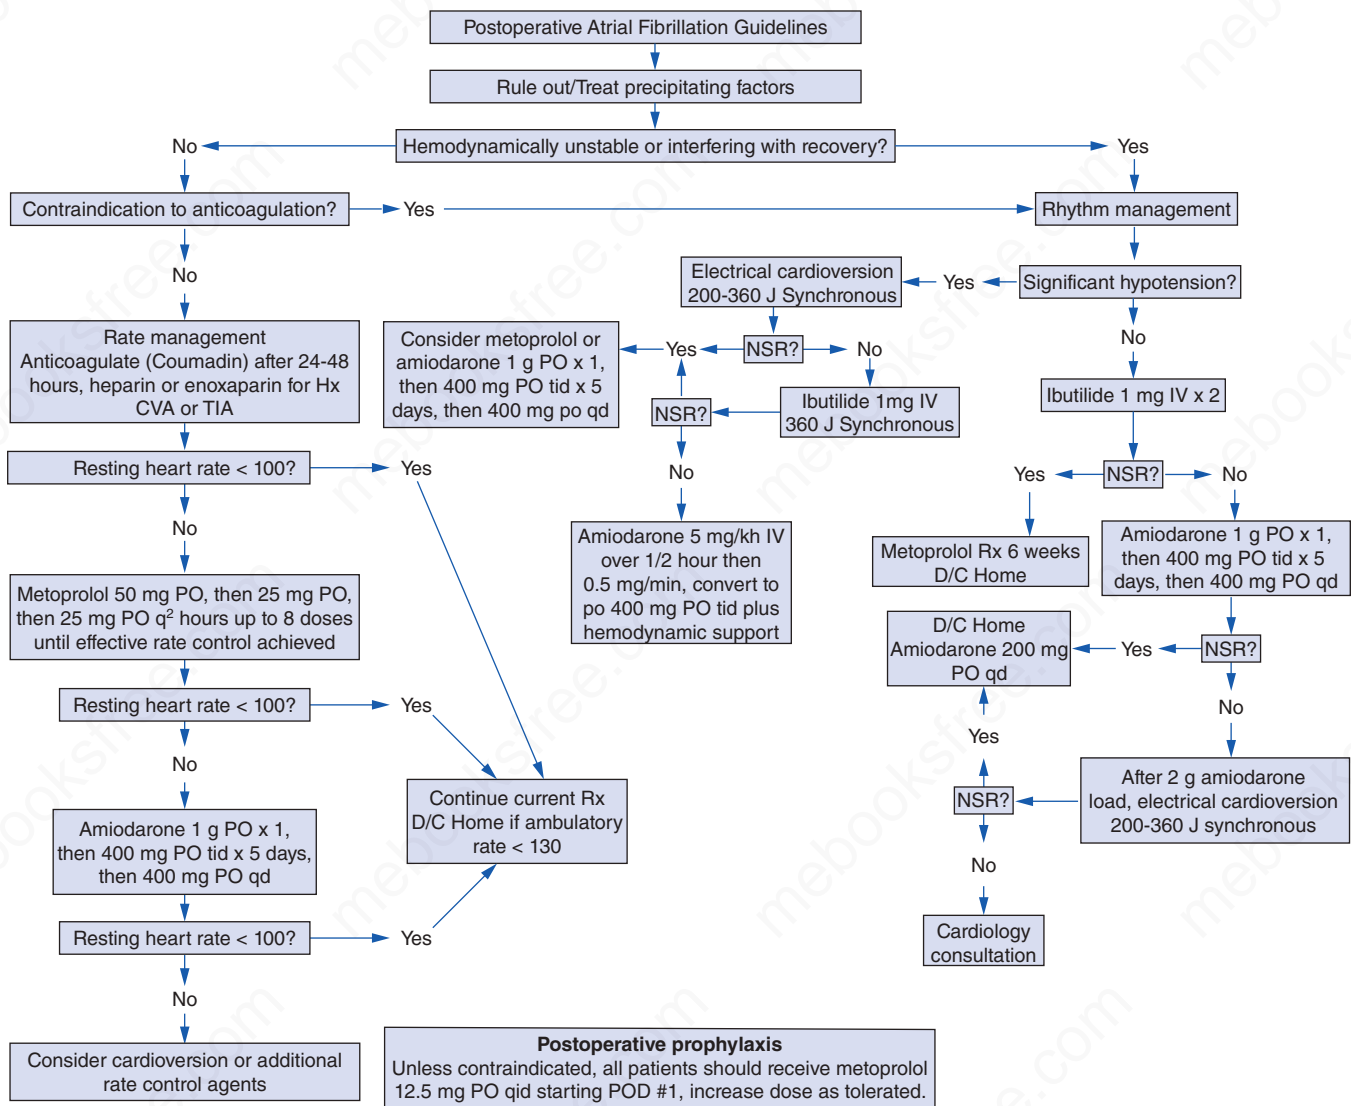

**Treatment.** There are many treatment strategies for the management of atrial fibrillation. We have developed the guidelines outlined in Table 17-1. The principle premise of this strategy is the recognition that for most patients with new onset atrial fibrillation, the arrhythmia is well tolerated and self-limited (90% of patients are in sinus rhythm within 6 to 8 weeks independent of treatment approach). The pursuit of a rate control and anticoagulation strategy typically produces outcomes

comparable to a rhythm control strategy. Our prophylactic regimen begins with metoprolol 12.5 to 25 mg orally (po) four times a day and is titrated upward as tolerated.

### STRATEGY FOR THE TREATMENT OF POSTOPERATIVE ATRIAL FIBRILLATION (FIG. 17-1)

**A. Initial assessment:** The management of atrial fibrillation should be guided by the answers to the following three questions:

**1. Is the patient symptomatic?** Atrial fibrillation is generally well tolerated, and over aggressive management can cause significant morbidity. Nonetheless, the first step in the management of atrial fibrillation is an assessment of its hemodynamic significance. Significant symptoms may respond to rate control alone or may require chemical or electrical cardioversion. Evidence

**FIGURE 17-1** Postoperative atrial fibrillation guidelines. (Reproduced with permission from Maisel WH, Rawn JD, Stevenson WG: Atrial fibrillation after cardiac surgery, *Ann Intern Med.* 2001 Dec 18;135(12):1061-1073.)

of compromise includes hypotension, changes in mental status, decreased urine output, impaired peripheral perfusion, symptoms of coronary ischemia, and decreased CO or increased filling pressures.

2. **What are the precipitating factors?** Appropriate management of atrial fibrillation requires identification and treatment of potential risk factors. Atrial fibrillation can result from ischemia, atrial distension, increased sympathetic tone, electrolyte imbalances (particularly hypokalemia and hypomagnesemia precipitated by diuresis), acid-base disturbances (particularly alkalosis), sympathomimetic medications (inotropes, bronchodilators), beta blocker withdrawal, pneumonia, atelectasis, and pulmonary embolism.
3. **What are the goals of therapy?** Hemodynamic stability is the primary goal. For most patients, rate control is sufficient since 90% of patients with new onset atrial fibrillation following cardiac surgery will be in normal sinus rhythm within 6 weeks. In long-term studies of patients with chronic atrial fibrillation it has been difficult to show a benefit from rhythm control strategies.<sup>8</sup> Optimal target heart rates depend on many patient-specific factors. A randomized study comparing strict control (heart rate less than 80) to lenient control (heart rate less than 110) in permanent atrial fibrillation found fewer adverse events in the lenient control group.<sup>9</sup> Evidence of hemodynamic compromise or interference with recovery should prompt chemical or electrical cardioversion.

**B. Drug therapy:** Agents can be conveniently divided into rate control and rhythm control agents, although beta blockers are also effective in converting atrial fibrillation postoperatively. Mono drug therapy is generally better than poly drug therapy.

#### Rate control agents

1. **Beta blockers.** Metoprolol should be first line therapy in most patients and can be given orally or intravenously. Metoprolol should be titrated to effect with a heart rate goal typically less than 110 beats/minute at rest. The suggested treatment for new onset atrial fibrillation is 50 mg po, followed by 25 mg po every 2 to 3 hours until NSR or adequate rate control is achieved. Some patients may require oral doses over 400 mg/day.
2. **Calcium channel blockers.** Diltiazem is the agent of choice. It can be given orally starting at 30 mg po three times a day. It can also be initiated as a bolus of 0.25 mg/kg IV, followed by 0.35 mg/kg IV, followed by a continuous infusion at 5 to 15 mg/h.
3. **Digoxin** can be considered in patients with contraindications to beta blockers, in particular those with poor ejection fraction. There is evidence that it increases atrial automaticity. It has a half-life of 38 to 48 hours in patients with normal renal function, significant potential toxicity, and a narrow therapeutic range. Levels must be monitored, particularly in patients with renal insufficiency. Many agents, including amiodarone, increase its serum level.

#### Antiarrhythmics

##### 1. Metoprolol

**2. Ibutilide.** Ibutilide is given as a 1-mg intravenous bolus and repeated once if cardioversion fails to occur. Patients need to be monitored for a small but significant incidence of torsade de pointes which may be increased if given in conjunction with amiodarone.

**3. Amiodarone** can cause myocardial depression, heart block, and acute pulmonary toxicity; significant hypotension is most commonly associated with rapid bolus infusion. Significant toxicity is associated with prolonged use of amiodarone, and consideration should be given to discontinuing the drug within six weeks of surgery.

**4. Adenosine** is helpful in the treatment of supraventricular tachycardia. (It should be avoided in transplant recipients, partially revascularized patients and in patients with atrial flutter).

**5. Dronedarone.** Dronedarone is an amiodarone analog without iodine moiety in its structure, and is similar to amiodarone with regard to its structural and electrophysiological properties.<sup>10</sup> It has been associated with increased mortality in patients with severely depressed left ventricular function.<sup>11,12</sup> It appears to be less toxic but also less effective than amiodarone.<sup>13</sup>

**C. Electrical cardioversion:** Electrical cardioversion should be used emergently for the treatment of hemodynamically unstable atrial fibrillation. Synchronous cardioversion rather than defibrillation should be utilized to minimize the risk of precipitating ventricular fibrillation. Sedation should be used. In patients with atrial wires who are in atrial flutter, overdrive pacing can be attempted.

**D. Anticoagulation:** Patients who remain in atrial fibrillation for >24 hours or have multiple sustained episodes over this period should be started on coumadin in the absence of contraindications. Heparin (unfractionated IV or low molecular weight SQ) should be considered after 48 hours, particularly in patients with a history of stroke or TIAs or who have a low ejection fraction. Coumadin can be initiated in patients who may require permanent pacer placement as pacemakers can generally be safely placed with INR < 2. Postprocedure heparin bridging has been associated with significant rates of pocket hematoma formation.

## Postoperative Ischemia and Infarction

Postoperative ischemia and infarction can be caused by inadequate intraoperative myocardial protection, kinked, spasmed or thrombosed conduits, thrombosed endarterectomized vessels, or embolization by air or atherosclerotic debris. It should be suspected in the presence of otherwise unexplained poor pump function, ST changes, new bundle branch block or complete heart block, ventricular arrhythmias or enzyme elevation. Electrocardiographic changes should be correlated with the anatomy of known atherosclerotic or revascularized

territories. Air embolism preferentially involves the right coronary artery and inferior ST changes are generally present in the operating room. It typically resolves within hours. It is worth noting that nonspecific ST changes are common postoperatively and usually benign. Pericardial changes are generally characterized by diffuse concave ST elevations, accompanied by a pericardial rub and delayed in onset by at least 12 hours following surgery.

New wall motion abnormalities or mitral regurgitation diagnosed echocardiographically can help determine the hemodynamic significance of suspected ischemia or infarction. Knowledge of the quality of conduits, anastomoses, and target vessels is critical in planning management strategy (eg, there may be little to be gained and much to lose in attempting to improve flow to a small, highly diseased posterior descending artery with poor run-off). On the other hand, if significant myocardium appears at risk a timely trip to the operating room or the cardiac catheterization laboratory can dramatically improve outcomes. Ongoing ischemia should prompt consideration of standard treatment strategies including anticoagulation, beta blockade, and nitroglycerin as tolerated. Intra-aortic balloon pump placement should be considered to minimize inotrope requirements, decrease myocardial oxygen requirements and minimize infarct size.

## Right Ventricular Failure and Pulmonary Hypertension

Right ventricular failure can be a particularly difficult postoperative problem. It can be caused by perioperative ischemia or infarction or by acute increases in PVR. Preexisting pulmonary hypertension is commonly caused by left-sided heart failure, aortic stenosis, mitral valve disease, and pulmonary disease. Chronic pulmonary hypertension is characterized by abnormal increased vasoconstriction and vascular remodeling.<sup>14</sup> Acute increases in PVR are commonly caused by acute left ventricular dysfunction, mitral valve insufficiency or stenosis, volume overload, pulmonary edema, atelectasis, hypoxia, or acidosis. Pulmonary embolism should also be considered, but it is rare in the immediate postoperative period. As the right heart fails it becomes distended, CVP increases, tricuspid regurgitation may develop, and pulmonary artery pressures and left-sided filling pressures become inadequate. Strategies for reversing this potentially fatal process begin with identifying potentially reversible etiologies. Volume status and left-sided function should be optimized. The RV has its own Starling curve, and while the failing right ventricle (RV) often needs more volume to ensure adequate left-sided filling, overdistension will worsen function. Judicious use of positive end-expiratory pressure (PEEP) to recruit atelectatic lung and hyperventilation can decrease the impact of pulmonary vasoconstriction mediated by hypoxia and hypercapnia. Use of intravenous vasodilators to reduce PVR is frequently limited by systemic hypotension. Inotropes (typically milrinone which also provides vasodilation) can be beneficial. Vasopressin, unlike other pressors, appears to increase SVR

more than PVR.<sup>15</sup> Since no intravenous vasodilator is selective for the pulmonary vasculature, topical administration can be significantly more effective in reducing PVR without causing systemic hypotension. Inhaled NO and PGI<sub>2</sub> have comparable efficacy. They can also improve oxygenation by shunting blood to ventilated lung.

## Valve Diseases: Special Postoperative Considerations

### AORTIC VALVE REPLACEMENT

The different pathophysiologies associated with aortic stenosis (primarily a pressure overload phenomenon) versus aortic insufficiency (volume overload) can result in significantly different postoperative courses.

**Aortic Stenosis.** Aortic stenosis can lead to the development of a hypertrophied, noncompliant left ventricle (LV). For some patients, replacement of a stenotic valve allows a ventricle conditioned to pumping against abnormally high afterload to easily achieve supranormal levels of CO and BP postoperatively. Meticulous BP control is frequently required to avoid disrupting fresh suture lines. In some patients, the degree of ventricular hypertrophy can lead to dynamic outflow obstruction; the condition is most effectively treated with volume, beta blockers, and afterload augmentation. Even without dynamic outflow obstruction, reduced compliance (diastolic dysfunction) can create significant hemodynamic compromise if the patient becomes hypovolemic or loses normal sinus rhythm (up to 30% of stroke volume can be dependent on synchrony between atria and ventricles). The placement of atrial wires in addition to ventricular wires can provide significant advantages in the event that the patient is bradycardic or experiences heart block postoperatively.

**Aortic Regurgitation.** The LV in a patient with aortic regurgitation is frequently dilated without significant hypertrophy and often functions poorly postoperatively. Optimization of volume, afterload, inotropy, and rhythm in these patients is often challenging.

### MITRAL VALVE REPAIR/REPLACEMENT

**Mitral Regurgitation.** Following repair or replacement of an incompetent mitral valve, increased afterload and consequent greater wall stress unmask LV dysfunction. Frequently inotropic support and systemic vasodilation is required to reduce the afterload mismatch seen following surgery. Occasionally LV dysfunction can be the result of inadvertent suture placement compromising the circumflex coronary artery.

**Mitral Stenosis.** Unlike patients with mitral regurgitation, patients with mitral stenosis typically have preserved LV function. Exacerbation of preexisting pulmonary hypertension is common, however. Postoperative strategies focus

on optimizing right ventricular function and decreasing PVR.

## Cardiac Arrest and Cardiopulmonary Resuscitation

The incidence of cardiac arrest following cardiac surgery ranges between 0.7% and 2.9%. These patients represent a special case for application of advanced cardiac life support (ACLS) algorithms. The majority of these events happen in the immediate postoperative period when many patients are still intubated and monitored in the intensive care unit (ICU). In addition to ventricular arrhythmias, common etiologies for arrest in these patients include readily reversible causes: hypovolemia from hemorrhage, cardiac tamponade, acute hypoxia, electrolyte abnormalities, tension pneumothorax, pacing failure, and myocardial ischemia. Many of these patients develop clinical deterioration prior to the arrest which can provide clues to the mechanism of the arrest and guide therapy. Early recognition in a critical care environment, the presence of trained clinicians, patient-specific knowledge, and reversible etiologies combine to produce outcomes that are significantly better when compared to outcomes in the broader population of patients experiencing arrest. Cardiac surgery patients undergoing resuscitation in the 24 hours following surgery have survival rates up to 70%.<sup>16,17</sup>

The most important factors contributing to survival following cardiac arrest are prompt defibrillation and immediate, high quality, and uninterrupted chest compressions. There are special circumstances in cardiac surgery patients when chest compressions may be deferred. The European Resuscitation Council has recommended three successive (stacked) shocks for ventricular fibrillation or pulseless VT occurring in immediate postoperative cardiac surgery patients prior to chest compressions if defibrillation is immediately available.<sup>18</sup> Minutes matter<sup>19</sup> and patients at high risk for arrhythmias should have defibrillator pads placed postoperatively. Because chest compressions in the immediate postoperative period can cause myocardial injury, sternal and rib fractures, bypass graft injury, prosthetic valve dehiscence, lung injury, and hemorrhage,<sup>20</sup> it would be preferable to avoid compressions if return of spontaneous circulation (ROSC) can be achieved with electrical cardioversion. For asystole or severe bradycardia, pacing wires should be utilized when available prior to initiating chest compressions. Adding a ground wire in the skin can sometimes improve the capture of poorly functioning temporary pacing wires. Patients with pulseless electrical activity may respond to volume administration or pressor administration; if these interventions are ineffective, chest compressions should be initiated. Finally, if tamponade is suspected and emergency sternotomy is immediately available in the ICU, it is reasonable to minimize chest compressions and open the chest.

The efficacy of chest compressions can be monitored with preexisting arterial lines or with end-tidal CO<sub>2</sub> (ETCO<sub>2</sub>) monitoring (quantitative waveform capnography). These techniques can also minimize interruption of

chest compressions and help to identify ROSC. Systolic pressures close to 80 mm Hg or ETCO<sub>2</sub> > 10 mm Hg is considered to reflect adequate CPR. ETCO<sub>2</sub> > 40 is associated with ROSC.

If patients are not ventilated, intubation should be deferred and mask ventilation utilized until experienced personnel are available. Chest compressions should be interrupted only to insert the endotracheal tube through the vocal cords once visualized. Postoperative cardiac surgery patients are often very sensitive to increases in intrathoracic pressure and respiratory rates should be approximately 10 breaths per minute and minimal tidal volumes should be used.

Use of epinephrine should be limited and not follow standard algorithms in the resuscitation of cardiac surgery patients because of the potential for hypertension leading to suture line disruption and hemorrhage. Smaller doses may be cautiously titrated to effect. Amiodarone (300 mg IV) should be considered for persistent ventricular fibrillation or tachycardia resistant to electrical cardioversion.

Chest tubes should be placed in the mid-clavicular line in the second intercostal space if tension pneumothorax is suspected. Resternotomy should be considered if resuscitative efforts have failed to achieve ROSC within 5 to 10 minutes, particularly if tamponade is suspected. Ultrasonography can suggest, but not rule out, cardiac tamponade. Upon opening the chest, internal cardiac massage can be initiated. Clot should be evacuated, sources of bleeding identified, and bypass graft patency can be assessed.

Effective teamwork is a critical component of effective cardiopulmonary resuscitation. A call for additional help should be made if personnel resources are suboptimal. A team leader needs to be identified to manage the effort. If resources are adequate, the leader's role should be restricted to coordinating care. The leader should assign tasks after assessing a practitioner's competence to perform the assigned task. Communication should be closed loop; when team members are assigned a task they need to communicate that they understand the task and provide notification when they have completed it. The effective leader should rely on the collective knowledge of the team by actively soliciting information about the patient's condition prior to the arrest and exploring potential diagnoses and courses of action. As mentioned previously, ACLS algorithms were not developed for cardiac surgery patients specifically, and cardiopulmonary resuscitation should be performed with awareness of the special problems facing these patients postoperatively and with awareness of the specific circumstances of the patient. Knowledge of the patient's medical problems, operative details (including bleeding problems, hemodynamic instability coming off bypass, echocardiographic findings, and revascularization challenges) and postoperative course should guide strategy. Mobilization of personnel and equipment to open the chest should occur if resuscitation efforts are not immediately successful.

Training of practitioners in resuscitation is critical to optimization of outcomes. As important as knowing what to do in an emergency situation is to know how to do it. Mock

codes should focus on teamwork and effective leadership in addition to focusing on issues specific to cardiac surgery patients. Required equipment should be dedicated and readily available and all members of the team should know how to access it.

## BLEEDING, THROMBOSIS, AND TRANSFUSION STRATEGIES

One of the principle challenges of cardiac surgery is to achieve sufficient anticoagulation while supported on CPB without experiencing excessive bleeding postoperatively. Not surprisingly, patients undergoing off-pump CABG experience a significant reduction in postoperative bleeding and blood product transfusion requirements.<sup>21</sup> Excessive bleeding and its complications, including blood product transfusions, cause significant morbidity and mortality.

### Preoperative Evaluation

Preoperative evaluation includes documenting a history of abnormal bleeding or thrombosis, and obtaining basic coagulation studies, a hematocrit and platelet count. A history of recent heparin exposure associated with thrombocytopenia should suggest a diagnosis of heparin-induced thrombocytopenia (HIT). Confirmation of the presence of IgG directed against platelet factor 4 (the prevalence of these antibodies in patients with previous heparin exposure can be up to 35%)<sup>22</sup> requires either a delay in surgery until the assay is negative (usually 3 months), or if surgery is more urgently required, alternative anticoagulation strategies (bivalirudin<sup>23</sup>) can be considered. Preoperative medications that can increase bleeding risk are common. Aspirin inhibits cyclooxygenase, reduces the synthesis of thromboxane-A<sub>2</sub>, and decreases platelet aggregation. Preoperative aspirin use modestly increases postoperative bleeding, but preoperative and early postoperative use (ie, within 6 hours) is beneficial to outcome and ultimate survival.<sup>24</sup> Other antiplatelet agents have more profound impacts on platelet function. The glycoprotein IIb/IIIa inhibitors eptifibatide (Integrilin) and tirofiban (Aggrastat) are sufficiently short acting that surgery can be safely conducted despite recent exposure. Abciximab (Reopro) usually requires a 24 to 48-hour delay of surgery, if feasible, to avoid catastrophic bleeding. Clopidogrel (Plavix), prasugrel (Effient), and ticagrelor (Brilinta) inhibit the P<sub>2</sub>Y<sub>12</sub> component of platelet ADP receptors preventing ADP platelet activation. Discontinuing these agents 5 to 7 days before surgery will minimize bleeding, but they are often continued closer to the time of surgery because the risk of mortality is high from acute coronary stent occlusion, particularly in patients with recently placed drug-eluting stents. Customarily, warfarin (which inhibits the vitamin K-dependent clotting factors II, VII, IX, and X) is discontinued 4 to 7 days preoperatively to allow gradual correction of the INR. Although patients undergoing an

interruption in warfarin administration frequently receive bridging anticoagulation with heparin, increasing evidence suggests that this strategy increases bleeding without preventing thromboembolism.<sup>25,26</sup>

Newer oral anticoagulant agents such as direct thrombin inhibitors Dabigatran (Pradaxa) and direct factor Xa inhibitors including Rivaroxaban (Xarelto), Apixaban (Eliquis), and Edoxaban (Lixiana, Savaysa) have been developed recently. The long-term efficacy and safety of these target-specific oral anticoagulants are comparable with coumadin in specific applications. The half-life of these agents is shorter, making it easier to discontinue before elective cardiac surgery. Levels can be measured by thrombin time for Dabigatran and anti-factor Xa for Apixaban. However, reversal of anticoagulant effects of these agents in an urgent situation is challenging. Antifibrinolytic agents, DDAVP, prothrombin complex concentrates (PCCs), oral activated charcoal, and hemodialysis are suggested, but there is no high-quality evidence supporting the efficacy of these interventions. There are no data to support use of rFVIIa, FFP, or cryoprecipitate for reversal.

Preoperative anemia in patients undergoing cardiac surgery is associated with increased morbidity and mortality<sup>27,28</sup> and increased rate of intraoperative and postoperative red blood cell transfusion. Therefore, identifying and treating reversible causes of anemia is advisable. Elective surgeries should be delayed when possible to allow optimization of preoperative hemoglobin levels with iron supplementation and vitamin B12.<sup>29</sup> Administration of erythropoietin has not been demonstrated to reduce the need for RBC transfusion and may actually contribute to adverse outcomes.<sup>30</sup> Efforts to reduce phlebotomy volumes and frequency can have a significant impact on the incidence of perioperative anemia.<sup>31</sup>

### Intraoperative Strategies

Multiple intraoperative strategies have evolved to prevent unnecessary bleeding and blood product transfusion. Antithrombotics  $\Sigma$ -aminocaproic acid (Amicar) and Tranexamic acid (Cyclokapron) inhibit plasminogen activation and limit fibrinolysis. Topical use of tranexamic acid intraoperatively prior to closure has been shown to be a simple and effective way to reduce postoperative bleeding,<sup>32</sup> particularly in patients with friable tissue undergoing reoperations or with previous exposure to chest irradiation.

Retrograde autologous priming of the CPB circuit involves displacing circuit prime at the initiation of CPB by draining the patient's blood both antegrade through the venous cannula and retrograde through the arterial cannula.<sup>33</sup> This strategy has been shown to significantly decrease the requirement for blood transfusion following CABG. The use of heparin bonded circuitry has enabled the safe use of lower anticoagulation targets while on bypass. Careful attention to hemostasis intraoperatively and avoidance of excessive use of the cell saver (which depletes platelets and clotting factors) pays dividends postoperatively.

## Postoperative Bleeding

Most patients are mildly coagulopathic postoperatively, but only a minority bleeds excessively. Postoperative coagulopathy can be due to residual or rebound heparin effects following CPB, thrombocytopenia (qualitative and quantitative), clotting factor depletion, hypothermia, and hemodilution. Chest tube outputs persistently greater than 50 to 100 cc per hour or other clinical evidence of bleeding demand attention.

Strategies for avoiding postoperative hypothermia are also very important. Hypothermia ( $\leq 35^{\circ}\text{C}$ ) on arrival to the ICU is associated with delayed extubation, shivering, and increased peripheral  $\text{O}_2$  consumption, hemodynamic instability, atrial and ventricular arrhythmias, increased SVR, and coagulopathy.

The treatment of postoperative bleeding depends initially upon making a judgment: Is bleeding surgical, coagulopathic, or both? Surgical bleeding is treated as quickly as possible by reexploration while coagulopathies can be corrected in the ICU. Coagulopathic patients demonstrate microvascular bleeding (often bleeding from wound edges and puncture sites) and rarely have significant clot formation in their chest tubes. Standard maneuvers include warming the patient, controlling BP, increasing PEEP, infusing additional  $\Sigma$ -aminocaproic acid, calcium gluconate and blood products. In general, blood products should not be used to correct coagulation abnormalities unless the patient is bleeding significantly. All allogeneic blood products can contribute to transfusion-related lung injury and have other adverse effects. Protamine is rarely indicated and can increase bleeding. Desmopressin (DDAVP) is a synthetic vasopressin analog which acts by increasing the concentration of Von Willebrand factor, an important mediator of platelet adhesion. It is of benefit in patients with von Willebrand's disease and in patients with severe platelet dysfunction secondary to uremia. It is sometimes used for bleeding associated with antiplatelet agents, but there is little evidence to support this practice.

Recombinant factor VIIa (rFVIIa) is a drug approved for use in hemophiliacs that has been used successfully to stop bleeding in patients with life-threatening hemorrhage after cardiac surgery. In combination with tissue factor, it activates the extrinsic coagulation system via factor X, resulting in thrombin generation and prompt correction of the PT. It has a significant risk of systemic thrombosis and should be reserved for otherwise uncontrollable bleeding.<sup>34</sup>

Prothrombin complex concentrates (PCCs) are indicated for the urgent reversal of acquired coagulation factor deficiency induced by vitamin K antagonist (ie, warfarin) therapy in adult patients with acute major bleeding, and can reduce the need for FFP transfusion. PCCs have less risk of graft or prosthetic valve thrombosis when compared to factor VIIa.

## Mediastinal Reexploration

Reexploration should be considered when computed tomography (CT) outputs are  $>400$  mL/h for 1 hour,  $>300$  mL/h for 2 to 3 hours and 200 mL/h for 4 hours (Table 17-2)<sup>35</sup> or

if signs of tamponade or hemodynamic instability develop. Tamponade should be considered in the presence of hypotension, tachycardia, elevated filling pressures, increasing inotrope requirements, pulsus paradoxus, and/or equalization of right and left atrial pressures. An echocardiogram may be useful in this situation but cannot rule out tamponade. Chest X-rays (CXRs) are a necessary element of the evaluation for bleeding, look for widening of the mediastinum or evidence of hemothorax. CXRs should be repeated on all patients with initial high chest tube output that later subsides to ensure that chest tubes have not clotted.

## Autotransfusion

Autotransfusion of shed mediastinal blood remains controversial. It can be lifesaving in the presence of catastrophic bleeding. Red blood cell viability in unwashed shed mediastinal blood is comparable to that of autologous whole blood.<sup>36</sup> Additionally, there is evidence indicating no apparent clinical coagulopathy (low fibrinogen levels, but normal coagulation times at 1 and 24 hours) following reinfusion of shed blood.<sup>37</sup> This method of blood salvage is without allogeneic transfusion risks and has been shown to decrease transfusion requirements.<sup>38</sup> Autotransfusion should be avoided in patients with infectious endocarditis, hematologic diseases such as sickle cell or hemolysis, or if exogenous chemicals such as hemostatic agents or topical antibiotics were used during the operation.

## Blood Transfusion

Recent guidelines<sup>39</sup> have highlighted the risks associated with blood transfusion and advocated restrictive transfusion strategies. The STS guidelines recommend transfusion for patients who have bled more than 30% of their blood volume or who are bleeding uncontrollably. In stable postoperative patients, it is recommended that transfusion be considered only if Hb falls below 7 g/dL (hematocrit  $< 21\%$ ). This recommendation is based, in large part, on the only significant randomized control trial examining the impact of transfusion strategies on outcome. The Canadian Critical Care Trials group found that patients randomized to a Hb target of 7 g/dL versus 10 g/dL had equivalent outcomes. Patients who were younger or less critically ill had a statistically significant improvement in survival if they received less blood.<sup>40</sup> Retrospective studies in cardiac surgery have shown a durable and dose-related association between transfusion and survival<sup>41</sup> (see Fig. 17-2). In addition, blood transfusion has been linked to an increase in postoperative infection, lung injury and prolonged intubation, myocardial ischemia and infarction, renal failure, stroke, and increased ICU length of stay, hospital length of stay, and overall cost.<sup>42,43</sup> A study examining patients undergoing cardiac surgery in the UK found that patients who received blood were more likely to experience death, infections, ischemic complications (myocardial infarction, stroke, and renal failure) and prolonged stays in the hospital.<sup>44</sup> The guidelines support transfusion above a Hb of 7 g/dL in patients with evidence of end-organ ischemia, but the evidence supporting

**FIGURE 17-2** Survival after isolated CABG stratified by number of RBC units transfused. Increasing number of perioperative RBC transfusions results in incremental decreases in postoperative survival.<sup>67</sup> Solid lines are parametric estimates enclosed within dashed 68% confidence limits. RBC, red blood cell. (Reproduced with permission from Koch CG, Li L, Duncan AI, et al: Transfusion in coronary artery bypass grafting is associated with reduced long-term survival, *Ann Thorac Surg*. 2006 May;81(5):1650-1657.)

these recommendations rely almost entirely on expert consensus. In a well-designed propensity matched study, researchers compared Jehovah's witness patients (who refuse blood transfusion based on religious belief) with non-witness patients who received blood after cardiac surgery. Witnesses, who received no blood, had similar late survival compared with a matched group of cardiac surgical patients who received RBCs, and experienced fewer postoperative myocardial infarctions, a lower incidence of prolonged ventilation, less reoperation for bleeding, shorter ICU stays, and a lower hazard for in-hospital death.<sup>45</sup> They then compared witnesses with non-witnesses who did not receive blood and found comparable results.<sup>46</sup> There is little evidence supporting the belief that transfusion of stored, allogenic blood acutely improves oxygen carrying capacity. Stored blood is deficient in 2,3 DPG (and less capable of releasing oxygen to tissues) and nitric oxide; it also contains cells which are less flexible and may be more likely to occlude capillaries.

Blood transfusions have immunomodulating effects (by either alloimmunization or tolerance induction) that may increase the risk of nosocomial infections, transfusion-associated graft versus host disease, transfusion-related lung injury (TRALI), cancer recurrence, and the possible development of autoimmune diseases later in life. Furthermore, the risk of "newer" transfusion-transmitted diseases has become recognized. Proinflammatory mediators and cytokines have been associated with an increased risk of wound infection, sepsis, pulmonary and renal insufficiency.<sup>47</sup>

## Heparin-induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is an immune-mediated syndrome affecting up to 3% of patients undergoing cardiac surgery. A complex of platelet factor 4 (released by

activated platelets) and heparin stimulate the production of IgG antibodies (detected by an anti-PF4 assay) which cause vigorous platelet and monocyte activation and aggregation. This process results in platelet consumption and thrombin production causing in turn a drop in platelet count and systemic thrombotic complications. These can include microangiopathic thrombosis in the digits, deep vein thrombosis and pulmonary embolism, and end-organ injury including stroke, renal failure, and gut ischemia. Thrombocytopenia is typical following CPB and is secondary to hemodilution, platelet destruction and aggregation. The platelet count usually reaches its nadir by the first or second postoperative day followed by a steady recovery. A second drop in platelet count of more than 30 to 50% of the postoperative peak 5 to 14 days after cardiac surgery is strongly suspicious for HIT syndrome. More rarely, patients may develop HIT earlier (within the first four postoperative days) without the characteristic postoperative rebound in platelet count. It can also occur later (weeks after hospital discharge).<sup>48,49</sup>

Antiplatelet antibodies are more common than thrombotic complications in patients undergoing cardiac surgery. The presence of anti-PF4 antibodies is detected utilizing an enzyme-linked immunoabsorbent assay (ELISA). The test is very sensitive (>95%) but has only a 75 to 85% specificity. A positive test occurs when optical density (OD) values exceed 0.4. Some suggest the threshold of OD > 1 is associated with a higher likelihood of thrombotic events compared with OD values between 0.4 and 0.99.<sup>50</sup> The diagnosis can be confirmed with a more specific functional assay, typically, a serotonin release assay.

Once suspected, all heparin products must be discontinued, heparin-coated lines must be removed, and a direct thrombin inhibitor (bivalirudin, lepirudin, or argatroban) can be initiated. Warfarin, because it inhibits the synthesis of protein C, should be avoided initially. Bivalirudin is often the preferred thrombin inhibitor because its administration typically does not elevate the INR significantly (when compared to argatroban) making the transition to subsequent warfarin administration less complicated. Platelet transfusions can exacerbate thrombosis and are not recommended. When diagnosis is confirmed anticoagulation therapy with thrombin inhibitors should be continued until recovery of the platelet count followed by a transition to warfarin.<sup>51,52</sup>

## RESPIRATORY CARE

### Postoperative Pulmonary Pathophysiology

Patients undergoing heart surgery experience a spectrum of pulmonary dysfunction following heart surgery. The lungs become atelectatic during bypass and become edematous as a result of fluid shifts and the inflammatory response provoked by the bypass circuit. Increases are seen in the A-a gradient and pulmonary shunt fraction with a resultant decrease in compliance and impaired oxygenation. Many inflammatory mediators have been implicated. Complement is activated (C3a,

C5b-C9) and can directly damage pulmonary endothelium as well as sequester neutrophils. When activated these neutrophils release oxygen free radicals and proteases furthering injury. Macrophage cytokine production and platelet degranulation has also been demonstrated in models of bypass-induced lung injury.<sup>53</sup> TRALI can also exacerbate lung dysfunction.

In spite of increased knowledge of the mechanisms of injury, pharmacologic interventions have not proved effective in preventing it. To the contrary, administration of methylprednisolone in a randomized double-blinded study significantly increased A-a gradient and shunt fraction, decreased both static and dynamic compliance and delayed early extubation in a dose-dependent manner.<sup>54</sup>

## Assessment on Arrival

On arrival to the intensive care unit, auscultation of the lungs should be performed to assure equal breath sounds and absence of bronchospasm. Ventilator settings should aim to minimize barotrauma and transition to a spontaneous ventilatory mode in a timely manner.<sup>55</sup> A review of the initial postoperative CXR should confirm proper endotracheal tube position 2 to 3 cm above the carina, proper nasogastric tube, and intravenous line placement. Clinicians should be alert for pneumothoraces, hemothoraces, and a widened mediastinum. Arterial blood gas should confirm adequate oxygenation, and absence of hypercapnea or metabolic acidosis. Arterial blood gas results should be correlated with pulse oximetry, minute ventilation, and end tidal CO<sub>2</sub> measurements.

## Troubleshooting Hypoxia

As discussed above, oxygenation in all patients will be diminished compared to baseline. The inability to wean F<sub>i</sub>O<sub>2</sub> below 50% within the first few postoperative hours should prompt a reevaluation for treatable causes. Sometimes simply replacing the pulse oximeter probe onto another finger or an earlobe will improve reported oxygen saturation. This is particularly true in patients with peripheral vasoconstriction, and more frequent ABGs may be necessary for correlation. The use of vasodilators including nitroglycerin, milrinone, sodium nitroprusside, and nicardipine can increase shunt fraction (by inhibiting hypoxic pulmonary vasoconstriction in poorly ventilated regions of the lung) enough to cause significant hypoxia. Increasing PEEP to improve alveolar recruitment is frequently beneficial.<sup>56</sup> Nebulizer treatments decrease bronchospasm, and repeat CXR may demonstrate pneumothorax, retained hemothorax, retained mediastinal hematoma, atelectasis, or a new infiltrate representing aspiration.

Atelectasis, particularly in the left lower lobe, is present to some degree in nearly all patients. Bibasilar atelectasis is believed to be the combined product of the prolonged supine position, and intraoperative muscle relaxation allowing upward displacement of abdominal contents and the diaphragm. This reduces functional reserve capacity by up to 1 L. On the left, this is compounded by pleurotomy for internal

mammary artery take-down, compression of the left lung and decreased ventilatory tidal volumes to clear the field for IMA dissection. Lobar atelectasis, especially when associated with mucus plugging, can be improved by bronchoscopic aspiration in up to 80% of cases.<sup>57</sup> A prospective study comparing bronchoscopy to aggressive chest physiotherapy found the two techniques to be equally effective,<sup>58</sup> but only if the chest physiotherapy regimen is adhered to.

## Sedation

Sedation and pain relief in cardiac surgery “fast-tracking” relies on short-acting agents including propofol, fentanyl, and midazolam. Dexmedetomidine is a highly selective  $\alpha_2$ -adrenoreceptor agonist and has anxiolytic, sympatholytic, and analgesic effects without contributing to respiratory depression, oversedation, or delirium. It may provide myocardial protection, and has been shown to improve outcomes in cardiac surgery.<sup>59</sup> Hypotension and bradycardia can complicate its use.

## Early Extubation

Stable patients with a normal mental status can often be extubated either in the operating room or within a few hours following arrival in the intensive care unit. Once an arterial blood gas has confirmed adequate oxygenation and ventilation, pulse oximetry and monitoring of minute ventilation or end tidal CO<sub>2</sub> can guide extubation, often without the need for subsequent blood gases.

Although hemodynamically unstable patients can improve following a reduction in airway pressures or extubation, a more cautious approach to early extubation should be taken in patients with preoperative pulmonary failure requiring intubation, uncompensated congestive heart failure with pulmonary edema, cardiogenic shock (including a requirement for intra-aortic balloon counterpulsion), deep hypothermic circulatory arrest, persistent hypothermia < 35.5°C; persistent hypoxia P<sub>a</sub>O<sub>2</sub>:F<sub>i</sub>O<sub>2</sub> < 200, persistent acidosis with pH < 7.30, persistent mediastinal bleeding, or cerebrovascular accident or reduced mental status (inability to follow commands or protect airway).

## Ventilator Weaning and Extubation

Prolonged mechanical ventilatory support is a source of significant morbidity and mortality. In general, every effort should be made to wean the patient from the ventilator. Minimizing barotrauma has been shown to improve outcomes both in patients with severe lung injury and in those with more normal lung function. Spontaneous ventilatory modes (pressure support) are typically better tolerated by patients and are associated with lower airway pressures. Most ventilated patients do not need to be unconscious. Oversedation can cause hypotension, delirium, and prolong intubation. Benzodiazepine infusions and prolonged propofol

administration should be avoided as these agents promote delirium and accumulate.

The decision to extubate must take into account the adequacy of oxygenation and ventilation on minimal ventilatory support as well as an estimate of the patient's ability to manage secretions and protect his or her airway.<sup>60</sup> Finally, an assessment of the patient's ability to perform the work of breathing needs to be made. For patients unable to wean from the vent immediately following surgery, a spontaneous breathing trial (SBT) (30 minutes of spontaneous breathing with 5 cm H<sub>2</sub>O of pressure support or unassisted breathing through a T-tube) has been shown to be the most accurate predictor of a successful extubation. Breathing trials are typically discontinued for signs of distress such as respiratory frequency > 35/min, O<sub>2</sub> saturation < 90%, HR > 140 bpm, SBP > 180 or < 90 mm Hg, agitation, diaphoresis, or anxiety.<sup>61</sup> The minute ventilation V<sub>E</sub> and maximal inspiratory pressure is significantly less predictive of successful extubation than a successful SBT.<sup>62</sup>

The strategy of daily or intermittent SBTs has been directly compared to weaning strategies based on stepwise reduction of the frequency of intermittent mandatory ventilation (IMV), or stepwise reduction of the level of pressure-support ventilation (PSV). Daily or intermittent SBTs lead to successful extubation 2 to 3 times earlier than either IMV or PSV weans.

## Extubation Failure

Overall, approximately 5% of cardiothoracic patients require reintubation.<sup>63</sup> Patients with COPD have a 14% incidence,<sup>64</sup> while those with a past history of stroke have a 10% incidence.<sup>65</sup> Other risk factors include NYHA class IV functional status, renal failure, need for intra-aortic balloon counterpulsation, reduced pO<sub>2</sub>:F<sub>i</sub>O<sub>2</sub>, reduced vital capacity, longer operating room time, a longer CPB run, and a longer initial ventilatory requirement.<sup>66</sup> Unfortunately for ICU patients reintubation is typically a predictor of increased length of stay and increased mortality.

## Chronic Ventilation and Tracheotomy

In the early 1960s, translaryngeal intubation was associated with a prohibitively high rate of tracheal stenosis. As a result, a consensus existed that tracheotomy should be performed for patients requiring mechanical ventilation for longer than 3 days.<sup>67</sup> Low-pressure cuffs and soft tubes have since decreased the urgency of this intervention. A consensus subsequently evolved advocating that patients who continue to require mechanical ventilation at two weeks should undergo tracheotomy. Several trials have suggested that earlier discontinuation of mechanical ventilation and reduced complications are associated with earlier tracheotomy.<sup>68</sup> Tracheostomy results in reduced dead-space and airway resistance, is more comfortable for the patient, and usually allows the patient to participate more in the recovery process. It has been suggested that clinician behavior is positively affected by the presence of a tracheostomy tube; more aggressive attempts at

weaning and discontinuation of mechanical support may be made because reconnecting the ventilator is easy.

Percutaneous dilatational tracheotomy (PDT) performed in the ICU has increasingly been recognized as a safe procedure. A recent randomized prospective study of medical patients projected to require more than 14 days of mechanical ventilation<sup>69</sup> compared two groups: PDT within 48 hours and 14 to 16 days. One hundred twenty patients were enrolled. In the early PDT group, there was a strongly significant reduction in duration of mechanical ventilation (7.6 ± 4.0 vs 17.4 ± 5.3 days, *p* < .001), incidence of pneumonia (5 vs 25%, *p* < .005), and mortality (31.7 vs 61.7%, *p* < .005). There was no difference in incidence or severity of tracheal stenosis identified in-hospital and at 10 weeks.

## Pleural Effusion

Accumulation of fluid in the pleural space is common after cardiac surgery, particularly on the left side, and often resolves with time and diuresis. Contributory factors can include fluid overload, residual hematoma which can draw fluid into the pleural space, bleeding, pericardial and pleural inflammation (postpericardiotomy syndrome), atelectasis, hypoalbuminemia, pneumonia, or pulmonary embolism. Pleural effusion can cause chest pain or heaviness, shortness of breath, or hypoxia. Symptomatic effusions can be treated with thoracentesis. Nonsteroidal anti-inflammatory agents and colchicine can be used to treat postpericardiotomy syndrome. Tube thoracostomy drainage may be necessary until resolution of the inciting process. Placed utilizing the Seldinger technique, smaller diameter tubes are often better tolerated than traditional chest tubes. In contrast, a significant hemothorax may need to be evacuated surgically to avoid subsequent development of fibrothorax requiring decortication.

## Pneumonia

Nosocomial pneumonias increase postoperative mortality. The incidence of ventilator associated pneumonia increases approximately 1% per day.<sup>70</sup> Clinical diagnosis involves identification of a new or progressive infiltrate on CXR, change in character of sputum, leukocytosis, and fever.<sup>71</sup> Expecterated sputum cultures are considered to be very inaccurate, and directed bronchoscopic sampling is preferred. Proper bronchoalveolar lavage requires large volumes of irrigant (>100 cc) and is infrequently performed. More commonly tracheobronchial aspiration is performed using several milliliters of normal saline. A Gram stain containing > 25 squamous epithelial cells per LPF indicates oral contamination. More than 25 neutrophils per LPF suggest infection. Quantitative culture of 10<sup>5</sup> to 10<sup>6</sup> cfu/cc ("moderate to numerous," "3 to 4+") is indicative of infection, while ≤ 10<sup>4</sup> cfu/cc ("rare to few," "1 to 2+") is more suggestive of colonization. Gram-negative organisms are the most common, and should be the target of first-line empiric antibiotic coverage. Specific patient and hospital factors and culture results and sensitivities will further refine antibiotic therapy.<sup>72</sup>

The important role of pulmonary toilet in both the prevention and treatment of nosocomial pneumonias cannot be over emphasized. All patients should be encouraged to get out of bed and ambulate (even if attached to the ventilator), turn, cough, and deep breathe. Chest physiotherapy and bronchodilators can also provide benefits. Sterile-in line suctioning should be performed in ventilated patients to clear secretions. Nasotracheal suctioning is effective in extubated patients. Therapeutic fiberoptic bronchoscopy can also be performed.

## Pulmonary Embolism

Deep venous thrombosis (DVT) and pulmonary thromboembolism (PE) are considered uncommon in the cardiac surgery population. The reported incidence of PE ranges from 0.5 to 3.5%, accounting for only 0.3 to 1.7% of perioperative deaths. This is believed to be due to large intraoperative doses of heparin, impaired platelet function post-CPB, increased use of antiplatelet agents and anticoagulants, and early ambulation. A recent autopsy study demonstrated a 52% incidence of DVT. Twenty percent of deceased cardiac surgery patients had small pulmonary emboli,<sup>73</sup> and PE was identified as the cause of death in 7%. Unfortunately, risks of bleeding and HIT make the choice of heparin DVT prophylaxis problematic. Intermittent pneumatic compression devices are effective if patients and staff are compliant with their use.

The diagnosis of PE requires a high index of suspicion, and should be considered in any postoperative patient who develops an increased  $\text{PaO}_2:\text{FiO}_2$  gradient, shortness of breath, or reduced exercise tolerance, particularly in the setting of a clear or unchanged CXR or thrombocytopenia consistent with HIT. Diagnosis is reliably obtained by PE-protocol thin-cut high-speed helical computed tomography of the chest,<sup>74</sup> although accuracy is still influenced by pretest probability.<sup>75</sup>

## RENAL AND METABOLIC SUPPORT

### Perioperative Renal Dysfunction/Insufficiency

The new onset of renal dysfunction following cardiac surgery is correlated with significant morbidity and mortality. The incidence of acute renal failure (ARF) in CABG patients in the 1997 STS database was 3.14%, and 0.87% of these patients required dialysis.<sup>76</sup> Chertow studied 43,642 VA patients undergoing CABG or valve surgery.<sup>77</sup> The overall risk of ARF requiring dialysis was 1.1%. The mortality rate in this group was 63.7% compared with 4.3% in patients without ARF. Decreased myocardial function and advanced atherosclerosis were independent risk factors for the development of dialysis-dependent renal failure.

Patients with preoperative renal dysfunction (serum creatinine > 1.5 mg/dL) have a higher incidence of stroke, bleeding complications, dialysis, prolonged mechanical ventilation, length of stay, and death. Chertow found that preoperative renal function correlated with postoperative renal failure. The risk of ARF was 0.5%, 0.8%, 1.8%, and 4.9%

with baseline serum creatinine concentrations of <1 mg/dL, 1.0 to 1.4 mg/dL, 1.5 to 1.9 mg/dL, and 2.0 to 2.9 mg/dL, respectively. Chronic dialysis patients undergoing cardiac surgery have an 11.4% operative mortality rate, a 73% complication rate, and 32% 5-year actuarial survival rate.<sup>78</sup> Cardiac surgery following renal transplantation has an associated operative mortality rate of 8.8%.<sup>79</sup>

To optimize preoperative renal function, contrast loads should be minimized and patients should be well hydrated and receive **renoprotective** agents (eg, *N*-acetylcysteine).

### Effects of Cardiopulmonary Bypass on Renal Function

Operative considerations include limiting the duration of CPB and maintenance of MAPs greater than 60 mm Hg. Additional effects of CPB include trauma to blood constituents, especially erythrocytes, with increased free hemoglobin levels and microparticle embolic insults to the kidneys. Hypothermia (during rewarming, vasodilation and hyperemia of tissue beds can result in third spacing of fluid), hemodilution (reduces viscosity of blood and plasma oncotic pressure) and ischemia reperfusion injury can influence renal function. Additionally, CPB leads to an increased release of catecholamines, hormones (rennin, aldosterone, angiotensin II, vasopressin, atrial natriuretic peptide, urodilatin<sup>80</sup>) and inflammatory cytokines (kallikrein, bradykinin) which also affect renal function adversely. These adverse stimuli cause low renal blood flow, a decreased glomerular filtration rate and an increase in renal vascular resistance. Hypotension and pressor agents accentuate this response. Ultrafiltration is utilized in long pump runs to decrease volume overload in patients with renal dysfunction.

Independent of preoperative renal function, the primary postoperative goal is the maintenance of adequate renal perfusion pressure and a urine output greater than the 0.5 cc/kg/h. Brisk diuresis (>200 to 300 cc/h) is common following CPB. Volume replacement and maintenance of adequate BP and CO is required for adequate renal perfusion. The best measure of kidney perfusion is adequate urine output independent of diuretics. Beyond optimizing hemodynamics and avoiding nephrotoxic medications, there is no convincing evidence that treatment with diuretics, mannitol, dopamine, fenoldapam, nesiritide, or any other agent is renoprotective. This is not to say, however, that these agents are of no benefit in promoting diuresis and avoiding renal replacement therapies in the event of renal dysfunction.

### Electrolyte Disturbances

#### CALCIUM

Levels of ionized calcium (normal, 1.1 to 1.3 mmol/L) are critical for myocardial performance and hemostasis, and involved in reperfusion injury. Hypocalcemia causes a prolonged QT interval. Postoperatively hypocalcemia is common following CPB or an episode of hemodilution, sepsis,

or citrated blood transfusions. The concentration of calcium ion is greatest in the intracellular space, with small amounts in the extracellular fluid. Calcium levels bound to albumin change with the levels of serum albumin whereas ionized levels remain unchanged.

### POTASSIUM

Potassium fluxes during cardiac surgery can be significant and affect cardiac automaticity and conduction. Cardioplegia, decreased urine output, decreased insulin levels, and RBC hemolysis all contribute to hyperkalemia.<sup>81</sup> Brisk diuresis, insulin, and alkalosis can cause hypokalemia.<sup>82</sup> Aggressive treatment of hypokalemia decreases the incidence of perioperative arrhythmias. Serum potassium levels and replacement protocols are an integral part of early postoperative management. Serum potassium rises logarithmically with replacement; larger quantities are required to treat significant hypokalemia.

### MAGNESIUM

Magnesium (normal, 1.5 to 2 mEq/L) is the second most common intracellular cation after potassium. It is involved in endothelial cell homeostasis,<sup>83</sup> cardiac excitability and muscle contraction through its role as an ATP cofactor and calcium antagonist, and it is also closely involved in the regulation of intracellular potassium.<sup>84</sup> Following hemodilution and CPB, hypomagnesaemia is common (>70% of patients) and is associated with an increased risk of atrial fibrillation and torsade de pointes.<sup>85</sup>

## Endocrine Dysfunction

### DIABETES MELLITUS

Up to 30% of patients have diabetes (type I or II) in the cardiac surgery population. Following CPB the hormonal stress response (increased growth hormone, catecholamines, and cortisol) causes hyperglycemia (even in nondiabetics) with a decrease in insulin production; this may persist for up to 24 hours postoperatively and is exacerbated by exogenous catecholamine administration. Anthony Furnary was the first to demonstrate that moderate control of blood glucose levels with continuous insulin infusions reduces the incidence of sternal wound infection by an order of magnitude.<sup>86</sup> Work by Van den Berghe suggested that a more aggressive approach aimed at maintaining blood glucose levels at or below 110 mg/dL resulted in a reduction in mortality rate in critically ill patients, and guidelines were revised to encourage stricter control.<sup>87</sup> Subsequently, the NICE-Sugar-Study was performed to determine the optimal target range for blood glucose in critically ill patients.<sup>88</sup> In this study, tight control (utilizing a target of 81 to 108 mg per deciliter) was associated with a higher incidence of hypoglycemia and mortality than conventional control (utilizing a target of 180 mg/dL). The STS workforce on blood glucose management in cardiac surgery patients concluded that targets <180 mg/dL reduce mortality, morbidity, and the incidence of wound infection and improve long-term survival.

### ADRENAL DYSFUNCTION

The strain of cardiac surgery activates the hypothalamic-pituitary-adrenal axis and increases plasma ACTH and cortisol levels. Subclinical adrenal insufficiency is present in up to 20% of the elderly population and can be unmasked by the stress of surgery. Perioperative stress dose steroids should be considered for patients taking exogenous steroids within 6 months of surgery. Any patient exhibiting prolonged, unexplained vasodilatory shock should be suspected of having adrenal insufficiency. Critically ill patients with normal adrenal function should have high cortisol levels. If the diagnosis is in doubt, a cosyntropin stimulation test should be performed for diagnosis. In the interim, dexamethasone may be administered IV without interfering with the test.

## RELEVANT POSTOPERATIVE COMPLICATIONS

### Neurological

#### CENTRAL NERVOUS SYSTEM

The incidence of **stroke** following cardiac surgery is procedure specific and varies between 1 and 4%. Ricotta and colleagues associated carotid stenosis (>50%), redo heart surgery, valve surgery, and prior stroke with increased postoperative neurological risk.<sup>89</sup> John and colleagues reviewed 19,224 patients in New York State.<sup>90</sup> The stroke rate was 1.4% following CABG, with a 24.8% mortality rate in that group. Multivariable logistic regression identified the following predictor variables: calcified aorta, prior stroke, age, carotid artery disease, duration of CPB, renal failure, peripheral vascular disease, smoking, and diabetes. Intraoperative factors that may cause postoperative neurologic deficits include particulate macroembolization of air, debris, or thrombus, microembolization of white blood cells, platelets, or fibrin,<sup>91</sup> duration of CPB,<sup>92</sup> cerebral hypoperfusion during nonpulsatile CPB and hypothermic circulatory arrest.<sup>93</sup> Because of bleeding risk, patients presenting with stroke are not candidates for intraoperative thrombolytic interventions. Endovascular therapy may be beneficial in select patients with embolic occlusion if performed within 6 to 8 hours of the event, this window may be as long as 24 hours in patients with posterior circulation occlusion. If a patient is considered to be a candidate for endovascular intervention, a CT angiogram is required to define the anatomy of the vascular occlusion.

Neuropsychiatric deficits (neurocognitive dysfunction, delirium, seizures) are very common, occurring in up to 50 to 70% of patients following cardiac surgery. The cause of these neuropsychiatric disorders is uncertain and remains controversial. Although the dysfunction remains unclear, patients remain at risk for long-term cognitive decline. Van Dijk and colleagues<sup>94</sup> reviewed 12 cohort studies, a pooled analysis of 6 comparable studies showed 22.5% of patients to have a cognitive deficit at 2 months after operation. This may, however, be related to progression of underlying cerebrovascular disease rather than to CABG or CPB.<sup>95</sup>

Up to 50% of cardiac surgery patients experience delirium, particularly those with preexisting organic mental disorders, significant prior alcohol consumption, advanced age, or intracranial cerebral artery disease.<sup>96</sup> Perioperative medications, particularly benzodiazepines and opiates, as well as phenothiazines and anticholinergics can contribute to delirium.<sup>97</sup> There is increasing evidence that sedation with dexmedetomidine causes less delirium and results in improved outcomes when compared to sedation with benzodiazepines.<sup>98</sup> Right-sided parietal lobe lesions may present as delirium. Other causes of postoperative delirium in the cardiac intensive care patient include sleep deprivation, renal failure, hepatic failure, and thyroid abnormalities. Electroencephalograms on these patients are usually abnormal, whereas in primary psychiatric diseases they are normal. Treatment involves correcting metabolic abnormalities, establishing a normal sleep-wake cycle in extubated patients, minimizing medications likely to cause delirium, and providing ventilated patients with sedation holidays.

### BRACHIAL PLEXUS INJURY/PERIPHERAL NERVE INJURY

Excessive sternal retraction during a median sternotomy may cause a brachial plexus injury as the first rib may impinge the lower trunk and branches.<sup>99</sup> IMA harvesting may also cause damage to the brachial plexus with serious consequences.<sup>100</sup> Malpositioning of the upper limbs during surgery may result in a neuropraxia due to compression of the ulnar nerve.<sup>101</sup> Palsy or plegia of dorsiflexion and eversion of the foot can be caused by common peroneal nerve stretch or compression at the level of the head of the fibula.<sup>102</sup> Saphenous neuropathy (sensory changes on the medial side of the calf to the great toe) following open vein graft harvesting (less so with endoscopic harvest) is also a potential complication secondary to the avulsion of pretibial or infrapatellar branches of the nerve.<sup>103</sup>

### Gastrointestinal

Mesenteric ischemia following cardiac surgery is infrequent but often catastrophic.<sup>104</sup> Risk factors include duration of bypass (hypoperfusion), use of pressor support (sympathetic vasoconstriction), use of an IABP or other sources of atherosclerotic embolism, atrial fibrillation, peripheral vascular disease, and HIT. Early surgical intervention (<6 hours) is associated with a 48% mortality rate, and this rises to 99% with delays (>6 hours) in surgical intervention. Gastrointestinal bleeding is common and can cause significant morbidity. The incidence of gastrointestinal bleeding can be reduced with the use of H<sub>2</sub>-inhibitors, proton pump inhibitors and sucralfate.<sup>105</sup> Other gastrointestinal complications include pancreatitis (hyperamylasemia is present in 35 to 65% of patients and is associated with an overt pancreatitis rate of 0.4 to 3%),<sup>106</sup> acute acalculous cholecystitis (likely secondary to hypoperfusion or biliary stasis promoted by narcotics or parenteral nutrition<sup>107</sup>), dysphasia secondary to tracheal

intubation or perioperative use of TEE,<sup>108</sup> small or large bowel ileus (Ogilvie's syndrome is associated with long-term ventilation, narcotic use, and anticholinergic agents).<sup>109</sup> Preoperative liver dysfunction (noncardiac cirrhosis) is associated with a high incidence of postoperative morbidity and mortality (Child class A cirrhosis: 20% morbidity, 0% mortality; Child class B cirrhosis: 80% morbidity, 100% mortality). Although 20% of patients develop a transient hyperbilirubinemia, fewer than 1% have significant hepatocellular damage which progresses to chronic hepatitis or liver failure.<sup>110</sup> Liver failure associated with multisystem organ failure can lead to coagulopathy and hypoglycemia; these symptoms are generally associated with an extremely poor prognosis.

### Nosocomial Infections

Ten to twenty percent of cardiac surgery patients develop a nosocomial infection. Infections may be related to the surgical wound, lung, urinary tract, invasive lines or devices, or the gastrointestinal tract. Prolonged mechanical ventilation is associated with nosocomial pneumonia. Pneumonia is second only to urinary tract infection in frequency and carries the highest mortality rate. Smokers and COPD patients are most likely to be colonized preoperatively and have a higher incidence of pulmonary infection (15.3 vs 3.6% in controls).<sup>111</sup>

Catheter-related infections (ie, bladder and vascular related) are common in the intensive care unit. The most common pathogens are *Staphylococcus aureus* (12%), *coagulase-negative staphylococci* (11%), *Candida albicans* (11%), *Pseudomonas aeruginosa* (10%), and *Enterococcus* sp.<sup>112</sup>

### FEVER

Fevers are common in the intensive care setting, but are a poor indicator of postoperative bacteremia (3.2% incidence in 835 febrile CABG patients).<sup>113</sup> The yield of true positive bacteremia ranges from 4 to 5%, with a contamination rate ranging from 32 to 47%.<sup>114</sup> The incidence of false-positive blood culture results can be minimized by avoid blood draws from indwelling lines. Noninfectious causes of fever in cardiac surgery patients include myocardial infarction, post-pericardiotomy syndrome, and drug fever. Infectious causes include wound infection, urinary tract infection, pneumonia, catheter sepsis, and loculated areas of contaminated blood accumulation (eg, pericardial, pleural, retroperitoneal, and leg wound spaces).

### SEPSIS/SEPTIC SHOCK

Septic shock following cardiac surgery should prompt an aggressive search for etiology. Pathophysiologic features of sepsis include systemic inflammation, hypotension, and impaired fibrinolysis, leading to multiorgan failure, irreversible shock, and death (20 to 50% mortality has been reported).<sup>115</sup> MVO<sub>2</sub> can be abnormally high secondary to shunting and a failure to extract oxygen at the cellular level. In vasodilatory shock the maintenance of end-organ tissue perfusion is critical; this

includes aggressive fluid management and vasopressin.<sup>116</sup> Methylene blue (which inhibits NO synthesis) has been used successfully in refractory hypotension. Bernard and colleagues<sup>117</sup> in the PROW/ESS study group showed a distinct survival advantage in the treatment of severe sepsis utilizing drotrecogin alfa (activated) or recombinant human-activated protein C (Zigris). These agents reduce the systemic inflammatory, procoagulant, and fibrinolytic reactions to infection. In a randomized study of 1690 patients, the mortality rate was 30.8% in the placebo group versus 24.7% in the treatment group.

## WOUNDS

**Delayed Sternal Closure/Sternal Infection.** Complicated operations with persistent bleeding and hemodynamic instability (due to tissue edema) may preclude primary sternal closure. Delayed sternal closure allows hemodynamic stabilization, and diuresis.<sup>118</sup> Anderson and colleagues<sup>119</sup> outlined the Brigham and Women's Hospital experience: 1.7% (87 of 5177) open chests were managed with a hospital survival rate of 76%. Complications included deep sternal infection (n = 4), stroke (n = 8), and dialysis (n = 13). Multivariate analysis revealed mechanical ventricular assistance and reoperation for bleeding as independent predictors of in-hospital mortality.

**Superficial and Deep Sternal Wounds.** Superficial and deep sternal wound infections are significant complications of cardiac surgery. Deep sternal infection with associated mediastinitis occurs in 1 to 2% of cardiac operations, with a resultant mortality rate approaching 10%.<sup>120</sup> Common organisms include *Staphylococcus epidermidis*, *S. aureus* (including methicillin-resistant *S. aureus*), *Corynebacterium*, and enteric Gram-negative bacilli.<sup>121</sup> Patients predisposed to sternal infections include those with significant comorbidities (obesity, diabetes, COPD, renal dysfunction, low serum albumin), prolonged CPB, blood transfusions, reoperations, diabetics with bilateral IMA harvests,<sup>122</sup> and patients with hyperglycemia.<sup>123</sup> Simple preoperative measures such as clipping of chest hair, using Hibiclens washes, administration of adequate prophylactic antibiotics prior to skin incision, ensuring good intraoperative hemostasis without the use of bone wax, and closure with subcuticular sutures and Dermabond (topical adhesive) rather than skin staples. Effective glucose control during surgery and for at least 3 days postoperatively is associated with a significantly lower sternal wound infection rate.

Minor infections frequently respond to intravenous antibiotics, opening of the wound, and local wound care. Deeper infections require intravenous antibiotics (6 weeks); initial empiric therapy should consist of broad coverage against Gram-positive cocci and Gram-negative bacilli with the regimen adjusted when cultures (blood, mediastinal or deep sternal wound drainage) have been speciated. The mainstay of treatment is surgical exploration and extensive debridement which may require removal of the

sternum with primary or secondary closure with muscle or an omental flap.<sup>124</sup> Postoperative vacuum-assisted closure<sup>125</sup> of mediastinal wounds improves wound healing and reduces hospital length of stay.

## Nutrition

Preoperative debilitated or cachectic patients (ie, more than 10% weight loss over 6 months) with albumin levels of less than 3.5 g/dL<sup>126</sup> are exceptionally prone to complications following surgery. There is no evidence to support a role for preoperative hyperalimentation. Body mass index (a good nutritional index) of less than 15 kg/m<sup>2</sup> is associated with increased morbidity. Postoperative patients have accelerated catabolic protein losses, usually requiring 25 to 40 kcal/kg/day. Advances in immunonutritional pharmacology (arginine, glutamine, and n-3 fatty acids) in complex postoperative cardiac surgery patients may have a defined role in the future.<sup>127</sup>

# Temporary Mechanical Circulatory Support

Edwin C. McGee, Jr. • Nader Moazami

A number of ventricular assist devices (VADs) are available for acute circulatory support. As opposed to long-term VADs, which are designed primarily for bridge to transplantation or long-term support in the nontransplant patient, temporary VADs are designed to reestablish adequate organ perfusion rapidly. Patients in cardiogenic shock require early aggressive therapy. Despite relief of ischemia, inotropic drugs, and control of cardiac rhythm, some patients remain hemodynamically unstable and require some type of mechanical circulatory support in order to restore a normal cardiac output and maintain end-organ perfusion. Cardiogenic shock occurs in 2.4 to 12% of patients with acute myocardial infarction (AMI).<sup>1</sup> The landmark Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) trial demonstrated mortality of greater than 50% despite revascularization.<sup>2</sup> If instituted promptly, temporary mechanical support leads to improved survival in this group of patients.<sup>3</sup> The need for circulatory support in the postcardiotomy period is relatively low and has been estimated to be in the range of 0.2 to 0.6%,<sup>4</sup> but when it occurs, it needs to be managed effectively if the patient is to be salvaged. Additional indications for acute VADs are in chronic heart failure patients who suffer cardiovascular collapse, and severe cases of myocarditis and postpartum cardiomyopathy.

All practicing cardiac surgeons should have an understanding of current devices, and have at least one of these support systems available. Studies show that even smaller facilities that do not have advanced heart failure programs can have improved patient survival if a device can be implemented rapidly and the patient is transferred to a tertiary care facility with expanded capabilities.<sup>5</sup>

This chapter describes the devices currently available, indications for support, patient management, and the overall morbidity and mortality associated with temporary mechanical support. In addition, it describes some of the more promising devices that have just received approval or are currently undergoing trial. The goal of all temporary assist devices is to alleviate shock and establish an environment in which the native heart and end organs can recover. If recovery is unlikely, then a bridge to a long-term device, typically for bridging to a heart transplant, may be the best strategy. Rarely should

individuals be supported directly to heart transplantation from an acute support device, because the newer generations of long-term devices typically provide more reliable support and allow for better rehabilitation in an out-of-hospital setting. It may be possible to bridge a patient who is not a transplant candidate to a long-term device, but given that these patients often are older with comorbidities, bridging a patient from an acute VAD to a long-term DT pump must be done with caution.

## COUNTERPULSATION

Intra-aortic balloon pumps (IABPs) are often the first line of mechanical assistance utilized for patients in cardiogenic shock. The concept of increasing coronary blood flow by counterpulsation was demonstrated by Kantrowitz and Kantrowitz in 1953 in a canine preparation and again by Kantrowitz and McKinnon in 1958 using an electrically stimulated muscle wrap around the descending thoracic aorta to increase diastolic aortic pressure.<sup>6</sup> In 1961, Claus and colleagues used an external counterpulsation system synchronized to the heartbeat to withdraw blood from the femoral artery during systole and reinfuse it during diastole.<sup>7,8</sup> One year later, Mouloupoulos and colleagues produced an inflatable latex balloon that was inserted into the descending thoracic aorta through the femoral artery and inflated with carbon dioxide.<sup>8</sup> Inflation and deflation were synchronized to the electrocardiogram to produce counterpulsation that reduced end-systolic arterial pressure and increased diastolic pressure. In 1968, Kantrowitz reported survival of one of three patients with postinfarction cardiogenic shock refractory to medical therapy using an IABP.<sup>9</sup> These pioneering studies introduced the concept of supporting the failing circulation by mechanical means.

## Physiology

The major physiologic effects of the IABP are a concomitant reduction in left ventricular afterload along with an increase in coronary perfusion pressure secondary to an increase in aortic diastolic pressure.<sup>10</sup> Important related effects include

reduction in left ventricular systolic wall tension and oxygen consumption, reduction in left ventricular end-systolic and end-diastolic volumes, reduced preload, and an increase in coronary artery and collateral vessel blood flow.<sup>11</sup> Cardiac output increases because of improved myocardial contractility owing to increased coronary blood flow and the reduced afterload and preload, but the IABP does not directly move or significantly redistribute blood flow.<sup>12</sup> IABP counterpulsation reduces peak systolic wall stress (afterload) by 14 to 19% and left ventricular systolic pressure by approximately 15%.<sup>12</sup> Because peak systolic wall stress is related directly to myocardial oxygen consumption, myocardial oxygen requirements are reduced proportionately. As measured by echocardiography and color-flow Doppler mapping, peak diastolic flow velocity increases by 117% and the coronary flow velocity integral increases by 87% with counterpulsation.<sup>13</sup> Experimentally, collateral blood flow to ischemic areas increases up to 21% at mean arterial pressures greater than 90 mm Hg.<sup>14</sup>

Several variables affect the physiologic performance of the IABP. The position of the balloon should be just downstream of the left subclavian artery (Fig. 18-1). Diastolic augmentation of coronary blood flow increases with proximity to the aortic valve.<sup>15</sup> The balloon should fit the aorta so that inflation nearly occludes the vessel. Experimental work indicates that for adults, balloon volumes of 30 or 40 mL significantly improve both left ventricular unloading and diastolic coronary perfusion pressure when compared with smaller volumes. Inflation should be timed to coincide with closure of the aortic valve,

which for clinical purposes occurs at the dirotic notch of the aortic blood pressure trace (Fig. 18-2). Early inflation reduces stroke volume, increases ventricular end-systolic and -diastolic volumes, and increases both afterload and preload. Diastolic counterpulsation is visualized easily as a pressure curve in the arterial waveform and indicates increased diastolic perfusion of the coronary vessels (and/or bypass grafts).<sup>16</sup> Deflation should occur as late as possible to maintain the duration of the augmented diastolic blood pressure but before the aortic valve opens and the ventricle ejects. For practical purposes, deflation is timed to occur with the onset of the electrocardiographic R wave. Active deflation of the balloon creates a suction effect that acts to decrease left ventricular afterload (and therefore myocardial oxygen consumption).

Physiologic factors that influence the in situ hemodynamic performance of the IABP include heart rate and rhythm, mean arterial diastolic pressure, competence of the aortic valve, and compliance of the aortic wall. Severe aortic regurgitation is a contraindication to use of the IABP as a very low mean aortic diastolic pressures reduce aortic root pressure augmentation and coronary blood flow. A calcified, noncompliant aorta increases diastolic pressure augmentation but risks injury to the aortic wall. On the other hand, young patients with a highly elastic, compliant aorta may manifest decreased diastolic pressure augmentation.

For an IABP to perform optimally, a regular heart rate with an easily identified R wave or a good arterial pulse tracing with a discrete aortic dirotic notch is required. Current

**FIGURE 18-1** (A) Balloon inflation during left ventricular (LV) diastole occludes the descending thoracic aorta, closes the aortic valve, and increases proximal coronary and cerebral perfusion. (B) Balloon deflation during LV systole decreases LV afterload and myocardial oxygen demand.

**FIGURE 18-2** Illustration showing the effect of the intra-aortic balloon on aortic pressure. After ejection produces the pulse (A), inflation of the balloon increases aortic diastolic pressure (B). At end diastole, sudden deflation reduces aortic end-diastolic pressure (C) below that of an unassisted beat and reduces afterload and myocardial oxygen demand.

balloon pumps trigger off the electrocardiographic R wave or the arterial pressure tracing. Both inflation and deflation are adjustable, and operators attempt to time inflation to coincide with closure of the aortic valve and descent of the R wave. During tachycardia, the IABP usually is timed to inflate every other beat; during chaotic rhythms, the device is timed to inflate in an asynchronous fixed mode that may or may not produce a mean decrease in afterload and an increase in preload. In unstable patients, every effort is made to establish a regular rhythm, including a paced rhythm, so that the IABP can be timed properly. The newer-generation IABP consoles come with algorithms that select the most appropriate trigger mode and time inflation and deflation automatically which have been further enhanced by fiber-optic transducers at the tip of the IABP which do not require a conventional fluid-filled transducer to accurately reflect arterial pressure and are more easily timed.<sup>17</sup>

## Indications

The traditional indications for insertion of the IABP are cardiogenic shock, uncontrolled myocardial ischemic pain, and postcardiotomy low cardiac output.<sup>18</sup> Additional indications for IABP have broadened to include patients with high-grade left main coronary artery stenosis, high-risk or failed percutaneous transluminal coronary angioplasty, atherectomy, or stents; patients with poorly controlled ventricular arrhythmias before or after operation; and patients with postinfarction ventricular septal defect (VSD) or acute mitral insufficiency after myocardial infarction (MI).<sup>19</sup> Occasionally an IABP is used prophylactically in high-risk patients with poor left ventricular function (LVF) with either mitral regurgitation or preoperative low cardiac output owing to hibernating or stunned myocardium. These patients may benefit from temporary afterload reduction in

the prebypass period and during weaning from cardiopulmonary bypass.

## Techniques of Insertion

The IABP usually is inserted into the common femoral artery either by the percutaneous technique or surgical cut down. A cut down is used most often during cardiopulmonary bypass when the pulse is absent. To avoid a formal cut down, a femoral artery catheter may be inserted in anticipation of IABP use in patients undergoing complex procedures who have myocardial dysfunction. The superficial femoral artery is avoided because of its smaller size and increased possibility of leg ischemia. For patients with small vessels, a 7-French catheter without a sheath is recommended to lessen the possibility of leg ischemia. The iliac and axillary arteries and, very rarely, the abdominal aorta are infrequently used alternate sites.<sup>20,21</sup> Direct insertion into the ascending aorta can be used intraoperatively in patients with severe aortoiliac or femoral occlusive disease that prevents passage of the balloon catheter.<sup>22,23</sup>

An IABP is inserted using Seldinger's technique. In the catheterization laboratory, both the guidewire and balloon are monitored by fluoroscopy, but this is not essential if not readily available. In the operating room, the guidewire and balloon are typically placed and positioned under transesophageal echocardiographic guidance.<sup>24</sup> The catheter can be inserted without the sheath when the size of the common femoral artery is a concern.<sup>25</sup>

Typically patients with an IABP receive heparin for anticoagulation, but this practice varies from center to center. The exit site of the catheter must be kept clean with antiseptics and covered in an effort to prevent local infection or septicemia.

A percutaneous IABP can be removed without exposing the femoral puncture site. The exit site is prepped and securing sutures are cut. The balloon catheter is disconnected from the pump and completely deflated using a 50-mL syringe. When the balloon is removed, the proximal artery is compressed and retrograde bleeding is allowed, which flushes any distal clot into the wound. The distal femoral artery then is compressed, and antegrade flushing then is allowed. Finally, steady nonocclusive pressure is held over the femoral puncture site. Pressure is maintained over the puncture site for 30 minutes to ensure that thrombus closes the hole. If the balloon is inserted via a cut down, the balloon preferably is removed in the operating room. The puncture site is closed with sutures. If blood flow to the lower limb is impaired after removal, a formal thromboembolectomy is required.

If the percutaneous needle punctures the iliac artery above the inguinal ligament intentionally or inadvertently in obese individuals, removal should be done through a surgical incision in the operating room because the backward slope of the pelvis makes pressure difficult to maintain after withdrawal, and substantial occult retroperitoneal bleeding may occur.

An IABP may be useful before insertion of more long-term left ventricular assist systems to optimize perfusion and right ventricular function. Use of an IABP in patients with chronic systolic heart failure as a bridge to transplantation or left ventricular assist device (LVAD) therapy is a common practice with over half of the patients being stabilized with this strategy.<sup>26</sup> More importantly, placement of the IABP through a graft sewn to the subclavian artery is a strategy that has allowed ambulation of the patients while waiting for the next stage of therapy with a reported success rate of 93%.<sup>27</sup>

In this technique, a 6-mm graft is sewn to the artery in an end-to-side manner and the shortened standard IABP sheath is inserted into this graft.<sup>27</sup> The IABP is then placed through a separate stab wound, or through the externalized IABP sheath and then positioned under fluoroscopy and transesophageal echocardiography (TEE). The wound over the sheath is then closed. Some groups bury the hub of the IABP sheath, but our preference is to externalize it so that if the IABP needs to be repositioned, the wound does not need to be reopened.

In patients waiting for a new heart, the presence of an IABP qualifies a patient as 1A, or the highest status, on the UNOS heart transplant waiting list.

## Complications

Reported complication rates of the IABP vary between 12.9 and 29% and average approximately 20%.<sup>28</sup> Life-threatening complications are rare. Leg ischemia is by far the most common complication (incidence 9-25%); other complications include balloon rupture, thrombosis within the balloon, septicemia, infection at the insertion site, bleeding, false aneurysm formation, lymph fistula, lymphocele, and femoral neuropathy.<sup>29</sup> There is no significant difference in limb ischemia in the different types of IABPs clinically available.<sup>28,30</sup>

Balloon rupture occurs in approximately 1.7% of patients and usually is manifested by the appearance of blood within the balloon catheter and only occasionally by the pump alarm. Rupture may be slightly more common with trans-aortic insertion. Although helium usually is used to inflate the balloon, gas embolism has not been a problem. If rupture occurs, the balloon should be deflated forcibly to minimize thrombus formation within the balloon and should be promptly removed. If the patient is IABP dependent, a guidewire is introduced through the ruptured balloon, the original balloon is removed, and a second balloon catheter is inserted over the wire. If the ruptured balloon is not removed easily, a second balloon is inserted via the opposite femoral or iliac artery or through the axillary artery to maintain circulatory support.

Removal of a kinked or thrombosed ruptured balloon that cannot be withdrawn easily requires operative removal as forcibly removing a ruptured IABP which contains clot can disrupt the iliac or femoral artery upon removal and lead to uncontrollable hemorrhage. The catheter should be withdrawn as far as possible until resistance is met.

The location of the tip should be determined by x-ray or ultrasound, and an incision should be planned to expose that segment of the vascular system. The trapped balloon is removed through an arteriotomy after control of the vascular segment is obtained.

Although the incidence of clinically significant lower leg ischemia varies in from 9 to 25% of patients, up to 47% patients have evidence of ischemia during the time the IABP is used.<sup>29</sup> Thus, the preinsertion status of the pedal pulses should be determined and recorded before the IABP is inserted in every patient. After insertion, the circulation of the foot is followed hourly by palpating pulses or Doppler ultrasound. Foot color, mottling, temperature, and capillary refill are observed. The appearance of pain, decreased sensation, and compromised circulation indicate severe ischemia that requires restoration of the circulation to the extremity as soon as possible. There are three alternatives. If the patient is not balloon dependent, the balloon is removed immediately. In the majority of patients, this relieves the distal ischemia; a few patients require surgical exploration of the puncture site, removal of thrombus and/or emboli, and reconstruction of the femoral artery. If the patient is balloon dependent, a second balloon catheter can be introduced into the opposite femoral or iliac artery and the first is removed. Several risk factors for development of leg ischemia have emerged. Female gender, peripheral vascular disease, diabetes, cigarette smoking, advanced age, obesity, and cardiogenic shock are reported to increase the risk of ischemic complications after IABP. Because the IABP is inserted for compelling indications, identification of risk factors does not influence management, except to encourage removal of the device as soon as the cardiac status of the patient allows. In some series, longer duration of IABP counterpulsation is associated with an increased risk of complications.<sup>29</sup> Although most ischemic complications are the result of impairment of arterial inflow, severe atherosclerotic diseases of the descending thoracic aorta may produce embolization of atherosclerotic material. Approximately 1% of patients develop false aneurysms at the femoral puncture site either in the hospital or shortly after discharge, and rare patients develop an arteriovenous fistula. Both conditions are confirmed readily by duplex scanning.

## Results

Very few complications of IABP cause death. Rare instances of bleeding (retroperitoneal or aortic), septicemia, central nervous system injury, or aortic dissection may cause or contribute to a patient's death. Mortality is higher in patients with ischemic leg complications than in those without this complication.

Without revascularization, IABP produces a marginal increase in survival, but with revascularization, both short- and long-term survival, as well as quality of life have been shown to be improved.<sup>31</sup> However, mortality is high in patients who receive an IABP because of the cardiac problems that led to the need for the device. Overall hospital mortality

ranges from 26 to 50%.<sup>32,33</sup> Risk factors for hospital mortality include advanced age, female gender, high New York Heart Association (NYHA) class, preoperative nitroglycerin, operative or postoperative insertion, and transaortic insertion in one study and age and diabetes mellitus in another. A third study correlates hospital death with AMI, ejection fraction of less than 30%, NYHA class IV, and prolonged aortic cross-clamp and bypass times.<sup>34</sup> Time of insertion affects hospital mortality. Preoperative insertion is associated with a mortality of 18.8 to 19.6%.<sup>18</sup> Mortality for intraoperative insertion is 27.6 to 32.3%.<sup>17</sup> Postoperative IABO insertion is associated with a mortality of 39 to 40.5%. Mortality is highest at 68% for patients with pump failure, lowest at 34% for patients with coronary ischemia, and 48% for patients who had a cardiac operation. Long-term survival varies with the type of operation and is highest in patients who had cardiac transplantation or myocardial revascularization.<sup>18</sup> Patients who received an IABP and required valve surgery with or without revascularization have a poorer prognosis. Creswell and colleagues found 58.8% of all patients alive at 1 year and 47.2% alive at 5 years. Naunheim and associates found that nearly all survivors were in NYHA class I or II.<sup>34</sup> Approximately 18% of hospital survivors have some symptoms of lower extremity ischemia.

Given the overall ease of IABP insertion, excellent physiologic augmentation of coronary blood flow and left ventricular unloading, an IABP should be considered as the first line of mechanical support in patients who do not have significant peripheral vascular disease. There is some suggestion that preoperative prophylactic IABP insertion in high-risk patients (eg, left ventricular ejection fraction [LVEF] of less than 40%, unstable angina, left main stenosis of greater than 70%, or redo coronary artery bypass grafting [CABG]) can improve cardiac index, length of intensive care unit (ICU) stay, and reduce mortality.<sup>35</sup> However, with meticulous myocardial protection and the judicious use of inotropes, such as epinephrine and milrinone, most groups experienced in dealing with such high-risk patients do not find routine IABP insertion helpful.

According to latest 2013 ACC/AHA guidelines on ST elevation myocardial infarction (STEMI), use of MCS devices (including IABP) is reasonable in patients with STEMI who are hemodynamically unstable and require urgent CABG (Class IIa recommendation).<sup>36</sup> Prior to this, 2004 ACC/AHA and 2010 ESC STEMI guidelines listed specifically IABP use in cardiogenic shock as class 1B and 1C recommendations, respectively, although there were no randomized trials supporting those recommendations. The IABP SHOCK II trial was a recent randomized trial of 600 patients who presented with AMI and cardiogenic shock who were to be treated with revascularization strategies. Three hundred patients received an IABP and 298 patients were treated medically. The degree of shock, and patient characteristics were similar. In this trial, there was no difference in the 30-day mortality (IABP 39.7%: control 41.3%)<sup>37</sup> and also no differences in adverse events, leading to downgrading in guideline recommendation class.<sup>38</sup>

Many surgeons consider prophylactic insertion of IABP before high-risk cardiac surgery. Although the impact of this strategy is debatable, a recent meta-analysis of randomized-controlled trials has demonstrated that in high-risk patients, prophylactic IABP insertion leads to decrease in mortality, reduces the incidence of low output cardiac syndrome and translates into shorter ICU length of stay.<sup>39</sup> Application of IABP in postcardiac surgery varies widely. Most surgeons consider this as the first line of mechanical circulatory support in situations of persistent hypotension or low cardiac output in the immediate postoperative phase. Again, in postcardiotomy situations, in presence of persistent low cardiac output requiring high-dose pressor and inotropic support, the impact of IABP is limited and consideration for devices that can significantly increase flow should be given.

The standard IABP has a volume of 40 cc. A 50-cc IABP has been introduced and studies show that it leads to higher augmented diastolic pressure, greater systolic unloading, and a greater reduction of pulmonary capillary wedge pressure.<sup>40</sup>

While an IABP can be helpful in the management of shock patients, it is important to understand that it is not the final therapy in terms of mechanical support for the failing heart. If the shock state persists, as evidence by a depressed cardiac index, then some form of direct mechanical support must be implemented so as to restore adequate end-organ perfusion. Failure to adequately treat a patient in cardiogenic shock will most assuredly result in the patient's demise.

## DIRECT CIRCULATORY SUPPORT

### Background

The need for acute cardiac support beyond cardiopulmonary bypass was clear from the early days of cardiac surgery. In 1966, the first successful use of a LVAD was reported after a double-valve operation by DeBakey, who used an assist device that was implanted in an extracorporeal location between the left atrium and the axillary artery.<sup>41</sup> The patient was supported for 10 days on the pump, eventually was discharged home, and was a long-term survivor.<sup>41</sup>

### Ideal Device

The ideal acute support device should be capable of providing adequate flow, maximizing hemodynamics, and unloading the ventricle for patients of all sizes. Current devices have addressed the problem associated with variations in patient size by being designed as extracorporeal systems. Therefore, by virtue of having small-diameter cannulae transversing the chest, the pumps can support patients with varying body surface area. The disadvantages of such a system are the potential for driveline and mediastinal infections, as well as limiting patient mobility. In addition, the length of the cannula between the heart and the device, particularly the

inflow cannula, predisposes to areas of stasis and potential thrombus generation. All current pumps require anticoagulation, which increases the ever-present threat of early postoperative bleeding. In addition, requirements for transfusion of large amounts of coagulation factors and platelets enhance the inflammatory response that is induced by surgery and is further perpetuated by the circuit. Activation of the contact and complement systems and the release of cytokines by leukocytes, endothelial cells, and macrophages further increase the potential negative and detrimental effects of use of temporary assist devices.<sup>44</sup> The ensuing inflammatory cascade and volume overload can have detrimental effects on the pulmonary vascular resistance and lead to right ventricular overload, often necessitating the addition of a right ventricular assist device (RVAD).

Current temporary assist devices can be configured for biventricular support as needed, provided that the lungs can support oxygenation and ventilation. In cases of acute lung injury superimposed on circulatory failure, extracorporeal life support (ECLS) can be configured with conventional or the more recent centrifugal pumps.

The clinical scenarios that lead to the need for mechanical support all require that support be instituted in an expeditious manner. Therefore, all current devices must be easily implantable. In the postcardiotomy setting with access to the great vessels, the cannulae should allow the versatility of choosing any inflow or outflow site that is clinically indicated. In an active resuscitative setting, such as cardiac arrest in the catheterization laboratory, in which time is critical and transport to the operating room often impractical, percutaneous cannulation must be an option.

At present, the ideal device does not exist. Until innovations in the field of circulatory support lead to the development of an ideal device, the currently available technology must be tailored to the specific requirements of each patient, taking into consideration the duration of support needed.

## Indications for Support and Patient Selection

A wide range of indications exist for acute mechanical support, the primary goal of all being rapid restoration of the circulation and stabilization of hemodynamics. The routine use of TEE has helped greatly in assessing the etiology of cardiogenic shock by allowing evaluation of ventricular function, regional wall motion abnormalities, and valvular mechanics. In a patient with mechanical complications secondary to MI such as acute rupture with tamponade, acute papillary muscle rupture, or postinfarction VSD, emergent surgical correction may obviate the need for device support. Similarly, in the postcardiotomy setting with failure to separate from cardiopulmonary bypass, TEE may direct the surgeon to the need for additional revascularization and reparative valve surgery and successful weaning from bypass.

If echocardiography fails to reveal a surgically correctable cause for cardiogenic shock, most surgeons use hemodynamic

data to consider the need for mechanical assistance. These criteria include, but are not limited to, a cardiac index of less than 2.2 L/min/m<sup>2</sup>, systolic blood pressure of less than 90 mm Hg, mean pulmonary capillary wedge pressure or central venous pressure of greater than 20 mm Hg, and concomitant use of high doses of at least two inotropic agents.<sup>42</sup> These situations may be associated clinically with arrhythmias, pulmonary edema, and oliguria. In such circumstances, use of an IABP may be considered as the first step. In the postcardiotomy setting, the preceding hemodynamic criteria, in absence of mechanical support, are associated with a greater than 50% chance of mortality.<sup>31</sup> In this setting, some believe that earlier implantation of an assist device capable of supporting higher flows and allowing the heart to rest may improve results and allow for recovery of stunned myocardium.<sup>43</sup> Furthermore, pharmacologic agents such as the phosphodiesterase inhibitor milrinone, nitric oxide, and vasopressin have helped to optimize hemodynamics during this critical initial period, reducing the need for concomitant right ventricular support.<sup>44,45</sup>

Once mechanical assistance has been instituted, the stabilized patient can undergo periodic evaluation to assess native heart recovery, end-organ function, and neurologic status. If appropriate, evaluation for cardiac transplantation ensues. Patients without malignancy, severe untreated infection, or neurologic deficit and who are not at an advanced age are selected for cardiac transplantation if all other criteria are met, and there is no sign of cardiac recovery. In this subgroup, we generally transition to a chronic VAD until an organ becomes available, a strategy that has been termed “a bridge to a bridge,” in that a short-term device is used to “bridge” the patient to a more durable “bridge to transplant” VAD. In patients with improvement in myocardial pump function, the devices may be weaned and removed.

## DEVICES

Devices currently approved by the Food and Drug Administration (FDA) for temporary support include centrifugal pumps, roller pumps, venoarterial extracorporeal membrane oxygenation (ECLS, ECMO), the ABIOMED AB5000 Ventricle and Impella devices (ABIOMED, Danvers, MA), Thoratec Centrimag (Thoratec Inc., Pleasanton, CA), and the Thoratec paracorporeal VAD (pVAD) (Pleasanton, CA), and the TandemHeart system (CardiacAssist, Inc.). A number of other devices are undergoing investigation for short-term support.

## Continuous-Flow Pumps

Two types of pumps are available commercially for extracorporeal circulation: roller pumps and centrifugal pumps. In adults, roller pumps are used rarely, if ever, for temporary circulatory support beyond routine cardiopulmonary bypass applications because of important disadvantages. Although inexpensive, roller pumps are insensitive to line pressure and require

unobstructed inflow. Additionally, roller pumps may cause spallation of tubing particles and are subject to tubing failure at unpredictable times. These systems require constant vigilance and are difficult to operate for extended periods. Use of roller pumps beyond 4 to 5 hours is associated with hemolysis and, for this reason, is inappropriate for mechanical assistance that may involve several days to weeks of support.<sup>46</sup> Axial flow pumps, in which the pump rotor is parallel to the blood path, have entered the field of temporary support with the introduction of the Impella devices but most of the experience with temporary support devices has been with centrifugal pumps.

### CENTRIFUGAL PUMPS

Centrifugal pumps are familiar assist systems because of their routine use in cardiopulmonary bypass. In these devices, the blood path is perpendicular to the rotor. Although many different pump-head designs are available, they all work on the principle of generating a rotary motion by virtue of moving blades, impellers, or concentric cones. These pumps generally can provide high flow rates with relatively modest increases in pressure. They require priming and de-airing prior to use in the circuit, and the amount of flow generated is sensitive to outflow resistance and filling pressures. The differences in design of the various commercially available pump heads are in the numbers of impellers, the shape and angle of the blades, and the priming volume. The Medtronic Bio-Pump® (Medtronic Bio-Medicus, Inc., Eden Prairie, MN), which is based on two concentric cones generating a rotary motion, has been extensively utilized in the field of acute circulatory support.<sup>47</sup> The pump heads are disposable, relatively cheap to manufacture, and mounted on a magnetic motorized unit that generates the power that drives the pump. Although earlier designs caused mechanical trauma to the blood elements leading to excessive hemolysis, the newly engineered pumps are less traumatic and can be used for longer periods.

The Rotoflow (Maquet Cardiovascular) is another example of a centrifugal pump that is extensively utilized in the field of acute circulatory support.

**Complications.** Complications with temporary mechanical assistance are high and are very similar for patients on centrifugal pump support or ECLS. The major complications reported by a voluntary registry for temporary circulatory assistance using primarily LVADs, RVADs, and biventricular assist devices (BVADs) are bleeding, persistent shock, renal failure, infection, neurologic deficits, thrombosis and emboli, hemolysis, and technical problems. Neurologic deficits occurred in approximately 12% of patients, and in Golding's experience, noncerebral emboli occurred equally often.<sup>48</sup> Golding also found that 13% of patients also developed hepatic failure. An autopsy study found anatomical evidence of embolization in 63% of patients, even though none had emboli detected clinically.<sup>49</sup>

**Results.** Although a meaningful comparison of results of centrifugal support from different institutions is not possible, in general, overall survival has been in the range of

21 to 41%. A voluntary registry reported the experience with 604 LVADs, 168 RVADs, and 507 BVADs; approximately 70% were with continuous-flow pumps and the remainder with pulsatile pumps.<sup>50</sup> There were no significant differences in the percentage of patients weaned from circulatory assistance or the percentage discharged from the hospital according to the type of perfusion circuitry. Overall, 45.7% of patients were weaned, and 25.3% were discharged from the hospital.<sup>50</sup> The registry also reports that long-term survival of patients weaned from circulatory support is 46% at 5 years.<sup>50</sup> Most of the mortality occurs in the hospital before discharge or within 5 months of discharge.

Golding reported an identical hospital survival rate for 91 patients in 1992 using only centrifugal pumps, and Noon reported that 21% of 129 patients were discharged.<sup>49,51</sup> Patients who received pulsatile circulatory assistance were supported significantly longer than those supported by centrifugal pumps, but there were no differences in the percentage of patients weaned or discharged. Survivors were supported an average of 3.1 days using continuous-flow pumps. Patients supported for AMI did poorly; only 11.5% survived to be discharged. Joyce reports that 42% of patients supported by Sarns impeller pumps eventually were discharged.<sup>52</sup>

### EXTRACORPOREAL LIFE SUPPORT (ECLS/ECMO)

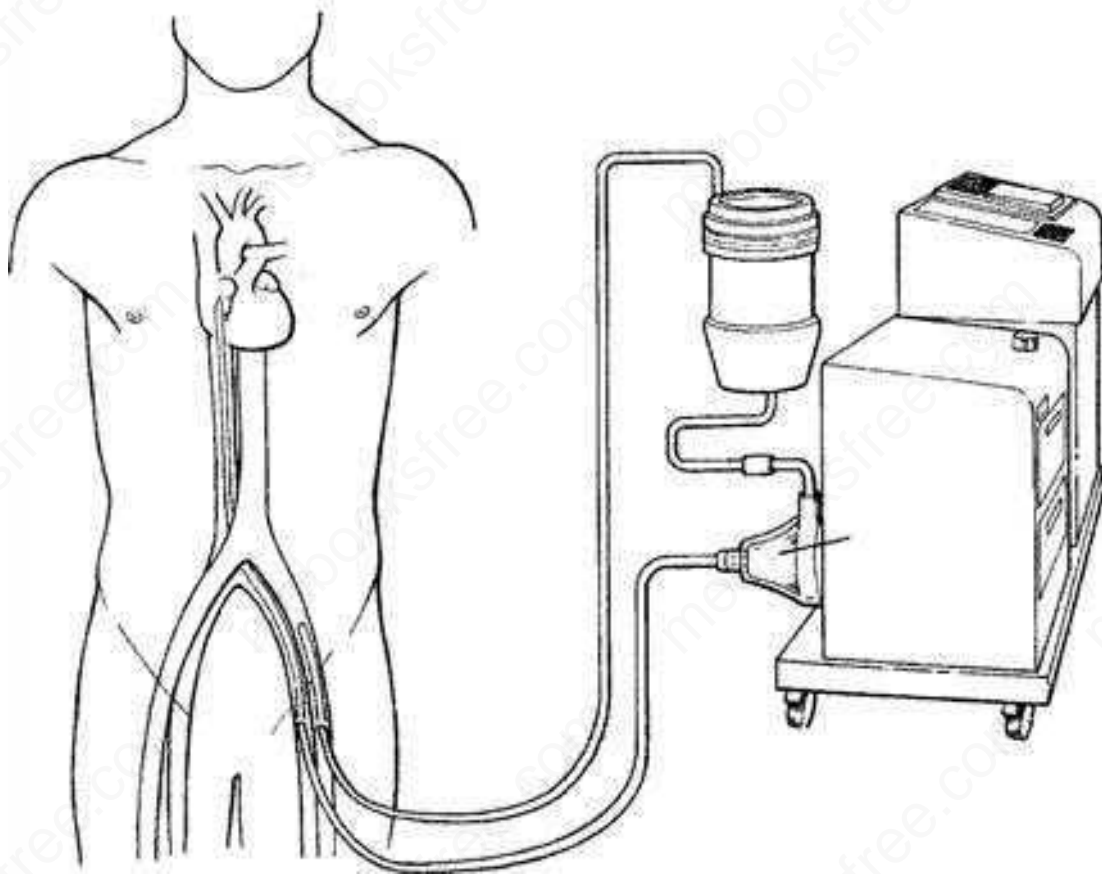

By the 1960s, it was clear that cardiopulmonary bypass was not suitable for patients requiring circulatory support for several days to weeks. The development of ECLS as a temporary assist device (also referred to as *extracorporeal membrane oxygenation* [ECMO]) is a direct extension of the principles of cardiopulmonary bypass and follows the pioneering efforts of Bartlett and colleagues in demonstrating the efficacy of this technology in neonatal respiratory distress syndrome.<sup>53</sup>

There are a number of key differences between cardiopulmonary bypass and ECLS. The most obvious difference is the duration of required support. Whereas cardiopulmonary bypass typically is employed for several hours during cardiac surgery, ECLS is designed for longer duration of support. With ECLS, lower doses of heparin are used, and reversal of heparin is not an issue. Because a continuous circuit is used, areas of stasis, such as the cardiotomy suction and venous reservoir, are not present. These differences are thought to reduce the inflammatory response and the more pronounced coagulopathy that can be seen with cardiopulmonary bypass<sup>54</sup> although there is generally a rapid rise of inflammatory cytokines with initiation of ECLS support.<sup>55</sup>

A typical ECLS circuit is demonstrated in Fig. 18-3. The system consists of the following:

1. *Hollow-fiber membrane oxygenator with an integrated heat-exchange system.* The microporous membrane provides the necessary gas-transfer capability via the micropores where there is direct blood-gas interface with minimal resistance to diffusion. By virtue of the membranes being close to each other, the diffusion distance has been reduced without a significant pressure drop across the system. Control of oxygenation and ventilation is relatively easy. Increasing

**FIGURE 18-3** Percutaneous extracorporeal membrane oxygenation (ECMO) support is attained via femoral vessel access. Right atrial blood is drained via a catheter inserted into the femoral vein and advanced into the right atrium. Oxygenated blood is perfused retrograde via the femoral artery. Distal femoral artery perfusion is not illustrated.

the total gas flow rate increases  $\text{CO}_2$  removal (increasing the “sweep”) by reducing the gas-phase  $\text{CO}_2$  partial pressure and promoting diffusion. Blood oxygenation is controlled simply by changing the fraction of  $\text{O}_2$  in the gas supplied to the oxygenator.

2. *Centrifugal pump.* These pumps are totally nonocclusive and afterload dependent. An increase in downstream resistance, such as significant hypertension, will decrease forward flow to the body. Therefore, flow is not determined by rotational flow alone, and a flowmeter needs to be incorporated in the arterial outflow to quantitate the actual pump output. If the pump outflow should become occluded, the pump will not generate excessive pressure and will not rupture the arterial line. Similarly, the pump will not generate significant negative pressure if the inflow becomes occluded. This protects against cavitation and microembolus formation. The newer generation magnetically levitated centrifugal pumps have been also used recently in the ECLS circuit and may have less traumatic effect on the blood elements.<sup>56</sup>
3. *Heat exchanger.* This allows for control of blood temperature as it passes through the extracorporeal circuit. Generally, the transfer of energy occurs by circulating nonsterile water in a countercurrent fashion against the circulating blood. Use of

water as the heat-exchange medium provides an even temperature across the surface of the heat exchanger without localized hot spots. The use of a heat exchanger allows for maintenance of normothermia given the potential heat loss that can occur through the long circuit.

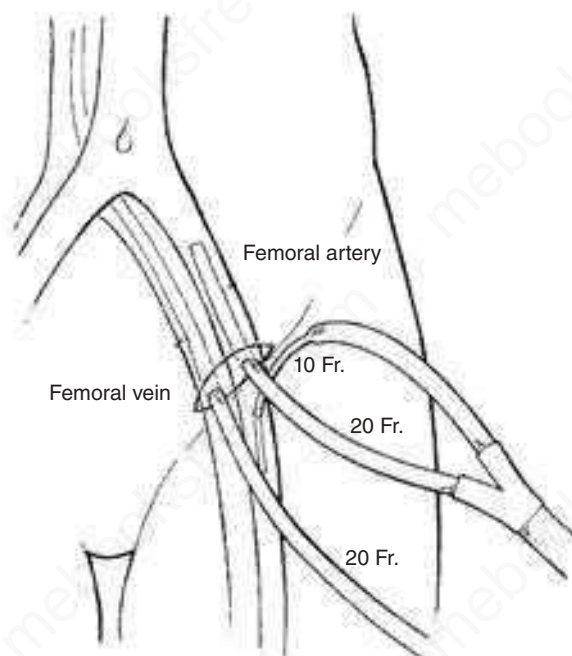

4. *Circuitry interfaced between the patient and the system.* The need for systemic anticoagulation on ECLS and the complications associated with massive coagulopathy and persistent bleeding during the postcardiotomy period led to the development of biocompatible heparin-bonded bypass circuits. In 1991, the Carmeda Corporation in Stockholm, Sweden, released a heparin-coating process that could be used to produce an antithrombotic surface.<sup>57</sup> This process was applied to extracorporeal tubing and the hollow-fiber microporous oxygenator surface.<sup>58</sup> Initial experience suggested that the need for systemic anticoagulation had been eliminated. In addition, heparin coating has been associated with a decrease in the inflammatory response with reduced granulocyte<sup>59</sup> and complement activation.<sup>60</sup> Bindslev and colleagues<sup>61</sup> and Mottaghy and colleagues<sup>62</sup> reported excellent hemodynamic support with minimal postoperative blood loss in experimental animals for up to 5 days. Magovern and Aranki reported similar excellent results with clinical application.<sup>63,64</sup>

Although these heparin-bonded circuits were initially thought to completely eliminate the need for heparinization, thrombus formation without anticoagulation remains a persistent problem. In a study of 30 adult patients with cardiogenic shock who underwent ECLS using the heparin-bonded circuits and no systemic anticoagulation, 20% of patients developed left ventricular thrombus by TEE, and an additional 6% had a visible clot in the pump head.<sup>65</sup> Protamine administration after starting ECLS can precipitate intracardiac clot. If the left ventricle does not eject and blood remains static within the ventricle, clot formation is more likely. Intracavitary clot is more likely in patients with MI owing to expression of tissue factor by the injured cells. Protamine may bind to the heparinized coating of the new circuit and negate an anticoagulant effect.<sup>66</sup>

**Cannulation.** The main difference between the centrifugal pump and ECLS is the presence of an in-line oxygenator. As a result, ECLS can be used for biventricular support by using central or peripheral cannulation. Intraoperatively, the most common application of ECLS has been for patients who cannot be weaned from cardiopulmonary bypass after heart surgery. In these cases, the existing right atrial and aortic cannulas can be used. An alternative strategy is to convert the system to peripheral cannulas, which potentially permits later decannulation without opening the chest.

Cannulation is accomplished by surgical cut down or percutaneous insertion. The entire vessel does not need to be mobilized, and exposure of the anterior surface of the vessels typically suffices. A purse string suture is placed over the anterior surface of the vessel. Typically, arterial cannulae of 16 to 20 French and venous cannulae of 18 to 25 French are used. The cannulation is performed under direct vision using Seldinger's technique. A stab incision is made in the skin with a no. 11 blade knife, a needle is inserted through the stab incision into the vessel, and a guidewire is advanced gently. Dilators then are passed sequentially to gently dilate the tract and the insertion point in the vessel. The cannulae then are inserted, the guidewire is removed, and a clamp is applied. For venous drainage, a long venous cannula is directed into the femoral vein to the level of the right atrium under transesophageal echocardiographic guidance.

To minimize limb complications from ischemia, one strategy is to place an 8- to 10-French perfusion cannula in the superficial femoral artery distal to the primary arterial inflow cannula to perfuse the leg (Fig. 18-4). This cannula is connected to a tubing circuit that is spliced into the arterial circuit with a Y-connector. The distal cannula directs continuous flow into the leg and significantly reduces the incidence of leg ischemia. It should be noted, however, that limb ischemia associated with long-term peripheral cannulation relates not only to arterial perfusion, but also to the relative venous obstruction that can occur with large venous lines. In such circumstances distal venous drainage can be established by splicing another small venous cannula into the circuit.

**FIGURE 18-4** Surgical exposure of the femoral vessels facilitates cannulation for ECMO. A small 10-French cannula is used to perfuse the distal femoral artery.

An alternative strategy is to completely mobilize the common femoral artery and sew a 8- or 10-mm short Dacron graft to its anterior surface as a “chimney.” The graft serves as the conduit for the arterial cannula. Alternatively a standard perfusion connector may be secured in the graft and hooked to the 3/8 tubing of the circuit. This strategy also allows for a more secure connection and avoids problems with inadvertent dislodgement of the cannulas because of loosening of the purse strings or tourniquets.

In general, complete percutaneous placement of arterial cannulae is avoided to prevent iatrogenic injury during insertion and ensure proper positioning of the cannula. However, when venovenous bypass is the only mode of support needed, percutaneous cannulation is performed. Surgical exposure is not necessary, and bleeding is less with this technique.

Central cannulation sometimes is indicated because of either severe peripheral vascular disease or the desire to deliver the highly oxygenated blood directly to the coronary arteries and cerebral circulation. In patients with an open chest and right atrial cannulae may be used, but our preference is to anastomose a graft to the ascending aorta and cannulate the right atrium from the femoral vein. Reinforcing purse string sutures are placed and tied over rubber chokers and buttons for later tying at decannulation. The catheters are brought through the chest wall through separate stab wounds, and after bleeding is secured, the chest may be closed.

An alternative central cannulation site is the axillary artery. The most secure cannulation strategy for the axillary artery is to sew an 8- or 10-mm graft to the vessel as a “chimney.” The cannula then is placed in the graft and tied securely with several circumferential sutures and zip ties. Clinicians must be

vigilant for progressive arm edema, which can be controlled by partial occlusion of the distal axillary artery by vessel loop.

Once instituted, the system is simple enough to be monitored by trained ICU nurses and maintained by a perfusionist on a daily basis. Evidence of clots in the pump head requires a change. Leakage of plasma across the membrane from the blood phase to the gas phase may be a problem, gradually decreasing the efficiency of the oxygenator and increasing resistance to flow and necessitating oxygenator exchanges. Using this system, ECLS flows of 4 to 6 L/min are possible at pump speeds of 3000 to 3200 rpm. Higher pump speeds are avoided to minimize mechanical trauma to blood cells. Other means of improving flow include transfusion of blood, crystalloid, or other colloid solutions to increase the overall circulating volume.

Physiologically, ECLS will unload the right ventricle but will not unload the compromised left ventricle, even though left ventricular preload is reduced.<sup>68</sup> In normal hearts, the marked reduction in preload and small increase in afterload produced by the arterial inflow from the ECLS system reduce wall stress and produce smaller end-diastolic left ventricular volumes because the heart is able to eject the blood it receives. However, if the heart is dilated and poorly contracting, the increase in afterload provided by the ECLS system offsets any change in end-diastolic left ventricular volume produced by bypassing the heart. The heart remains dilated because the left ventricle cannot eject sufficient volume against the increased afterload to reduce either end-diastolic or -systolic volume. ECLS, therefore, theoretically may increase left ventricular wall stress and myocardial oxygen consumption unless the left ventricle is mechanically unloaded. If the PCWP remains high and there is evidence of pulmonary congestion, a left-sided vent, which is spliced into the venous limb of the circuit is indicated. Most groups are finding that direct LV decompression is the effective form of left-sided drainage.

As mentioned, the versatility of ECLS is that it allows rapid restoration of circulation by peripheral cannulation during active resuscitation in the setting of acute cardiac arrest, acute pulmonary embolism, or patients in cardiogenic shock, who cannot be moved safely to the operating room.

An isolated RVAD is rarely indicated in the postcardiotomy setting because, in general, these patients have global biventricular dysfunction. ECLS as an RVAD (with outflow to the pulmonary artery) may be used only in patients with good function of the left ventricle who manifest right ventricular failure and hypoxia or in patients who manifest RV failure after implantation of a long-term LVAD.

**Complications.** The experience in adults with ECLS for postoperative cardiogenic shock is associated with high rates of bleeding. Surgical bleeding from the chest is exacerbated by anticoagulation and the consumptive coagulopathy caused by the ECLS circuit. Even without the chest wound, bleeding was the major complication in a large study of long-term ECLS for acute respiratory insufficiency.<sup>67</sup> Muehrcke reported experience with ECLS using heparin-coated

circuitry with no or minimal heparin.<sup>68</sup> The incidence of reexploration was 52% in the Cleveland Clinic experience; transfusions averaged 43 units of packed cells, 59 units of platelets, 51 units of cryoprecipitate, and 10 units of fresh-frozen plasma. Other important complications associated with ECLS using heparin-coated circuits included renal failure requiring dialysis (47%), bacteremia or mediastinitis (23%), stroke (10%), leg ischemia (70%), oxygenator failure requiring change (43%), and pump change (13%).<sup>68</sup> Nine of 21 patients with leg ischemia required thrombectomy and one amputation. Half the patients developed marked left ventricular dilatation, and six patients developed intracardiac clot detected by TEE. Intracardiac thrombus may form within a poorly contracting nonejecting left ventricle or atrium because little blood reaches the left atrium with good right atrial drainage. We have observed intracardiac thrombus which is related to left ventricular dysfunction and stagnant flow. In patients on temporary VADs in whom LV clot forms, the clot is removed at the time of permanent VAD implantation.

**Results.** The Cleveland Clinic reported their results looking at 202 adults with cardiac failure.<sup>69</sup> With an extended follow-up of 7.5 years (mean 3.8 years), survival was reported to be 76% at 3 days, 38% at 30 days, and 24% at 5 years. Patients surviving 30 days had a 63% chance of being alive at 5 years, demonstrating that the high early mortality remains the Achilles heel of this technology. Interestingly, patients who were weaned or bridged to transplantation had a higher overall survival (40 and 45%, respectively). Failure to wean or bridge was secondary to end-organ dysfunction and included renal and hepatic failure and occurrence of a neurologic event while on support.

The Quadrox D oxygenator (Maquet Cardiovascular) has hollow fibers constructed of poly-methylpentene (PMP) as opposed to the standard microporous polypropylene hollow fiber oxygenators. PMP membrane oxygenators have less plasma leakage and are as such more durable. It has demonstrated improved oxygenator durability, which has led to longer periods of support ECLS. Pokersnik and colleagues from the Cleveland Clinic Foundation compared outcomes of patients supported with ECLS from 2005 to 2010.<sup>70</sup> Forty-nine patients received ECMO following cardiac surgery. Patients were divided into three groups. Group 1 patients received a biomedicus pump with an affinity oxygenator, Group 2 patients received a Biomedicus pump with a Quadrox D oxygenator, and Group 3 patients received a Rotaflo pump with a Quadrox D oxygenator. Despite oxygenator durability improving markedly with the introduction of the Quadrox D (oxygenator exchange rate dropping from 64-70%), survival in the groups improved only from 27 to 33% with the newer systems. Formica and colleagues from Italy demonstrated a similar survival rate of 28% in a mixed group (n = 25) of primary and postcardiotomy cardiogenic shock patients who were placed on the Rotaflo ECLS (Maquet Cardiovascular) system which uses the Quadrox D oxygenator.<sup>71</sup>

## NEWER DEVICES

**Cardiohelp™ (Maquet Cardiovascular).** Cardiohelp™ is a compact ECLS system with a low priming volume and an integrated oxygenator similar to the quadrox (Fig. 18-5). The small size of the system lends itself to transport both in and out of the hospital. Arit and colleagues reported the feasibility and effectiveness of the Cardiohelp in safely transporting patients with cardiogenic shock. From 2007 to 2010, 20 shock patients were transferred from five different hospitals while supported on Cardiohelp. The patients were treated with angioplasty (n = 2), CABG (n = 6), pulmonary embolectomy (n = 1), and permanent LVAD (n = 1) after arrival at the accepting hospital. Overall survival was 62%.<sup>72</sup>

**TandemHeart.** The TandemHeart PTVA (percutaneous ventricular assist) System (CardiacAssist, Inc., Pittsburgh, PA) has 510K FDA approval for short-term (<6 hours) mechanical support. It was envisioned for the short-term support of high-risk percutaneous interventions in the catheterization lab.<sup>73</sup> The device is powered by a small hydrodynamic centrifugal pump that resides in a paracorporeal location. The rotor of the pump is suspended and lubricated by a fluid interface of heparinized saline. Cannulas are introduced from the femoral vessels by either percutaneous or direct insertion techniques. Pump inflow is achieved by a novel, proprietary 21-French cannula delivered across the atrial septum. Outflow typically is directed into the common femoral artery (Fig. 18-6). Position is facilitated and confirmed by fluoroscopy and intracardiac ultrasound.<sup>74</sup>

As opposed to an ECLS circuit, excellent left atrial decompression is achieved as long as the inflow cannula is appropriately positioned. The device can be introduced either in the catheterization laboratory using fluoroscopy or directly in the operating room using TEE guidance. Most of the experience with the device has been in the catheterization laboratory, where it has been used extensively to facilitate high-risk

percutaneous interventions.<sup>75</sup> Flows of up to 4 L are typical. With surgically implanted larger cannulae flows up to 8 L are possible.

The TandemHeart can be configured in many ways to achieve effective mechanical support. The inlet and outlet connectors to the pump are 3/8-3/8 connectors, and as such can be connected to any of a number of commercially available percutaneous or surgically implanted cannulae.

Patients with this device are typically kept in bed, given that the device is inserted through the femoral vessels. An activated clotting time (ACT) of 200 seconds is targeted while the patients are on support. The TandemHeart is a very versatile system that can be deployed and discontinued rapidly. One beneficial aspect for postcardiotomy support is that the entire device can be removed in the ICU without reopening the patient's chest. RVAD configurations with right atrial inflow and outflow to the main pulmonary artery are possible in both open<sup>76</sup> and percutaneous configurations.<sup>77</sup> Traditionally, for percutaneous RVAD, the 21-French transeptal cannula was directed into the main pulmonary artery under fluoroscopy, and a separate right atrial cannula was placed via a femoral vein.<sup>77</sup> While achievable, the vascular access requirements were cumbersome. The PROTEK Duo (CardiacAssist, Inc.) Cannula is a dual lumen catheter designed for veno-venous ECMO. With proper positioning, it can be configured as a single cannula percutaneous RVAD. When faced with a patient that needs biventricular support, some groups are splicing an oxygenator into the circuit and using right atrial or bi-atrial drainage. In essence such a configuration converts the assist system to ECLS circuit.<sup>78</sup> With transeptal drainage, the issues of left-sided congestion, which sometimes plague ECLS patients, are nonexistent.

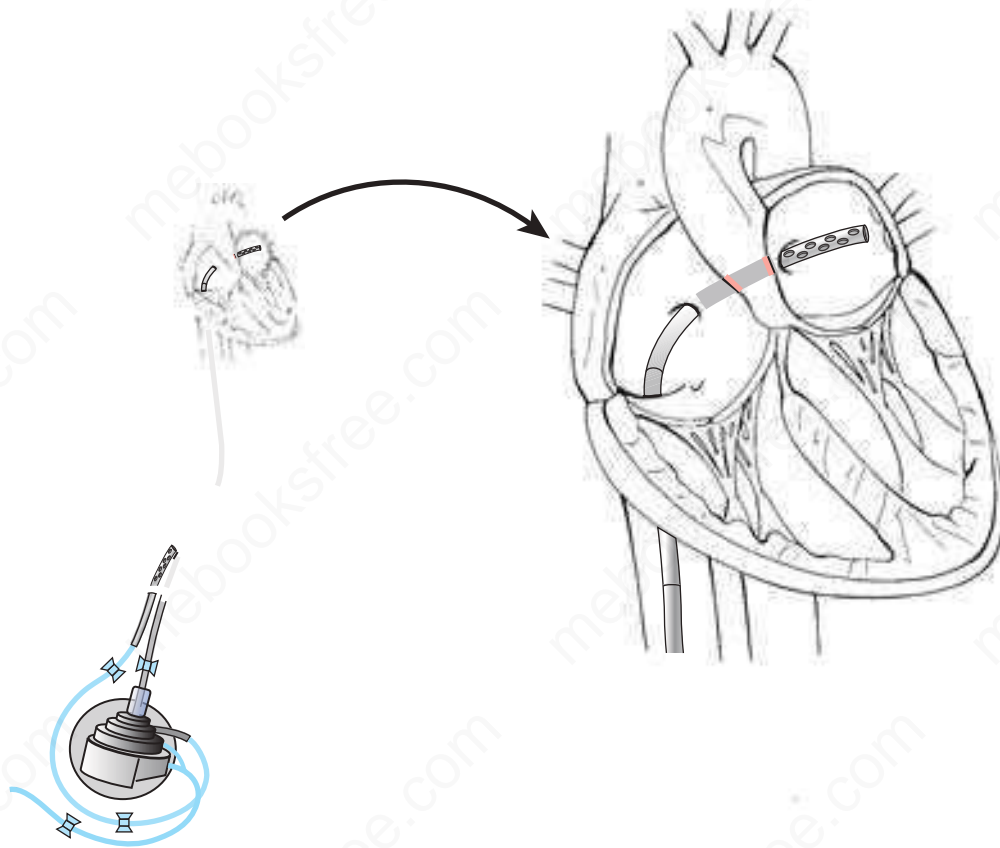

Karr and colleagues reported 117 patients supported with the TandemHeart. Fifty-six patients (47.9%) were undergoing CPR. Thirty-day and six-month survival were 59.8% and 54.7%, respectively. The authors concluded that the TandemHeart percutaneous VAD effectively and rapidly reversed cardiogenic shock refractory to IABP and vasopressor support.<sup>79</sup>

Gregoric and reported the outcomes of eight patients in shock secondary to critical aortic stenosis supported with preoperative TandemHeart. Five were receiving chest compressions at the time of TandemHeart insertion. All underwent conventional aortic valve replacement after a mean duration of support of 6 days. One patient died of postoperative sepsis. The other seven patients were discharged from the hospital and were all alive at the time of the report.<sup>80</sup>

Brinkman and the group at Medical City Dallas reported on the outcomes of 22 patients supported with the TandemHeart device. Mean duration of support was 6.8 days with no pump failures or pump-related neurologic events. Three patients developed bleeding and two patients had lower extremity ischemic complications. In 11 patients who were neurologically intact at the time of TandemHeart insertion, five went on to receive transplants while on TandemHeart support, three went on to permanent LVAD placement, and two patients recovered. Of 11 patients with indeterminate

**FIGURE 18-5** Cardiohelp. (Courtesy of Maquet Cardiopulmonary GmbH.)

**FIGURE 18-6** Transeptal inflow cannula of the TandemHeart device. (Used with permission from CardiacAssist, Inc., Pittsburgh, PA.)

neurologic status or multiorgan failure, seven died, two went on to receive permanent LVADs, one was transplanted, and one patient recovered.<sup>81</sup>

It should be noted that use of a TandemHeart beyond 6 hours and use with an oxygenator are off-label uses of the device. It is important to remember that when placing a long-term VAD in a patient on Tandem support, it is necessary to repair the atrial septum. Failure to do so can lead to hypoxia caused by entrainment of unoxygenated blood across the atrial septal defect created by the TandemHeart inlet cannula.

**CentriMag.** The CentriMag (Thoratec, Inc., Pleasanton, CA) pump is a centrifugal pump with a fully magnetically levitated impeller (Fig. 18-7).<sup>83</sup> Very little friction is generated and it requires only a very small priming volume. It can be configured for both right- and left-sided heart support typically with central cannulation via median sternotomy. With good cannula placement, more than 9 L of support can be achieved. It has FDA 510K approval for 6 hours of use as an LVAD and has FDA approval for use as a temporary RVAD for 30 days.

The group at the University of Minnesota reported the outcomes of 12 patients supported with CentriMag BiVADs.<sup>83</sup> Of 12 patients who presented in cardiogenic shock, eight

went on to receive long-term implantable VADs, two recovered, and two died. Thirty-day survival was 75% and 1-year survival was 63%.<sup>83</sup>

Mohamedali and colleagues reviewed the outcomes of 48 patients supported with biventricular Centrimag in shock

**FIGURE 18-7** Thoratec CentriMag. (Used with permission from Thoratec, Inc., Pleasanton, CA.)

patients as a bridge to decision from 2008 to 2013. Thirty-day survival was 56% (27 of 48) with 9 patients explanted for recovery and 14 being transitioned to a durable LVAD.<sup>84</sup>

Takayama and colleagues from Columbia reported the results of 148 patients supported with CentriMag in either biventricular (67%), isolated RVAD (26%) or LVAD (8%). They reported an overall 30-day survival of 69% and 1-year survival of 49%. Failure of medical management and graft failure after heart transplantation had improved outcomes when compared to patients with postcardiotomy failure.<sup>85</sup>

The group at the University of Pittsburgh reported the results of using CentriMag as a temporary RVAD. The indication for RV support was postcardiotomy RV failure in seven (24%), RV failure postcardiac transplant in 10 (35%), and RV failure post-LVAD placement in 12 (41%) patients. The RVAD was able to be weaned in 43% of postcardiotomy patients, 70% of transplant patients, and 58% of LVAD patients after a mean duration of support of 8 days. The authors concluded that the CentriMag was easy to implant, provided effective support, and was easy to wean with low overall morbidity.<sup>86</sup>

Lazar and colleagues from the University of Rochester reported 34 patients who required CentriMag RVAD after Heartmate II insertion. The mean duration of biventricular support was  $17 \pm 11.9$  days. Survival to discharge was not statistically different between patients receiving an isolated LVAD (95.2%) and those that required a CentriMag RVAD (88.2%). One-year survival was 87% with LVAD only compared to 77% for those requiring a temporary CentriMag RVAD ( $p = 0.03$ ) (ATS 2013).<sup>87</sup>

As with similar pumps, the CentriMag can be configured with an oxygenator to create an ECLS circuit.<sup>88</sup> The group from Penn State compared mechanical pump function between the CentriMag pump and the much less expensive Rotoflow in a mock ECLS loop fitted with the Quadrox D and using blood and found that maximal pump flow and shut off pressure were higher in the Rotoflow than the CentriMag implying better mechanical performance. The authors concluded that it was much more economically prudent to use the Rotoflow system as it was 20 to 30 times less expensive than the CentriMag and demonstrated improved performance.<sup>89</sup>

## AXIAL FLOW PUMPS

**Impella.** The Impella device is a microaxial pump, with both peripheral and central cannulation configurations available. In either case, the pump is directed across the aortic valve into the left ventricle (Fig. 18-8). The cannula portion of the device, which sits across the aortic valve, is contiguous with the integrated motor that comprises the largest diameter section of the catheter. The small diameter of the cannula is designed to allow easy coaptation of the aortic valve leaflets around it, resulting in minimal aortic valve insufficiency. Its hemodynamic support results from the design feature that provides active forward flow that increases net cardiac output, and its ability to address the needs for myocardial protection stems from simultaneously

**FIGURE 18-8** Impella device. (Used with permission from Abiomed, Inc, Danvers, MA.)

unloading work from the ventricle (decreasing myocardial oxygen demand) and augmenting coronary flow thereby increasing oxygen supply.<sup>90-92</sup>

Three versions for left ventricular support are available: 2.5 and CP that are inserted percutaneously and a 5.0 version that requires surgical approach for deployment. Typically, the catheter-pump motor is deployed across the aortic valve under fluoroscopic or echocardiographic guidance and blood is aspirated through the distal tip-inlet area from the left ventricle, and pumped into the ascending aorta at the proximal tip-outlet area of the catheter motor. The catheter has pressure transducers on each end, and effectively measures pressures on each side of the aortic valve, making it possible to adjust or reposition the device without need for additional imaging in case of catheter displacement after insertion. The Impella RP is the newest addition with the goal of providing percutaneous support for the failing right ventricle. It is deployed via the femoral vein, across pulmonary valve aspirating blood from inferior vena cava and pumping it into the pulmonary artery (Fig. 18-9). Impella R generates more than 4 L/min of flow and uses a 22F catheter.

Each of the available devices is designed for a particular application depending on the desired flow level. As with all LVADs, the actual flow depends on adequacy of blood return to the left side of the heart, which in return depends on right ventricular function, pulmonary vascular resistance, and adequate blood volume. Impella 2.5 generates up to 2.5 L/min of flow and requires a 12F catheter for insertion. Its use is now typically reserved for high risk percutaneous catheter-based

**FIGURE 18-9** The Impella RP device. (Used with permission from Abiomed, Inc, Danvers, MA.)

therapies involving coronary interventions or high-risk ablation procedures.<sup>93,94</sup> Impella CP generates up to 4 L/min of flow and requires a 14F catheter for insertion and may be more appropriate for patients in low cardiac output state who need rapid percutaneous stabilization. If time allows for surgical access, the Impella 5.0 which generates up to 5 L/min of flow may be more appropriate. Since this device requires a 21F catheter, surgical cut down to the femoral artery, or more commonly insertion through a vascular graft sewn to the axillary artery is required for placement.

Experience with Impella 2.5 is largely with high-risk percutaneous interventions in which the device maintains hemodynamic stability during balloon inflation and stent deployment. In addition, in cases of MI it may help in reducing infarct size. In a recent prospective randomized trial, 20 patients underwent high-risk percutaneous coronary intervention (PCI) while being supported with the Impella 2.5.<sup>93</sup> All patients had poor LVEF and had interventions on the left main or the last remaining patent conduit. Patients with recent STEMI or cardiogenic shock were excluded. The primary safety end point was the incidence of major adverse cardiac events at 30 days. The primary efficacy end point was freedom from hemodynamic compromise during intervention. The Impella 2.5 device was implanted successfully in all patients. The mean duration of circulatory support was  $1.7 \pm 0.6$  hours (range, 0.4-2.5 hours). Mean pump flow during PCI was  $2.2 \pm 0.3$  L/min. At 30 days, the incidence of major adverse cardiac events was 20%. (Two patients had a periprocedural MI, and two patients died at days 12 and 14.) There was no evidence of aortic valve injury, cardiac perforation, or limb ischemia. Two patients (10%) developed mild, transient hemolysis without clinical sequelae. None of the patients developed hemodynamic compromise during

PCI.<sup>93</sup> The more recent follow up to that study, the PROTECTII Trial<sup>95</sup> 452 symptomatic patients with complex 3 vessel coronary artery disease or unprotected left main and poor LVEF were randomized between IABP (n-226) versus Impella 2.5 (n-226) during percutaneous intervention. Impella 2.5, as expected, provided superior hemodynamic support compared to the IABP during the intervention. However, the 30 day incidence of major adverse event was similar in both groups. Based on a substudy of PROTECT II trial in patients undergoing PCI due to three-vessel disease with impaired LVEF and MCS support, Impella 2.5 had better 90-day outcomes compared to IABP, lower rate of repeating revascularization, less readmissions and adverse events.<sup>96</sup>

Several studies looked at potential survival benefit of Impella systems compared to alternatives in cardiogenic shock. Based on one unadjusted retrospective comparison, there has been no difference in survival between Impella 5.0 and ECMO, while blood transfusion and arterial thrombotic events were more common in the ECMO group.<sup>97</sup> On the other hand, it has been suggested that Impella 5.0 improves survival in postcardiotomy shock patients with residual cardiac output of 1 L/min or more.<sup>98</sup>

Depending on severity, peripheral vascular disease, atherosclerosis, as well as small vessel size, are considered relative contraindications due to risk of leg ischemia, and technical difficulties in catheter placement.<sup>99-103</sup> Other contraindications include mechanical aortic valve, heavily calcified aortic valve, and aortic regurgitation. Some consider aortic regurgitation a relative contraindication emphasizing decreased pump efficacy as the only undesired effect.

Impella RP (Fig. 18-9) is a fairly new addition to the Impella family, with data on its use and performance still being scarce, but highlighting an expanding role of pVADs in right ventricular support.<sup>104,105</sup> Impella RP US clinical trial is currently underway with expected completion date June 2016 (ClinicalTrials.gov Identifier: NCT01777607).

### Heartmate PHP™

The Heartmate PHP™ (Fig. 18-10) is a microaxial pump similar in concept to the Impella devices. It is designed to be placed through the femoral artery and directed across the aortic valve into the left ventricle. The pump is introduced via a 13-French introducer, which allows for percutaneous insertion. Once the pump is in the left ventricle, the segment of the catheter that houses the pump is unsheathed and expands to 24 Fr. It is then withdrawn so that it straddles the aortic valve. It is marketed as providing 4 to 5 L/min flow. It has recently received CE mark approval and as such is commercially available in Europe.

**The SHIELD II** (Coronary InterventionS in HIgh-Risk PatiEnts Using a Novel Percutaneous Left Ventricular Support Device) U.S. IDE Clinical Trial is a prospective, randomized, multi-center, study comparing HeartMate PHP™ (Percutaneous Heart Pump) to the Impella® 2.5 in patients undergoing high-risk PCI. The study will randomize up to 425 patients at up to 60 sites.<sup>106</sup>

## Pulsatile Pumps

### ABIOMED AB VENTRICLE/AB5000

The AB5000 circulatory support system, introduced in 2004, consists of the pneumatically driven AB ventricle and the AB5000 console, which utilizes vacuum-assisted drainage. The ventricle is designed for short-to-intermediate (<3 months) support and incorporates many of the features of the ABIOCOR total artificial heart. It is driven pneumatically with valves that are constructed of Angioflex, ABIOMED's proprietary polyether-based polyurethane plastic. Inflow cannulae can be configured for atrial or ventricular placement.

**Cannulation.** ABIOMED cannulae are constructed from polyvinyl chloride and have a velour body sleeve that is tunneled subcutaneously. Three sizes of wire-reinforced inflow cannulas are available commercially. These include malleable

32-, 36-, and 42-French cannulas. Arterial cannulas have a precoated Dacron graft attached and are available in two sizes: a 10-mm graft for anastomosis to the smaller and lower-resistance pulmonary artery and a 12-mm graft for anastomosis to the ascending aorta.

Careful cannula insertion is important for optimal performance. The combination of the high vacuum setting and smaller cannula size can lead to hemolysis.<sup>107</sup> Optimal cannula placement without chamber collapse or a high-velocity jet at the inflow cannula tip must be confirmed by TEE before leaving the operating room. Anticoagulation to an ACT of 200 seconds is recommended.

Venous inflow must be unimpeded, and outflow grafts must not be kinked. In addition, careful consideration must be given to cannula position when bypass grafts cross the epicardial surface of the heart. Depending on the location of these grafts, these cannulae must be placed such that graft compression cannot occur. The three-dimensional layout of

this geometry must be visualized and thought out in advance, particularly if chest closure is planned. Any graft compression will make recovery unlikely.

It is technically much easier to use cardiopulmonary bypass for placement of these cannulas, although off-pump insertion is possible and may be preferable in certain clinical situations, particularly for isolated right-sided support. A side-biting clamp typically is used on the aorta to perform the outflow anastomosis. If the patient is on cardiopulmonary bypass, the pulmonary artery anastomosis can be done without the need of a partial cross-clamp. The length of the graft is measured from the anticipated skin exit site to the site of anastomosis, and the preclotted Dacron graft is cut to an appropriate length such that there is no excessive tension or any kinking. The cutaneous exit site is planned so that approximately 2 cm of the velour cuff extends from the skin and the remainder is in the subcutaneous tunnel. The cannula is not tunneled subcutaneously until after completion of the anastomosis. For the aortic anastomosis, incorporation of a Teflon or pericardial strip helps to control suture-line bleeding. If an off pump insertion is planned, cannulae must be tunneled before anastomosis.

For atrial cannulation, a double-pledged purse string suture using 3-0 polypropylene is placed concentrically. Tourniquets must be secured firmly to prevent inadvertent loosening of the purse string suture and bleeding from the insertion sites. In addition, the heart, generally, is volume loaded to prevent air embolism during insertion.

For pump inflow, the 36-French malleable cannula is typically used because it provides versatility to accommodate variations in anatomy and clinical conditions. Left atrial cannulation can be achieved via the interatrial groove, the dome of the left atrium, or the left atrial appendage. The right atrial appendage provides the most hemostatic way to cannulate the right atrium because securing ligatures can be placed about the appendage and cannula to afford hemostasis. Alternatively, the body of the right ventricle or left ventricular apex may be cannulated. In the absence of left ventricular clot, the cannula can be introduced through a cruciate-shaped ventriculotomy. Ventricular cannulation offers the advantages of excellent ventricular decompression, which may enhance ventricular recovery. Bleeding in the setting of a recent MI is a consideration, but usually is not a problem if careful reinforced sutures are placed. A purse string of 00 polypropylene suture passed through a collar of bovine pericardium is a helpful hemostatic adjunct in particularly friable ventricles. Additionally, a hand-made or preordered chimney made from a preclotted graft sewn to a felt collar facilitates ventricular cannulation. A "top-hat"-type conduit is constructed and with the "brim" sewn to the left ventricle using mattress sutures. A ventriculotomy is made and a cannula is introduced through the conduit. If recovery occurs, the graft can be stapled to achieve hemostasis. It is simply removed and the site closed or converted to a more formal inlet cannulation if a long-term device must be used.

The consoles for the ABIOMED device are relatively simple to operate. The control system automatically adjusts

the duration of pump diastole and systole primarily in response to changes in preload. Pump rate and flow are visible on the display monitor. With the AB5000, console vacuum is adjusted to the lowest possible setting that provides adequate flow.

**Complications.** A report by Anderson and colleagues looked at the outcomes of patients transferred on the ABIOMED BVS5000, which is no longer being produced, at "spoke" centers and converted to the AB5000 at "hubs." Fifty patients were studied over a 2-year period with a survival to either recovery, transplant, or destination VAD of 42%.<sup>108</sup>

#### THORATEC VENTRICULAR ASSIST DEVICE-TLC

The Thoratec pVAD (Thoratec Laboratories Corp., Pleasanton, CA) was introduced clinically in 1976 under an investigational device exemption and was approved for bridge to heart transplantation in 1995 and postcardiotomy support in 1998, respectively.

The device is a pneumatically driven pulsatile pump that contains two seamless polyurethane bladders within a rigid housing. The inlet and outlet ports contain mono-strut tilting-disk valves to provide unidirectional flow. The effective stroke volume of each prosthetic ventricle is 65 mL. The pneumatic drive console applies alternating negative and positive pressures to fill and empty each prosthetic bladder. Multiple settings can be adjusted to potentially optimize pump filling to provide univentricular (LVAD or RVAD) or biventricular support (BVAD).

Thoratec pumps reside on the upper abdominal wall and are connected to the heart with large wire reinforced cannula. The dual drive console is a large, wheeled pneumatic controller that is used early in the patient's course to optimize VAD parameters. The TLC-II driver is smaller and is approved for out-of-hospital use.

**Cannulation.** Device implantation typically is performed on cardiopulmonary bypass. It is important to select the cannula position and cutaneous exit sites carefully. The pump should be planned to rest on the anterior abdominal wall. Lateral placement may lead to excessive tension at the skin exit sites and prevent formation of a seal. Approximately 1.5 to 2 cm of the felt covering of the cannulas must extend beyond the skin exit site, with the remainder in the subcutaneous tunnel to promote ingrowth of tissue and create a seal. The distance between the inlet and outlet portion of the pump is 4 cm, and the distance between the inlet and outlet cannulas of the pump should be planned accordingly. The cannulae must be long enough to allow for pump connection but should be trimmed to prevent the pump from kinking when the patient sits.

The arterial cannulas are available with a 14-mm graft (for the pulmonary artery) or an 18-mm graft (for the aorta) and must be cut to length after the appropriate exit site has been selected. They come in two lengths, 15 and 18 cm, which again are selected based on the patient's anatomy and the

planned exit site. The graft is generally sewn on the aorta or pulmonary artery after applying a partial-occluding clamp and sewn with 4-0 polypropylene suture with or without a strip of pericardium or Teflon felt for reinforcement. Inflow can be accomplished by cannulation of the atria or the ventricles.<sup>109</sup> All cannulations generally are reinforced with a double layer of pledgeted concentric purse string sutures. For atrial cannulation, a 51-French right-angled cannula is available in two lengths, 25 and 30 cm. For the left atrium, the cannula is inserted through the atrial appendage, the interatrial groove, or the superior dome of the left atrium. For right atrial cannulation, the cannula is inserted ideally into the right atrial appendage and directed toward the inferior vena cava.

Inflow cannulation of the left ventricle is preferred over left atrial cannulation<sup>109</sup> because it provides better drainage, higher flows, and perhaps improves the chance of myocardial recovery. Left ventricular cannulation also decreases the amount of stasis in the LV in the poorly contractile heart, which decreases thrombus formation. Atrially cannulated patients who develop thrombus are at high risk for thromboembolic complication because the ventricle usually continues to eject. Left ventricular cannulation is achieved by placing a concentric layer of pledgeted horizontal mattress sutures at the apex of the left ventricle or the acute margin of the right ventricle (superior to the posterior descending artery). The previously placed sutures are passed sequentially through the cuff, the apex of the heart is elevated, the left ventricle cored, and the cannula seated. The cannula then is inserted and secured by tying the sutures. The free end can then be directed out through the previously planned cutaneous exit site, and a tubing clamp placed to maintain hemostasis until the pump is connected. Connecting the cannulae to the pump is difficult and must be done with care. The connections to the pump have a sharp, beveled edge that should be directed carefully under gentle pressure to fit the cannulas without damaging the inner surface of the tube. In addition, if this tip bends, it may provide a nidus for thrombus formation. Gentle hand pumping can be performed to ensure complete air evacuation using an aortic vent. De-airing of pVADs is best achieved by keeping the heart full and keeping the pumps full at all time.

**Complications.** The complications reported for patients bridged to transplantation are similar to those reported for postcardiotomy patients. In a multicenter trial, the most common complications were bleeding in 42%, renal failure in 36%, infection in 36%, neurologic events in 22%, and multisystem organ failure in 16% of patients.<sup>110</sup> Similar complications have been reported from other centers.<sup>111,112</sup>

**Results.** After cardiotomy, results are similar to those obtained with ECLS and the ABIOMED BVS 5000. In a review of 145 patients with nonbridge use of the Thoratec device, 37% were weaned and 21% were discharged. More experienced centers have achieved hospital survival rates of greater than 40%.<sup>111,112</sup>

The Thoratec premarket approval experience for the treatment of 53 patients with postcardiotomy heart failure had an in-hospital survival of 28%. The majority of these patients were supported with a BVAD.<sup>110</sup> The Bad Oeynhausen group, however, has reported a 60% survival for postcardiotomy patients supported with the Thoratec device.<sup>111,112</sup>

During the era of large pulsatile first-generation VADs, Thoratec pVADs were the main stay of support for smaller individuals needing mechanical support, or for those needing biventricular support as a bridge to transplant. With the advent of smaller continuous flow devices such as the HeartWare HVAD that can support smaller patients and that can be configured for biventricular support, the use of the pVAD has waned. However, these devices are still available and approved for mechanical support of both ventricles and for postcardiotomy support.

## Device Selection

To date, insufficient data exist to recommend one device over another for patients who require temporary mechanical support. Use of a particular device often is based on availability rather than science.

For centers with multiple devices, patient presentation and cardiopulmonary status determine the device selected. Patients undergoing cardiopulmonary resuscitation are best served by urgent femoral cannulation. This avoids the time delay of transportation and sternotomy. Patients with severe hypoxia and lung injury either from aspiration or pulmonary edema benefit from the oxygenation and lung rest provided with ECLS. In all ECLS patients, it is important to adequately lower the left atrial pressure, because hypoxia secondary to continued pulmonary venous congestion precludes weaning of the ECLS circuit. Direct venting of the left ventricle is increasing gaining favor as it not only decompresses the pulmonary bed but it also mitigates formation of LVA thrombus.

For postcardiotomy support, typically patients are supported for 48 to 72 hours while transplant evaluation is completed. Then they are transitioned to a more long-term device if myocardial recovery has failed. This approach avoids high-risk emergency heart transplantation and provides the time necessary for improved organ function.

Biventricular support is often required for fulminant myocarditis. Recovery may be possible, but often requires long-term support with a chronic device.

The TandemHeart with percutaneous transseptal left atrial drainage is a very attractive option for patients sustaining arrest in the catheterization laboratory, but required expertise with transeptal techniques. The Cardiohelp, Impella CP, may and Heart mate PHP also has a role to play in this patient population.

## Patient Management

The ultimate goal is to maintain optimal perfusion of all end organs, to allow time for recovery from an acute hemodynamic insult and prevent further deterioration of organ

function. Ideally, pump flow would achieve a mixed venous saturation of greater than 70%. Low-flow states can often be corrected by intravascular volume expansion. With centrifugal pumps, speed can be adjusted to control flow and allow some degree of cardiac ejection to decrease the likelihood of stasis and intracardiac thrombus formation. Increasing flow rates by using excessive pump speeds can also cause significant hemolysis. Fluid administration to expand intravascular volume is the best way to increase flow. However, right-sided heart failure also may manifest as a low-flow state in the presence of low pulmonary artery pressures. This condition usually requires the institution of right-sided circulatory support and is associated with a lower overall survival.

### VENTILATORY SUPPORT

Peak inspiratory pressures are maintained below 35-cm H<sub>2</sub>O. Inspired oxygen is set initially at 100% with a positive end-expiratory pressure of 5-cm H<sub>2</sub>O. Fractional inspired oxygen then is decreased gradually to less than 50%, with partial pressure of oxygen maintained at between 85 and 100 mm Hg. These measures are instituted to diminish the deleterious effect of barotrauma and oxygen toxicity in the setting of lung injury.

### BLEEDING/ANTICOAGULATION

Anticoagulation should be done judiciously to weigh the balance of excessive risk of bleeding against clot formation in the pump. Platelet counts decrease within the first 24 hours of support; therefore, counts are monitored every 8 hours, and platelets are transfused to maintain counts above 50,000/mm<sup>3</sup> during routine support and above 100,000/mm<sup>3</sup> if bleeding is present. Fresh-frozen plasma and cryoprecipitate are given to control coagulopathy and maintain the fibrinogen concentration at greater than 250 mg/dL and also replace other coagulation factors consumed by the circuit. Anticoagulation is achieved by systemic heparinization with a continuous infusion starting at 8 to 10 µg/kg/h and titrated to maintain the partial thromboplastin time at between 45 and 55 seconds once hemostasis is achieved. In most cases, heparin infusion is started within 24 hours if used in the postcardiotomy setting, but sooner in patients without a sternotomy. One must be constantly vigilant for the signs of tamponade, which is heralded by falling pump flows, falling mixed venous saturation, rising filling pressures, and falling hemoglobin. Every effort must be made to alleviate tamponade and achieve hemostasis before transferring a patient. An ambulance is far less suited to the management of tamponade or ongoing hemorrhage than is the operating room. In reality bleeding is far more of a lethal problem in the first days of support than is thromboembolism, and anticoagulation should be used judiciously.

### FLUID MANAGEMENT

Patients are diuresed aggressively while on support to minimize third-space fluid accumulations. If response to diuretic therapy is suboptimal, we use continuous ultrafiltration or

continuous venovenous hemodialysis. This system permits control over fluid balance that can be adjusted for volume removal and also allows for dialysis as needed.

### NEUROLOGIC MONITORING

Patients are sedated with fentanyl or propofol infusion to maintain comfort. Muscle paralysis is used as needed to decrease the energy expenditure and chest wall stiffness to allow for optimal adjustment of the ventilation parameters. All patients are assessed periodically off sedation to establish neurologic function. Response to simple commands, ability to move all extremities, and spontaneous eye movements are used as gross indications of intact sensorium. A low threshold of obtaining computed tomographic scans of the head is exercised if any change is noted or index of suspicion is high.

### WEANING

A weaning trial is usually attempted after 48 to 72 hours of support. It is critical not to rush weaning and to allow time for myocardial as well as end-organ recovery. The principle of weaning is common to all devices, and all have various controls available that allow reduction in flow, thereby enabling more work to be performed by the heart. Flow is reduced gradually at increments of 0.5 to 1 L/min. Adequate anticoagulation is critical during this low-flow phase to prevent pump thrombosis, and, in general, it is not recommended to reduce flow to less than 2.0 L/min for a prolonged period. We add additional heparin during this period to maintain an ACT of more than 300 seconds. With optimal pharmacologic support and continuous TEE evaluation of ventricular function, flows are reduced while monitoring systemic blood pressure, cardiac index, pulmonary pressures, and ventricular size. Maintenance of cardiac index and low pulmonary pressures with preserved LVF by echocardiography suggests that weaning is likely. A weaning failure manifests as a falling systemic blood pressure along with a drop in cardiac output and rising pulmonary artery pressures. A failed attempt at weaning should result in resumption of full flow. Absence of ventricular recovery after several weaning attempts is a poor prognostic sign. Patients who are transplant candidates undergo a full evaluation and subsequently are staged to a long-term ventricular assist device as a bridge to cardiac transplantation. We and others have found that early conversion to chronic ventricular support is beneficial and improves the low survival that is associated with cardiogenic shock, particularly in the postcardiotomy setting.

### CONCLUSION

Currently a number of options exist for temporary circulatory support, and with advances in technology, the number of devices will expand. Each device has advantages and disadvantages, and to date, none satisfies all the requirements of an ideal device. We have clearly learned many lessons that should direct the development of systems and strategies that maximize survival and reduce complications. In this arena, better understanding of the host inflammatory response,

appreciation of the induced derangement in the coagulation cascade, and development of systems that do not require anticoagulation should improve overall outcomes. In addition, development of therapies that alter reperfusion injury and preserve organ function is important.

Risk analysis also has taught us that patients requiring postcardiotomy support generally fit into a particular profile. Specifically, these are patients who require emergency operations, have poor ventricular reserve, are older, and have extensive atherosclerotic coronary disease and preexisting renal dysfunction. Preoperative awareness should prompt maximization of medical pharmacologic support and a readiness to implement mechanical devices early in the face of cardiac pump failure.

Use of the standard centrifugal pump gradually has fallen out of favor. Use of the Thoratec pVAD has also waned with the emergence of less morbid and more patient-friendly long-term pumps. Traditional ECLS/ECMO has seen a resurgence with smaller more compact systems like the Cardiohelp device. Other centers effectively utilize acute support devices such as the TandemHeart and CentriMag or Impella 5.0. Traditionally, transplantation after transition to long-term LVADs has been the only therapy available for patients supported with acute support devices who have not manifested recovery. Recently improved results have been reported with the use of a continuous-flow pump in stage D heart failure patients who are not transplant candidates.<sup>113</sup> Historically salvage rates for patients in cardiogenic shock, transitioned to destination VADs have been poor, given that typically DT patients are older with more comorbid conditions than patients being bridged to transplantation.<sup>114</sup> Hopefully earlier use of more effective and less morbid acute support devices can improve results in this population.

Recently a consensus statement on the use of percutaneous support devices was generated by both surgical and cardiology authors representing several societies.<sup>3</sup> The take home message of this important manuscript is that patients with cardiogenic shock represent a multidisciplinary challenge and acute support devices play an ever increasing role in the care of these critically ill patients.

## KEY POINTS

1. Recognize cardiogenic shock in the preoperative and postoperative patient.
2. Have available at your institutions at least one of the available temporary support systems.
3. Initiate pharmacologic and first-line mechanical support (IABP) in the shock patient.
4. Attempt to treat the causative issue.
5. Recognize when these conservative methods fail, and act quickly to implement direct cardiac support to restore adequate end-organ perfusion and decompress the heart.
6. Initiate discussions with a center at which advanced heart failure therapies (transplant/long-term VAD) are possible.
7. Stabilize the patient and initiate transfer to a tertiary center for definitive therapy/weaning.

# Myocardial Revascularization with Percutaneous Devices

James M. Wilson • James T. Willerson

At its height, the success of surgical coronary revascularization spurred improvement in catheter-based technology—first for imaging quality, and later for attempted therapy. In 1974, Andreas Gruentzig completed the development of a double-lumen balloon catheter that was miniaturized for use in coronary arteries. Soon afterward, techniques for percutaneous transluminal coronary angioplasty (PTCA) expanded as technical breakthroughs were applied to subselective catheters, devices, guidewires, balloon materials, coronary stents, and circulatory support. Currently, trial evidence attests that percutaneous therapy is useful as a treatment in patients with poorly controlled angina whose anatomy does not imply a survival benefit from revascularization, and for emergency revascularization during ST-segment elevation myocardial infarction (MI). Surgical and percutaneous revascularization, however, cannot be considered equivalent.<sup>1</sup>

## BALLOON ANGIOPLASTY

### Principles

In the early balloon angioplasty era, several technical limitations restricted the use of percutaneous techniques to low-risk patients with proximal, discrete coronary artery stenoses, and procedural outcomes lacked predictability. As advances in tools and techniques were developed, higher-risk patients became candidates for percutaneous therapy. Over time, several principles for safety and success were recognized (Table 19-1).

### Tools

#### GUIDING CATHETERS

Guiding catheters differ from diagnostic catheters in that a wire braid supports a thin catheter wall, allowing for a larger central lumen and providing enough rigidity to support the advance of subselective catheters to the distal regions of the coronary bed. The anatomy of the ascending aorta and the origin of the treated coronary artery determine which shape of guiding catheter will provide the most secure positioning (Fig. 19-1). The choice of guiding catheter often is the deciding factor for success when the arterial anatomy is

challenging or when complications increase procedural difficulty. Guiding-catheter manipulation is a common cause of procedural complications that necessitate the urgent transition to coronary artery bypass surgery.

A recent innovation in guiding catheter technology is the Guideliner®. The Guideliner is a device for subselective

**TABLE 19-1: Principles of Percutaneous Coronary Intervention**

1. The patient's outcome is a function of age, comorbidity, and coronary morphology
2. The procedure's outcome is a function of coronary morphology and proper planning (ie, sequence and equipment choices, such as guidewires and device)
3. Proximal and distal control of the treated vessel must be maintained
  - a. Choose proper guide catheter support
  - b. Maintain distal wire position
  - c. Keep the guide, device, and distal wire tip visible during any movement of any device
4. The needs and limits to treatment options such as devices, adjuvant medical therapy, contrast use, and circulatory support are determined by
  - a. vascular access
  - b. the patient's condition (eg, stable angina or acute myocardial infarction)
  - c. ventricular function
  - d. comorbidities such as diabetes mellitus, renal insufficiency
5. The following factors can lead to failure:
  - a. Incomplete understanding of the three-dimensional anatomy of the course to be taken and lesion to be treated
  - b. Unrealistic interpretation of
    - i. the capacity of available techniques to achieve success
    - ii. the amenability of specific anatomy to percutaneous manipulation
  - c. Ignorance of or inattention to technique in subselective device movement
  - d. Inattention to anticoagulation
  - e. Inattention to catheter hygiene (minimizing blood and contrast stagnation within the guiding catheter or other devices)

intubation of the coronary artery branches or saphenous vein grafts; its design borrows from that of the original Palmaz-Schatz stent platform. Subselective delivery of a catheter at or beyond the origin of a lesion substantially increases the probability of successful stent delivery. Most useful in delivering stents to the obtuse marginal saphenous vein graft, the Guideliner has been used for almost every difficult anatomic variant.<sup>2</sup>

## GUIDEWIRES

When the guiding catheter's position remains secure, the guidewire allows control of the distal vessel. Different wires vary in stiffness, coating, diameter, and design of the distal steering tip. For most procedures, the chosen wire is a 190- to 300-cm monofilament that is 0.0254 to 0.0356 cm in diameter, with either a graded tapering segment welded to the tip

**FIGURE 19-1** Commonly used guiding catheters are shown in the relaxed state (A) and as engaged with the coronary ostia in preparation for PCI: left Judkins (B), left Amplatz (C), XB (extra backup) (D), right Judkins (E), right Amplatz (F), and left coronary bypass (G). PCI = percutaneous coronary intervention. (Reprinted with permission from Cordis Corporation, a Cardinal Health company.)

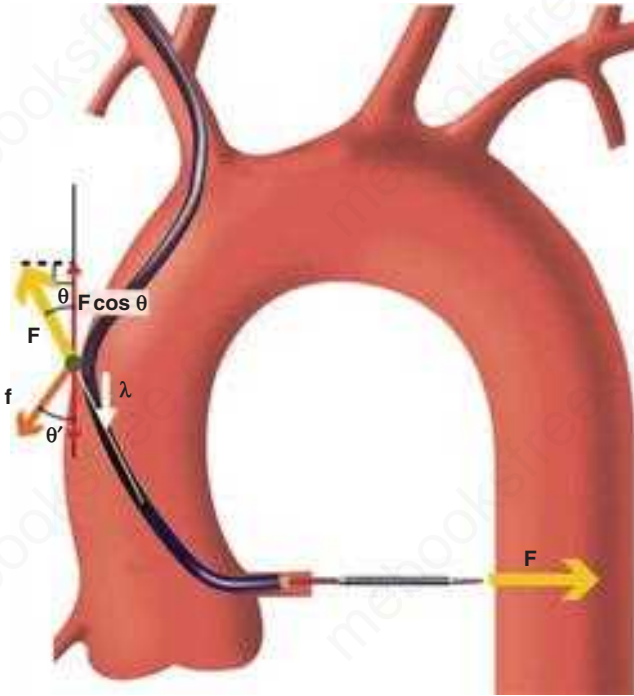

**FIGURE 19-1** (Continued)

or a gradual taper of the monofilament. The central wire core at the tip is “plastic,” or malleable, and may be shaped by the operator. In many wire designs, a wire coil wrapped around the central filament projects a blunter, less traumatic tip to the vessel that it must traverse. Generally, the softest tip is the safest tip. However, in certain situations, such as treatment of a chronic total occlusion, a stiffer wire tip with a bonded, hydrophilic coating, rather than the wire coil, is frequently most effective. Although using these stiffer, “slicker” wires increases the likelihood of crossing the lesion successfully, the wires also increase the risk of complications, such as the creation of a subintimal wire course, the induction of dissection, or the perforation of the vessel (Fig. 19-2).

#### TOOLS FOR LUMEN EXPANSION

Most subselective devices for coronary artery manipulation are balloon inflation catheters or something similar. Balloon catheter designs vary in the placement of the proximal opening of the central lumen. The “on the wire” design has a central lumen that extends the length of the catheter. This design affords the best trackability and capability for maneuvering through difficult anatomy, but it requires an assistant to manipulate the wire during device advance. The “monorail” design has a central lumen, extending only through the distal balloon shaft of the catheter. The remaining catheter shaft communicates only with the balloon lumen. This design,

**FIGURE 19-2** Support for subselective device introduction into the coronary vessels is determined primarily by the shape of the guiding catheter in relation to the anatomy of the ascending aorta and the origin of the left main coronary artery. Shown graphically, advance of the device forces the catheter backward. This movement is opposed by the alignment of the catheter with the coronary artery and by friction developing through contact between the primary curve of the catheter and the opposing wall of the aorta. (Reproduced with permission from Ikari Y, Nagaoka M, Kim JY, et al: The physics of guiding catheters for the left coronary artery in transfemoral and transradial interventions, *J Invasive Cardiol*. 2005 Dec;17(12):636-641.)

though less trackable, allows the procedure to be performed without the need for an assistant.

Properties of the angioplasty balloon include compliance, maximally tolerated pressure, profile, and friction coefficient. Compliance, or growth under pressure, and maximally tolerated pressure are a function of balloon wall thickness and material. Compliance is divided into three categories depending on the growth of the balloon under pressure: noncompliant, semicompliant, and compliant. The thin-walled, compliant balloon has the lowest deflated profile, which allows the device to pass through the most severely occluded vessels. However, the balloon may not expand uniformly or lengthen when exposed to high pressures, such as pressures in excess of 20 atm (15,200 mm Hg), which are required to dilate hard and heavily calcified stenoses or stents. A variety of balloon coatings may be used to reduce the friction coefficient or protect the lumen from abrasion (eg, from passing a stent).

#### ANTITHROMBOTIC THERAPY

During an angioplasty procedure, blood may stagnate in the guiding catheter or near the treated lesion when a wire or

device is placed within the lumen of the target lesion. In addition, metallic components of the guidewire or other devices attract fibrinogen, thus stimulating thrombosis. Therefore, a thrombus may form easily unless prevented with intense anticoagulation therapy (Table 19-2).<sup>3</sup> Most angioplasty procedures are performed with unfractionated heparin (UFH) titrated to an activated clotting time (ACT) value of more than 300 seconds.<sup>4</sup> Alternative anticoagulants, such as low-molecular-weight heparins and direct antithrombin antagonists, may be used.<sup>5-9</sup> Direct thrombin inhibitors may be associated with reduced risk for major bleeding complications but are not reversible in the event that emergency surgical referral is needed.<sup>10</sup> Antiplatelet therapy also reduces the risk of thrombosis at the treated lesion. In addition to aspirin and thienopyridines, glycoprotein IIb/IIIa (GP IIb/IIIa) complex inhibitors may be administered in specific circumstances. The GP IIb/IIIa complex inhibitors are unique in their ability to impair platelet-platelet aggregation, regardless of the type or intensity of stimulus. Anticoagulation is titrated to a lower intensity (an ACT of 200-250 seconds) when GP IIb/IIIa inhibitors are used.

#### Mechanisms

Balloon angioplasty transmits increased intraluminal pressures circumferentially to the rigid intimal surface of the diseased vessel. Because atherosclerotic lesions typically are heterogeneous in their circumferential distribution and physical characteristics, the nondiseased or less diseased wall may be overstretched during balloon inflation. In most instances, the lesion segment with the greatest structural integrity is a focal point for applied stress. Adjacent regions of the vascular wall can shift, and the diseased, inelastic intima can fracture. Although this mechanism allows balloon expansion and an increase in luminal diameter, extension of the fracture into the intima-media border creates a dissection plane, the growth of which is determined by the mechanical characteristics of the lesion and the amount of force applied. If growth of the dissection plane results in significant displacement of the diseased intima, the vessel will close. This event, termed *abrupt* or *acute occlusion*, complicates about 10% of balloon angioplasty procedures. Overstretching the minimally diseased or nondiseased wall without causing plaque fracture typically results in early recoil of the treated lesion to its original state.

After balloon deflation, a small amount of thrombus accumulates, providing the stimulus and framework for colonization by inflammatory cells and myofibroblasts and the eventual, local synthesis of temporary (intimal hyperplasia) and permanent (collagen-rich) connective tissue. In addition, mechanical injury to the media and adventitia results in scar formation. The scar's contracture may reduce vessel cross-sectional area—a phenomenon termed *negative remodeling*.<sup>11,12</sup> During vascular healing, the encroaching intimal hyperplasia that peaks in volume at about 3 months, combined with negative remodeling, results in restenosis after 40 to 50% of balloon angioplasty procedures.<sup>13-15</sup>

**TABLE 19-2: Adjunctive Pharmacologic Therapy for PCI**

Drug	Use	Setting	Dose	Duration of effect	Duration of therapy	Complications
Aspirin	Antiplatelet	All PCI	81 mg	5-7 days	Permanent	GI bleeding
Clopidogrel	Antiplatelet	All PCI	600 mg 6 h before PCI + 75 mg/day afterward	5-7 days	6 mo-1 year	Bleeding TTP (rare)
Prasugrel <sup>3</sup>	Antiplatelet	All PCI	60 mg bolus + 10 mg/day	72 h	6 mo-1 year	Bleeding
Ticagrelor <sup>3</sup>	Antiplatelet	All PCI	180 mg bolus + 90 mg 2/2	48 h	6 mo-1 year	Bleeding Dyspnea
Abciximab	Antiplatelet	ACS	0.25 µg/kg bolus + 0.125 µg/kg/min	72 h	12 h	Bleeding Thrombocytopenia
Eptifibatide	Antiplatelet	ACS	Two 180-µg/kg boluses (10 min apart) + infusion 2 µg/kg/min	4 h	12-72 h	Bleeding
Tirofiban	Antiplatelet	ACS	0.4 µg/kg/min for 30 min, then 0.1 µg/kg/min	4 h	12-72 h	Bleeding
Heparin	Anticoagulation	All PCI	100 IU/kg *60 IU/kg	6 h	During procedure	Bleeding Thrombocytopenia Thrombosis
Bivalirudin	Anticoagulation	UFH alternative	1 mg/kg bolus + 2.5 mg/kg/h for 4 h	2 h	During procedure + 4-6 h if no clopidogrel bolus	Bleeding
Argatroban	Anticoagulation	UFH alternative	350 µg/kg bolus + 25 µg/kg/min	2 h	During procedure + 4-6 h if no clopidogrel bolus	Bleeding
Enoxaparin	Anticoagulation	UFH alternative	1 mg/kg *0.7 mg/kg	6 h	During procedure	Bleeding
Dalteparin	Anticoagulation	UFH alternative	100 IU/kg *70 IU/kg	6 h	During procedure	Bleeding
Acetylcysteine	Contrast nephropathy prophylaxis	GFR < 60 mL/min	600 mg every 12 h	Unknown	Begin 12 h before and continue for 12 h afterward	None
Verapamil/ diltiazem/ nicardipine	Vasodilator	No-/slow-reflow	0.1-0.5 mg IC	20-30 min	As needed	Hypotension Bradycardia
Nitroprusside	Vasodilator	No-/slow-reflow	30 µg IC	30-60 s	As needed	Hypotension
Adenosine	Vasodilator	No-/slow-reflow	50 µg IC	30 s	As needed	Bradycardia

\*Recommended dose in conjunction with glycoprotein IIb/IIIa inhibitor therapy.

ACS = acute coronary syndrome; GFR = glomerular filtration rate; GI = gastrointestinal; IC = intracoronary; mo = month; PCI = percutaneous coronary intervention; TTP = thrombotic thrombocytopenic purpura; UFH = unfractionated heparin.

## Outcomes

In approximately 2 to 10% of balloon angioplasty procedures, intimal dissection, thrombosis, and perhaps medial smooth muscle spasm combine to produce abrupt closure.<sup>16,17</sup> Abrupt closure may be treated successfully with repeat balloon inflation but is treated more commonly with stent implantation.<sup>18</sup> The specter of abrupt closure and MI or emergency bypass surgery and its complications historically has limited the application of balloon angioplasty.

In patients with stable angina, mortality from balloon angioplasty procedures is 1% at 1 month.<sup>19</sup> About half of the deaths are the result of a procedural complication, and most are related to low cardiac output (Table 19-3).<sup>20</sup> Although the incidence of restenosis (>50% diameter stenosis during follow-up) is 40 to 50% within 6 to 9 months of a PTCA procedure,<sup>13,15,21</sup> only 25% of patients report recurrent angina that warrants further investigation.<sup>22</sup> Patients with restenosis have an increased risk of MI and needing coronary artery bypass surgery.<sup>23</sup>

**TABLE 19-3: Causes of Death after Percutaneous Transluminal Coronary Angioplasty<sup>20</sup>**

Low-output failure	66.1%
Ventricular arrhythmias	10.7%
Stroke	4.1%
Preexisting renal failure	4.1%
Bleeding	2.5%
Ventricular rupture	2.5%
Respiratory failure	2.5%
Pulmonary embolism	1.7%
Infection	1.7%

Modified with permission from Malenka DJ, O'Rourke D, Miller MA, et al: Cause of in-hospital death in 12,232 consecutive patients undergoing percutaneous transluminal coronary angioplasty. The Northern New England Cardiovascular Disease Study Group, *Am Heart J*. 1999 Apr;137(4 Pt 1):632-638.

## DEVICE-ASSISTED ANGIOPLASTY

### Stents

The two failure modes of balloon angioplasty—abrupt closure and restenosis—have stimulated the development of a myriad of devices, all intended to reduce procedure-related risk, the risk of restenosis, or both. Only coronary stenting has been shown to be advantageous over balloon angioplasty alone, except in severely calcified lesions (Table 19-4). There are numerous coronary stent designs, but the majority of those in current use consist of a cylinder that is made from stainless steel (or an alloy, such as cobalt chromium) and that has been “carved,” creating a so-called slotted-tube design. Stent expansion creates a series of interlocking cells, resembling a cylindrical mesh-work (Fig. 19-3). Stents are thus deformable, but when expanded, they maintain sufficient rigidity to act as scaffolding after the angioplasty balloon is deflated. Intimal disruption is contained and far less likely to propagate and occlude the treated vessel. In addition, the rigid framework left behind becomes part of the vessel wall, addressing the issue of remodeling, which is one of the mechanisms of restenosis.

Stents allow safe expansion of the vessel beyond that typically achieved with PTCA at the time of balloon expansion;

however, stent use increases the thrombotic and inflammatory responses of the vessel wall. The increased injury and a foreign-body response to stent struts result in a more intense and prolonged local inflammatory response.<sup>24</sup> Consequently, stent placement paradoxically exacerbates intimal hyperplasia.<sup>25,26</sup> If one uses the late (6 or 9 months) loss in lumen diameter after stent implantation as a measure of intimal hyperplasia, even the most modern stent designs fall within a range of about 0.8 mm—more than twice the loss incurred after PTCA (0.32 mm). As a result, with regard to restenosis after angioplasty, the impact of stenting for percutaneous coronary revascularization (PCR) is rather small in comparison with that of PTCA.<sup>25,26</sup> Intimal hyperplasia and restenosis risk are primarily functions of the size of the treated lumen on completion of the procedure, the length of the treated lesion, and the presence of unstable angina, hypertension, and diabetes mellitus (Table 19-5).<sup>27-29</sup> Long-term follow-up studies indicate that a stent that does not reocclude during the first 6 to 9 months after implantation is not subject to late, rapid disease progression.<sup>30-34</sup>

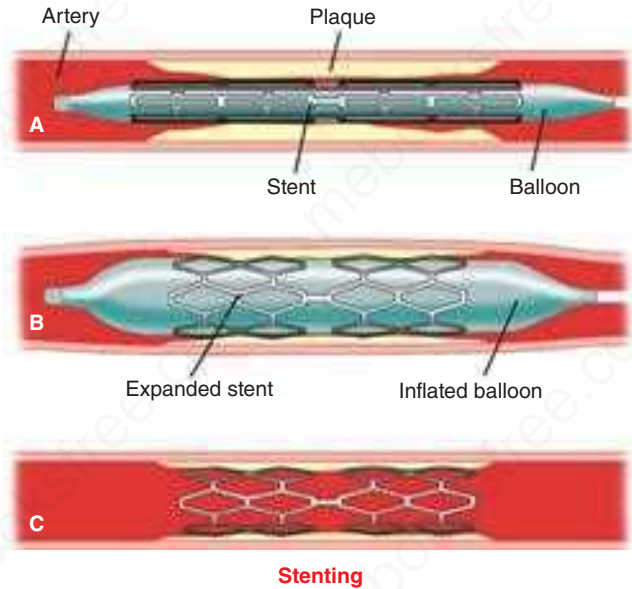

By reducing the likelihood of abrupt closure requiring emergency coronary artery bypass surgery and of restenosis, stent-assisted angioplasty is more effective than routine balloon angioplasty for virtually any type of coronary artery lesion. Registry data describe a risk for emergency surgery of only 0.3 to 1.1% and a procedural mortality of less than 1%.<sup>35-38</sup> The likelihood of procedural complications may be estimated on the basis of lesion characteristics (Table 19-6).<sup>39</sup> Depending on lesion characteristics and the number of lesions treated, after 1 year, 5 to 10% of patients require coronary artery bypass surgery, and 15 to 20% undergo a second percutaneous coronary intervention (PCI) procedure.<sup>40-43</sup> After 5 years, 10 to 15% of patients require another revascularization procedure because of the development of severe stenosis at an untreated site.<sup>34</sup> Diabetes increases the risk for adverse outcomes by increasing the risk of restenosis and disease progression at untreated sites.

As noted previously in the description of the guidewire, iron components of stent struts attract fibrinogen and provide a site for platelet attachment and thrombosis. The increased risk of thrombosis at the treated site persists until endothelialization is complete. As a result, more intense antithrombotic therapy is required during the procedure and for up to 1 year afterward.<sup>44,45</sup>

**TABLE 19-4: Devices Used for Coronary Angioplasty**

	Experience	Ease of use	Complications	Efficacy	Lesion type
Standard balloon angioplasty	++++	++++	+	+++	Any
Cutting balloon	+	++	++	+++	Calcified lesion, ISR, bifurcation
Rotational atherectomy	+++	+	+++	+++	Heavily calcified, nondilatable ISR
Directional atherectomy	+	+	+++	+	Bifurcation, ostial lesion
Laser atherectomy	++	++	++	++	Calcification, ISR, thrombus
Aspiration (mechanical)	++	+	+	++	Thrombus
Aspiration (manual)	+	+++	+	++	Thrombus

ISR = in-stent restenosis.

**FIGURE 19-3** The coronary stent is a metallic “meshwork” that increases its rigidity when cold worked by balloon expansion. But-tressing of the vascular wall, propagation of dissection, and early vascular recoil are reduced significantly. (Used with permission from Texas Heart Institute, www.texasheart.org.)

Stents may be used as a drug-delivery system. However, rather than simply applying a drug to the stent’s surface from which it will dissipate quickly, drug delivery is controlled by using a surface polymer or by altering the design or the material used to construct the stent.<sup>46</sup> This drug-delivery device, called a *drug-eluting stent* (DES), allows the drug to be applied at high concentrations at the site of interest and reduces the probability of systemic toxicity.

DESs reduce the primary determinant of restenosis by 50 to 100%, as determined by measuring late lumen loss after angioplasty (Fig. 19-4). Studies that examined the efficacy of the DES resulted in the introduction of new nomenclature for the follow-up endpoints. The most useful follow-up endpoint is termed *target vessel failure* (TVF), signified by cardiac death, MI, or repeat

**TABLE 19-5: Approximate Risk of Restenosis Stratified by Final Lumen Diameter and Stent Length**

Final lumen diameter (mm)					
	2.0	2.5	3.0	3.5	4.0
<b>Stent length (mm)</b>					
15	32%	22%	14%	8%	4%
30	42%	30%	20%	11%	7%
45	52%	39%	28%	15%	10%
60	60%	47%	35%	20%	13%

Data from de Feyter PJ, Kay P, Disco C, et al. Reference chart derived from post-stent-implantation intravascular ultrasound predictors of 6-month expected restenosis on quantitative coronary angiography, *Circulation* 1999 Oct 26;100(17):1777-1783.

**TABLE 19-6: Risk Factors for Ischemic Events After Stent Placement<sup>39</sup>**

- Strongest correlates**

  - Degenerated SVG
- Moderately strong correlates**
- Length  $\geq 10$  mm
  - Lumen irregularity
  - Large filling defect
  - Calcium + angle  $\geq 45$
  - Eccentric
  - Severe calcification
  - SVG age  $\geq 10$  years

**Outcomes**

Group	Definition	Death/MI/Emergency CABG (%)
Highest risk	Either of the strongest correlates	12.7
High risk	$\geq 3$ moderate correlates	8.2
Moderate risk	1-2 moderate correlates	3.4
Low risk	No risk factors	2.1

CABG = coronary artery bypass graft surgery; MI = myocardial infarction; SVG = saphenous vein graft.

revascularization of the treated vessel. One year after the procedure, the risk of TVF is reduced from 19.4 to 21% with a bare-metal stent (BMS) to 8.8 to 10% with a DES.<sup>40,43,47</sup>

Reduced rates of repeat intervention after DES placement have been reported for every type of lesion studied except bifurcation lesions, for which the risk of restenosis remains significant, and the risk of potentially fatal early thrombosis is as high as 3.5% (Table 19-7).<sup>40,43,48-66</sup> Although the use of a DES reduces the rate of failure of long-term treatment and of repeat

**FIGURE 19-4** The effect of various stents on intimal hyperplasia in randomized trials is shown. A bare-metal stent’s intimal hyperplasia thickness, or late loss, shown on the left, is compared with the late loss of drug-eluting stents shown at the right. BMS, bare-metal stent.

**TABLE 19-7: The Clinical Impact of Drug-eluting Stents**

Population	Endpoint	BMS (%)	DES (%)
Total <sup>40,43</sup>	TVF	20-24.1	9.9-10.8
Diabetes mellitus <sup>60</sup>	MACE 9 mo	27.2-36.3	11.3-15
Insulin-treated <sup>53</sup>	MACE 9 mo	31.5	19.6
Myocardial infarction <sup>65</sup>	TVR 8 mo	32	18

procedures, this reduction does not translate to a reduced risk of procedure-related complications.<sup>67</sup> In addition, incomplete healing, a response to the eluting polymer, or both confer an increased risk of stent thrombosis that extends beyond 1 year.<sup>68</sup> As a result, after intervention with a first-generation DES or in a patient with acute coronary syndrome (ACS), dual antiplatelet therapy should be continued for at least 1 year in all patients and indefinitely in patients with complex lesions. Newer-generation DESs allow for more rapid reendothelialization and a slight increase in late loss without increasing the risk of in-stent restenosis. As a result, the duration of dual antiplatelet therapy can safely be reduced to less than a year. For clinically stable patients, only 6 months of dual therapy is required, which increases the number of patients who may safely receive a DES while facing the prospect of noncardiac surgery in the near future.<sup>69</sup>

## Other Devices

### PERFUSION BALLOONS

Before coronary stents came into routine use, abrupt closure owing to dissection could be treated with repeat balloon inflation and, if that was unsuccessful, with coronary artery bypass surgery. Prolonged balloon inflation generally was necessary for successfully restoring patency, but in the event of failure, transport for emergency surgery often was accompanied by severe ischemia of the treated territory. As a result, balloon catheters with a short third-lumen opening just proximal and distal to the balloon were developed. These catheters, or “perfusion balloons,” allowed prolonged balloon inflation with far less ischemia and could be used to ameliorate ischemia during transport for surgery after an unsuccessful procedure. Since the introduction of the coronary stent, the use of perfusion balloons has become rare.

### ATHERECTOMY

When the concept of reducing the bulk of the obstructing atheroma was first introduced, it was quite attractive.

The idea was to reduce vessel wall thickness, or “debulk,” allowing balloon expansion at a lower pressure. Theoretically, with less force applied for lumen expansion, the likelihood of abrupt closure would be reduced, as would the degree of arterial injury at the time of treatment. Several devices used for debulking have been developed and studied, including directional coronary atherectomy, percutaneous transluminal rotational ablation, and laser ablation. Unfortunately, when subjected to rigorous examination, debulking devices were found to provide no substantial advantage over plain balloon angioplasty in achieving procedural success or avoiding restenosis.<sup>70-73</sup> Although each device has acquired a specific niche (see Table 19-4), their routine use is generally associated with an increased risk of procedural complications, including perforation and MI.<sup>73-75</sup>

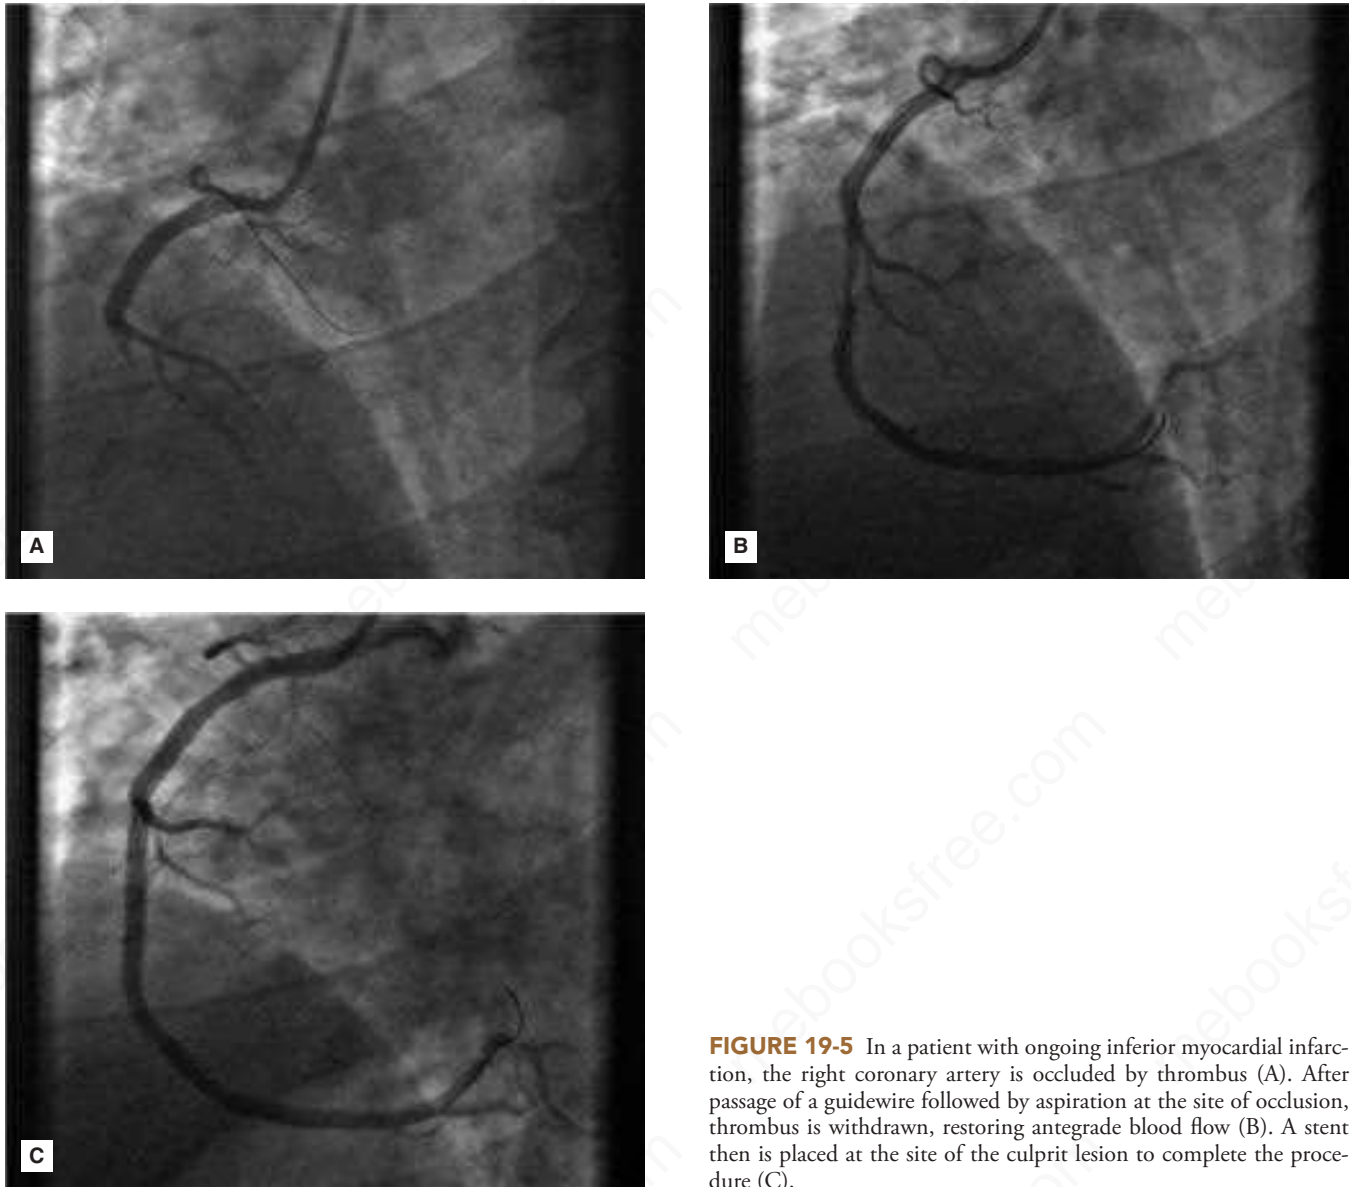

Rotational atherectomy requires additional discussion because unlike the other types of atherectomy, it is still commonly used. The Rotablator (Boston Scientific Corporation, Natick, MA) is an olive-shaped device coated with diamond chips that is attached to an electrical motor that can rotate the device at high speeds. The device is designed to abrade a rigid atherosclerotic intima, creating microemboli that are small enough to pass through the coronary microcirculation without incident. It is also useful as an initial treatment method for very rigid, heavily calcified lesions. However, the concept of rotational atherectomy is not without shortcomings. Microembolization is likely to exacerbate ischemia and therefore is contraindicated when there are thrombotic lesions, if there is impaired microcirculatory flow associated with a recent MI, or if the treated vessel is the last remaining patent vessel. Use of this device is also associated with an increased risk of perforation in highly angulated lesions. Another recently developed form of atherectomy is the single-bladed rotational atherectomy device used for “orbital” atherectomy. This treatment’s place in the PCI armamentarium has not yet been fully determined.<sup>76</sup>

### ASPIRATION DEVICES

Several coronary aspiration devices are available to reduce the risk of distal embolization and to diminish the local concentration of prothrombotic and vasoactive substances. These devices range from a simple end-hole catheter attached to a syringe to a complex suction catheter with or without an associated mechanical disrupter. These devices forcibly extract components of the thrombus or atheroma.<sup>77</sup> Their use may improve flow after the treatment of thrombus-laden lesions or saphenous vein grafts (Fig. 19-5).<sup>78</sup>

### EMBOLIC PROTECTION DEVICES

During balloon angioplasty, mechanical dissolution of thrombus (if any is present) may result in macroembolization and distal vessel occlusion. The high-pressure manipulation of an atheromatous lesion also may free cholesterol crystals and other components of the lesion, resulting in distal microembolization, thrombosis, and slow- or no-reflow phenomenon.

**FIGURE 19-5** In a patient with ongoing inferior myocardial infarction, the right coronary artery is occluded by thrombus (A). After passage of a guidewire followed by aspiration at the site of occlusion, thrombus is withdrawn, restoring antegrade blood flow (B). A stent then is placed at the site of the culprit lesion to complete the procedure (C).

Several devices have been developed to reduce the frequency or impact of distal embolization. These devices may be placed distal or proximal to the treated lesion. Distal devices are mounted on the guidewire and use either a suspended micropore filter to trap particulate matter of 100 to 150  $\mu\text{m}$  or larger or balloon occlusion of the treated vessel with posttreatment aspiration to capture embolized material. Proximally placed devices temporarily interrupt flow and aspirate the treated vessel. The PercuSurge GuardWire Plus (Medtronic, Minneapolis, MN) is a balloon occlusion and aspiration device that underwent testing in vein grafts in the Saphenous Vein Graft Angioplasty Free of Emboli Randomized trial.<sup>79</sup> The trial showed a 42% reduction in creatine kinase (CK) elevations and more than a 50% reduction in the no-reflow phenomenon.<sup>79</sup> Unfortunately, these results did not apply to patients with MI.<sup>80</sup>

## IMAGING DEVICES

Angiography allows imaging of the coronary lumen but may be unreliable in patients with severe calcification, difficult branching patterns, or previously placed coronary stents. Furthermore, a thrombus that may increase the risk associated with PCR may go undetected by standard angiography. Therefore, several alternative imaging methods have been developed to improve diagnosis, to plan revascularization efforts, and to evaluate the success of such efforts. Angioscopy or fiber-optic imaging requires occluding the imaged vessel and perfusing it with saline. Although angioscopy is a useful tool to investigate the presence or components of thrombus within coronary vessels, it has not been a useful adjunct to PCR. In contrast, intracoronary ultrasonography has proved especially useful. Ultrasonography allows accurate

determination of vessel size, luminal reduction, lesion components, and the progress of revascularization attempts. Ultrasound guidance for stent implantation is associated with a greater than 30% reduction in the need for repeat procedures.<sup>81</sup> Of equal importance, intracoronary ultrasonography is an invaluable research tool used to investigate the accuracy of contrast angiography and the impact of mural lesion components on complications and outcomes after angioplasty.

Optical coherence tomography uses the characteristics of light reflection to determine tissue characteristics, providing a visual representation of the interrogated artery that provides information about both anatomy and disease state. It is useful as a research tool, providing extremely accurate tissue thickness measurements, as well as spectacular anatomic images. Unfortunately, at the level of clinical care, optical coherence tomography offers little more information than intracoronary ultrasonography but increases case complexity.<sup>82</sup>

### DEVICES THAT MEASURE LESION SEVERITY

The hemodynamic significance of coronary lesions, the appropriateness of a treatment, and the success of treatment may be determined by one of the following two means: a guidewire that measures the velocity of blood flow within coronary arteries, and a calculation of the pressure distal to a coronary lesion.

A miniaturized Doppler-equipped guidewire with a 12-MHz transducer uses a pulsed interrogation that samples 5.2 mm beyond the guidewire tip at an angle of 14° on either side. Assuming that the cross-sectional area of the interrogated vessel remains constant during all measurements, the ratio of the velocities measured reflects the ratio of blood flow between any two measurements. The most important and reliable parameter that a flow probe measures is the ratio of resting flow to vasodilated coronary flow, a value known as coronary flow reserve. When measured with the Doppler probe, the value is termed coronary velocity reserve (CVR). As a coronary lesion becomes flow limiting, attempts to normalize tissue perfusion by autoregulation result in arteriolar dilatation at rest. Therefore, the administration of an arteriolar vasodilator such as adenosine will have little additional effect on flow velocity. The absence of an appropriate increase in velocity during adenosine- or dipyridamole-induced arteriolar vasodilation produces abnormal flow reserve. A CVR less than 2.0 indicates hemodynamically significant lesions.

The CVR measurement reflects changes in flow relative to an assumed normal baseline state but is subject to error when baseline flow is abnormal. Examples of abnormal states include left ventricular (LV) hypertrophy, fibrosis, and perhaps anemia. In addition, abnormally large or small driving pressure gradients may fall outside the range of normal coronary autoregulation, altering the basal-to-hyperemic ratio. Failure to achieve arteriolar dilatation in response to adenosine or dipyridamole will produce an abnormal calculated flow reserve. Conditions that affect arteriolar dilatation include diabetes mellitus, amyloidosis, and recent caffeine or theophylline ingestion.

An alternative to flow measurement is pressure measurement proximal and distal to the lesion in question. Under normal conditions, epicardial vessels present little detectable resistance to flow. Therefore, driving pressure ( $P_{Ao}$ ) and arteriolar resistance pressure ( $P_{RA}$ ) determine maximal coronary blood flow. The presence of a flow-limiting coronary lesion will cause some of the driving pressure to be lost, so maximal flow will depend on the distal coronary pressure ( $P_d$ )-to- $P_{RA}$  gradient and arteriolar resistance. Therefore, the fraction of maximal basal flow that remains possible in the presence of the lesion is

$$\dot{O}_{\text{lesion}} / \dot{O}_{\text{no lesion}} = (P_d - P_{RA} / R_{\text{basal}}) / (P_{Ao} - P_{RA} / R_{\text{basal}})$$

Canceling resistance and assuming that right atrial pressure remains constant result in a very simple relationship:

$$\dot{O}_{\text{lesion}} / \dot{O}_{\text{no lesion}} = P_d / P_{Ao}$$

This ratio, called the myocardial fractional flow reserve (FFR), is obtained after the administration of adenosine. An FFR of 0.75 or less is used to identify a hemodynamically significant lesion. Routine use of FFR to ensure the necessity of PCI reduces the risk of adverse events, both immediately and 1 year after the procedure.<sup>83</sup>

Physicians who care for patients with coronary artery disease differ widely in their estimates of the severity of a coronary lesion. Fortunately, that conflict can be objectively resolved with FFR. Using FFR to guide revascularization decisions in most cases improves the revascularization decision, helps in assigning the patient the most appropriate care, and reduces the risk of complications and repeat procedures.<sup>84</sup> Absent an alternate physiologic cue for revascularization, FFR should guide the decision in all but the most obvious cases.

### BRACHYTHERAPY

Before the advent of DESs, restenosis after angioplasty or stent implantation could be treated by medical therapy, repeat angioplasty, or coronary artery bypass surgery. The high frequency of restenosis led to a large population of patients with multiple treatment failures, intractable symptoms, and prohibitive contraindications to surgical treatment. Because a proportion of the cell population colonizing a treated lesion and contributing to restenosis arose from the media of the treated lesion, radiation therapy to prevent cell replication was proposed. The well-recognized dangers of high-dose, external-beam radiation limited dosing to local application, but this therapy still was seen as posing a substantial risk. Although radiation brachytherapy is a source of increased adverse events when used as a treatment for de novo coronary lesions, it has been used with some (albeit limited) success to treat refractory in-stent restenosis.<sup>85,86</sup>

### CIRCULATORY SUPPORT

Performing a percutaneous revascularization procedure includes an obligatory period of ischemia in the treated region. The duration of ischemia may be prolonged in the event of abrupt closure or distal embolization, and

**TABLE 19-8: A Score Predicting the Need for Circulatory Support<sup>87</sup>**

Six arterial segments	LAD, D <sub>1</sub> , S <sub>1</sub> , OM, PLV, PDA
Score 1	Target lesion or any additional lesion with >70% diameter stenosis
Score 0.5	Subtended region is hypokinetic but has no stenosis
For a score >3	Consider IABP

D<sub>1</sub> = first diagonal branch; IABP = intraaortic balloon pump; LAD = left anterior descending artery; OM = obtuse marginal branch; PDA = posterior descending artery; PLV = posterior left ventricular artery; S<sub>1</sub> = first septal branch.

recovery may be incomplete or delayed for a period of days, as in the treatment of acute MI. For patients with depressed LV systolic function and for those in whom the treated territory is large, there is a risk for developing cardiogenic shock during and after the procedure. This risk substantially increases the possibility of acute renal failure, stroke, and death. The likelihood of shock complicating an angioplasty procedure may be predicted by using a scoring method that incorporates the extent and severity of systolic dysfunction present before the procedure and the extent that can be expected as a result of the procedure (Table 19-8).<sup>39,87</sup> Elective placement of an intraaortic balloon pump (IABP) is associated with a reduced risk of hypotension and major complications.<sup>88</sup>

The percutaneous left ventricular assist device (pLVAD) is a miniaturized axial-flow pump that is being used increasingly to support patients in shock or during high-risk angioplasty procedures.<sup>89</sup> The pLVAD is capable of providing up to 4 L/min of additional blood flow. The pLVAD and its variants are superior to the balloon pump in providing circulatory support and avoiding flow-related complications. However, complications at the access site and with the flow delivery limit their application to the highest-risk patients for whom we do not have an objective measure (score) to ensure benefit.<sup>90-92</sup>

## COMPLICATIONS

In addition to abrupt closure and restenosis, there are several other potential complications of PCR that may influence the risk-to-benefit ratio for an individual patient. These complications include bleeding, vascular access-site complications, stroke, radiocontrast nephropathy (RCN), and MI owing to distal embolization.

### Hemorrhage

Bleeding that necessitates transfusion or results in hemodynamic instability occurs in 0.5 to 4% of PCR procedures, depending on patient variables (eg, age, gender, presence of peripheral vascular disease), procedural variables (eg, location of femoral arteriotomy, duration), and pharmacologic

variables (eg, intensity of antithrombotic therapy).<sup>4</sup> Several devices have been designed to improve femoral hemostasis after sheath removal, but none has proven superior to standard compression hemostasis.<sup>93</sup> With the availability of lower-profile equipment, the radial artery is being used with greater frequency, which results in a reduction in bleeding and access-site complications.<sup>94,95</sup>

### Ischemia

Stroke complicates approximately 0.18% of PCR procedures.<sup>96</sup> Its occurrence is associated with increased age, depressed LV ejection fraction, diabetes mellitus, saphenous vein graft intervention, and complicated or prolonged procedures requiring the placement of an IABP.<sup>97</sup>

The frequency with which MI complicates PCR procedures depends on the definition of MI.<sup>98</sup> If MI is defined as the presence of new Q wave, the incidence is 1%,<sup>99</sup> whereas if MI is defined as any elevation of the MB fraction of CK (CK-MB), the incidence is as high as 38%.<sup>98</sup> Using more stringent definitions of infarction, such as greater than 3 or 10 times the upper limit of normal, reduces the reported values to 11 to 18% or 5%, respectively.<sup>99-101</sup> Actually, any elevation carries prognostic significance, but elevation above three times the upper limit of normal is accepted as a definition of periprocedural MI.

Elevated markers of myocardial injury may be seen after apparently uncomplicated procedures.<sup>98</sup> One mechanism for such events is microscopic distal embolization. When severe, microscopic distal embolization of a coronary artery creates the angiographic appearance of slow vessel filling, it is termed *no-* or *slow-reflow*. No-reflow is seen most often during saphenous vein graft angioplasty but also may complicate rotational atherectomy and primary PCR for acute MI. Methods of quantifying abnormal flow after PCR include a subjective estimation of flow velocity, the thrombolysis in myocardial infarction (TIMI) flow rate (III, normal; II, slow; I, minimal contrast material flow beyond the treated site; and 0, no flow), and the more objective method of corrected TIMI frame count. Individual frames of the angiographic image are counted from the time of contrast material entry into the treated vessel until a predetermined distal landmark is reached. No-reflow may be a brief and self-limiting phenomenon, but when prolonged, it is associated with increased mortality.<sup>102</sup> Pharmacologic manipulations, including intracoronary verapamil, adenosine, and nitroprusside administration, may be used in an attempt to prevent or treat the no-reflow phenomenon (see Table 19-2).

Perforation of the coronary artery complicates 0.5% of angioplasty procedures,<sup>103</sup> and its frequency increases almost 10-fold when ablation devices are used (1.3% for ablation vs 0.1% for PTCA;  $p < .001$ ). Coronary artery perforation occurs more frequently in elderly and female patients (Table 19-9).<sup>103,104</sup>

Pericardial tamponade is frequently but not invariably associated with coronary artery perforation. The overall incidence

**TABLE 19-9: Coronary Artery Perforations Classified by Severity**

Type	Incidence	Treatment	Mortality
I: A visible extraluminal crater without extravasation*	26%	Nonsurgical 95% of the time	Rarely fatal
II: Pericardial or myocardial blushing*	50%	Requires surgery 10% of the time	13%
III: 1-mm-diameter perforation with contrast material streaming	26%	Requires surgery or covered stent	63%

\*Typically a result of improper guidewire manipulation or placement. See Fig. 19-6.

Modified with permission from Ellis SG, Ajluni S, Arnold AZ, et al: Increased coronary perforation in the new device era. Incidence, classification, management, and outcome, *Circulation* 1994 Dec;90(6):2725-2730.

of tamponade after PCI is 0.12% and doubles when ablation devices are used. Tamponade associated with PCI is recognized 55%<sup>105</sup> of the time during or after the procedure while the patient is still in the catheterization laboratory and 45% of the time after the patient leaves the laboratory.<sup>100</sup> A minority of episodes of late tamponade (13%) are associated with recognized coronary artery perforation. Tamponade requires surgical treatment in 39% of patients, is closely associated with MI complicating PCR, and carries a mortality rate of 42%.<sup>105</sup>

The covered stent that was developed to prevent, but failed to reduce the risk of, saphenous vein graft restenosis<sup>106</sup> currently is used as a rescue device after coronary artery perforation or for the treatment of coronary or saphenous vein graft aneurysms (Fig. 19-7).<sup>107</sup> When a covered stent is used to treat coronary artery perforation, the need for emergency surgery is reduced, as is the risk of coronary artery perforation. A small number of patients, however, still require surgery.<sup>108</sup>

**FIGURE 19-6** In cases of early saphenous vein graft closure with myocardial infarction and postinfarction angina, attempts to access the culprit native vessel with a stiff guidewire have led to coronary perforation. Shown in this injection of the left coronary artery are occlusions of the left anterior descending and left circumflex coronary arteries. Staining is seen (arrows) in the region of the attempted recanalization of the left circumflex coronary artery, indicating perforation (type II). The patient was treated successfully with reversal of anticoagulation and temporary occlusion of the circumflex with the PTCA balloon. PTCA, percutaneous transluminal coronary angioplasty.

## Toxicity

Acute renal failure after exposure to radiocontrast material, or RCN, is poorly understood. Its occurrence is a function of age, congestive heart failure, hemodynamic instability, diabetes mellitus, preexisting renal insufficiency, anemia, peripheral vascular disease, and the amount of contrast material administered.<sup>109-111</sup> The incidence of RCN after

**FIGURE 19-7** A large saphenous vein graft aneurysm (A) is treated with a covered stent (B).

coronary angiography is 5 to 6%, and the nadir of renal function occurs 3 to 5 days after the procedure.<sup>112</sup> Even a transient decline in renal function leads to an increased risk of ischemic cardiovascular events during follow-up, and renal failure necessitating hemodialysis is seen in about 10% of patients with RCN, increasing both short- and long-term mortality.<sup>109,110,113</sup>

The only methods for reducing the risk of RCN are the use of iso-osmolar contrast, volume expansion, and, perhaps, acetylcysteine administration. Using iodixanol, an iso-osmolar nonionic contrast agent, reduces the incidence of RCN after noncardiac angiography.<sup>114</sup> Giving four oral doses of *N*-acetylcysteine (600 mg each; two doses on the day before and two on the day of the procedure) to prevent RCN has had varied outcomes in several studies.<sup>115,116</sup> Administering crystalloid solution in volumes sufficient to maintain brisk urine flow, perhaps aided by alkalinization of urine pH, is the most effective intervention for preventing RCN by ensuring an adequate volume state.<sup>117</sup>

## SPECIAL CIRCUMSTANCES

### Acute Coronary Syndromes

Successful PTCA and stent implantation (in most instances) within the first 6 hours of ST-segment-elevation MI is at least as effective as, and perhaps more effective than, thrombolytic agents in limiting myocardial damage and improving in-hospital survival.<sup>118-120</sup> The routine use of coronary stents for acute MI is associated with a restenosis rate of 17% and a 6-month event-free survival of 83 to 95%.<sup>121-124</sup> The use of DESs reduces the risk of any adverse event from 17 to 9.4% at 300 days.<sup>57</sup> After failed attempts at thrombolysis or for patients with cardiogenic shock who received thrombolysis, stent revascularization increases myocardial salvage and reduces the risk of death, heart failure, or reinfarction.<sup>125-128</sup>

Attempts to reduce the impact of reperfusion injury have been mostly ineffective. However, one remains promising: the occlusion of mitochondrial pores, which allows the release of newly generated oxygen free radicals into the cytosol. Oxygen radicals represent a form of second messenger system inside the cell, triggering inflammatory response, prothrombotic behavior, and apoptosis. Uncoupling these responses has, historically, been the purview of statins and other cholesterol-lowering drugs. However, cyclosporine, typically considered an immunosuppressant, may also be effective in blocking mitochondrial release of oxygen radicals. The results of small, early trials are a source of enthusiasm, but confirmation in larger trials is necessary.<sup>129</sup>

### Previous Coronary Artery Bypass

Stent implantation with the assistance of embolic protection devices is the preferred method for percutaneous treatment of occluded saphenous vein grafts.<sup>79,126</sup> The use of distal embolic protection reduces the risk of periprocedural MI from 14.7 to 8.6%.<sup>79</sup> Unfortunately, diseased grafts have a high probability

of developing new lesions, reducing long-term event-free survival. After stent implantation, overall survival is 79% at 4 years, but survival free of MI or another revascularization procedure is only 29%.<sup>130-134</sup> DESs reduce the risk of restenosis after saphenous vein graft PCR but do not affect the likelihood of disease progression elsewhere in the diseased graft.<sup>52</sup>

## THE FUTURE

The future of interventional cardiology lies in reducing procedural risk and extending treatment durability. For many patients, the goal of providing durable treatment success has been very nearly achieved with the introduction of DESs, an approach that has yet to be fully explored. However, a DES does not reduce procedural risk, and problems remain for patients with diffuse atherosclerosis, diabetes mellitus, bifurcation lesions, and ACSs. In cases in which it is not clear whether PCI or surgical revascularization is more likely to produce a favorable outcome, the Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery (SYNTAX) score can be used to make an objective decision.<sup>135</sup> The original SYNTAX score was developed to quantify—wholly on the basis of angiographic findings—the procedural risk and the odds of long-term success of revascularization by DES placement or surgical procedures. A modified version of the score includes clinical risk factors that appear to add predictive value to that of the anatomic data: LV function, renal function, and lung disease (for the latest version of the SYNTAX score calculator, see <http://syntax-score.com>). Using this combined scoring method, the likely short- and long-term outcomes of both surgical and percutaneous revascularization may be compared objectively to guide the choice of revascularization method. The adoption, utilization, and regular refinement of the SYNTAX score will be difficult but necessary to match the right patient to the right treatment (Table 19-10).<sup>136</sup>

Ironically, the goal of reducing procedural risk has been pursued most effectively for saphenous vein graft

**TABLE 19-10: Factors Used to Compute the SYNTAX Score**

The following characteristics are used to score each coronary lesion with a diameter stenosis of  $\geq 50\%$  in a vessel at least 1.5 mm long:

Dominance (right or left)
Total occlusion
Trifurcation
Bifurcation
Aorto-ostial
Severe tortuosity
Length > 20 mm
Heavy calcification
Thrombus
Diffuse disease

Data from The Syntax Score. TCT2008. Syntax.

revascularization with the development of distal embolic protection devices. However, for native-vessel interventions, particularly those performed during ACSs, further advances will probably be pharmacologic rather than technical. As evidenced by observations of ischemic preconditioning, modification of myocardial energy metabolism with drugs, such as ranolazine and others, represents a means of improving the heart's ability to withstand ischemia, thus temporizing the impact of temporary vascular occlusion and macro- or micro-embolization.<sup>137-139</sup> In addition, inhibitors of the protein kinase family of enzymes, central to intracellular signaling, also may improve the heart's ability to withstand ischemia and reduce the severity of reperfusion injury.<sup>129</sup>

Local drug delivery has been met with great success in reducing the problem of restenosis. However, there are numerous methods of modifying the physiology that drives intimal hyperplasia after stent implantation. New DES platforms offer the alternative of eluting multiple drugs at different rates, thereby reducing the need for systemic medical therapy, such as prolonged dual antiplatelet therapy. In addition, complex molecules that can be absorbed by the body are being developed as stent platforms. The use of a stent that delivers antithrombotic and antiproliferative drugs could conceivably allow PCR protection from acute closure, recoil, thrombosis, and restenosis without contributing to vessel rigidity that increases the difficulty of subsequent procedures.

A growing number of patients who are surviving longer with severe multivessel coronary artery disease remain hampered by severe angina pectoris. In many instances, years of slow, steady disease progression have left extensive collateral vessels that prevent infarction and the near or complete loss of major branch vessels. These patients currently have no option for percutaneous or surgical revascularization. For this population, the use of stem cells, perhaps the most efficient producers of cytokines and growth factors in their proper sequence, has been met with early success. Direct injection of stem cells into regions of ischemic myocardium improves walking time and reduces the frequency of angina attacks.<sup>140</sup>

## KEY POINTS

1. Percutaneous revascularization is best used to control unacceptable symptoms in patients whose anatomy suggests low procedural risk and a good probability of long-term success.
2. Stent implantation substantially improves the safety of PCI, and the use of DESs reduces the likelihood of long-term treatment failure. However, the use of DESs requires that patients be candidates for long-term, dual antiplatelet drug therapy.
3. Measurement of the FFR is crucial for determining the necessity of revascularization. In addition, its routine use for evaluating moderate lesions reduces the risk of major procedural complications compared to angiographic analysis alone.

4. When possible, all saphenous vein graft interventions should be performed with distal protection devices in place.
5. In patients who, for clinical reasons, can be treated by either percutaneous or surgical means, the modified SYNTAX score should be used to ensure an objective decision regarding the most appropriate therapy.

# Myocardial Revascularization with Cardiopulmonary Bypass

Michael H. Kwon • George Tolis, Jr. • Thoralf M. Sundt

Coronary artery disease (CAD) remains the single largest killer of Americans, accounting for almost half a million deaths per year. It imposes a particular burden on the elderly, with more than 80% of all CAD deaths occurring in those over age 65.<sup>1</sup> The magnitude of this impact takes on great significance because it is expected that the number of Americans older than 65 years of age will more than double over the next four decades.<sup>2</sup> If you add to this aging population the anticipated increase in the prevalence of important risk factors for CAD such as diabetes mellitus (DM) and obesity, the population at risk for CAD can only be expected to increase.

Myocardial revascularization represents an effective treatment strategy shown to prolong survival. Techniques of revascularization include percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery, which can be performed with or without cardiopulmonary bypass. Current techniques for CABG can be carried out with low perioperative morbidity and mortality, with excellent long-term outcomes despite an increasing risk profile.<sup>3</sup> CABG surgery with cardiopulmonary bypass remains the standard by which the other techniques (ie, PCI, off-pump CABG, robotic CABG, hybrid revascularization) are measured.<sup>4,5</sup> It is expected that it will continue to be a cornerstone in the management of CAD in the foreseeable future.

## HISTORY OF CORONARY ARTERY BYPASS GRAFTING

The modern era of myocardial revascularization with cardiopulmonary bypass began in 1954 when Dr. John Gibbon reported the development of the cardiopulmonary bypass machine.<sup>6</sup> An additional seminal advance occurred with the development of coronary angiography by Mason Sones at the Cleveland Clinic in 1957, which opened the door to the

elective treatment of coronary atherosclerosis by means of direct revascularization.<sup>7</sup> Initial reports by Rene Favaloro and Donald B. Effler on their techniques to treat clinical events associated with stenotic lesions of the coronary arteries culminated in the first large series of aorto-to-coronary artery venous grafts reported in 1969.<sup>8</sup> Simultaneously Dudley Johnson of Milwaukee published a series of 301 patients in 1969.<sup>9</sup> The success of these techniques was soon demonstrated in larger series initiating the modern era of coronary artery surgery.

## INDICATIONS FOR SURGICAL CORONARY REVASCLARIZATION

The practicing cardiac surgeon is confronted with no clinical question more often than, “Is coronary bypass indicated in this patient?” In brief, the indications established by the American College of Cardiology Foundation and the American Heart Association (ACCF/AHA) consensus panel are based predominantly on the results of trials comparing surgical revascularization with medical therapy for patients with chronic stable angina.<sup>10</sup> Three major historical trials, the Coronary Artery Surgery Study (CASS), the Veterans Administration Coronary Artery Bypass Cooperative Study Group, and the European Coronary Surgery Study (ECSS), demonstrated the greatest survival benefit of revascularization to be among those patients at highest risk of death from the disease itself as defined by the severity of angina and/or ischemia, the number of diseased vessels, and the presence of left ventricular dysfunction.<sup>11-13</sup> Even as the technology and methods for all manner of revascularization strategies improve, the principles established by these seminal trials continue to serve as the basis upon which the results of newer trials designed to study specific populations, clinical scenarios, and anatomic patterns of disease are compared and interpreted.

## Clinical and Laboratory Assessment of Coronary Artery Disease

A surgeon's first introduction to a patient with CAD is frequently a conventional coronary angiogram. Indeed most studies of coronary revascularization have stratified risk and grouped patients according to the number and distribution of coronary lesions. For the purposes of this discussion, and in an effort to be consistent with the large body of literature upon which the current ACCF/AHA guidelines are based, "significant" stenosis is defined as  $\geq 70\%$  reduction in luminal diameter of a coronary artery other than the left main coronary artery (LMCA) for which  $\geq 50\%$  reduction is considered significant.<sup>10</sup> A major development in the last decade in assessing the severity of coronary disease has been the introduction of the SYNTAX score,<sup>14</sup> which is a pure angiographic score of severity and complexity that has recently been validated to correlate with 3-year outcomes in patients with triple vessel and/or main stem disease. It uses dedicated computer software to assign points to each lesion based on length, degree of stenosis, and relation to areas of bifurcation/trifurcation, such that the higher the overall score, the more complex the coronary disease. Although the anatomic distribution and severity of hemodynamically significant coronary lesions determines, in large part, the optimal therapy (CABG, PCI, or medical therapy), the clinical presentation and results of noninvasive studies of myocardial perfusion and function are necessary to characterize the pathophysiologic implications of the angiographic disease and its impact on prognosis and, therefore, to make a clinically appropriate recommendation. In the technological era in which we practice, the importance of the clinical history bears emphasis, particularly in an aging population. Because one of the objectives of surgery is to improve symptoms and quality of life, a thorough appreciation of the patient's functional status is a prerequisite in selecting the optimal therapeutic strategy.

The system proposed by the Canadian Cardiovascular Society for grading the clinical severity of angina pectoris is widely accepted (Table 20-1). Unfortunately, angina is a highly subjective phenomenon for both patient and physician, and prospective evaluation of the assessment of functional

classification by the CCS criteria has demonstrated a reproducibility of only 73%.<sup>15</sup> Furthermore, there may be a strikingly poor correlation between the severity of symptoms and the magnitude of ischemia, as is notoriously the case among diabetic patients with asymptomatic "silent ischemia."

Electrocardiography (ECG), if abnormal, is helpful in assessing ischemic burden. Unfortunately, it demonstrates no pathognomonic signs in half of patients with chronic stable angina. Still the monitoring of an ECG under stress conditions is simple and inexpensive, and is therefore useful as a screening examination. Among patients with anatomically defined disease, stress ECG provides additional information about the severity of ischemia and the prognosis of the disease. The sensitivity of the test increases with age, with the severity of the patient's disease, and with the magnitude of observed ST-segment shift.<sup>16</sup> If ST-segment depression is greater than 1 mm, stress ECG has a predictive value of 90%, whereas a 2-mm shift with accompanying angina is virtually diagnostic.<sup>17</sup> Early onset of ST-segment depression and prolonged depression after the discontinuation of exercise are strongly associated with significant multivessel disease. Unfortunately, many patients cannot achieve their target heart rates owing to beta blockade or a limitation to their exercise tolerance caused by coexisting disease, decreasing the usefulness of this test in these often high-risk patients. Resting abnormalities in the ECG may also limit the predictive accuracy of the test.

Perfusion imaging with thallium-201 or a technetium-99m-based tracer may be particularly useful in patients with abnormalities on their baseline ECG. Reversible defects demonstrated by comparison of images obtained after injection of the tracer at peak stress with rest images is indicative of ischemia, and hence viability. An irreversible defect indicates a nonviable scar. The results obtained with both tracers are similar, with the average sensitivity around 90% and specificity of approximately 75%.<sup>18</sup> For patients unable to exercise, pharmacologic vasodilators such as adenosine or dipyridamole may be used with similar sensitivity.<sup>19</sup>

Echocardiographic imaging during exercise or pharmacologic stress has gained increasing popularity among cardiologists. Comparative studies have demonstrated accuracy similar to that of nuclear studies with sensitivity and specificity both around 85%.<sup>18</sup> Patients unable to exercise may be stressed with high-dose dipyridamole, or more commonly dobutamine at doses from 5 to 40  $\mu\text{g}/\text{kg}/\text{min}$ . An initial augmentation of contractility followed by loss or "drop out" is diagnostic of ischemia (and accordingly viability), whereas failure to augment contractility at low dose suggests scar. Additionally, information regarding concomitant valvular disease may be obtained during the examination.<sup>20</sup>

## Guidelines for Revascularization

In any discussion regarding the discrete indications for coronary revascularization, it is critical to bear in mind that the overarching goal of revascularization is to either improve

**TABLE 20-1: Canadian Cardiovascular Society Angina Classification**

### Canadian Cardiovascular Society

#### Angina Classification

- 0 = No angina
- 1 = Angina only with strenuous or prolonged exertion
- 2 = Angina with walking at a rapid pace on the level, on a grade, or upstairs (slight limitation of normal activities)
- 3 = Angina with walking at a normal pace less than two blocks or one flight of stairs (marked limitation)
- 4 = Angina with even mild activity

symptoms, prolong survival, or, inasmuch as is inextricably tied to both of these goals, to delay and prevent the complications of coronary disease in order to provide improved quality of life over the period of prolonged survival. With this fundamental principle in mind, the guidelines for surgical revascularization established by the ACCF/AHA were significantly revised in terms of organizational structure in 2011 to reflect this understanding (Tables 20-2 and 20-3).<sup>10</sup> These guidelines outline the recommendations regarding whether revascularization is indicated by either CABG or PCI in comparison to medical therapy in specific subsets of patients grouped primarily by the goal of revascularization (either improvement of survival or improvement of symptoms). Indications are then only secondarily stratified by the anatomic pattern and severity of coronary lesions, taking into account the number of involved vessels, involvement of the LMCA, the proximal left anterior descending artery (LAD). Only after these two distinctions are made are the effects of baseline clinical scenario (eg, presence of diabetes, severity of left ventricular dysfunction, presence of unstable angina, non-ST elevation and ST elevation myocardial infarction [MI], and the calculated operative mortality, among others) taken into account to determine the recommendations for specific situations.<sup>21,10</sup> The basis for these guidelines resides in the large body of literature comparing medical therapy with CABG and PCI in patients with stable angina.

Recommendations are categorized into classes whereby Class I denotes that the benefit exceeds the risk and the procedure/treatment should be performed, Class IIa denotes that the benefit likely exceeds the risk and that it is reasonable to administer the treatment, Class IIb may be equivalent to or exceed the risk but additional studies are necessary to confirm, and that the treatment may be considered. Finally Class III represents a recommendation to not perform the procedure or treatment as it is known to have no benefit and in some cases be harmful.<sup>10</sup> Each recommendation is paired with a description of the strength of evidence available to support the recommendation, and ranges from Level A, denoting data derived from multiple randomized controlled trials or meta-analyses, Level B which denotes data from a single randomized trial or nonrandomized studies, and Level C which represents data from just consensus opinions from experts, case studies, and or previously established standard of care.<sup>10</sup>

The complexity of the guidelines reflects the overall complexity and heterogeneity of the patient population presenting with CAD. With the major components of the guidelines summarized at face value in Tables 20-2 and 20-3, this section of the chapter aims to simultaneously deepen and simplify the understanding of these guidelines by (1) providing the historical background from seminal randomized controlled trials and registry studies that provided the basis for how to assign patients with stable angina to surgical revascularization versus PCI or medical therapy, and (2) provide an update on the more recent trials that inform the current guidelines in order to provide a framework for how to approach a patient presenting with CAD today.

## APPROACH TO THE LITERATURE

Before reviewing the results of the seminal trials of CABG versus medical therapy performed in the 1970s and those of newer prospectively randomized trials comparing the results of surgery with PCI and medical therapy, some limitations of these trials and of those that followed must be recognized. First, in retrospective or registry studies, it is difficult to ensure comparable patient populations by virtue of the extraordinary anatomical and physiologic complexity of CAD as well as the heterogeneity of the patient substrate. Differences in ventricular function and comorbidities such as age, diabetes, peripheral vascular disease, and pulmonary disease may have a profound impact on outcomes such as survival or quality of life. For example, caution must be exercised in interpreting the results of nonrandomized and registry reports of PCI versus surgery, because the patients subjected to the former more often have one- or two-vessel disease,<sup>22,23</sup> whereas the latter commonly have three-vessel or left main disease.<sup>22,23</sup> Attempts to correct for selection bias with statistical techniques such as propensity matching are only as valid as the parameters entered into the model. Data less tangible than gender or chronologic age, such as socioeconomic status or “physiologic age,” are not easily accounted for in such analyses and yet may be a critical determinant of outcomes. Despite this limitation, retrospective and registry data provide a better glimpse of the real world of CAD. Most prospective randomized trials include only a fraction of the total population undergoing revascularization by virtue of strict entry criteria. For example, the Bypass Angioplasty Revascularization Investigators (BARI) trial entered only 5% of total patients screened.<sup>24</sup> Although more recent randomized controlled trials of PCI versus CABG have had better yield (41–71%), these studies have focused on specific subset populations including patients with diabetes, and those with three-vessel and/or left main coronary disease.<sup>4,25,26</sup> Therefore, although the prospectively randomized studies do provide objective data directly applicable to the specific patient subset represented in the study, extrapolation of the results to the more heterogeneous populations seen clinically can only be made if the implicit caveats are clearly understood. We must be mindful of the inescapable tradeoff between selection bias in registry studies and entry bias in randomized studies.

Second, as a consequence of the overrepresentation of patients at lowest risk of death in randomized trials, most are statistically underpowered with respect to survival analysis. For example, given current survival statistics, we would need approximately 2000 patients in each arm of a study to detect a 30% difference in mortality. The problem is compounded by the exclusion of the very patients for whom one would anticipate a survival advantage with adequate revascularization, such as those with depressed ventricular function. Randomized studies frequently employ softer endpoints such as angina or quality of life, or create composites of qualitatively different endpoints, such as death, stroke, and MI. Meaningful analysis is further complicated

**TABLE 20-2: 2011 AHA/ACC Guidelines for CABG**
**Revascularization to Improve Survival Compared with Medical Therapy**

Anatomic setting	Class of recommendation	LOE
<b>Unprotected left main or complex CAD</b>		
CABG and PCI	I—Heart Team approach recommended	C
CABG and PCI	IIa—Calculation of STS and SYNTAX scores	B
<b>Unprotected left main*</b>		
CABG	I	B
PCI	IIa—For SIHD when both of the following are present: <ul style="list-style-type: none"> <li>Anatomic conditions associated with a low risk of PCI procedural complications and a high likelihood of good long outcome (eg, a low SYNTAX score of <math>\leq 22</math>, ostial or trunk left main CAD)</li> <li>Clinical characteristics that predict a significantly increased risk of adverse surgical outcomes (eg, STS-predicted risk of operative mortality <math>\geq 5\%</math>)</li> </ul>	B
	IIa—For UA/NSTEMI if not a CABG candidate	B
	IIa—For STEMI when distal coronary flow is TIMI flow grade $< 3$ and PCI can be performed more rapidly and safely than CABG	C
	IIb—For SIHD when <i>both</i> of the following are present: <ul style="list-style-type: none"> <li>Anatomic conditions associated with a low-to-intermediate risk of PCI procedural complications and an intermediate to high likelihood of good long-term outcome (eg, low-to-intermediate SYNTAX score of <math>&lt; 33</math>, bifurcation left main CAD)</li> <li>Clinical characteristics that predict an increased risk of adverse surgical outcomes (eg, moderate–severe COPD, disability from prior stroke, or prior cardiac surgery; STS-predicted risk of operative mortality <math>&gt; 2\%</math>)</li> </ul>	B
	III: Harm—For SIHD in patients (vs performing CABG) with unfavorable anatomy for PCI and who are good candidates for CABG	B
<b>Three-vessel disease with or without proximal LAD artery disease</b>		
CABG	I	B
	IIa—It is reasonable to choose CABG over PCI in patients with complex three-vessel CAD (eg, SYNTAX $> 22$ ) who are good candidates for CABG	B
PCI	IIb—Of uncertain benefit	B
<b>Two-vessel disease with proximal LAD artery disease</b>		
CABG	I	B
PCI	IIb	B
<b>Two-vessel disease without proximal LAD artery disease</b>		
CABG	IIa—With extensive ischemia	B
	IIb—Of uncertain benefit without extensive ischemia	C
PCI	IIb—Of uncertain benefit	B
<b>One-vessel proximal LAD artery disease</b>		
CABG	IIa—With LIMA for long-term benefit	B
PCI	IIb—Of uncertain benefit	B
<b>One-vessel disease without proximal LAD artery involvement</b>		
CABG	III: Harm	B
PCI	III: Harm	B
<b>LV Dysfunction</b>		
CABG	IIa—EF 35 to 50%	B
	IIb—EF $< 35\%$ without significant left main CAD	B
PCI	Insufficient data	
<b>Survivors of sudden cardiac death with presumed ischemia-mediated VT</b>		
CABG	I	B
PCI	I	C
<b>No anatomic physiologic criteria for revascularization</b>		
CABG	III: Harm	B
PCI	III: Harm	B

\*In patients with multivessel disease who also have diabetes, it is reasonable to choose CABG (with LIMA) over PCI (Class IIa/LOE B). CABG, coronary artery bypass graft; CAD, coronary artery disease; COPD, chronic obstructive pulmonary disease; EF, ejection fraction; LAD, left anterior descending; LIMA, left internal mammary artery; LOE, level of evidence; LV, left ventricular; PCI, percutaneous coronary intervention; SIHD, stable ischemic heart disease; STEMI, ST-elevation myocardial infarction; STS, Society of Thoracic Surgeons; SYNTAX, Synergy Between Percutaneous Coronary Intervention With Taxus and Cardiac Surgery; TIMI, Thrombolysis in myocardial infarction; UA/NSTEMI, unstable angina/non-ST-elevation myocardial infarction; UPLM, unprotected left main disease; VT, ventricular tachycardia.

**TABLE 20-3: 2011 AHA/ACC Guidelines for CABG**

**Revascularization to Improve Symptoms with Significant Anatomic ( $\geq 50\%$  Left Main or  $\geq 70\%$  Non-Left Main CAD) or Physiological (Fractional Flow Reserve  $\leq 0.80$ ) Coronary Artery Disease**

Clinical setting	Class of recommendation	LOE
<b><math>\geq 1</math> significant stenoses amenable to revascularization and unacceptable angina despite GDMT</b>		
CABG	I	A
PCI	I	A
<b><math>\geq 1</math> significant stenoses and unacceptable angina in whom GDMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences</b>		
CABG	IIa	C
PCI	IIa	C
<b>Previous CABG with <math>\geq 1</math> significant stenoses associated with ischemia and unacceptable angina despite GDMT</b>		
PCI	IIa	C
CABG	IIb	C
<b>Complex three-vessel CAD (eg, SYNTAX score <math>&gt; 22</math>) with or without involvement of the proximal LAD artery and a good candidate for CABG</b>		
CABG	IIa—CABG preferred over PCI	B
<b>Viable ischemic myocardium that is perfused by coronary arteries that are not amenable to grafting</b>		
Transmyocardial laser Revascularization (TMR)	IIb—TMR as an adjunct to CABG	B
<b>No anatomic or physiologic criteria for revascularization</b>		
CABG	III: Harm	C
PCI	III: Harm	C

CABG, coronary artery bypass graft; CAD, coronary artery disease; GDMT, guideline-directed medical therapy; PCI, percutaneous coronary intervention.

by relatively short-term follow-up in most studies. Events such as the need for subsequent revascularization and recurrence of angina characteristically occur at different time intervals after these therapies (restenosis after PCI vs graft occlusion after CABG), and an 8- to 10-year follow-up period is needed to adequately compare long-term results. Patients themselves are also generally interested in outcomes measured in years, not months.

Significant improvements in each of the treatment strategies for CAD are occurring constantly. Examples include the increased use of antiplatelet agents, angiotensin-converting enzyme inhibitors, lipid-lowering therapy, internal thoracic aortic (ITA) grafts, and drug-eluting stents (DESs). These advances, along with aggressive secondary prevention after revascularization, have steadily reduced the morbidity and mortality of CAD in all patients, making differences in the hard endpoint of survival difficult but not impossible to demonstrate for any therapy.<sup>27</sup> This trend will likely increase as the beneficial effect of secondary prevention becomes more widely appreciated.

## Comparative Trials of Revascularization versus Medical Therapy in Stable Angina

### MEDICAL THERAPY

In the decades since CABG surgery was popularized and coronary angioplasty introduced, an enormous volume of data on the results of invasive revascularization has been collected. Remarkably, almost from the outset many of these studies have been prospectively randomized. Yet in the current era there is a dearth of data concerning pharmacologic therapies for chronic CAD despite remarkable recent drug development. For example, although nitrates are unquestionably effective in relieving symptoms, the impact of long-acting nitrates on clinical outcomes has never been rigorously tested. Furthermore, there has been only one trial of beta-blocker therapy in the treatment of angina, the Atenolol Silent Ischemia Study, which demonstrated benefit for patients with mild effort induced angina or silent ischemia.<sup>28</sup> There remain no randomized studies examining the impact of beta blockers on survival on patients with stable angina. The only evidence for improved survival with beta-blocker use comes from one recent registry study demonstrating a statistically insignificant trend toward improved survival for post-MI patients who received beta blockers.<sup>29</sup> A handful of studies of combination therapy with beta blockers and calcium channel blockers have also demonstrated antianginal benefit, but again without any evidence that there is any impact on survival.<sup>30-32</sup>

### SURGICAL VERSUS MEDICAL THERAPY

Three major randomized studies, the CASS,<sup>12</sup> the Veterans Administration Cooperative Study Group (VA),<sup>13,33</sup> and the ECSS,<sup>34,35</sup> as well as several other smaller randomized trials,<sup>36-38</sup> conducted between 1972 and 1984, provide the historical foundation for comparing the outcomes of medical and surgical therapy. Despite the limitations noted in the preceding, these studies are remarkably consistent in their major findings, and the qualitative conclusions drawn from them continue to be generalizable to current practice.

The central message from all of these studies is that the relative benefits of bypass surgery over medical therapy on survival are greatest in those patients at highest risk as defined by the severity of angina and/or ischemia, the number of diseased vessels, and the presence of left ventricular dysfunction.<sup>39</sup> For example, thus far, no study has shown survival benefit for CABG over medical therapy for patients with single-vessel disease not involving the proximal LAD. Accordingly, the current guidelines recommend that CABG be performed on a Class I recommendation for all unprotected left main disease,<sup>39-41</sup> three-vessel disease,<sup>35,39,42-44</sup> and two-vessel disease with proximal LAD disease,<sup>35,39,42-44</sup> but only with a Class IIa recommendation for two-vessel disease without proximal LAD involvement if extensive ischemia exists,<sup>45</sup> and one-vessel proximal LAD disease.<sup>10,46,47</sup> It should be emphasized, however, that these trials involved primarily patients with moderate chronic stable angina. These conclusions may, therefore, not necessarily apply to patients with

unstable angina or to those with more severe degrees of chronic stable angina.

A landmark meta-analysis by Yusuf et al, of the seven randomized trials cited in the preceding demonstrated a statistically enhanced survival at 5, 7, and 10 years, for surgically treated patients at highest risk (4.8% annual mortality) and moderate risk (2.5% annual mortality), but no evidence of a survival benefit for those patients at lowest risk.<sup>39</sup> The overall survival benefit at 12 years for the three large and four smaller randomized studies is shown in Fig. 20-1. Nonrandomized studies have also demonstrated a beneficial effect of surgery on survival of patients with multivessel disease and severe ischemia regardless of left ventricular function.<sup>25-28</sup>

Following this, between 1997 and 2004, there were three randomized controlled trials of invasive revascularization by PCI or CABG versus medical therapy. Their results make an even stronger case for revascularization. In the Asymptomatic Cardiac Ischemia Pilot (ACIP) trial, patients with anatomy amenable to CABG were randomized to angina-directed antiischemic therapy, drug therapy guided by noninvasive measures of ischemia, or revascularization by CABG or PCI.<sup>45</sup> At 2 years, there was a statistically significant difference in mortality of 6.6% in the angina-guided group, 4.4% in the ischemia-guided group, and 1.1% in the revascularization group. The rates of death or MI were also statistically different at 12.1%, 8.8%, and 4.7%, respectively, that is, both symptoms and survival were improved with revascularization. The Medicine, Angioplasty, or Surgery Study (MASS-II) trial randomized patients with multivessel disease among medical therapy, PCI, and CABG.<sup>48,49</sup> Although survival at 1 year was equivalent, freedom from additional intervention was 99.5% for surgical patients and 93.7% for medically treated patients. Reintervention was, incidentally, even higher in the PCI group than the medical group, with 86.7% free of additional intervention. Angina was superior in the CABG

**FIGURE 20-1** Survival (mortality) curves for all medically and surgically treated patients with chronic stable angina enrolled in seven prospective randomized controlled trials. (Reproduced with permission from Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass graft surgery on survival: overview of 10-year results from randomised trials by the Coronary Artery Bypass Graft Surgery Trialists Collaboration, *Lancet*. 1994 Aug 27;344(8922):563-570.)

group (88%) than in the PCI group (79%) or medical therapy group (46%). Meanwhile the 10-year survival rates were 74.9% with CABG, 75.1% with PCI, and 69% with MT.<sup>49</sup> In the Trial of Invasive versus Medical Therapy in Elderly Patients with Chronic Symptomatic Coronary-Artery Disease (TIME) study, elderly patients were studied with chronic angina. This failed to demonstrate a difference between optimized medical therapy and an invasive revascularization strategy (PCI or CABG) in terms of symptoms, quality of life, and death or nonfatal MI (20% vs 17%,  $p = .71$ ). However, medically treated patients were at higher risk because of major clinical events (64% vs 26% for invasive,  $p < .001$ ), which were mainly attributable to rehospitalization and revascularization.<sup>50</sup> In this trial of severely symptomatic elderly patients, it was encouraging that the price of an initially conservative strategy, followed by crossover to revascularization in approximately 50% of patients, was not paid for in terms of death or MI.<sup>50</sup>

Early historical concern over a prohibitive operative mortality among patients with impaired ventricular function has been superseded by the recognition that the survival of these patients on medical therapy was much worse than their survival with revascularization. This, coupled with ever-improving surgical techniques, such as advances in myocardial preservation and perioperative support, has made this specific subgroup the one in which the relative survival benefit of surgical therapy is the greatest. Accordingly, *left ventricular dysfunction in patients with documented ischemia is now considered an important indication*—rather than contraindication—for surgical revascularization.<sup>10,12,39,51-53</sup> More recently, the Surgical Treatment for Ischemic Heart failure (STICH) trial was conducted to better evaluate the effect of CABG plus optimal medical therapy to optimal medical therapy alone, an effect that the trial investigators perceived to not have been well-established by the studies referenced above considering (1) the general exclusion of patients with severe left ventricular dysfunction in the three landmark trials from the 1970s and (2) the improvements in both medical and surgical therapy that had developed since then.<sup>53</sup> The study of 1212 patients with an ejection fraction (EF) less than 35% and CAD amenable to CABG demonstrated a nonsignificant trend toward decreased mortality from any cause in the CABG group (36%) compared to the medical therapy group (41%). The trial has been criticized for being underpowered, and with just 56 months of mean follow-up and a large percentage of patients in the medical therapy group crossing over into the CABG group (17%) during the study period thereby potentially diminishing the statistical impact of CABG, many have interpreted this to represent evidence that the presence of left ventricular dysfunction remains an important indication to perform CABG for survival benefit. Indeed, the ACCF/AHA guidelines consider left ventricular (LV) dysfunction to represent a Class IIa recommendation for performing CABG if the EF is 35 to 50%, but only Class IIb recommendation if the EF is <35%, in part based on the results of the STICH trial.<sup>10</sup> In addition, recent evidence that ischemic, viable, hypokinetic myocardium (hibernating or stunned) regains

stronger contractile function after effective revascularization, has prompted expansion of the indications for surgical revascularization among patients with severe left ventricular dysfunction to include patients who would otherwise be considered candidates for cardiac transplantation.<sup>54</sup> This subject is discussed in more detail in the following.

In summary, the current guidelines recommend on the basis of a survival advantage that CABG be performed instead of medical therapy alone on a Class I recommendation for all unprotected left main disease,<sup>39-41</sup> three-vessel disease with or without proximal LAD involvement,<sup>35,39,42-44</sup> and two vessel-disease with proximal LAD disease<sup>35,39,42-44</sup>; with a Class IIa recommendation for two-vessel disease without proximal LAD involvement but with the presence of extensive ischemia,<sup>45</sup> one-vessel proximal LAD disease,<sup>10,46,47</sup> and moderate LV dysfunction (EF 35-50%)<sup>39,54-57</sup>; and with a Class IIb recommendation for two-vessel disease without proximal LAD disease or extensive ischemia,<sup>44</sup> and in patients with severe LV dysfunction (EF < 35%)<sup>39,53-57</sup> (Fig. 20-2).

Apart from affording a survival benefit, CABG is also indicated for the relief of angina pectoris and improvement in the quality of life. Between 80 and 90% of patients who are symptomatic on medical therapy become symptom-free after

CABG in the early period while approximately 60% remain symptom-free at up to 10 years.<sup>49</sup> This benefit extends to low-risk patients for whom survival benefit from surgery is not likely.<sup>39</sup> Thus, for example, whereas on the basis of a survival advantage alone CABG is only indicated for one-vessel disease if the vessel involved is the left main (Class I) or the proximal LAD (Class IIa), a symptomatic patient with single-vessel disease in any anatomic position represents a Class I, Level A indication to perform either CABG or PCI on the basis of symptom improvement (Fig. 20-2).<sup>10,49,50,58-60</sup> Consensus agreement by the ACC/AHA recommends on a Class IIa basis CABG is recommended for patients with at least one significant coronary lesions in any position and unacceptable angina (1) for whom guideline-directed medical therapy (GDMT) cannot be implemented because of medication contraindications, adverse effects, or patient preferences; and (2) complex three-vessel CAD (eg, SYNTAX score > 22) with or without involvement of the proximal LAD and a good candidate for CABG (CABG preferred over PCI in this situation).<sup>10,44,61-63</sup> Relief of symptoms appears to relate to both the completeness of revascularization and maintenance of graft patency, with the benefit of CABG diminishing with time. Recurrence of angina following CABG surgery occurs at rates of 3 to 20% per year. Although enhanced survival is reported when an ITA graft is used to the LAD, there is no significant difference in postoperative freedom from angina.<sup>46,47</sup> This may be because of vein graft occlusion or progression of native disease in grafted or ungrafted vessels.<sup>13</sup>

Unfortunately, few patients experience an advantage in work rehabilitation with surgery as compared with medical management. Generally, employment declines in both groups and is determined nearly as much by socioeconomic factors as age, preoperative unemployment, and type of job as by type of therapy or clinical factors such as postoperative angina. Notably, surgical revascularization has not been shown to reduce the incidence of nonfatal events such as MI, although this may be because of perioperative infarctions that offset the lower incidence of infarction in each study follow-up.<sup>64,65</sup>

PCI VERSUS MEDICAL THERAPY

PCI continues to evolve as a therapy from its historical roots as a procedure entailing balloon angioplasty alone, followed by the introduction of bare metal stents (BMSs), and subsequently DESs. Despite this evolution and the attendant reduction in overall in-stent restenosis rates in the DES era, and despite a multitude of evidence in both early and more recent trials demonstrating the ability of PCI to effectively reduce the incidence of angina compared to medical therapy in patients with stable ischemic heart disease, there remains no definitive evidence in any study to date that PCI improves survival rates or rates of subsequent MI in this patient population.<sup>43,60,66-71</sup>

It is worth describing the specifics of several representative studies on patients with multivessel disease. In the Randomized Intervention Treatment of Angina (RITA)-2, of 1018 patients with stable angina randomized to medicine

**FIGURE 20-2** Extension of survival in months for various subgroups of patients with chronic stable angina treated by surgery as compared with those treated by medicine in seven prospective randomized controlled trials. (Reproduced with permission from Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass graft surgery on survival: overview of 10-year results from randomised trials by the Coronary Artery Bypass Graft Surgery Trialists Collaboration, *Lancet*. 1994 Aug 27;344(8922):563-570.)

or PCI, one-third had two-vessel disease and 7% had three-vessel disease.<sup>59</sup> Perhaps surprisingly, at a median follow-up of 2.7 years, the primary endpoints of death or MI had occurred twice as often in the PCI group (6.3 vs 3.3%,  $p < .02$ ). Surgical revascularization was required during the follow-up interval in 7.9% of the PCI group and repeat angioplasty was required in 11%. In the medical group, 23% of patients required revascularization. Angina relief and exercise tolerance were improved to a greater degree in the angioplasty group early, but this difference disappeared by 3 years. These results are echoed in the MASS-II trial, in which angina relief was superior with PCI, but rates of intervention/reintervention were actually higher in the PCI group.<sup>48,49</sup> This supports an initial strategy of medical therapy in patients with stable ischemic heart disease.

More recently, the COURAGE trial randomized 2287 patients with stable angina and objective evidence of ischemia to contemporary medical therapy or PCI and medical management (3% of the stents used were DESs). All patients received long-acting metoprolol, amlodipine, and/or isosorbide mononitrate, as well as lisinopril or losartan. Patients had aggressive antilipid therapy and appropriate antiplatelet therapy. The primary finding of this trial was a lack of benefit of PCI over best medical therapy for death, MI, or other major cardiovascular events.<sup>60</sup> Although this result has caused much controversy in the cardiology community, it is consistent with older studies.

A meta-analysis of percutaneous interventions versus medical management was published in 2005.<sup>68</sup> In patients with stable CAD, no benefit was found for invasive therapy in terms of death, MI, or need for subsequent revascularization. In 2014, Windecker et al performed a large scale meta-analysis of 100 trials comparing both CABG and PCI to medical therapy found that patients who received new generation everolimus- and zotarolimus-based (Resolute) DESs but not older generation DESs (sirolimus, paclitaxel, and Endeavor zotarolimus), BMSs, or balloon angioplasty alone, had reduced mortality compared to medical therapy.<sup>71</sup> However, given the limitations of this study, including the inclusion of only one trial comparing newer generation DESs to medical therapy and absence of individual patient data, the general consensus remains that unless and until further evidence is collected to the contrary, all patients with stable coronary disease should have a trial of optimized medical therapy before invasive intervention in the form of PCI. Accordingly there are no Class I recommendations for PCI in the setting of stable ischemic heart disease in the 2011 ACCF/AHA guidelines.<sup>10</sup> Based on subgroup analysis from the SYNTAX trial (discussed further in the next section), however, it is recommended on a Class IIa basis for stable ischemic heart disease patients with unprotected left main disease for benefit if they meet the following criteria: (1) anatomic conditions associated with a low risk of PCI complications and have a high likelihood of good long-term outcome; for example, low SYNTAX score  $\leq 22$ , ostial or trunk left main CAD; and (2) clinical characteristics that impart a high risk of

morbidity and mortality with CABG (eg, Society of Thoracic Surgeons (STS)-predicted mortality  $> 5\%$ ).<sup>72</sup>

## PCI VERSUS CABG

**Randomized Studies.** A number of studies comparing an initial strategy of angioplasty versus early surgery have been carried out, all with similar results. It is important to recognize that, as a rule, these studies are comparisons of treatment strategies and not head-to-head comparisons of revascularization techniques. Accordingly, crossover is permitted and endpoints are selected to determine adverse consequences of the algorithm on an “intention to treat” basis.

Most early trials of CABG versus PCI have in common that PCI was performed first in the form of balloon angioplasty alone, followed by those including BMS deployment with angioplasty. In all, over 20 randomized controlled trials comparing CABG with PCI in the form of angioplasty or BMS implantation have been conducted, and on this basis the following conclusions were made by Bravata et al<sup>73</sup> in a recent systematic review and cited in the establishment of the ACC/AHA 2011 guidelines:<sup>10</sup> (1) Survival is similar after CABG and PCI at both 1 year and 5 years, (2) incidence of MI was similar at 5 years after randomization, (3) CABG produced more effective relief from angina than with PCI at 1 and 5 years, and (4) repeat coronary revascularization was less frequent after CABG than after PCI. In other words, at least in the early era of PCI, CABG appears to have a benefit over PCI only insofar as it improves symptoms and reduces the need for repeat coronary revascularization, but without any improvement in overall survival or incidence, which reflects the results of even the earliest studies ever conducted on this topic, beginning with the 1994 Swiss trial of just 134 patients<sup>74</sup> and both the MASS<sup>75,76</sup> and MASS-II<sup>48,49</sup> trials. The oft-quoted BARI, Emory Angioplasty versus Surgery Trial (EAST), RITA, CABRI, and GABI multivessel PCI versus CABG surgery trials,<sup>77-81</sup> with only a few nonreproducible exceptions, generally support the same conclusions above.

Most of the early studies quoted above share the limitation that, in general, only a very small minority of patients undergoing revascularization at any center were entered into these trials.<sup>82,83</sup> Accordingly, the populations included in the trials may not be generally reflective of clinical practice. For instance, few patients in these studies had significant LV dysfunction and most randomized patients had only one- or two-vessel disease. In the RITA trial, approximately one-third of patients had single-vessel disease.<sup>77</sup> Among clinically eligible patients in the BARI<sup>80,84</sup> and EAST<sup>81</sup> trials, approximately two-thirds of patients were excluded on angiographic grounds that included chronic total occlusion, LMCA stenosis, diffuse disease, or other anatomical factors making PCI potentially dangerous. Consequently, these randomized trials contain only a portion of the spectrum of patients with CAD encountered clinically. Entry bias has a significant impact on the likelihood of observing an outcome difference among therapies. Because a high proportion of the randomized patients are in the low-risk group, it is possible that any potential survival

benefit of CABG surgery over PCI in high- and moderate-risk groups may be masked.<sup>83</sup>

A second consideration in evaluating these studies is that the success of revascularization procedures depends not only on the criteria employed to define success, but also on the interpretation of those criteria by both patient and physician. In the 1985 to 1986, National Heart, Lung, and Blood Institute PCI Registry, 99% of patients were discharged alive from hospital, and 92% did not sustain a MI or require CABG surgery.<sup>85</sup> In the BARI trial, 99% of patients survived hospitalization and 88.6% of PCI-treated patients did not have MI or require repeat revascularization by angioplasty or surgery during the initial hospitalization.<sup>80</sup> Employing event-free criteria (death, MI, CABG) for the initial hospitalization, PCI can be judged successful. However, if a repeat revascularization procedure within 5 years is regarded as a negative outcome, then far fewer patients are treated successfully. Regardless, the lack of differences in mortality or MI rates permits individuals to select one or the other procedure as initial therapy without the likelihood that they will pay a price with their health.

Considering event-free survival as a more meaningful endpoint than overall survival, several more recent studies of CABG versus early era PCI (balloon angioplasty only) have demonstrated an advantage with surgery. The Argentine Randomized Trial of Coronary Angioplasty versus Bypass Surgery in Multi-vessel Disease (ERACI) trial conducted between 1988 and 1990 demonstrated no difference in death or MI, but superior event-free survival in the CABG group at 1 and 3 years.<sup>86,87</sup> In the French Monocentric Study, 152 patients with multivessel disease underwent PCI or CABG.<sup>88</sup> Again, superior event-free survival was seen in the surgical group, driven predominantly by a lesser need for subsequent revascularization. Comparing CABG to PCI with BMS implantation, Mercado et al performed a meta-analysis of the ARTS, ERATSII, MASS-II, and SOS trials that demonstrated similar rates of death, MI, or stroke at 1 year and higher repeat revascularization rates with PCI.<sup>89</sup> A meta-analysis of 5-year data was also recently published, confirming the 1-year results with repeat revascularization significantly more frequent after PCI than CABG (29% vs 7.9%).<sup>90</sup>

In large part fueled by recognition of the relatively high rates of in-stent restenosis seen with bare metal stents (22-32% at 6 months),<sup>91,92</sup> many investigators had hoped that by lowering the rates of early restenosis,<sup>67</sup> the introduction of DESs to the PCI armamentarium might improve overall PCI outcomes and expand the indications for PCI over CABG in a wide variety of clinical scenarios. The Synergy between PCI with Taxus and Cardiac Surgery (SYNTAX) trial, assessed the optimal revascularization strategy for patients with three-vessel or left main CAD by randomizing 1800 patients to either CABG or paclitaxel-based DESs.<sup>4</sup> At 12 months, the rates of MI and death were similar between groups, but stroke was significantly more common in the CABG patients (2.2% vs 0.6% at 1 year). It should be noted that the CABG group had much less aggressive medical management postoperatively, including fewer patients on antiplatelet medications, which may account for some of the increase in stroke risk.

Despite the use of DESs, the rates of reintervention were still significantly higher (13.5% vs 5.9%) in the PCI group than the CABG group. Because of the lack of difference in early mortality and MI, some cardiologists have begun to suggest that left main should no longer be an indication for CABG.<sup>93</sup> However, others maintain that the evidence for PCI is still inadequate and that the greater freedom from reintervention with CABG suggests that CABG remains the treatment of choice for patients with left main disease.<sup>94</sup> Meanwhile, the SYNTAX scores themselves, which grade the severity and complexity of coronary disease according to a variety of anatomic features (extent, location, severity), were defined in post hoc analyses as low for scores  $\leq 22$ , intermediate for scores 23 to 32, and high if  $\geq 33$ . While the incidence of major adverse cardiac events (MACE) for patients undergoing CABG versus PCI were similar in subgroup analysis of low SYNTAX score patients, those with an intermediate or high SYNTAX score had lower incidence of MACE with CABG.<sup>4</sup> Furthermore, at 3-year follow-up, those with three-vessel disease had significantly lower mortality in the CABG group compared to the DES group (6.2% vs 2.9%).<sup>63</sup> CABG appears to be preferable to PCI for those with diffuse and complex CAD. It is on this basis that CABG is recommended over PCI on a Class IIa basis for patients those with three-vessel disease (regardless of proximal LAD involvement) in patients with SYNTAX scores  $> 22$  who are good candidates for CABG.<sup>10</sup>

Notably, the SYNTAX trial also brought to light the concept of the Heart Team approach, described in the SYNTAX trial as a system in which a team consisting of a heart surgeon, an interventional cardiologist, and often the general cardiologist (if available) discuss each case and decide on the basis of mutual agreement the optimal method of revascularization in multidisciplinary fashion. The Heart Team approach, while not validated by any follow-up randomized controlled trial is recommended on a Class I basis for all patients presenting with unprotected left main or complex CAD.<sup>10</sup>

Since the SYNTAX trial, there have been five additional randomized controlled trials comparing CABG to PCI. Two of these trials discuss PCI with DESs in comparison to minimally invasive direct coronary artery bypass and therefore are less germane to the present discussion regarding on-pump CABG. The PRECOMBAT trial showed that PCI using DES was noninferior to CABG in UPLM at 2 years for composite endpoint and will be discussed further in the forthcoming section on left main disease.<sup>95</sup> Meanwhile, the CARDia trial achieved the modest goal of demonstrating that in patients with multivessel CAD and DM, PCI with the use of DES is noninferior to CABG at 1 year with respect to a composite endpoint of all-cause mortality, MI, and stroke.<sup>96</sup> The FREEDOM trial, which was designed similarly for a similar population but had nearly four times the study population size, demonstrated that for patients with DM and advanced CAD, CABG resulted in lower rates of the same composite endpoint compared to PCI with DES (18.7% vs 26.6%),<sup>26</sup> which is the first time a randomized trial of CABG versus PCI with DES has demonstrated this effect. A recent 2014 meta-analysis of six randomized trials of multivessel CAD whose

goal was to accurately reflect the more modern era in which DES and arterial grafts are used more frequently in PCI and CABG, respectively, demonstrated that with a weighted average follow-up of 4.1 years, CABG was associated with significantly lower mortality, lower incidence of MI, and repeat revascularization.<sup>97</sup> These new findings, which now demonstrate a survival advantage and not just freedom from repeat revascularization and symptom improvement with CABG over PCI, were not available at the time of the writing of the 2011 ACCF/AHA guidelines, but have implications for the management of patients in the future if further evidence supporting the same conclusions is gathered.

**Nonrandomized Database Comparisons.** The information provided by randomized studies is complemented by information gleaned from large, prospectively managed, non-randomized database studies. Such registries provide insight into the management of the sizeable population of patients who would not have been eligible for randomization. The 1994 Duke Cardiovascular Disease Databank study was one of the first large registry studies that established much of what we know today about the benefit of CABG compared to PCI insofar as it is dependent on the severity of coronary disease.<sup>22</sup> From a practical standpoint, in this database study and in the randomized trials, the effect of revascularization on survival depended largely on the extent of the CAD and is an example of the concept of benefit in relationship to a “gradient of risk.” For the least severe (one-vessel) disease, there were no survival advantages of revascularization over medical therapy in up to 5 years of follow-up.<sup>22</sup> For intermediate levels of CAD severity (ie, two-vessel disease), there was a higher 5-year survival rate for patients undergoing revascularization than for those treated medically. For patients with the most-severe CAD (ie, three-vessel disease), CABG surgery provided a significant and consistent survival advantage over medical therapy. PCI appeared prognostically equivalent to medical therapy in these patients, but only a small number of patients in this subgroup underwent angioplasty. In comparing PCI with CABG surgery, PCI demonstrated a small survival advantage over CABG surgery for patients with less-severe two-vessel disease, whereas CABG surgery was superior for more severe two-vessel disease (ie, proximal LAD involvement).<sup>22</sup>

Several additional studies in the subsequent PCI with BMS era confirmed these findings. A study of 1999 cases from the New York State Database between 1993 and 1998 showed that a survival benefit was observed with angioplasty at 3 years for those patients with single-vessel disease not involving the LAD, whereas those with LAD or three-vessel disease had superior outcomes with surgery.<sup>98</sup> In a much larger CABG versus PCI registry study from the BMS era, survival was again higher among the 37,212 patients who underwent CABG than among the 22,102 patients who underwent stent placement after adjustment for known risk factors<sup>61</sup> (Fig. 20-3). This study has limitations of being a nonrandomized study and subject to bias; however, the surprising finding of a survival advantage apparent as early as 3 years postprocedure suggests that improvements in

**FIGURE 20-3** PCI is directed against specific culprit lesions. By bypassing diseased vessels, CABG surgery treats both culprit lesions and future culprit lesions. (Reproduced with permission from Opie LH, Commerford PJ, Gersh BJ: Controversies in stable coronary artery disease, *Lancet*. 2006 Jan 7;367(9504):69-78.)

cardiac surgical anesthetic care, myocardial protection, and intensive care management have at least matched if not surpassed advances in percutaneous technology. It is important to note that while PCI targets the culprit lesion, CABG surgery targets both the culprit lesion and potential future culprit lesions by bypassing the diseased vessel. Considering the finding that medium- and long-term clinical outcome after PCI (ie, beyond one year postprocedure) is more dependent on the progression of coronary disease in other culprit lesions than restenosis of the stented lesion,<sup>99</sup> this in part may explain the apparent mortality benefit derived with CABG that has persisted despite advances in stent technology that have resulted in lower restenosis rates (Fig. 20-3).<sup>100</sup>

In the DES era, five of six large registry studies concluded that patients undergoing CABG have lower mortality than those receiving PCI with DES.<sup>62,101-105</sup> In particular, the ASCERT study, upon which the Society of Thoracic Surgeons ASCERT Long-Term Survival Probability Calculator ([ascertcalc.sts.org](http://ascertcalc.sts.org)) is based, evaluated outcomes of almost 200,000 patients over the age of 65 years with multivessel disease undergoing nonemergent revascularization, and showed that although there was no difference in adjusted mortality in the CABG and PCI groups at 1 year, CABG patients had significantly lower mortality at 4 years (16.4% vs 20.8%).<sup>104</sup> The long-term benefit of CABG compared to PCI was independent of age, sex, diabetes, renal function, and lung disease and was evident even for patients with propensity scores most consistent with selection for PCI. Another registry study of over 105,000 propensity-matched United States Medicare beneficiaries undergoing either CABG or PCI between 1992 and 2008 showed that at 5 years, patients undergoing CABG had a higher survival rate (74.1% vs 71.9%), an effect which was more pronounced in those with diabetes, tobacco use, heart failure, and peripheral artery disease.<sup>105</sup>

In summary, although not void of limitations that randomized controlled trials and associated meta-analyses overcome, these large registry studies provide a more real-world picture of revascularization in actual clinical practice, and support the findings of newer randomized controlled trials that CABG confers survival benefit over PCI, especially in

patients with multivessel and complex CAD, even in the era of DES use and the attendant lower rates of restenosis.

## Special Circumstances

### ACUTE CORONARY SYNDROMES

The acute coronary syndromes (ACS) cover a wide spectrum from ST-segment elevation MI (STEMI) with underlying coronary obstruction to Prinzmetal's or variant angina in patients with coronary vasospasm in the absence of significant underlying obstruction. The term non-ST-segment elevation (NSTEMI) ACS encompasses the entities of unstable angina, non-Q-wave MI, and postinfarction angina. They denote acute, symptomatic imbalances of the myocardial oxygen supply-demand ratio over a short time span. Prinzmetal angina, or coronary vasospasm, is diagnosed definitively by electrocardiograms obtained during the episode of pain and is treated medically. Unstable angina is not a uniform clinical entity, but comprises the spectrum of myocardial ischemia between chronic stable angina and MI, and is defined as a recent change in the severity, character, or trigger threshold of chronic stable angina or new-onset angina. Approximately 5.6 million Americans have chronic angina, and about 350,000 develop new-onset angina each year. Unstable angina develops in approximately 750,000 Americans each year and is associated with subsequent MI in approximately 10%. Postinfarction angina is defined as the presence of angina or other evidence of myocardial ischemia in a patient with a recent (1- to 2-week) Q-wave or non-Q-wave MI.

**CABG in ST Elevation Myocardial Infarction.** Prompt myocardial revascularization has been shown to improve outcomes compared to no reperfusion in almost all groups of patients who present after an acute STEMI. Because the degree of improvement in long-term outcomes is dependent on the time from symptom onset to revascularization,<sup>106,107</sup> PCI, which in general can be initiated more quickly than CABG, is performed as the primary therapy in most cases, relegating CABG largely to a secondary position in this setting (performed in less than 5% of STEMI cases<sup>108</sup>). In the majority of PCI cases, the culprit lesion can be determined and successfully stented open, with subsequent improvement in myocardial ischemia. However, in certain cases where coronary disease is diffuse and not amenable to stent placement, or in the setting of complications from PCI such as coronary dissection, perforation with tamponade, stent deployment failure, or hyperacute stent closure, revascularization is either not technically possible or remains incomplete with ongoing ischemia. Emergency CABG in current practice is reserved and, in fact, recommended on a Class I basis primarily for survival benefit in the following circumstances: (1) after unsuccessful or complicated PCI with ongoing ischemia;<sup>109</sup> (2) mechanical complication of acute MI requiring surgery including ventricular septal defect, free wall rupture, or papillary muscle with acute mitral regurgitation;

(3) cardiogenic shock, defined as systolic blood pressure < 90 mm Hg for over 30 minutes requiring supportive measures, cardiac index  $\leq 2.2$  L/min/m<sup>2</sup>, pulmonary capillary wedge pressure  $\geq 15$  mm Hg, and/or evidence of end-organ malperfusion;<sup>106,107,110</sup> and (4) patients with life-threatening arrhythmias in the presence of significant left main or three-vessel CAD.<sup>10,111</sup> The SHOCK study randomized patients to emergency revascularization versus initial medical stabilization in patients presenting with STEMI and cardiogenic shock and found that among those who were revascularized early, CABG group (36%) of patients had similar survival to those undergoing PCI despite higher rates of diabetes and complex coronary anatomy in the CABG subset.<sup>110</sup>

The timing of CABG after STEMI remains controversial, but overall the evidence suggests that mortality appears to peak in the 7-to-24-hour period after symptom onset. Several studies have shown that CABG with in-hospital mortality rates of 10.8% if performed within 6 hours of onset, 23.8% at 7 to 24 hours after onset, 6.7% at 1 to 3 days, 4.2% at 4 to 7 days, and 2.4% after 8 days. Another study showed that mortality was 6.1% for CABG performed within 6 hours, 50% at 7 to 23 hours, and 7.1% at 15 days or greater.<sup>109</sup> A reasonable approach appears to be emergency CABG within the 6-hour timeframe if possible to maximize myocardial salvage. Those who present after the 6-hour window would likely benefit from a delay of three to four days to improve survival and decrease bleeding complications.<sup>108,109,112</sup>

**CABG in Non-ST Elevation Myocardial Infarction and Unstable Angina.** The initial approach to the patient with NSTEMI ACS is pharmacologic stabilization followed by risk stratification. The latter is based on multiple clinical, demographic, and ECG variables in addition to the use of serum biomarkers. The TIMI (Thrombosis in Myocardial Infarction) risk score, which takes into account a variety of the above clinical factors, is widely used as a prognostic tool to determine in patients with unstable angina or NSTEMI the 14-day risk of all-cause mortality, new or recurrent MI, or severe recurrent ischemia requiring urgent revascularization,<sup>113</sup> and is often used to risk-stratify patients to a strategy of either immediate angiography, an invasive approach (angiography followed by revascularization by either PCI or CABG), or a conservative approach (initial period of medical therapy intensification). Those with hemodynamic instability, cardiogenic shock, severe LV dysfunction, persistent or recurrent angina at rest despite intensive medical therapy, mechanical complications, sustained ventricular tachycardia, and dynamic ST-T changes, are usually considered high risk irrespective of the TIMI score which does not account for these factors. Patients at intermediate or high risk (the majority) undergo early angiography with a view to revascularization. In many parts of the world, however, angiographic facilities are limited and an alternative approach based upon pharmacologic stabilization followed by mobilization and risk stratification using stress testing is employed.

In general for those undergoing angiography, the choice of PCI versus CABG is largely determined by the anatomy and

specific clinical features as in the general population presenting with stable ischemic heart disease, as per the ACCF/AHA guidelines.<sup>10</sup>

### ASYMPTOMATIC CORONARY ARTERY DISEASE

The role of revascularization either by PCI or CABG versus medical therapy in the setting of asymptomatic CAD has been studied in the ACIP trial.<sup>114</sup> Of 558 patients with CAD and medically controlled angina, treatment was randomized to either revascularization or medical therapy directed toward eliminating angina or eliminating ischemia during ambulatory ECG. Revascularization was more effective than medical therapy in relieving ischemia, and CABG was superior to PCI (70% freedom from ischemia vs 46%,  $p < .002$ ). Mortality at 1 and 2 years was superior for revascularization as compared with angina-directed medical therapy, but not superior to ischemia-directed medical therapy.<sup>45,114</sup> The greatest benefit was among those patients with the most severe disease. Importantly, many of these patients with “silent ischemia” on ambulatory ECG monitoring did have symptomatic angina at other times and thus were not truly asymptomatic.

The documentation of ischemia, however, is critical. Several studies emphasize the flaws in the assumption that one can identify future culprit lesions in the absence of symptoms or documentation of ischemia. Among patients undergoing serial coronary arteriography who subsequently developed acute MI or unstable angina, the severity of stenosis at the time of initial angiogram is poorly predictive of the culprit lesion causing the acute ischemic syndrome.<sup>115,116</sup> In most cases the severity of the lesion responsible for subsequent ischemia was less than 50%, and in many patients it was not present at all on the initial angiogram, raising concern regarding the number of asymptomatic or minimally symptomatic patients undergoing angioplasty without stress testing.<sup>117</sup> Bech and associates have demonstrated that fractional flow reserve exceeded 0.75 in 91 of 325 patients planned for PCI without noninvasive evaluation of ischemia, and that among those patients, angioplasty had no impact on event-free survival or angina.<sup>118</sup>

### DRUG-ELUTING STENTS

Recent progress in stent technology, particularly the introduction of DESs, has further reduced the incidence of restenosis. The use of stents has reduced adverse remodeling, and stents-eluting medications such as sirolimus, paclitaxel, or everolimus, are having a profound effect on the patterns of interventions for CAD. When compared with bare-metal stents, DES have not been shown to convey any advantage in terms of MI or mortality, but do demonstrate decreased rates of angiographic restenosis in a meta-analysis of 11 randomized trials.<sup>67</sup> The results of both randomized controlled trials and observational studies comparing CABG to PCI using DES are described in the preceding section, and suggest that the addition of DES, while successful in decreasing the restenosis rate inherent in BMS, the indications for PCI

and CABG have not changed.<sup>101</sup> Some of the most recent studies comparing these two strategies (FREEDOM trial, a meta-analysis of six randomized trials by Sipahi et al, and the ASCERT study)<sup>26,97,104</sup> have actually demonstrated a long-term survival benefit of CABG over PCI despite the use of DES in the PCI groups. It is important to note that because DES is associated with higher rates of in-stent thrombosis (as distinct from restenosis), patients receiving DES in general require 6 to 12 months of dual antiplatelet therapy (usually clopidogrel and aspirin) to minimize this risk.<sup>119</sup> Consideration for CABG or BMS should be given over DES on an individualized basis for patients in whom comorbid conditions will require withholding clopidogrel in order to perform subsequent surgery.

### LEFT MAIN DISEASE

Left main CAD is present in about 5% of patients undergoing coronary angiography,<sup>120</sup> and when present is associated with multivessel CAD around in 70% of patients.<sup>4,94</sup> Significant unprotected left main disease (ie, left main disease without any preexisting distal CABGs) has been considered an indication for CABG rather than PCI for many years, but recently studies have begun to question this. A handful of registry studies<sup>25</sup> as well as subgroup analysis of the SYNTAX trial,<sup>72</sup> and finally several randomized trials of CABG versus PCI with DES<sup>95,121</sup> have suggested that PCI may be an acceptable method of revascularization in patients with left main disease. In a matched cohort of more than 1100 patients with unprotected left main disease, there was no difference in the rates of death or the composite outcome of death, Q-wave MI, or stroke between patients undergoing CABG or PCI despite a greater rate of target-vessel revascularization in the PCI group, including the patients who received DES.<sup>25</sup> The PRECOMBAT trial compared PCI using sirolimus-eluting stents to CABG in patients with left main disease and found that the risk of major adverse cardiac or cerebrovascular events (MACCE) was not significantly higher after PCI compared to CABG at two years, but did have about double the incidence of repeat revascularizations.<sup>95</sup> A subgroup analysis of patients in the SYNTAX trial presenting with left main disease supported these findings by showing that PCI with a paclitaxel-eluting DES did not increase the 12-month rate of MACCE in comparison to CABG, but did have a higher rate of repeat revascularization.<sup>72</sup> Five-year outcomes also demonstrate the same findings qualitatively.<sup>122</sup> However, when grouped according to SYNTAX score, while those with low or intermediate scores had similar outcomes regardless of the method of revascularization, those with high-risk scores (>32) undergoing PCI had higher incidence of MACCE than CABG patients.<sup>72,122,123</sup> Based primarily on this evidence, the ACCF/AHA guidelines regard PCI as a Class IIa or IIb recommendation in patients with unprotected left main disease and stable ischemic heart disease depending on how favorable the anatomy and how high the overall surgical risk (Class IIa if SYNTAX score is  $\leq 22$  and STS-predicted mortality is  $\geq 5\%$ , Class IIb if SYNTAX score < 33 and STS-predicted mortality > 2%).<sup>10</sup> PCI may

be performed on a Class IIa recommendation if the patient is having unstable angina/NSTEMI and is not a CABG candidate due to high risk of operative morbidity and mortality, or in the setting of a STEMI when distal coronary flow is grade 3 and PCI can be performed more rapidly than CABG.<sup>10</sup> For all other instances (ie, the majority of patients), until additional data are gathered to the contrary, CABG remains the definitive Class I-recommended treatment for most patients with unprotected left main disease.<sup>10</sup> The EXCEL trial which is currently ongoing seeks to compare CABG to PCI using newer generation everolimus-eluting stents in patients with unprotected left main disease.

### SEVERE LEFT VENTRICULAR DYSFUNCTION

Left ventricular dysfunction is a predictor of increased operative risk for most cardiac surgical procedures, and in the early days of coronary revascularization these patients were not offered CABG. Like age, however, it is also a strong predictor of poor outcome with medical therapy. Accordingly, more recently significant LV dysfunction has been considered an indication rather than contraindication to surgical revascularization. In some patients, LV function has been shown to improve—sometimes dramatically so—after revascularization, leading to the concept of “hibernating” or “stunned” myocardium.<sup>124,125</sup> The identification of viable myocardium, which is potentially recoverable, depends on the identification of preserved metabolic activity by positron emission tomography, cell membrane integrity by thallium-201 or technetium-99m single-photon emission computed tomography (SPECT), or dobutamine stress echocardiography.<sup>126</sup>

Five studies from the early era of CABG as well as several meta-analyses of these studies and others that followed showed that patients with LV systolic dysfunction (mainly mild to moderate) showed that CABG conferred improved survival in comparison to medical therapy.<sup>39,54-57,127</sup> In regards to severe left ventricular dysfunction, however, as mentioned above the STICH trial, showed no reduction in all-cause mortality for CABG in comparison to GDMT in patients with CAD amenable to CABG with an EF of <35%.<sup>53</sup> CABG did, however, demonstrate a benefit compared to medical therapy with respect to the composite endpoint of death from any cause or (1) hospitalization for heart failure, (2) hospitalization for cardiovascular access, (3) hospitalization for any cause, and (4) revascularization with PCI or CABG. In other words, event-free survival was better with CABG in this population, suggesting that with longer follow-up, an overall survival benefit might resolve. The study is being continued out to 10 years of follow-up.

The relative roles of CABG and PCI in this population are not clearly defined despite the number of randomized trials of PCI versus surgery, largely because these patients were excluded from trial entry. In an early multicenter study of patients with left ventricular dysfunction (EF < 40%), slightly more than one-fourth of the patients died in the 2 years following multivessel PCI.<sup>128</sup> The majority of studies comparing CABG to PCI in this population have demonstrated similar survival,<sup>129-133</sup> while some showed improved outcomes with

CABG.<sup>62</sup> Overall, aside from the STICH trial, there remains a paucity of meaningful randomized trial data informing the choice of CABG versus PCI in the setting of left ventricular dysfunction. For patients with LV dysfunction and CAD amenable to revascularization, the recommendation is to perform CABG on a Class IIa basis if the EF is slightly depressed (35-50%), and on a Class IIb basis if the EF is very low (<35%) as long as the LMCA is not involved, in which case CABG is more clearly indicated.<sup>10</sup> The ACCF/AHA guidelines recommend that patients in this category should have the method of revascularization tailored to clinical variables such as the presence of renal disease, diabetes, and the complexity of the coronary anatomy.<sup>10</sup>

### CHRONIC TOTAL OCCLUSION

Chronic, totally occlusion of a coronary artery is found on up to 20% of all coronary angiograms, and of these, three-fourths have multivessel disease.<sup>134,135</sup> Revascularization is not possible nor attempted in 65% of patients with chronic total occlusion.<sup>134</sup> This population remains poorly studied in the randomized trials of multivessel PCI versus CABG as 35 to 37% of the patients excluded from the overall study were disqualified because of the presence of a chronic total occlusion of a coronary artery serving viable myocardium. Notably, the SYNTAX trial did not exclude patients with chronic total occlusion (a condition which alone contributes 10 to 15 points to the SYNTAX score), and found that complete revascularization, which has a known association with reduction in long-term mortality, MI, and repeat coronary interventions,<sup>136</sup> was significantly higher in patients treated with CABG compared to PCI (69% vs 49%).<sup>4</sup> Considering that the presence of chronic total occlusion was the most common reason for the inability to achieve complete revascularization in the PCI group, this may account for the lower rates of major adverse cardiovascular events including death in the CABG group compared to PCI.<sup>135</sup> However, success rates for achieving complete revascularization by PCI continue to improve as the interventional cardiology community increases its aggressiveness in using PCI to treat these lesions, as evidenced by the recent launching of at least three trials (EXPLORE, DECISION-CTO, and EURO-CTO), all designed to determine the benefit of PCI in this setting compared to medical therapy.<sup>134</sup> In summary, CABG surgery improves survival in patients with multivessel and complex CAD compared with PCI, in large part due to the ability of CABG to provide higher rates of complete revascularization.

### THE ELDERLY

Age is a predictor of operative risk in most models, but is also a predictor of poor outcome with medical therapy in the presence of CAD. Mortality is estimated to be approximately 8 to 11% in octogenarians after CABG.<sup>137</sup> The Swiss Multicenter Trial of invasive versus medical therapy in the elderly (TIME) trial examined 301 patients over the age of 75 years with chronic angina and randomized them to medical therapy with or without invasive evaluation.<sup>50</sup> Of those

undergoing angiography, two-thirds had revascularization. At the 1-year follow-up interval, there was no statistical difference in death or nonfatal MI rates. Symptoms and quality of life were also similar. However, there was a substantial increased risk of rehospitalization with revascularization in those who had medical treatment. Early interest in using off-pump CABG as a method of reducing risk in the elderly has not demonstrated any benefit in comparison to traditional on-pump CABG in two randomized controlled trials focusing specifically on patients aged 75 years and older.<sup>138,139</sup> A recent propensity-matched analysis of 1932 patients in this same age group showed that CABG and PCI with DES outcomes were similar at a mean follow-up interval of 1.5 years, with a higher incidence of repeat revascularization in the PCI group, similar to the conclusions drawn from studies in younger populations.<sup>140</sup> These data suggest that invasive evaluation should be offered to elderly people who are symptomatic only after adequate medical therapy. The choice of mode of revascularization will be particularly impacted in this group of patients by the presence of comorbidities that may increase the risk of surgical intervention, such as cerebrovascular disease, renal dysfunction, and pulmonary disease.

## DIABETES MELLITUS

It has been recognized for many years that patients with DM are at higher risk following percutaneous<sup>141</sup> or surgical<sup>142</sup> revascularization. The BARI trial was the first trial large enough to identify significant differences in outcome between diabetic and nondiabetic patients. In this study, which included 353 diabetic patients, a survival benefit was observed among insulin-dependent patients undergoing CABG with an ITA, as compared with those undergoing PCI. The explanation for this is not entirely clear, although an intriguing observation is that while the incidence of subsequent MI is similar between groups, survival after MI is superior among those who have undergone surgical revascularization.<sup>143</sup> In fact, unlike nondiabetics, diabetics suffering spontaneous Q-wave MI were more than 10 times as likely to die with their infarction if they had been treated with PCI as compared with CABG. This survival difference was even more pronounced at 7 years with 76.4% of diabetics in the surgical arm alive as compared with 55.7% in the angioplasty arm.<sup>144</sup>

The physiologic basis for this difference remains a matter of speculation, although the completeness of revascularization may be a factor. Because of the significant incidence of restenosis after PCI in diabetics, Van Belle and colleagues<sup>145</sup> analyzed EF at 6 months and long-term cardiac mortality and morbidity among 513 diabetic patients stratified according to the presence of occlusive restenosis ( $n = 94$ ), nonocclusive restenosis ( $n = 257$ ), and no restenosis ( $n = 162$ ). The mortality risk rose with restenosis (24% without restenosis, 35% with nonocclusive restenosis, and 59% with occlusion), and EF fell with occlusion (decrease of  $4.8 \pm 12.6\%$ ).

The results of the BARI trial prompted retrospective post hoc analyses of several earlier trials. The results have been variable. There was a nonsignificant trend for better survival among diabetic patients treated surgically in the EAST

trial.<sup>146</sup> A meta-analysis of pooled data pertaining to diabetic patients from CABRI, EAST, and RITA, however, found similar 5-year mortality rates following CABG or PCI.<sup>147</sup> Meanwhile, a larger meta-analysis of 10 randomized trials showed that long-term survival rates in patients with diabetes were lower in patients receiving PCI with balloon angioplasty or BMS compared to CABG.<sup>133</sup>

The follow-up study to BARI, BARI-2D,<sup>148</sup> enrolled 2368 patients with DM and stable CAD and randomized them to receive either intensive medical therapy or intensive medical therapy and prompt revascularization (CABG or PCI left to clinical judgment). At 5 years there was no difference in survival or freedom from major cardiovascular events (MI or stroke) between medical therapy and revascularization groups. This trial was not designed to compare CABG and PCI in diabetes, but rather to examine a strategy of intensive medical therapy compared with revascularization. However, in the stratum of patients who received CABG, there were fewer major cardiovascular events when compared with medical therapy (22.4 vs 30.5%,  $p = .002$ ). In the stratum of patients who received PCI, there was no difference in major cardiovascular events when compared with medical therapy.

In terms of more recent randomized trials, the SYNTAX trial showed that those with higher SYNTAX scores had higher rates of repeat revascularization after PCI than after CABG.<sup>149</sup> More importantly, the FREEDOM trial demonstrated the most definitive and current evidence that even in the DES era, CABG confers survival benefit over PCI in diabetics with multivessel disease. It compared CABG to PCI with sirolimus- and paclitaxel-eluting stents in 1900 patients with multivessel disease and diabetes and found that 5-year rates of a composite endpoint of death from any cause, nonfatal MI, or nonfatal stroke were significantly lower in the CABG group compared to PCI (18.7 vs 26.5%)<sup>26</sup>, supporting the results of the BARI and BARI-2D trials, but with the added caveat that the difference in outcomes was driven by a lower rate of MI and death from any cause in the CABG group.

Diabetes is a condition characterized biologically by an inflammatory, proliferative, and prothrombotic state. This may account in part for the increased risk of restenosis and occlusion. Because diabetics tend to have more diffuse disease, the importance of complete revascularization, which is more often achieved surgically than percutaneously, may be enhanced. Another explanation may have more to do with patient selection than vascular biology. It has long been recognized from the previously cited studies that the survival advantage of CABG over medical therapy is greater the more extensive the coronary disease; and more recent studies of PCI versus CABG have demonstrated similar trends. Diabetic patients tend to have more extensive disease, and in BARI diabetic patients had a higher frequency of three-vessel disease, diffuse disease, proximal LAD disease, and left ventricular dysfunction.

From a clinical standpoint with regard to patient selection for coronary revascularization and the method of revascularization, the assessment of diabetics should be made on standard principles, namely the severity and extent of coronary

disease, the potential for complete revascularization, the presence or absence of left ventricular dysfunction, and the technical suitability of the lesions for PCI. The results of the aforementioned studies suggest that a preference for surgical over percutaneous revascularization remains appropriate among diabetics, especially those with complex disease and/or ventricular dysfunction. As evident from the results of the FREEDOM and SYNTAX trials, this recommendation has not changed since the introduction of DESs.

### END-STAGE RENAL DISEASE

End-stage renal disease (ESRD) is a growing problem. Cardiovascular disease is the most common cause of death among those with ESRD; therefore, there will likely be high rates of revascularization required in these patients in the future. Comorbidities complicating surgical or percutaneous revascularization, such as diabetes, hypertension, and calcified vessels, are more common in patients with ESRD, increasing the risk of intervention. A study conducted by the Northern New England Consortium found dialysis-dependent patients with renal failure to be 3.1 times more likely to die after CABG after adjusting for known risk factors (OR 3.1, [2.1 to 3.7],  $p < .001$ ).<sup>150</sup> They also found significantly increased rates of mediastinitis (3.6% vs 1.2%) as well as postoperative stroke (4.3% vs 1.7%). The long-term survival was also decreased with renal failure, which was found to be a highly significant predictor of mortality after adjustment.<sup>151</sup> Despite these risks, the prognosis without surgical correction of CAD is poor. Revascularization in patients with ESRD is associated with improved survival compared with medical management,<sup>152-154</sup> with some studies showing that CABG confers improved survival compared to PCI.<sup>152,153,155-159</sup>

### Concomitant Carotid Disease

Perioperative stroke remains one of the most dreaded complications associated with CABG, and aside from the debilitating features of the stroke itself, it is associated with 21 to 23% hospital mortality.<sup>160,161</sup> Concomitant carotid artery disease is present in approximately 8% of patients undergoing CABG (range 2-22%, depending on the definition of stenosis, method of diagnosis, and frequency of screening).<sup>162-165</sup> Its presence increases the risk of perioperative stroke in some<sup>166-169</sup> but not all studies,<sup>170-173</sup> and as such, the question of whether to intervene on the carotid artery, with the goal of decreasing the perioperative as well as long-term stroke rate, has garnered significant attention in the literature. Controversy continues regarding the utility and indications for carotid endarterectomy (CEA) either before (staged), during (concomitant), or after (reverse-staged) CABG, especially in patients with asymptomatic carotid artery stenosis for whom data regarding increased risk of perioperative stroke are less well-established. This section will describe the relationship between extracranial carotid artery stenosis and neurologic outcomes after CABG and discuss the approach to determining whether and in what manner intervention on the carotid artery is indicated.

### PERIOPERATIVE STROKE

**Incidence and Causes of Perioperative Stroke.** The overall incidence of perioperative stroke or TIA after CABG has been decreasing in the last two decades. Several large registry studies from prior to 2002 had estimated the incidence to be around 3%,<sup>160,174</sup> but recently a large registry study of almost 1.5 million patients undergoing isolated CABG between 2000 and 2009 in all STS-participating institutions has put that risk at about 1.2%.<sup>175</sup> The most common cause of strokes after CABG is not embolism from carotid plaques, but rather athero- or thromboembolism from complex plaques liberated from the ascending aorta as a result of direct physical manipulation inherent in the conduct of the CABG operation including cross-clamping, aortic cannulation, and the creation of proximal graft anastomoses.<sup>176,177</sup> Other causes include intracardiac emboli which can arise in the setting of valvular disease, atrial fibrillation, prosthetic valve implantation, suture lines, left-sided heart catheters, mural thrombus after MI, and less commonly, entrapped air. Finally, miscellaneous causes of perioperative stroke include small-vessel occlusive disease, cerebral hypoperfusion from low perfusion pressure during cardiopulmonary bypass, perioperative MI, acute arterial dissection from cannulation, and cerebral hemorrhage. Overall cardioembolic sources including those from the aorta and the aortic arch account for about 75% of perioperative strokes after CABG, while large artery stenosis, which includes carotid artery disease, accounts for 5%.<sup>172</sup> Although carotid disease is implicated in only a small minority of perioperative strokes, it is the one situation in which the surgeon can take definitive action to remove the pathology and in so doing, potentially also decrease the risk associated therewith.

**Risk Factors for Perioperative Stroke.** Age is one of the most well-established risk factors for the development of perioperative stroke. In a study from 1986, Gardner et al, showed that stroke rates increased with age, such that those younger than 45 years had stroke rates of 0.2%, rising to 3.5% for those in their 60s and 8.0% for those older than 75 years.<sup>178</sup> Another study in 1992 showed that stroke rates were 0.9% for those younger than 65 years but 8.9% for those older than 75 years. Other risk factors from the cardiac surgery literature include aortic calcification, renal failure, prior stroke, tobacco use, age, peripheral vascular disease, diabetes, and carotid artery disease.<sup>161,179</sup>

**Relationship of Carotid Stenosis to Perioperative Stroke.** There are several major studies dating back to the 1980s that show an increased risk of perioperative stroke after cardiac surgery in patients with significant carotid artery stenosis. In 1987, Brener and colleagues showed that among 4047 patients undergoing cardiac surgery, stroke or transient ischemic attacks (TIAs) occurred in 9.2% of patients with asymptomatic carotid artery stenosis (defined as greater than 50% luminal narrowing on carotid angiography), while those without had a stroke rate of 1.9%.<sup>166</sup> Faggioli and colleagues investigated this in 1990 and found similarly that those with

>75% carotid stenosis and age over 60 years, the rate of stroke was 15% versus 0.6% in patients in the same age group without carotid stenosis.<sup>167</sup> CEA appeared to have a protective effect; none of the patients who underwent this procedure concomitantly (19 patients) had strokes, while 14.3% (4 of 28 patients) who had carotid stenosis but did not undergo CEA developed strokes.<sup>167</sup> For patients 65 years or older, who are at higher risk of stroke from any cause to begin with, the degree of carotid artery stenosis was shown to affect the perioperative stroke rate such that the total neurologic event rate (stroke or TIA) was 2.5% for <50% stenosis, 7.6% for ≥50% stenosis, 10.9% for ≥80% stenosis, and 10.9% for unilateral occlusion.<sup>180</sup>

It remains unclear, however, to what extent the presence of carotid stenosis in this patient population is the direct causative element in the development of perioperative stroke, or whether its main significance is as a marker of advanced overall cardiovascular disease. Determining which of the strokes occurring in those with significant carotid stenosis actually occur ipsilaterally has given further insight into what the actual impact of performing CEA would be, especially in asymptomatic patients. Several small retrospective studies have shown that the perioperative stroke rate directly attributable to ipsilateral carotid stenosis is small in asymptomatic patients.<sup>172,173</sup> Li et al showed that among 18 patients with ≥50% carotid stenosis who developed perioperative stroke after CABG, only four occurred on the same side as the disease itself, and that of these four, the carotid was totally occluded in three patients, that is, not amenable to intervention. Therefore only one of 18 strokes was potentially preventable by CEA. Since 2005, there have been four studies demonstrating a 0% rate of stroke in patients with asymptomatic carotid stenosis of ≥50% (n = 156) and ≥70% (n = 42).<sup>170,171,181,182</sup> These data suggest, though not definitively, that at least for asymptomatic patients, the risk of perioperative stroke directly attributable to the carotid stenosis itself may be minimal, lending credence to the idea that carotid disease is perhaps more of a surrogate and that prophylactic CEA may have little benefit.

**Relationship of Uncorrected Carotid Stenosis to Late Stroke.** The potential benefit of CEA in patients who have asymptomatic carotid artery disease has been shown to extend beyond the immediate perioperative period. Barnes et al showed that at 22 months following CABG in 40 patients with untreated asymptomatic carotid stenosis, the mortality rate was 10% while 17.5% had suffered a stroke.<sup>183</sup> One half of the patients had progression of the severity of carotid disease by noninvasive testing. Another study found that at 48 months, the risk of stroke after CABG in the setting of uncorrected significant carotid disease was 10%, that is, tenfold higher than patients who underwent combined CABG and CEA.<sup>184</sup> Contemporary randomized trials of surgery versus medical therapy for significant carotid stenosis have defined the late risk of carotid-related stroke in medically treated patients. In the Asymptomatic Carotid Surgery trial, actuarial risk of stroke at 5 years was

12% in medically treated patients with asymptomatic high-grade carotid stenosis.<sup>185</sup>

#### INDICATIONS FOR NONINVASIVE CAROTID TESTING

While some centers have practiced a policy of screening all patients undergoing CABG for carotid disease, studies have shown that identifying patients who are at high risk of having significant carotid disease to begin with can be screened selectively with negligible impact on the overall sensitivity. A retrospective analysis of 1421 patients undergoing CABG limited routine screening by ultrasound to only those that met the following criteria: age over 65 years, history of a stroke or TIA, and presence of a carotid bruit.<sup>186</sup> The investigators determined that this reduced the need for preoperative testing by 40% overall while missing only 2% of all candidates with ≥70% carotid stenosis. The ACCF/AHA issued a Class IIa recommendation that carotid artery duplex scanning should be performed for patients who have clinical features associated with a high risk of concurrent carotid artery stenosis, including age over 65 years, left main coronary stenosis, peripheral vascular disease, history of stroke or TIA, hypertension, smoking, and DM.<sup>10</sup>

#### MYOCARDIAL ISCHEMIC EVENTS IN PATIENTS AFTER CAROTID ENDARTERECTOMY

The incidence of CAD in the general population of patients undergoing CEA is high. A study from the Cleveland Clinic found that in patients studied with routine preoperative coronary angiography prior to planned CEA, only 7% had normal coronary arteries, while 28% had mild-to-moderate CAD, 30% had advanced but compensated disease, 28% had severe but correctable disease, and 7% had severe, inoperable CAD.<sup>187</sup> Early studies demonstrated that the risk of perioperative MI in the setting of CAD as significantly higher (4.3% compared to 0.5%).<sup>188</sup> Hertzner and colleagues showed that for patients undergoing CEA, MI caused more late deaths (37%) than did stroke (15%), with improved 10-year survival in the cohort of patients who had undergone incidental CABG compared to those with suspected but undocumented coronary disease (55% vs 32%).<sup>189</sup>

#### COMBINED CORONARY AND CAROTID REVASCULARIZATION

**Guidelines for Combined Coronary and Carotid Revascularization.** To date, there exist no randomized trials comparing a combined or staged approach to carotid disease in asymptomatic patients to CABG alone. The CABACS trial which began in 2010 is currently ongoing and will report on the relative incidence of strokes and death from any cause by randomly assigning patients to concomitant (ie, synchronous) CEA and CABG versus CABG alone in patients with high grade carotid stenosis undergoing CABG.<sup>190</sup> Until then, the current guidelines from the ACCF/AHA are based on a large body of retrospective data that have not conclusively established the optimal approach

to treating this patient population. Indeed, the formal Class I recommendation is that for patients with clinically significant carotid artery disease for whom CABG is planned, a multidisciplinary team consisting of a cardiac surgeon, cardiologist, neurologist, and vascular surgeon should convene and determine an individualized plan regarding whether and when to perform CEA.<sup>10</sup> Meanwhile, for patients with a previous TIA or stroke and a significant carotid artery lesion ( $\geq 50\%$  stenosis), combined CABG and carotid revascularization is recommended on a Class IIa basis. The sequence and timing of intervention is determined by the relative magnitudes of cerebral and myocardial dysfunction.<sup>10</sup> Finally, in patients scheduled for CABG who have no history of TIA or stroke but have bilateral severe (70–99%) carotid stenosis or unilateral severe carotid stenosis with a contralateral occlusion, combined carotid revascularization is recommended on a Class IIb basis.<sup>10</sup>

These guideline recommendations notwithstanding, Cambria and colleagues at our institution have argued that if one accepts that (1) uncorrected carotid stenosis is associated with an increase in stroke risk for patients with severe carotid and CAD who have only isolated CABG; (2) CEA is the indicated treatment for severe symptomatic and asymptomatic carotid stenosis; (3) CAD increases the early and late risk of death for CEA patients; and (4) CABG is an indicated treatment for CAD, then the important question becomes not the indication for but the timing of the two operative procedures. It is on these grounds that some surgeons in our institution have, since the 1970s, taken an aggressive approach to patients with both CAD and carotid stenosis, with the concomitant operation used as the standard approach.

**Staged versus Concomitant Carotid and Coronary Artery Operations.** The technique of performing CEA before coronary bypass grafting is referred to, by convention, as a *staged procedure*, while performing the CABG first and the CEA in delayed fashion is termed a *reverse staged procedure*. Performing both procedures under the same general anesthetic administration is a *concomitant procedure*.

On the one hand, performing CEA first might increase the risk of perioperative MI, while performing CABG first might increase the risk of perioperative stroke. If the patient does not have signs of active ischemia or hemodynamic instability, especially if the CEA can be performed safely with regional anesthesia, most agree that performing CEA first is a reasonable strategy. This argument is strengthened further in elderly patients with a history of prior stroke or TIA in whom the incidence of perioperative MI might be expected to be significantly higher. Meanwhile, for patients with active ischemia and/or hemodynamic instability secondary to coronary disease, the reversed staged procedure is sometimes favored, especially for those with asymptomatic carotid stenosis and no history of stroke or TIA. These general principles are considered on a case-by-case basis without the benefit of any randomized controlled trial data to definitively support one strategy versus the other.

The American Academy of Neurology (AAN) systematically reviewed all studies with over 50 patients comparing staged versus concomitant CEA and CABG and found that for nine studies evaluating concomitant CEA and CABG, the overall rate of stroke was 3%, while MI occurred in 2.2%, and death in 4.7%. In the one study included in this review describing staged CEA followed by CABG, the stroke rate was 1.9%, while MI occurred in 4.7%, and death in 1.6%. The AAN concluded that there was no clear general argument for one strategy versus the other based on these data.<sup>191</sup>

At our institution, the concomitant approach has been the standard strategy for most patients presenting with asymptomatic severe carotid stenosis and CAD amenable to CABG. Akins et al published a series of 500 patients who underwent a concomitant operation between 1979 and 2001 and found that hospital mortality was 3.6%, MI rate was 2.0%, and stroke occurred in 4.6%.<sup>192</sup> While 66% were neurologically asymptomatic preoperatively, 21% had prior TIAs while 13% had a prior stroke. The degree of coronary disease was relatively severe with 75% presenting with three-vessel disease and 42% presenting with significant left main disease. Three-fourths had unstable angina, and 53% had prior MI. The operation was performed either urgently or emergently in 54% of patients. In other words, the outcomes delineated above are rather favorable considering the patient population included. Of the 23 strokes that occurred, 12 were ipsilateral to the CEA and 11 were contralateral or bilateral, suggesting that this strategy may have neutralized the impact of carotid stenosis as a risk factor for stroke during CABG. The upcoming CABACS trial will, as the first randomized trial to shed light on the question of how these interventions should be sequenced, shed some light on the controversy inherent in these results, albeit on a significantly limited subset of the patients seen in actual clinical practice, that is, those undergoing elective CABG who have asymptomatic carotid stenosis.<sup>190</sup>

## PREDICTION OF OPERATIVE RISK

Prediction of risk-adjusted outcomes permits both the surgeon and the patient to weigh the potential benefits of operation against risks of perioperative morbidity and/or mortality. The patient's comprehension of benefit versus risk is paramount to informed consent before coronary artery bypass surgery. Accurate risk-adjusted prediction of postoperative morbidity and mortality also provides an important quality improvement tool to understand and examine the variability in institutional and individual surgeon performance.

A number of cardiac surgery databases have been used to develop risk models for predicting operative morbidity and mortality in patients undergoing CABG.<sup>21</sup> One of the more user-friendly risk assessment tools is that provided by the STS Risk Calculator (<http://www.sts.org/quality-research-patient-safety/quality/risk-calculator-and-models/risk-calculator>), which provides an assessment of individual patient operative risk derived using the STS database (Table 20-4). The STS risk algorithm is proprietary and is based on data voluntarily

**TABLE 20-4: Independent Variables Associated with Mortality after Isolated Coronary Artery Bypass Graft Surgery**

Variable	Odds ratio	95% Confidence interval
Multiple reoperations	4.19	3.61-4.86
First reoperation	2.76	2.62-2.91
Shock	2.04	1.90-2.19
Surgery status	1.96	1.88-2.05
Renal failure/dialysis	1.88	1.80-1.96
Immunosuppressants	1.75	1.57-1.95
Insulin-dependent diabetes mellitus	1.5	1.42-1.58
Intra-aortic balloon pump use	1.46	1.37-1.55
Chronic lung disease	1.41	1.35-1.48
Percutaneous transluminal coronary angioplasty, 6 h	1.32	1.18-1.48

Data were collected from 503,478 patients undergoing isolated CABG in the United States from 1997 to 1999 from Society of Thoracic Surgeons' database. Variables are listed in decreasing order of importance.

Data from Shroyer AL, Coombs LP, Peterson ED, et al: The Society of Thoracic Surgeons: 30-day operative mortality and morbidity risk models, *Ann Thorac Surg.* 2003 Jun;75(6):1856-1864.

CABG, coronary artery bypass graft.

submitted by participating centers on 503,478 patients undergoing isolated CABG in the United States from 1997 to 1999; the application is available for public use.

Overall, the average risks of 30-day operative death and major complication for patients reported to the STS database undergoing CABG from 1997 to 1999 were 3.05 and 13.4%, respectively. Specific complications included stroke (1.6%), renal failure (3.5%), reoperation (5.2%), prolonged ventilation (5.9%), and sternal infection (0.63%). Risk models were developed using multivariate analysis to stratify the strength of the association from among 30 potential preoperative risk factors for mortality and major complications as shown in Tables 20-5 and 20-6. Except for deep sternal wound infection, the development of any of these complications correlated with an increased risk-adjusted operative mortality.<sup>193</sup>

A preliminary sense of operative mortality can be derived simply from an understanding of the core variables most predictive of risk in the aforementioned data sets. The strongest predictors of operative mortality include nonelective surgery, low EF, and prior heart surgery. Chronic comorbidities are also associated with an increased operative mortality after coronary bypass, including treated diabetes, peripheral vascular occlusive disease, chronic renal insufficiency, and chronic obstructive pulmonary disease (COPD).<sup>21</sup>

## Patient Evaluation

Regardless of the risk model applied, there is no substitute for clinical evaluation of the patient. Unfortunately, all too often

**TABLE 20-5: Variables Associated with Development of a Major Complication after Isolated Coronary Artery Bypass Graft Surgery**

Variable	Odds ratio	95% Confidence interval
Renal failure/dialysis	2.49	2.41-2.58
Multiple reoperations	2.13	1.92-2.36
Shock	1.86	1.78-1.95
Intra-aortic balloon pump use	1.78	1.72-1.84
First reoperation	1.75	1.70-1.81
Insulin-dependent diabetes mellitus	1.59	1.54-1.64
Surgery status	1.58	1.53-1.63
Chronic lung disease	1.41	1.38-1.45
Immunosuppressants	1.34	1.26-1.43
Percutaneous transluminal coronary angioplasty < 6 h	1.33	1.23-1.43

Any major complication is defined as the composite outcome of stroke, renal failure, prolonged ventilation, mediastinitis, or reoperation. Data collected from 503,478 patients undergoing isolated CABG in the United States from 1997 to 1999 from the Society of Thoracic Surgeons' database. Variables are listed in decreasing order of importance.

Data from Shroyer AL, Coombs LP, Peterson ED, et al: The Society of Thoracic Surgeons: 30-day operative mortality and morbidity risk models, *Ann Thorac Surg.* 2003 Jun;75(6):1856-1864.

the assessment focuses disproportionately on coronary anatomy and insufficiently on the nature, duration, and severity of ischemic symptoms, as well as signs and symptoms of congestive heart failure (CHF). In addition, history of or coexisting cerebrovascular and/or peripheral vascular disease, malignancy, sternal radiation, COPD, DM, or renal and/or hepatic insufficiency can have major impact on the operative morbidity and even mortality, not all of which are captured in risk models.

Current medications and dosages with special attention to antiplatelet agents such as clopidogrel must be reviewed. Operation in the setting of recent clopidogrel use is associated with excessive bleeding and need for reoperation.<sup>194</sup> Most surgeons recommend 5 days from the last administered dose of clopidogrel before undertaking CABG with cardiopulmonary bypass. The same holds true for several new antiplatelet medications routinely used in clinical cardiology practice, such as prasugrel as well as medications used as substitutes for warfarin in patients with atrial fibrillation (eg, dabigatran).

Physical examination of the lungs and heart should focus on the stigma of ischemic and valvular heart disease. Cardiac murmurs warrant further evaluation. Additionally, the adequacy of presternal soft tissues to permit wound closure should be considered and evidence of venous varicosities or prior vein stripping may impact plans for conduit harvest. Peripheral pulses should be documented as their presence or absence may impact from which leg to harvest the vein or

Data collected from 503,478 patients undergoing isolated CABG in the United States from 1997 to 1999 from the Society of Thoracic Surgeons' database. Variables are listed in decreasing order of importance.

CVA, cerebrovascular accident; HTN, history of hypertension; IABP, intra-aortic balloon pump; IDDM, insulin-dependent diabetes mellitus; NIDDM, non-insulin-dependent diabetes mellitus; PTCA, percutaneous transluminal coronary angioplasty; PVD/CVD, peripheral vascular disease/cardiovascular disease.

Data from Shroyer AL, Coombs LR, Peterson ED, et al: The Society of Thoracic Surgeons: 30-day operative mortality and morbidity risk models, *Ann Thorac Surg*. 2003 Jun;75(6):1856-1864.

place an intra-aortic balloon pump (IABP). A detailed neurologic examination of the ulnar, radial, and median nerves should be documented in the case of planned radial artery (RA) harvest.

Diagnostic evaluation should be directed by the clinical assessment, but at a minimum should include a renal panel (creatinine), complete blood count, and chest x-ray. The ECG should be reviewed for the evidence of previous MI and conduction abnormalities. Radiologic evaluation should rule out concomitant neoplasm, active pulmonary infection, and/or ascending aorta calcification; the latter should be further assessed with a noncontrast computed tomographic (CT) scan because it will impact the location for arterial cannulation and aortic cross-clamp placement.

Hemodynamically significant coronary artery lesions on angiography are conventionally defined as those lesions with a 50% loss of arterial diameter, which is sufficient to impair coronary blood flow reserve and distal coronary pressure.<sup>21</sup> An assessment should be made of left ventricular function and regional wall motion abnormalities as well as the presence and degree of valvular abnormalities, including aortic stenosis and mitral regurgitation with echocardiography. Left ventriculography is not routinely performed and is reserved for patients who require direct pressure measurements of left ventricular pressures to further assess the gradient through the aortic valve. In cases where a previous sternotomy has

been performed and the internal thoracic arteries have not been utilized, their patency and integrity should be assessed at the time of cardiac catheterization since these conduits could have been injured at the time of sternal wire placement during chest closure. This becomes especially important if the saphenous veins are not available for the procedure and revascularization is dependent on the integrity of the internal thoracic artery (ITA).

It is in the surgeon's best interest to develop a good relationship with the patient and his or her significant others. Specifics including the risks, benefits, and alternatives to surgery need to be discussed to permit an informed decision. Ideally, this discussion is held in the presence of the patient's significant others, because patients often have difficulty absorbing the details of the discussion at the time related to the stress of the situation. Should the patient experience a major complication or mortality, it is often the patient's significant others with whom the surgeon will most often interact. Additionally, anticipated need for postoperative rehabilitation, as well as the time course of recovery is also of interest to all parties. A clear understanding of the expectations for the perioperative period will reduce everyone's anxiety about surgery and may promote early patient recovery. Good rapport with patients and their significant others is also the physician's best protection from litigation should untoward events occur.

## BYPASS CONDUITS

### Internal Thoracic Artery

The left ITA as a bypass graft to the left anterior descending coronary artery has been proven to provide superior early and late survival and better event-free survival after CABG.<sup>46</sup> The unparalleled long-term patency and better clinical outcomes associated with the use of the ITA make it the conduit of first choice for anastomosis to the left anterior descending coronary artery in almost all patients regardless of age, and establish an argument to use the right ITA as conduit to other targets as well.

### CHARACTERISTICS

The ITA demonstrates remarkable resistance to development of atherosclerosis, which may be in part attributable to a greater resistance of its endothelium to harvest injury as compared with the saphenous vein. Under electron microscopy examination, thrombogenic intimal defects are essentially nonexistent in the ITA but are commonly detected in venous grafts.<sup>195</sup> Perhaps more significantly, however, is the nonfenestrated internal elastic lamina of the ITA that may inhibit cellular migration, thereby preventing initiation of intimal hyperplasia. In addition, the medial layer of the ITA is thin, with fewer smooth muscle cells and a lesser proliferative response to known mitogens such as platelet-derived growth factor and pulsatile mechanical stretch.<sup>196,197</sup>

The endothelium of the ITA is itself unique as well. With a significantly higher basal production of the vasodilators nitric oxide and prostacyclin, the ITA demonstrates a favorable response to pharmacologic agents commonly used in the postoperative period. For instance, the ITA shows vasodilation in response to milrinone and yet does not vasoconstrict in response to norepinephrine.<sup>198</sup> Furthermore, nitroglycerin causes vasodilation in the ITA, but not in the saphenous vein.<sup>199</sup> The endogenous secretion of such vasodilators may also have a “downstream” effect on the coronary vasculature, explaining the common observation that the native coronary vessel itself often appears relatively protected from progressive atherosclerotic disease distal to the anastomosis. Finally, the ITA exhibits remarkable remodeling over time, adapting to the demand for increased flow by often increasing in diameter over time as observed on late postoperative angiograms, a phenomenon mediated by the endothelium.<sup>200</sup>

### SURGICAL ANATOMY OF THE INTERNAL THORACIC ARTERY

The ITA arises from the undersurface of the first portion of the subclavian artery opposite the thyrocervical trunk. The left ITA originates as a single artery in 70% of patients and as a common trunk with other arteries in 30%. In contrast, the right ITA originates as a single artery in 95% of cases.<sup>201</sup> At the level of the clavicle and the first rib, the ITA passes at first downward and medially behind the subclavian

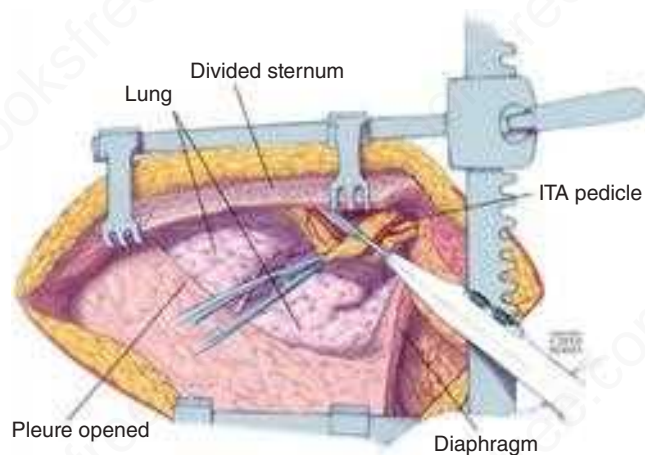

vein and lateral to the innominate vein. In this area, the phrenic nerve crosses the ITA from its lateral to its medial side, before contacting the pericardium. The phrenic nerve crosses anterior to the ITA 66% of the time on the left and 74% of the time on the right.<sup>201</sup> It is important to keep these relations in mind to avoid phrenic nerve injury during proximal ITA harvest.

Below the first costal cartilage the ITA descends almost vertically and slightly laterally at a short distance from the margin of the sternum. The ITA lies posterior to the cartilages of the upper six ribs and the intervening internal intercostal muscles. In the upper chest there is a bare area of variable length where the ITA is covered only by the endothoracic fascia and parietal pleura. Below this level the transversus thoracis muscle covers the posterior surface of the ITA. The mean distance of the left ITA from the sternal margin at the level of the first intercostal space is  $10.5 \pm 3.2$  mm, whereas at the level of the sixth intercostal space the distance increases to  $20.0 \pm 6.7$  mm. The right ITA is slightly closer to the sternal margin than the left ITA. At the level of the sixth rib the ITA bifurcates into its terminal branches: the musculophrenic and superior epigastric arteries. The length of the ITA in situ ranges from 15 to 26 cm, with a mean of  $20.4 \pm 2.1$  cm; the left ITA is slightly longer than the right.<sup>201</sup> A pair of internal mammary veins (venae comitantes) accompanies the ITA; at the most superior portion these veins form a single vessel, which runs medial to the artery and drains into the innominate vein.

### PEDICLED HARVEST TECHNIQUE

After the sternum is divided, the left ITA is harvested using an internal mammary retractor to expose the internal mammary bed (Fig. 20-4). Excessive distraction of the sternal leaves can cause costal fractures or dislocation of the costosternal joints, resulting in severe postoperative pain as well as brachial plexus injury. The parietal pleura and loose connective tissue with accompanying fat is dissected away from the chest wall. It is our preference to enter the left pleural space widely to allow easier exposure of the ITA, especially in its most proximal aspect, and to permit the ITA to fall into a more lateral and posterior path upon wound closure, keeping the ITA medial to the lung, lateral to the pericardium, and away from the posterior table of the sternum. This makes it less susceptible to injury during potential sternal reentry in the future. Slightly rotating the operating table to the patient's left and decreasing the patient's tidal volume can aid in the visualization.

The ITA is identified lateral to the border of the sternum by inspection of the bare area or by palpation in the area of artery covered by muscle. It can be harvested using either a pedicled, semiskeletonized, or a skeletonized technique. When taken as a pedicle, the dissection plane can be started in the bare area of the ITA at the level of the third or fourth rib or at the level of the lower sternum. The intercostal space is avoided as the initial point of exposure because it contains the branch vessels. The endothoracic fascia is incised medially for

**FIGURE 20-4** Internal thoracic artery (ITA) harvest. A self-retaining mammary retractor is used for exposure of the ITA bed. The left pleura is dissected away from the mammary pedicle and opened along the course of the ITA. The endothoracic fascia is incised medial and lateral to the ITA pedicle. The pedicle is carefully separated with blunt dissection from the underside of the rib. Gentle traction on the pedicle exposes arterial and venous branches at the level of the intercostal spaces; vessels are clipped on the ITA side and cauterized or clipped on the chest wall side. The proximal dissection is carried to the inferior border of the subclavian vein; the distal dissection is then carried to the level of the ITA bifurcation. The trans versus thoracis muscle must be divided to expose the ITA bifurcation. The ITA is divided after full heparinization, either at the end of harvest or just before grafting of the left anterior descending (LAD) artery. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

a distance of about 4 cm using the electrocautery at low setting (ie, 20). The pedicle is carefully separated from the chest wall using gentle blunt dissection with the electrocautery tip. Exposure can be enhanced by pushing the pedicle away with closed forceps or by gently grasping the fascia. The ITA is a fragile vessel and the conduit should never be grasped with the forceps. Gentle posterior traction on the pedicle allows exposure of arterial and venous branches, which should be clipped and divided.

After the pedicle has been freed for about 4 cm, the endothoracic fascia is incised laterally, allowing the pedicle to fall away from the chest wall. Dissection is continued proximally and distally to the level of the subclavian vein and ITA bifurcation. Attention should be given to avoid injury to the phrenic nerve during the proximal exposure. Once the dissection is completed, the patient is heparinized (fully or partially) and the pedicle sprayed with a papaverine solution (1 cc [30 mg] of papaverine added to 9 cc of saline). Three minutes after heparinization, the distal ITA is doubly clipped just proximal to the bifurcation and the artery divided. An atraumatic bulldog clamp is applied to the distal end of the artery and the pedicle is kept in a papaverine soaked sponge until the vessel is anastomosed to the arterial target. Alternatively, the pedicle may be left in situ and transected just before using the conduit.

## SKELETONIZATION OF THE INTERNAL THORACIC ARTERY

Sternal blood flow decreases significantly after pedicled ITA harvest. Skeletonized harvest, however, reduces the degree of sternal ischemia. Two prospective randomized studies assessing sternal blood supply using bone scan with SPECT after skeletonized and pedicled harvest have demonstrated significant reduction in sternal vascularity after pedicled harvest, whereas skeletonized harvest resulted in minimal change in sternal blood supply. Multivariate analysis found harvesting technique to be the only factor responsible for postoperative sternal ischemia.<sup>202,203</sup>

Low rates of sternal wound infection have been reported using skeletonized bilateral ITA harvest. Matsa and associates observed a deep sternal wound infection rate of 1.7% among 765 patients undergoing bilateral skeletonized ITA harvest. Of note, sternal complications occurred in only 2.6% of 231 diabetic patients in this study, which was not significantly different from that of the nondiabetic patients.<sup>204</sup> In Calafiore and coworkers' review of 842 patients undergoing bilateral skeletonized ITA harvest compared with a historical nonskeletonized bilateral ITA control group, skeletonized harvest was associated with a reduced incidence of sternal wound complications (4.5%) versus pedicle harvest (1.7%). Diabetic patients in the study derived the greatest benefit from skeletonized harvest with respect to sternal wound complications: 10% in the pedicle harvest versus 2.2% in the skeletonized harvest groups.<sup>205</sup>

Using the skeletonized harvest technique, only the artery is mobilized, leaving the internal thoracic venous plexus intact. Although skeletonization is a technically more demanding and time-consuming procedure, it increases luminal diameter and free flow compared with a pedicled graft, and also provides a longer conduit.<sup>206</sup> Some surgeons have expressed concerns regarding functional integrity, vasoreactive profile, and early and long-term patency; however, several investigators have shown no difference in endothelial integrity, endothelial-dependent or neurogenic-dependent vasoreactivity between the techniques of pedicle or skeletonized harvest.<sup>205,207,208</sup> Furthermore, there does not appear to be any difference with respect to early and midterm patency.<sup>209,210</sup>

## PATENCY

The superior late patency of an ITA graft to the left anterior descending coronary artery compared to a saphenous vein graft (SVG) was initially demonstrated by Barner and colleagues in the 1985.<sup>211</sup> Superior patency translates into improved 10-year survival (left internal thoracic artery [LITA]-to-LAD artery 82.6% vs SVG-to-LAD artery 71%) with less incidence of MI, hospitalization for cardiac events, and cardiac reoperations.<sup>46</sup> The superior performance of ITA grafts appears to persist in the current era despite the use of agents to improve vein graft performance. In the BARI trial the patency rates at 1 and 4 years for ITA grafts were 98 and 91% compared with vein grafts, which were 87 and 83%, respectively.<sup>212,213</sup> The superior patency of the ITA becomes

even more prominent with longer follow-up. In an angiographic study of 1408 symptomatic post-CABG patients, patency rates for the LITA at 10 and 15 years were 95 and 88%, respectively, whereas SVG patencies were 61 and 32% at the same time intervals.<sup>214</sup>

## Radial Artery

The use of the RA as a conduit for coronary bypass was originally described by Carpentier and associates in 1973. Spasm of the artery was common during surgery and was managed by mechanical dilation. The initial results were disappointing with 32% of grafts occluded at 2 years.<sup>215</sup> Accordingly, the RA was abandoned as a conduit for CABG. Acar and colleagues revived the use of the RA after several grafts, angiographically demonstrated to be "occluded" early postoperatively, were patent during restudy 15 years later. Acar postulated that harvest injury was responsible for the spasm/graft occlusion.<sup>216</sup> Proponents of the RA as a conduit have demonstrated encouraging mid- and long-term results with a pedicled harvesting technique and pharmacologic manipulation to prevent RA vasospasm.<sup>217</sup> As a result, this conduit has enjoyed a remarkable resurgence of interest as a supplementary arterial conduit for coronary revascularization.

## CHARACTERISTICS

Histologically, the RA has a fenestrated internal elastic lamina and a thicker wall than the ITA with a higher density of myocytes in its media.<sup>218</sup> The RA is also more likely to have atherosclerotic changes at the time of harvest than the ITA, with 28% of RAs having some degree of demonstrable atherosclerosis, as compared with only 6% of ITAs. Whether these differences indicate that the RA will prove more susceptible to graft atherosclerosis with reduced patency is unknown.<sup>219</sup>

Physiologically, the RA is equally sensitive to norepinephrine as the ITA; however, given its greater muscle mass, it generates a higher force of contraction, accounting for its well-recognized propensity for spasm.<sup>220</sup> Fortunately, the RA also readily responds to a variety of vasodilators, including calcium channel blockers, papaverine, nitrates, and milrinone. In vitro, nitroglycerine appears to be the most effective agent for inhibiting and reversing RA spasm.<sup>221</sup> Additionally, nitroglycerin has been shown to be better tolerated clinically, equally effective, and less expensive than diltiazem in prophylaxis of RA spasm after CABG in a prospective randomized trial.<sup>222</sup>

## SURGICAL ANATOMY OF THE RADIAL ARTERY

The RA originates from the brachial artery just proximal to the biceps tendon. In the proximal forearm the RA courses underneath the brachioradialis muscle. As it courses distally, it emerges from the lower surface of the muscle, becoming more superficial, and runs beneath the antebrachial fascia between the tendon of the brachioradialis muscle and the flexor carpi radialis muscle and anterior to the radius and

pronator quadratus muscle. The recurrent RA originates from the lateral aspect of the RA soon after its origin from the brachial artery. Multiple small muscular branches emerge from the deep and lateral surfaces of the artery. At the wrist the RA gives rise to the palmar carpal branch, the dorsal carpal branch, the superficial palmar branch, and the deep palm.<sup>223</sup> Throughout its course, the RA is accompanied by a rich plexus of venae comitantes. The average length of the RA ranges between 18 and 22 cm with an internal diameter of 2 to 3 mm.<sup>224</sup>

## HARVEST TECHNIQUE

It is most common to consider the patient's nondominant arm for harvest, partially out of concern for the impact of even subtle neurologic changes, and partially given the convenience of harvesting the left RA simultaneously with the left ITA. The extremity of interest must have adequate ulnar collateral circulation to ensure viability of the hand. Assessment of collateral circulation is best performed via noninvasive duplex ultrasonography.<sup>225</sup> The RA of the dominant hand can also be harvested if needed. Tatoulis and associates reported 261 patients undergoing bilateral RA harvesting with safe functional outcomes of both extremities.<sup>226</sup>

The arm is prepped circumferentially and the hand wrapped in a sterile fashion. The upper extremity is placed on an arm board perpendicular to the long axis of the operating table. As shown in Fig. 20-5, a medially curved incision is made on the skin overlying the RA from a point 2 cm proximal to the styloid process of the radius to a point 2 cm distal to the elbow crease and 1 cm medial to the biceps tendon. The subcutaneous tissue is divided with the cautery. The dissection can be initiated at either end depending on the surgeon's preference. The deep fascia of the forearm is incised directly over the RA.

The RA is harvested as a pedicle with minimal manipulation using sharp dissection, diathermy, or the harmonic scalpel (our preferred method). There are data to suggest that early graft flow is superior when the harmonic scalpel is used.<sup>227</sup> On the proximal half of the forearm, gentle lateral retraction of the brachioradialis muscle aids exposure. At the distal end of the dissection the satellite veins are identified and divided. The proximal end of the dissection is marked by the radial recurrent artery branch and a large venous plexus in the medial aspect of the RA. It is our routine to leave the recurrent radial branch intact. The artery is divided proximally and distally and stored in a room temperature solution of lactate, nitroglycerin, and papaverine.

After the RA is removed from the forearm, hemostasis of the operative field is obtained and the arm is closed in multiple layers. A closed suction drain is placed, which we feel helps reduce postoperative seroma formation. A circumferential elastic wrap is applied. The arm is then abducted and secured to the table. Reports of endoscopic RA harvest are beginning to emerge with good functional and cosmetic results; nonetheless the impact of the technique on graft patency is unknown.<sup>228</sup> We have not adopted the technique.

**FIGURE 20-5** Radial artery harvest. A medially curved incision is made on the forearm over the artery. The deep fascia of the forearm is incised directly over the artery. The brachioradialis muscle is retracted laterally. Dissection is begun at the distal end and the satellite veins are divided. The RA is harvested as a pedicle with minimal manipulation. The proximal end of the dissection is marked by the radial recurrent branch, which is left intact. After the pedicle is free and heparin has been given, the artery is divided proximally and distally and stored in a room temperature solution of lactate, nitroglycerin, and papaverine. Hemostasis of the operative field is obtained and the arm is closed in multiple layers. A closed suction drain is placed. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Two cutaneous nerves are of importance to note during RA dissection. The lateral antebrachial cutaneous nerve lies superficial to the belly of the brachioradialis muscle and runs close to its medial border. Placing the skin incision medial to the edge of the brachioradialis prevents potential injury. Damage to this nerve will produce paresthesias and numbness of the radial aspect of the volar forearm. The superficial branch of the radial nerve lies under the brachioradialis muscle and in the proximal two-thirds of the forearm runs parallel to the RA. Injury to this nerve will result in paresthesias and numbness of the thumb and the dorsum of the hand. The nerve can best be protected by avoiding excessive lateral retraction on the brachioradialis muscle.<sup>223,229</sup> Transient paresthesias, numbness, and thumb weakness are common and are reported by almost a third of patients after RA harvest; fortunately, the symptoms gradually resolve with time so that after 1 year only 10% of patients have residual complaints with only 1% reporting their symptoms as severe.<sup>230-232</sup>

The radial can also be harvested endoscopically through a small incision overlying the artery at the wrist, using a smaller size endoscope than the one normally used for endoscopic saphenous vein harvesting. A long shafted harmonic scalpel can also be used with this technique. Proponents of endoscopic RA harvesting have reported this to be a safe and effective technique, with less pain and fewer wound complications than the open surgical technique,<sup>233</sup> and has become the harvesting method of choice of some centers.<sup>234</sup>

## PATENCY

Acar and associates in 1992 reported on 122 radial grafts with a 100% patency rate at 2 weeks and 93% patency at 9 months.<sup>235</sup> The results appear durable with reported patencies at 48 months of 89%. Several factors may affect RA graft patency, however, including both target artery runoff and competitive flow. In the prospective, randomized Radial Artery Patency Study, more severe target coronary artery stenosis was associated with lower rate of occlusion (>90% stenosis = 5.9% vs 70 to 89% stenosis = 11.8%).<sup>236</sup> The graft failure rate is highest if the target vessel is the right coronary artery system, but this may be related more to the coronary artery than the bypass conduit; one study showed equal patency of RA and saphenous vein bypass grafts to the right coronary artery.<sup>237-239</sup>

The proximal RA can be sutured to the ITA as a T- or Y-graft (composite), sutured directly to the ascending aorta, or sutured to the proximal portion or hood of a separate vein graft. In addition, a segment of vein can be interposed between the aorta and proximal RA in an end-to-end fashion. Comparisons have been made between the T- or Y-graft and direct aortic anastomosis methods. Maniar et al found at approximately 30 months follow-up, a significantly greater incidence of postoperative angiography for recurrent angina among patients with direct aortic anastomosis as compared with patients with composite anastomosis (19% vs 11%).<sup>237</sup> There is controversy here, however, as Jung et al found that 1-, 2-, and 5-year patency rates were significantly better with

direct aortic anastomosis as compared with composite anastomosis.<sup>240</sup> Importantly, it appears that the overall patency of RA grafts to ideal targets may be superior to that of saphenous vein bypass grafts at 5 years, 98% versus 86%.<sup>241</sup>

## Other Arterial Conduits

A variety of arterial conduits have been used in patients in whom no other conduits are available. The gastroepiploic artery (GEA) for the most part is utilized as an alternative conduit or as part of an all-arterial revascularization strategy. Despite the enthusiastic support of a small cohort of surgeons, the widespread use of the GEA as a coronary conduit has not been adopted, perhaps because of the increased operative time and relative difficulty required to harvest the conduit, the potential for perioperative and long-term abdominal complications, and the lack of consensus on the long-term benefit for total arterial revascularization. Anecdotal use of the ulnar, left gastric, splenic, thoracodorsal, lateral femoral circumflex and inferior epigastric arteries as coronary graft conduits has been reported in the literature. The popularity of the RA, however, has in large measure superseded these options.

## Greater Saphenous Vein

The saphenous vein continues to be one of the most commonly used conduits in coronary bypass grafting. Characteristics that have solidified the greater saphenous vein as a coronary artery bypass conduit include its ease of harvest, ready availability, versatility, resistance to spasm, and thoroughly studied long-term results. Unfortunately there is a loss of clinical benefit after CABG because of time-related attrition. Accordingly, there is interest in pharmacologic strategies to maximize early and late venous graft patency.

Prospective randomized trials have shown that early aspirin administration reduces mortality after CABG. Aspirin within 48 hours after CABG also reduces early postoperative complications, including mortality, MI, stroke, renal failure, and bowel infarction.<sup>242</sup> More recently, it has been recognized that lipid-lowering agents reduce the progression of graft atherosclerosis.<sup>243,244</sup> Aggressive use of statins to achieve a low-density lipoprotein cholesterol < 100 mg/dL decrease by one-third the number of grafts affected with atherosclerosis at angiographic follow-up and also decreased the need for repeat revascularization.<sup>243</sup> With clear documentation of improved outcomes with these two pharmacologic strategies, systematic approaches to ensure their universal application are needed.<sup>21</sup>

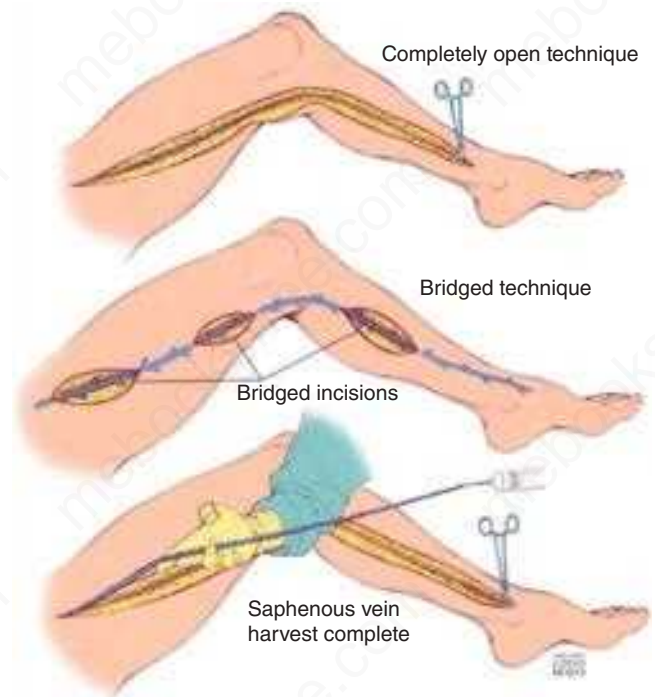

Finally, in the future, gene therapy may allow modification of the venous vascular endothelium to avert development of intimal hyperplasia. Unfortunately, the PREVENT IV trial, testing whether short-term angiographic vein graft failure could be diminished with treatment of the saphenous vein before grafting with edifoligide (an oligonucleotide decoy that binds to and inhibits E2F transcription factors), demonstrated no impact of the treatment.<sup>245</sup> The concept remains a

valid one, however, and gene therapy will continue to be an exciting area of investigation in the future.

## HARVEST TECHNIQUE

Saphenous vein harvest can be performed with an open or endoscopic technique. Open-vein harvest can be performed with a completely opened technique or bridged technique. In the completely open technique, an extensile skin incision provides the best exposure of the vein and may allow for harvest with the least amount of surgical trauma, but that advantage comes at the risk of higher rates of wound complications and postoperative pain. Bridged skin incisions may decrease pain and wound complications but may also increase surgical manipulation of the vein conduit.

Open-vein dissection can be started either in the upper thigh, above the knee, or at the ankle (Fig. 20-6). Some

**FIGURE 20-6** Saphenous vein harvest: open and bridged technique. Open technique (*top*): Dissection can be started in the upper thigh, above the knee, or at the ankle. Identification of the vein is easiest at the ankle, just above the medial malleolus. An incision is made overlying the vein and extended directly over its trajectory. The vein is dissected and all venous tributaries are ligated and divided in situ. Bridged technique (*middle*): Two- or three-step incisions are performed over the course of the vein. Dissection of the vein is carried in a similar fashion as the opened technique except that branches are divided in situ and ligated once the vein is explanted. Completed dissection (*bottom*): Once dissection is completed, the vein is ligated and divided proximally and distally. Stumps of side branches on the vein are left long and then are ligated flush with the vein, avoiding narrowing of the conduit. The vein is then gently flushed and stored in a solution of room temperature plasmalyte. The skin incisions are closed and the leg is wrapped with an elastic bandage. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

surgeons prefer to harvest vein from the lower leg because of a more appropriate vein caliber and wall thickness, as well as greater distance from the perineum (a potential source of infection). Others prefer to harvest vein from the thigh, arguing improved wound healing, particularly among patients with distal peripheral arterial occlusive disease. We are not aware of any data supporting one location over another. Because of the greater amount of adipose tissue present in the thigh area, wound breakdown in that location may prove more of a nuisance to treat. The fundamentals of vein harvest are to procure the conduit with a minimal amount of trauma to the vein. Specifically, the vein should not be grasped with forceps, stretched, or over-distended, because patency rates may be related to endothelial damage induced during harvest and preparation of the conduit. Identification of the vein is easiest at the ankle, just lateral to the medial malleolus.

In the completely open technique, a skin incision directly over the trajectory of the vein is made, taking care not to create skin flaps. Purposeful, directed, sharp dissection is used to free the vein from the surrounding tissue. Side branches on the vein can initially be left long. Once dissection is completed, the vein is ligated and divided proximally and distally. A blunt-tipped vein cannula is inserted into the distal end of the vein and the vein gently flushed and dilated with a room temperature solution of Plasmalyte™. The side branches can be clipped flush with the vein at this time, taking care to avoid narrowing of the conduit lumen.

When using a bridged technique, several step incisions are performed over the course of the vein. Dissection of the vein is otherwise carried out in a similar fashion as describe above. Exposure of the vein with the bridge technique may be less than optimal. Caution is necessary here to avoid excessive tension or manipulation of the conduit as an adjunct to deal with less than adequate exposure of those segments of the vein covered by a skin bridge. For all techniques of vein harvest located in the lower thigh and more distal, care should be taken to avoid trauma to the saphenous nerve, which is in close proximity to the vein. Injury to the nerve can result in debilitating postoperative neuralgia.

Endoscopic vein harvest starts with a 1.5- to 2.0-cm skin incision in the medial aspect of the extremity above the knee (Fig. 20-7). Carbon dioxide insufflation for visualization and dissection is established. Dissection is directed toward the groin region as far proximally as possible and then distally as far as needed to obtain the required length of conduit. Side branches are divided by using bipolar cauterizing scissors. Once dissection is completed, small skin punctures are made at the limits of the dissection and the vein exteriorized, ligated, and divided. The vein is removed and otherwise prepared in the standard fashion. Following skin closure, the leg is wrapped with a circumferential elastic bandage.

#### PATENCY

Minimally invasive harvest of the saphenous vein using an endoscopic technique is gaining popularity because it greatly reduces the wound morbidity associated with the open harvest techniques. Endoscopic harvest decreases wound

Endoscopic saphenous vein harvest

**FIGURE 20-7** Endoscopic saphenous vein harvest. A 2.0-cm skin incision is made in the medial aspect of the knee. CO<sub>2</sub> insufflation is established. Harvesting is directed toward the groin region as far proximally as possible. Side branches are divided by using bipolar cauterizing scissors. Once dissection is completed, a small puncture is made in the groin directly over the vein and the vein is exteriorized under endoscopic guidance. After removing the vein from the leg, side branches are clipped. If any branches have been avulsed, the vein is repaired with interrupted 7-0 polypropylene sutures. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

complication rates and produces an improved cosmetic result, although the operative time devoted to harvest is increased as are the number of defects to the harvested conduit requiring suture repair. Initial reports showed no detrimental effects of harvest technique on vein morphology, endothelial structure or function, or graft patency.<sup>246,247</sup> However, in recent report of 3000 patients treated with CABG, endovascular vein harvest was associated with higher rates of vein-graft failure, death, MI, and repeat revascularization.<sup>248</sup>

The polar opposite to endoscopic vein harvest is the “no-touch” technique in which the vein is removed with a pedicle of surrounding tissue. The harvested vein is not distended and it is stored in heparinized blood. In a randomized study of 104 patients using this technique, the angiographic patency at 18 months was 89% for conventional versus 95% for no-touch grafts. At 8.5 years, patency rates were 76% for the conventional group versus 90% for the no-touch group. Multivariate analysis showed that the most important surgical factors for graft patency were the technique of harvesting the conduit and the vein quality. By comparison, the patency of ITA grafts was 90% in the study.<sup>249</sup>

#### Other Venous Conduits

Alternative venous conduits such as the lesser saphenous and/or upper extremity cephalic veins are usually secondary choices for conduit. If it is planned to use either of these veins, preoperative vein mapping can help guide conduit harvest. The lesser saphenous vein can be harvested in a supine position through a lateral approach by flexing the hip and medially rotating the knee or by an inferior approach with straight elevation of the extremity. A skin incision is usually started midway between the Achilles tendon and the lateral malleolus. Dissection is carried proximally up the leg to the

popliteal fossa. Attention should be paid to avoid injuring the sural nerve.

The patency rate for arm veins is significantly lower than that of saphenous veins and for that reason they are considered conduits of last resort.<sup>250</sup> For cephalic vein harvest, the arm is prepared and positioned as during RA harvest. Incisions are placed along the medial and superior aspect of the arm. The cephalic vein is relatively thinwalled in comparison with the greater saphenous vein and is predisposed to aneurysmal dilatation.

## CONDUCT OF OPERATION

Procedures are done under general anesthesia with central venous access, radial arterial lines, and pulmonary artery catheters. Transesophageal echocardiography may be helpful for identifying unsuspected intracardiac lesions or aortic atherosclerosis, and for evaluating ventricular function at the end of the procedure. If ventricular function is poor, a femoral arterial line will facilitate later placement of an IABP. We routinely use a temperature-monitoring urinary catheter. The patient is positioned in the supine position with arms tucked at the side. Care should be taken to avoid peripheral nerve complications caused by pressure injury. The lower extremities are positioned with a slight external rotation and flexion of the knees to aid with groin exposure and harvesting of saphenous vein conduits. The patient is prepared and draped to include the lower neck, the chest, and abdomen between the anterior axillary lines, and the lower extremities circumferentially. The right subclavicular area should also be widely prepped in case the axillary artery needs to be used as a source of arterial inflow.

## Incisions

By far the most common approach for CABG is via median sternotomy. Cannulation for cardiopulmonary bypass, managing aortic valve insufficiency, monitoring the left ventricle for distention, and evacuating air all are easier with the midline approach. The skin incision extends from a point midway between the angle of Louis and the sternal notch to just below the tip of the xiphoid process. The scalpel is used to extend the incision through the subcutaneous tissues down to the sternum. Extensive Bovey cautery to the subcutaneous tissues should be avoided because tissue destruction here may result in increased risk of wound complication. Charcoal does not bleed, but neither does it heal.

Special attention should be devoted to identifying the middle of the sternum. The middle of the sternal periosteum is noted and marked with cautery, although we avoid scoring the periosteum continuously from notch to xiphoid as this devascularizes the periosteum unless the saw passes exactly down the line. The interclavicular ligament is divided in the sternal notch, allowing palpation of the posterior aspect of the sternal manubrium. The xiphoid process is identified and divided in the midline with heavy scissors and the midline diaphragmatic muscle attachments divided. A finger should

be inserted under the sternum to document a free space anterior to the pericardium. If there are no significant adhesions present, the sternum is divided with the oscillating saw. If the prepericardial space is adhered, the sternum should be divided using the microsagittal saw. The saphenous vein or the RA can be harvested simultaneous with the sternotomy. Once the sternum has been divided, the ITA is harvested as previously described.

## Cannulation and Establishment of Cardiopulmonary Bypass

The pericardium is divided vertically down to the diaphragm and the inferior attachment of the pericardium to the diaphragm is divided transversely. The remnant of thymic tissue and pericardial fat is divided in the midline to the inferior aspect of the left innominate vein.

If the RITA will be used in situ, the fat overlying the pericardium is removed from the diaphragm inferiorly, to the innominate vein superiorly and from the left phrenic to the right phrenic nerve. This significantly increases the reach of the in situ RITA, especially if it will be used in a retro-aortic fashion for left sided targets. Although only removal of the right sided anterior pericardial fat is necessary to maximize the reach of the RITA, we have found that it is quicker and dryer to remove the entire fat pad as a block.

Pericardial retraction sutures create a pericardial cradle or well to improve exposure of the ascending aorta and right atrium. The left pericardium is divided at the level of the great vessels toward the phrenic nerve to allow the completed ITA bypass graft to fall laterally into the pleural space away from the sternum. The distal ascending aorta is inspected and palpated for soft nonatherosclerotic areas suitable for arterial cannulation, root ventilation, proximal graft anastomoses, and aortic cross-clamp placement (Fig. 20-8). In some institutions, epicardial ultrasound of the ascending aorta is performed. Now is the time to redirect the conduct of the operation should the aorta harbor areas of significant calcification, a topic of later discussion.

Systemic anticoagulation is achieved with the intravenous administration of 300 U/kg of unfractionated heparin and the adequacy of anticoagulation documented by an activated clotting time over 450 seconds. In anticipation of aortic cannulation the systolic blood pressure should be reduced to about 100 mm Hg to minimize the risk of aortic dissection. Two partial-thickness concentric diamond-shaped purse-string sutures using 2-0 braided or monofilament nonabsorbable suture (such as Ethibond™ or Prolene™, respectively) are placed in the distal ascending aorta or proximal aortic arch, leaving enough room on the ascending aorta for all necessary proximal aortic work. The size of the purse strings should be large enough to accept the aortic cannula tip, usually 20-22 French. The ends of the sutures are passed through tourniquets that will be used for tightening the purse strings and securing the cannulation site after decannulation. The aortic adventitia within the purse strings

**FIGURE 20-8** Cannulation. After full systemic heparinization, cannulation of the distal ascending aorta is performed with an appropriately sized curved or straight tip aortic cannula. A two-stage venous cannula is used for access to the right atrium, usually through the right atrial appendage. An aortic root cardioplegia/vent is placed. A retrograde cardioplegia cannula may be placed at the discretion of the surgeon. Patients with significant aortic regurgitation will benefit from placement of a left ventricle vent (placed via the right superior pulmonary) to avoid distention of the left ventricle during infusion of cardioplegia into the aortic root. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

is divided in preparation for aortotomy. The adventitia just superior to the planned aortotomy is grasped with a forceps and an aortotomy equal in size to the cannula tip is created with a no. 11 scalpel blade. Bleeding is easily controlled with slight inferior traction of the forceps on the adventitia. The aortic cannula is inserted and properly positioned, and the purse strings are tightened. The tourniquets are secured to the aortic cannula with a heavy silk tie and then the cannula is secured to the skin.

Placement of the aortic cannula can result in acute aortic dissection. Intraluminal positioning of the cannula is confirmed by watching for the cannula to fill with arterial blood. The aortic cannula is de-aired and connected to the arterial end of the pump tubing. An additional method to assess for the presence of aortic dissection is to have the perfusionist check the wave form and pressure of the arterial cannula pulse and to deliver a test infusion of 50 to 100 mL of fluid through the cannula. If an aortic dissection is present, often the test infusion will result in an increase in arterial cannula pressure.

Venous cannulation is accomplished with a two- or three-stage venous cannula inserted in the right atrial appendage. A 2-0 Ethibond or Prolene purse-string suture is placed around the tip of the right atrial appendage. The purse string should be wide enough for easy access of the

selected venous cannula. An atriotomy is made with scissors at the tip of the appendage. Small bridging fibers of muscle are divided with scissors to permit easy entry of the cannula. The venous cannula is cautiously inserted, the tip of which should lie in the inferior vena cava. The purse-string suture is tightened and the tourniquet secured to the venous cannula with a heavy silk tie. The venous line is connected to the pump tubing.

An aortic root cannula is placed in the ascending aorta and retrograde cardioplegia cannula placed in the coronary sinus via the right atrium. The patient is placed on cardiopulmonary bypass at  $2.4 \text{ L/min/m}^2$  and may be perfused at normothermia or may be cooled to  $34^\circ\text{C}$ . Once the patient is on full bypass, flow ventilation is stopped. A left ventricle vent may be placed via the right superior pulmonary vein at this time if there is significant aortic regurgitation. Target vessels are easier to identify before cardioplegic arrest while they are fully distended in their native state. The locations of planned distal anastomoses are marked with a scalpel. The pump flow is turned down temporarily and the aortic cross-clamp applied just proximal to the arterial cannula and bypass flow returned to normal.

Cold blood cardioplegia ( $10 \text{ mL/kg}$ ) is administered and may be delivered antegrade, retrograde, or both, with special attention given during this time to look for evidence of aortic regurgitation such as a flaccid aorta and/or left ventricle distention. Two available options to treat significant aortic regurgitation include completion of the procedure using only retrograde cardioplegia or placement of a left ventricle vent via the right superior pulmonary vein (our preferred method). Rarely is aortic valve replacement required. Additional doses of cardioplegia ( $5 \text{ mL/kg}$ ) are given via the antegrade and retrograde catheters approximately every 20 minutes throughout the remainder of the cross-clamp period. Cardioplegiare dosing should be timed in such a way as not to interrupt the 'flow' of the operation.

## Distal Anastomoses

### LOCATION OF TARGETS AND SEQUENCE OF ANASTOMOSES

Arteriotomy sites should be chosen proximal enough to offer the largest-sized coronary target but distal enough to avoid areas of obstruction or significant atherosclerotic disease. Arteriotomies at bifurcations should be avoided. Diseased vessels with an intramyocardial course can often be localized by noting epicardial indentation, accompanying epicardial veins, or a whitish streak within the myocardium. Sharp dissection of overlying tissue is required to identify the desired target site. Often a very diseased vessel will be less diseased in the intramyocardial segment.

The LAD coronary artery can be particularly difficult to identify when it has an intramyocardial course. It can be relatively easy to inadvertently enter the right ventricular cavity while dissecting in the interventricular fat plane. If such a ventriculotomy is small, it can be closed with fine 6-0 polypropylene sutures, keeping in mind that the right ventricle

is a low-pressure chamber and deep bites of myocardium are not necessary. However, if the right ventricle has been opened for a distance, it is best repaired using interrupted, pledgetted 2-0 Prolene suture (MH needle) in a horizontal mattress fashion, passing the needle under the ITA-LAD anastomosis. If difficulty is encountered in identifying an LAD artery, a fine probe may be passed retrograde via a small transverse arteriotomy into the LAD artery at the apex of the heart. The tip of the probe can be palpated in the proximal portion of the artery and cut down on appropriately. The distal arteriotomy is repaired with interrupted fine suture (7-0 or 8-0 Prolene™). The repair can be done with or without a small vein patch.

The distribution of cardioplegia is usually relatively uniform; however, the sequence of anastomoses may be planned based on ischemic regions if myocardial protection is a particular concern. Grafting the most ischemic area first, using a distal-proximal routine, will permit early antegrade delivery of cardioplegia through the graft to the area of myocardial ischemia. Alternatively, the sequence of anastomoses may be dictated by the quality of the conduit itself, matching the best conduit to the most important territories. It is customary to perform the left ITA-to-LAD artery anastomosis last to avoid tension and potential disruption of the anastomosis.

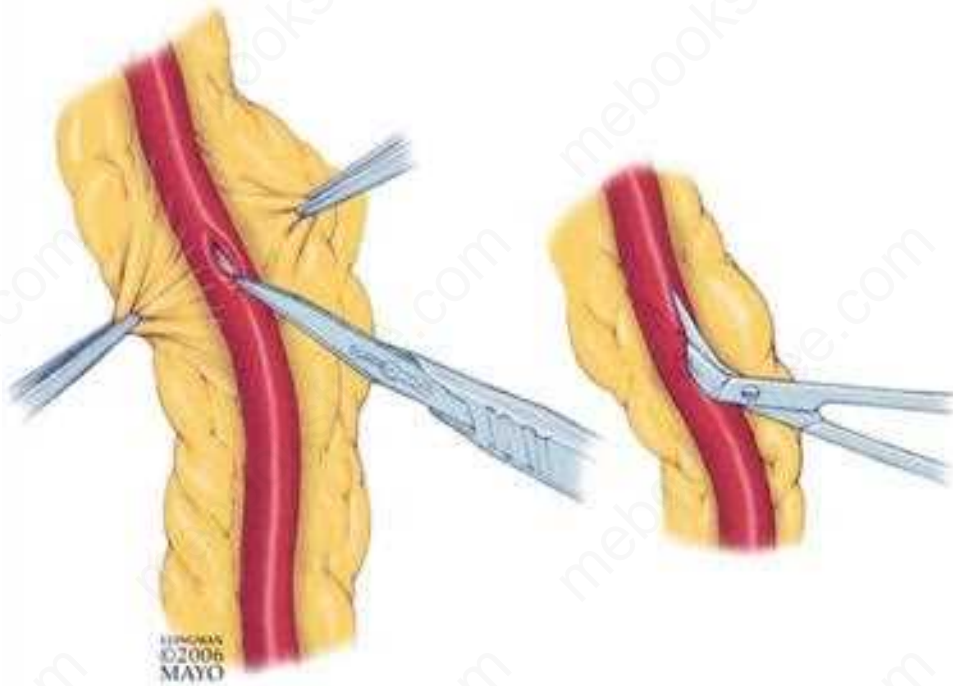

#### ARTERIOTOMY

The choice of the site of arteriotomy is critical. Opening into a plaque may force endarterectomy, whereas injury to the

posterior wall with the knife transforms a straightforward anastomosis into a complex repair. Silastic tapes placed proximally and distally around the coronary artery may help to stabilize the vessel, a technique often employed when grafting the distal right coronary artery or when there is significant back bleeding from the opened vessel. The arteriotomy is performed with a fine scalpel blade and extended with fine Pott's scissors proximally and distally. The arteriotomy should match the conduit diameter, and should be at least 1.5 times the luminal diameter of the distal coronary artery (Fig. 20-9).

#### ANASTOMOTIC TECHNIQUE

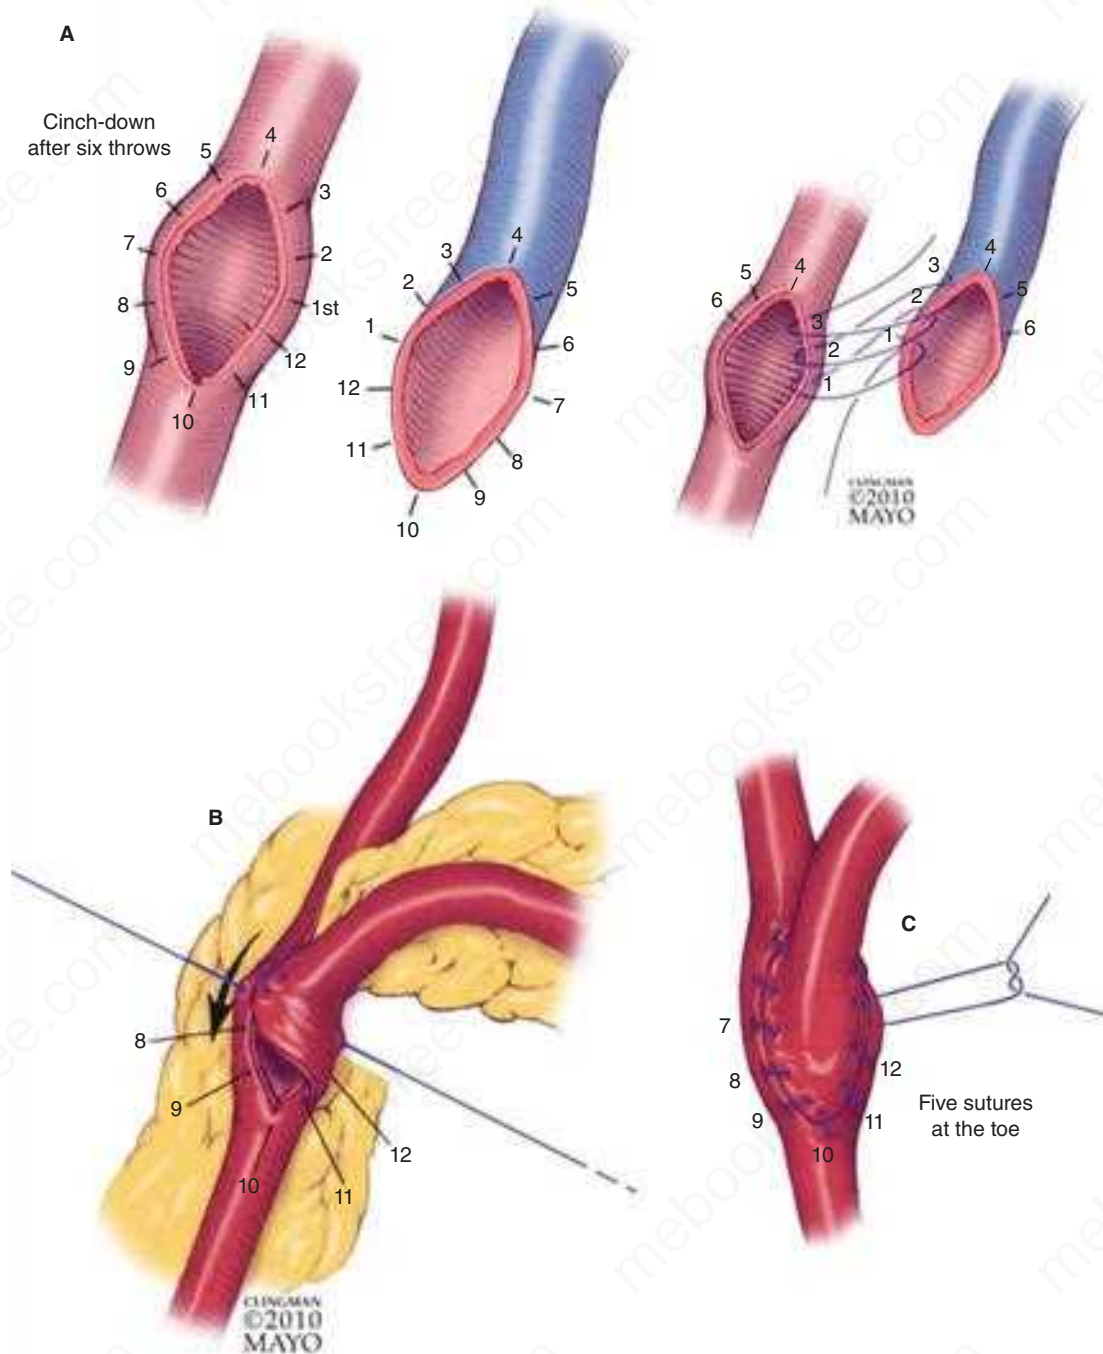

The goal of the anastomosis is to join the conduit and the target vessel with precise endothelial approximation affording minimal resistance to flow. The wall of the vessel should be handled with care, avoiding endothelial injury to prevent thrombotic complications. Coronary anastomoses are typically constructed with continuous 7-0 polypropylene suture. Sutures should be evenly spaced to prevent leaks at the conclusion of the anastomosis. In order to increase anastomotic area, we prefer to bevel the conduits at approximately 30° and notch them at the heel. Anastomoses are performed with continuous suture. We prefer a continuous, parachuting technique initiated at the heel for virtually all anastomoses regardless of their configuration (ie, end-to-side vs side-to-side sequential anastomosis).

**FIGURE 20-9** Distal anastomosis: *Arteriotomy*. Arteriotomy sites should be proximal enough to offer the largest-sized coronary target, and just distal enough to avoid the area of obstruction. Intramyocardial vessels can often be localized by noting epicardial indentation, accompanying epicardial veins, or a whitish streak within the myocardium. Sharp dissection of overlying tissue is then required to identify the desired target site. The arteriotomy is then performed with a no. 11 blade. The arteriotomy is extended with fine Pott's scissors proximally and distally. The arteriotomy should match the conduit diameter, and should be at least 1.5 times the diameter of the distal coronary. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Venous conduit is brought onto the field with a mosquito clamp on the adventitia at the toe of the conduit. An end-to-side anastomosis is accomplished with continuous sutures (Fig. 20-10). Starting at the 3 o'clock position on the right side of the vessel, the suture is passed outside-in on the conduit and then inside-out at the corresponding

location of the target coronary vessel. Two more sutures are taken before the heel (2 and 1 o'clock positions), one directly in the heel (12 o'clock), and then two more on the left side (11 and 10 o'clock positions) of the anastomosis before parachuting the conduit down to the target vessel.

**FIGURE 20-10** Distal anastomosis suture technique. (A) The conduit is beveled at 30 degrees and notched at the heel. We use a continuous, parachuting technique with 7-0 or 8-0 polypropylene suture. The conduit is brought onto the field with a mosquito clamp on the adventitia at the toe of the conduit. An end-to-side anastomosis is accomplished with 12 sutures. Starting at 3 o'clock on the right side of the vessel, the suture is passed outside-in on the conduit and then inside-out at the corresponding location of the target coronary vessel. (B) Two more stitches are taken before the heel, one directly in the heel, and then two more on the left side of the anastomosis before parachuting the conduit down to the target vessel. (C) The anastomosis is then completed by placing another six stitches evenly spaced in the same manner for the toe. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

The anastomosis is continued by placing additional sutures moving in a counterclockwise fashion around the anastomosis until the other thread is encountered. The technique encourages one to move out of the heel and toe areas of the anastomosis, minimizing the risk of narrowing the outflow. Care must be taken to prevent suturing the back wall of the coronary, and the proper amount of tension on the follow-through must be provided to avoid both leakage and a purse-string effect. Just before completion of the anastomosis, a 1-mm probe is passed proximally and distally to ensure patency. To prevent anastomotic tension and torsion, pedicled conduits (ie, left ITA) can be suture-fixed to the adjacent epicardium.

Sequential grafting permits efficient use of conduit and has the potential for increased flow in the conduit. When planning sequential anastomoses, the most distal anastomosis should be to the largest target vessel with the greatest outflow potential. If the reverse situation is created, the most distal anastomosis is at increased risk for failure, given the likelihood of preferential flow to the larger more proximal anastomosis.<sup>251,252</sup> A clear disadvantage of sequential grafting is the reliance of two or more distal targets on a single conduit and proximal anastomosis, placing a potentially larger region of the myocardium at jeopardy.<sup>252</sup>

Some surgeons avoid using the ITA for sequential grafting or as a donor for composite T or Y-grafting of other conduits because of concerns of compromising critical ITA-to-LAD flow. However, several series have demonstrated successful use of the ITA for sequential grafting of stenotic diagonal coronary arteries with excellent results.<sup>253,254</sup> The left ITA has also been used for multiple sequential anastomoses to the circumflex territory with grafting of the right ITA to the LAD artery.<sup>255</sup> Sequential grafting has also been performed with the right GEA as well as the RA.<sup>256,257</sup>

When constructing a sequential anastomosis, it is our preference to complete the distal anastomosis first and move proximally (Fig. 20-11). We feel that this facilitates determination of optimal inter graft spacing. In the case of the LAD-diagonal graft, however, it is easier to move from proximal to distal, performing the diagonal anastomosis first. Sequential side-to-side anastomoses may be perpendicular or longitudinal. When constructing perpendicular anastomoses care must be taken not to make the arteriotomies too long, as there is risk of creating a “gull-wing” deformity and placing the graft at jeopardy. Arteriotomies in both the conduit and target are made in the direction of the long axis of the vessel. The two incisions are then aligned perpendicular to one another and the anastomosis completed, creating a diamond-shaped anastomosis. The arteriotomy for longitudinal anastomosis may be made as long as necessary without risk of distorting the conduit. Typically, the longitudinal anastomosis is begun at the heel as previously described.

## Coronary Endarterectomy

Coronary endarterectomy predated CABG as a direct surgical approach to relieving coronary occlusive disease. Coronary

endarterectomy has been relegated to a position of secondary importance, however, thanks to the reliable and reproducible results obtained with CABG. Recently there has been increased interest in endarterectomy techniques, because the patient population coming to CABG has a greater atherosclerotic burden owing to diabetes, hyperlipidemia, and advanced age.<sup>258</sup> Most commonly, the need for endarterectomy arises intraoperatively when no soft site can be identified for arteriotomy or a vessel has been inadvertently opened in an extensively diseased area not amenable to grafting. Occasionally, endarterectomy is undertaken electively in patients with diffuse and extensive coronary disease with no other choices except transplantation.

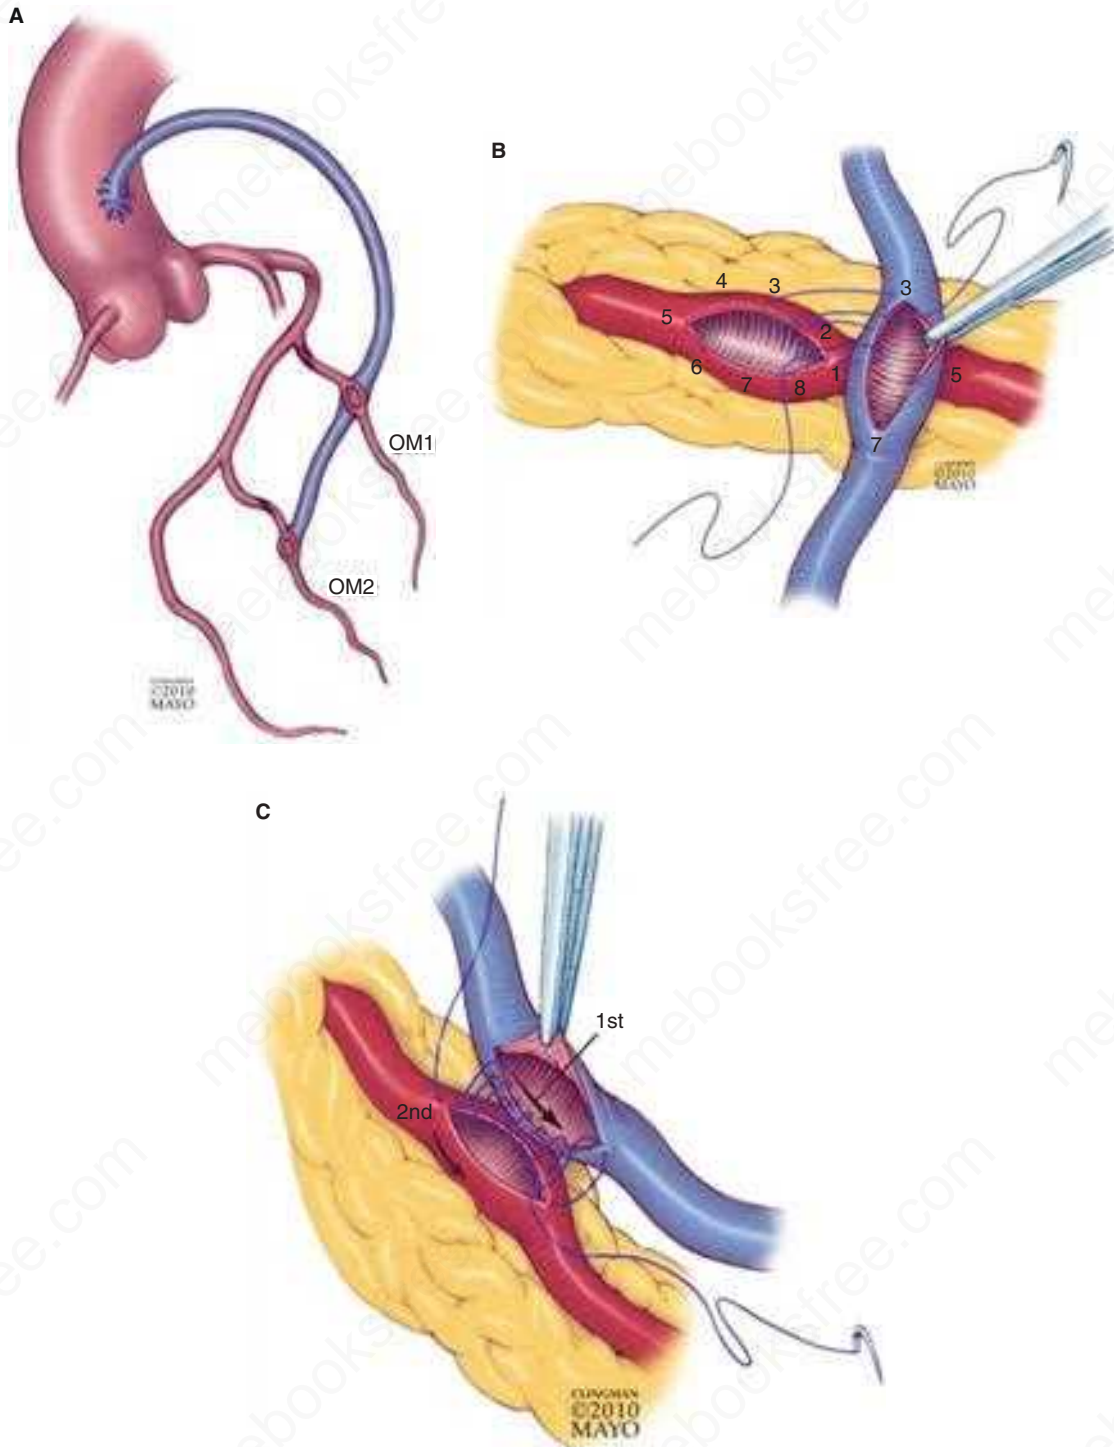

The perioperative risk of CABG with endarterectomy is higher than that for CABG alone in most studies. In a retrospective study of 1478 patients, the reported mortality rate with endarterectomy was 3.2%, which was higher than for CABG alone (2.2%). Perioperative MI rate was also higher in the endarterectomy group, 4.2% versus 3.4%. The risk of mortality appears to increase when multiple vessels require endarterectomy: single-vessel endarterectomy mortality = 1.8% versus multiple-vessel endarterectomy mortality = 5.5%.<sup>259,260</sup> There has been controversy regarding the risk of endarterectomy of the LAD, with some studies showing increased risk whereas others demonstrate no increased risk.<sup>259-261</sup>

The late results of endarterectomy are inferior to those of routine CABG, with reported 3-year patency for ITA grafts to endarterectomized LAD targets ranging from 74 to 80%.<sup>262,263</sup> Despite this, angina relief is remarkably good initially. Unfortunately, the rate of recurrent angina is somewhat higher than after uncomplicated CABG; reported recurrence of angina is 25% at 5 years after endarterectomy.<sup>260,264</sup> The reported 5-year survival following coronary endarterectomy ranges from 76 to 83%.<sup>260,264</sup> Among patients in whom bypass to more distal nondiseased segments is not possible, coronary endarterectomy with subsequent bypass offers a viable alternative to leaving a territory ungrafted.

## TECHNIQUE

The technique of endarterectomy requires that the central core be extracted adequately in order to relieve obstruction of the branch vessels. Patency of a graft to the endarterectomized vessel depends upon the adequacy of runoff and therefore the distal endpoints of the endarterectomy core must be smoothly tapered. If the core fractures leaving behind disease in side branches, distal counter-incisions may be needed to obtain a satisfactory result.

The RCA is the vessel most often endarterectomized, usually at the level of its bifurcation. A manual eversion endarterectomy is performed after entering at the vessel approximately 1 cm proximal to the crux. A circumferential plane of dissection between the core and the adventitia is developed with a fine coronary spatula. The core is transected proximally and gently grasped with DeBakey forceps while the spatula is used to tease the adventitia away from the core. The core is regrasped hand over hand as distally

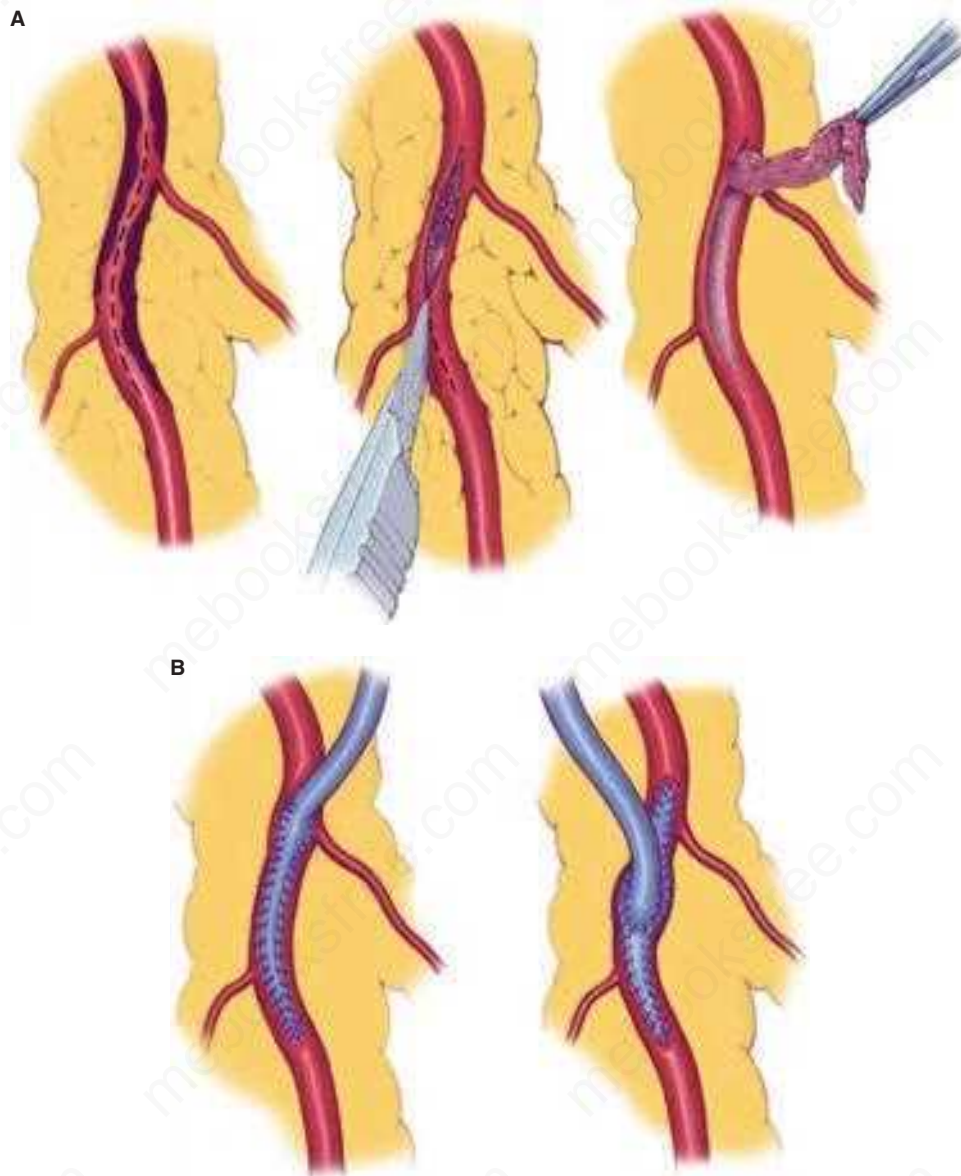

**FIGURE 20-11** Sequential anastomosis. (A) Order of anastomoses: The order in which sequential anastomoses are performed is important to facilitate optimal inter graft spacing and avoid kinking. The distal anastomosis is completed first and the more proximal sequential anastomosis is performed second, except for an LAD-diagonal graft, in which the diagonal is performed first followed by the LAD. (B) Perpendicular sequential side-to-side anastomosis: Arteriotomies are made in the direction of the long axis of the coronary and the conduit. Care must be taken not to make the arteriotomies too long, because there is risk of creating a “gull-wing” deformity. The two incisions are aligned perpendicular to one another. The suture is passed starting inside-out at the apex of the target coronary and then outside-in at the mid-portion the conduit. An eight-stitch anastomosis is completed creating a diamond-shaped anastomosis. (C) Longitudinal sequential side-to-side anastomosis: The arteriotomy for longitudinal anastomosis may be made as long as necessary without risk of distorting the conduit. The anastomosis is begun at the heel and the far wall is completed open. It is then parachuted down and the front wall completed. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

as possible to avoid fracture. When the crux is reached, the posterior descending artery and the left ventricular branch are endarterectomized separately. If endarterectomy of the proximal segment of the RCA is needed, we prefer to use an open technique because it is difficult to obtain nice tapering of the core at the takeoff of the acute marginal branches with a retrograde eversion endarterectomy. The vessel wall is then reconstructed with a long hood created with the bypass conduit of choice.

We prefer open extended technique when the LAD is endarterectomized (Fig. 20-12). The vessel is opened as far

proximal as possible if endarterectomy is anticipated. If the vessel has been opened in its mid-portion before it is apparent that endarterectomy is necessary, we extend the incision in the adventitia proximally before developing the endarterectomy plane. Retrograde eversion endarterectomy is dangerous because branch vessels will not be opened. Once the core is separated from the adventitia, it is transected proximally at the heel and the vessel is opened beyond the takeoff of the major diagonals to permit individual eversion endarterectomy of each of the branches. The segment is reconstructed with a long hood of the conduit of choice or a vein patch into

**FIGURE 20-12** Coronary endarterectomy: Open extended technique. (A) The extent of disease is evaluated to plan the length of the arteriotomy and endarterectomy. The arteriotomy is performed and extended as proximal as needed before the circumferential plane of dissection between the core and the adventitia is developed with a fine coronary spatula. Once the core is separated from the adventitia, it is transected proximally at the heel and the vessel is opened beyond the takeoff of the major branches to permit individual eversion endarterectomy of each of the branches. (B) The segment is reconstructed with a long hood of the conduit of choice. The segment may be reconstructed with a vein patch into which the conduit is anastomosed. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

which the ITA is anastomosed. The circumflex artery is the most infrequently endarterectomized vessel. Its rapid branching pattern makes satisfactory endarterectomy difficult. We tend to begin with an eversion technique, focusing our efforts on opening the largest distal branches as much as possible.

## Proximal Anastomoses

Proximal anastomoses of the saphenous vein or the RA to the aorta are performed after the distal anastomoses under the same cross-clamp clamp. Our preferred technique is to complete each respective bypass graft in a distal anastomosis-proximal anastomosis fashion. Completion of the each respective bypass graft allows antegradecardioplegia down the completed graft, aiding in myocardial protection. The single cross-clamp technique results in longer cross-clamp times than with the partial occlusion clamp method. However, the partial occlusion clamp technique requires additional aortic manipulation and although some authors have found this practice to be safe,<sup>265</sup> others have demonstrated that it carries a higher risk of neuropsychological deficits when compared with the single-clamp technique.<sup>266</sup>

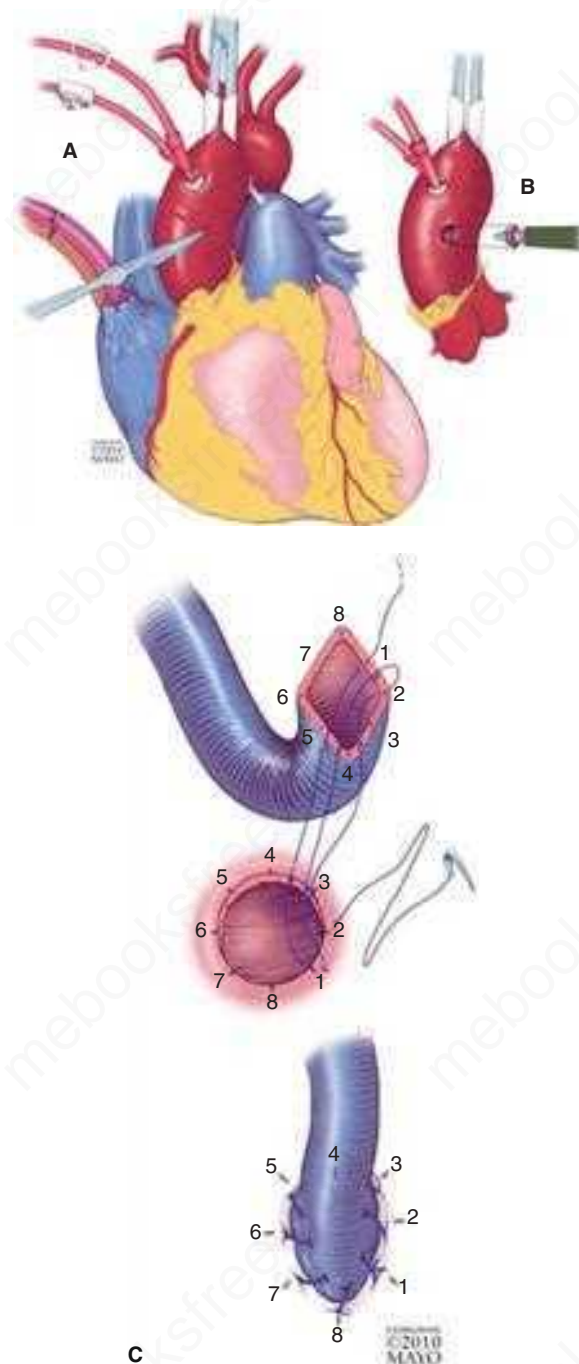

## ANASTOMOTIC TECHNIQUE

Once an appropriate site for aortotomy is identified, the fatty tissue overlying the aorta is removed (Fig. 20-13). An arteriotomy is created with a no. 11 blade, and a 4.0-mm punch used to create a circular aortotomy. The size of the punch may vary depending on the size of the conduit graft. The graft is measured to length with the aorta, right heart, and pulmonary artery full of blood. The graft is cut and the proximal aspect of the conduit beveled and notched at the heel. A running 5-0 polypropylene suture is used for a venous graft and a 6-0 polypropylene suture for an arterial conduit. The long axis of the graft is aligned at an appropriate angle to the ascending aorta. The anastomosis can be completed with continuous stitches. Symmetry in the spacing of sutures is paramount to obtain a hemostatic anastomosis. Free arterial grafts may also be sutured to the hood of a vein graft with continuous 7-0 Prolene suture.

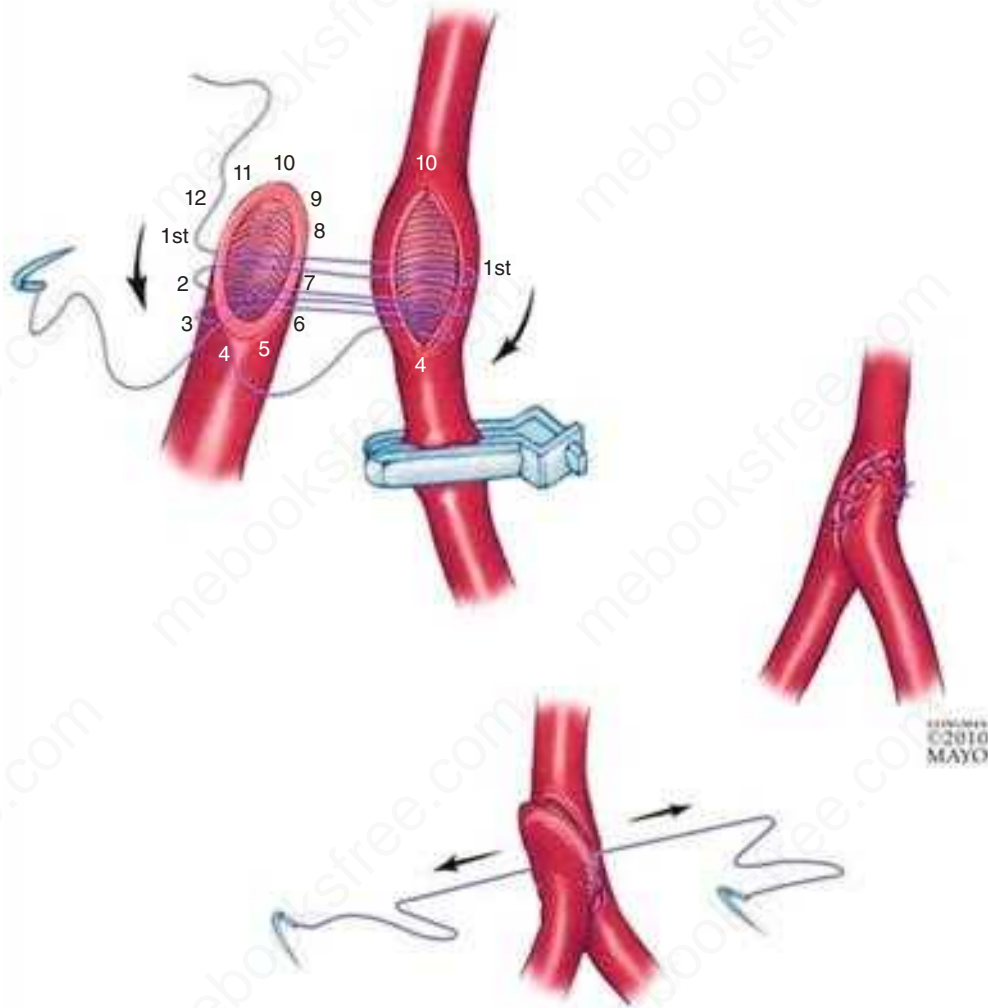

## COMPOSITE GRAFTS

As an alternative to proximal anastomosis to the aorta, a free graft can be anastomosed proximally to the pedicled ITA (Fig. 20-14). This technique has the theoretical advantage of providing a more physiologic arterial pressure waveform by attaching the conduit to a third-order vessel rather than to the aorta. Composite grafting is also a useful tool for the hostile, calcified ascending aorta or when there is a limited length of conduit available. It is also advantageous when there is a marked mismatch between aortic wall thickness and arterial conduit size.

A combination of composite and sequential grafting allows the opportunity to perform complete arterial revascularization with only ITA or with ITA and other arterial

**FIGURE 20-13** Proximal anastomosis. (A) The proximal anastomosis is performed using a single-clamp technique. The fatty tissue overlying the planned aortotomy site is removed. An arteriotomy is created with a no.11 blade. (B) A 4- to 5-mm aortic punch is used to create a circular aortotomy. The size of the punch will vary depending on the size of the conduit graft. (C) The proximal aspect of the conduit is beveled and then notched at the heel. A running 5-0 or 6-0 polypropylene suture is used for a venous graft and a 6-0 or 7-0 polypropylene suture for an arterial conduit. The long axis of the graft is aligned at an appropriate angle to the ascending aorta. The anastomosis can be completed with eight stitches in most cases; symmetry in the spacing between stitches is of paramount importance to ensure hemostasis. **FIGURE 20-14** Composite Y-graft. Y-graft anastomotic technique: A coronary artery bypass graft (CABG) is used as a donor site for the proximal anastomosis of another conduit. An incision is created in the donor conduit. The proximal end of the recipient conduit is then anastomosed to the donor site in an end-to-side fashion as previously described for a distal anastomosis. The recipient conduit is then gently parachuted down onto the donor conduit. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

conduits (Fig. 20-15). Multiple configurations of Y- and T-grafts can be devised to best suit the anatomic characteristics of each patient. Some authors have advocated even using the distal segment of the LITA as a composite graft off the composite RITA to further expand the reach of a complete arterial revascularization strategy.<sup>267</sup> The LITA has been shown to have more than sufficient flow reserve to supply flow to the entire coronary circulation.<sup>268</sup> The free right ITA, the RA, or other arterial conduit can be based in this manner.

All-arterial Y-grafts are usually planned in advance and constructed before the initiation of cardiopulmonary bypass. Special care must be taken during construction of composite grafts to avoid tension, rotational torsion, or narrowing of the inflow anastomosis. Disadvantages include technical difficulty and reliance upon a single inflow source for two or more distal targets.

### Management of the Atherosclerotic Ascending Aorta

Ascending aortic atherosclerosis has been consistently identified as a very important risk factor for stroke in multiple series. Routine epiaortic ultrasound should be performed to define the extent of atherosclerosis of the ascending aorta and its likelihood of embolization. Patients with severe atherosclerosis of the ascending aorta may require alternative strategies to prevent embolization of aortic atheroma. If the ascending aorta is hostile, we favor cannulation of the right axillary artery. Although most surgeons prefer to achieve axillary arterial inflow utilizing a chimney side graft, direct cannulation of the axillary artery with an appropriately designed axillary angled cannula is very safe and effective.<sup>269</sup> If necessary, aortic clamping may be performed in areas free of atheroma, usually in the more proximal ascending aorta.

**FIGURE 20-15** Total arterial revascularization: As shown, arterial revascularization can be performed using the right internal thoracic artery (RITA) off the left internal thoracic artery (LITA) as a Y-graft and liberal use of sequential grafting. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Coronary revascularization can be achieved with a variety of methods. Using a “no-touch” technique, revascularization can be done using only pedicled arterial conduits, and if proximal anastomoses are required they can be based off pedicled conduits or brachiocephalic vessels. Distal anastomoses can be performed with an “on pump, beating heart” technique without aortic cross-clamping but with vessel occlusion and stabilization techniques used in off pump surgery. This does not require cooling or LV venting, two necessary features of the similar but now obsolete cold fibrillatory arrest technique. Proximal anastomoses can be performed under deep hypothermic circulatory arrest or after graft replacement of the ascending aorta if there are large mobile atheromas.<sup>270</sup>

### Weaning from Cardiopulmonary Bypass

On completion of all anastomoses, the aortic cross-clamp is removed and a stable heart rhythm established. Some advocate allowing the heart to recover on full bypass for 10 minutes for each 60 minutes of aortic cross-clamp time.

During this time of recovery the patient is prepared for transition from supported circulation to native circulation. The aortic root vent and retrograde catheters are removed and the sites repaired with suture. The bypass grafts are checked for kinks, twists, or tension and for presence of hemostasis. The patient must be rewarmed to normothermia if cooled and the acid-base status and electrolyte abnormalities corrected. We place temporary atrial and ventricular pacing wires on all patients.

Weaning from cardiopulmonary bypass is otherwise the same as for other cardiac surgical cases. Issues particular to CABG include attention to avoid tension on the LITA from lung overinflation or overdistention of the heart, which may place all grafts on tension and disrupt anastomoses. If air has entered the heart, bubbles may pass into the aorta and down the bypass grafts causing arrhythmias and regional wall motion abnormalities. Treatment involves continued recovery on bypass and increasing the perfusion pressure as a means to drive the bubbles through the coronary circulation. Persistency of regional wall motion abnormalities may require bypass graft revision or placement of additional bypass grafts.

## OUTCOMES

### Operative Mortality

The risk profile of patients requiring isolated CABG in the United States changed significantly in the 1990s. Compared to previous decades, patients undergoing CABG are older, with a greater number of comorbidities, decreased left ventricular ejection fraction (LVEF), and a higher burden of atherosclerotic disease; however, early outcomes after CABG continue to improve. The STS database demonstrates that despite an increase in expected mortality from 2.6 to 3.4% (relative increase 30%) in the decade of the 1990s, the observed mortality actually decreased from 3.9 to 3.0% (relative decrease 23%).<sup>3</sup>

Similar observations have been made using the Veterans Affairs mandatory national database, where the unadjusted mortality rate for isolated CABG fell from 4.3% in 1989 to 2.7% in the year 2000.<sup>271</sup> In the private sector similar trends have been observed. In an analysis of outcomes of patients undergoing isolated CABG in the HCA system, a nationwide for-profit health care system involving 200 hospitals in 23 states, Mack and associates reported an ongoing decrease in unadjusted operative mortality among 51,353 patients, 80% of whom received CABG with cardiopulmonary bypass. In this study the operative mortality decreased from 2.9% in 1999 to 2.2% in 2002.<sup>272</sup>

This trend has continued throughout the first decade of the new millennium, with the observed mortality having declined to 1.9% in 2009 on the 1,297,254 patients who underwent isolated CABG during that time interval.<sup>175</sup> This represented a 24.4% reduction in operative mortality between 2000 and 2009.<sup>175</sup>

## Causes of Death

In a multicenter prospective study performed by the Northern New England Cardiovascular Disease Study Group, 384 deaths among 8641 consecutive patients undergoing isolated CABG between 1990 and 1995 were analyzed with respect to the mode of death. The mode of death was defined as the seminal event that precipitated clinical deterioration and ultimately resulted in the patient's demise. Heart failure was judged to be the primary mode of death for 65% of the patients, followed in frequency by neurologic causes (7.3%), hemorrhage (7%), respiratory failure (5.5%), and dysrhythmia (5.5%). The greatest variability in mortality rates observed across surgeons in the study was attributable to differences in rates of heart failure.<sup>273</sup> Cardiac causes were also identified by Sergeant and colleagues as the most common causes of death in a series of 5880 patients undergoing CABG between 1983 and 1988.<sup>274</sup>

## Operative Morbidity

### MYOCARDIAL DYSFUNCTION

Postoperative myocardial dysfunction and cardiac failure after CABG may be related to preoperative ischemic injury, inadequate myocardial protection, incomplete revascularization, or postoperative graft failure. The spectrum of myocardial injury varies from subtle degrees of global myocardial ischemia to transmural infarction. The incidence of myocardial injury identified varies with the sensitivity of the method used for detection as well as the threshold set. Some studies have reported perioperative MI rates as high as 10% of patients with associated worse clinical outcomes (death, MI, or revascularization).<sup>275</sup>

Some elevations of cardiac-specific enzymes are ubiquitous after CABG; however, most would agree that elevations in creatinine kinase-myocardial bound (CK-MB) greater than five times the upper limit of normal (ULN) value are considered significant. In a prospective study of 2918 patients undergoing CABG, 38% of patients had a CK-MB > 5 ULN and 17% had a CK-MB > 10 ULN with an incidence of new Q-wave MI of 4.7%.<sup>276</sup> Troponin may be a more sensitive marker than CK-MB, but its role in large populations of CABG patients is still to be defined.<sup>277</sup> Prominent elevations of CK-MB and troponin have been associated with global ischemia, MI, low cardiac output, and increased operative mortality, as well as increased midterm and long-term mortality.<sup>276,277</sup>

Transient myocardial dysfunction necessitating low-dose inotropic support for a short period of time is also common after CABG. Significant postoperative myocardial dysfunction manifest clinically as low cardiac output syndrome may be defined by the need for postoperative inotropic support or IABP support to maintain a systolic blood pressure > 90 mm Hg or a cardiac index > 2.2 L/min. The reported incidence of low output syndrome varies depending on the defining criteria and has a reported incidence of 4 to 9%.<sup>278,279</sup> Low output syndrome has been shown

to be a marker for increased operative mortality by 10- to 15-fold.<sup>280</sup> Independent predictors of low output syndrome in order of importance include LVEF < 20%, reoperation, emergency operation, female gender, diabetes, age older than 70 years, left main disease, recent MI, and triple-vessel disease.<sup>278</sup>

### ADVERSE NEUROLOGIC OUTCOME

Neurologic deficits after coronary surgery are divided into two types: type 1 deficits include major neurologic deficits, stupor, and coma; type 2 deficits are characterized by deterioration of intellectual function and memory. The incidence of type 1 deficits was reported to be 1.6% in a large review by the Northern New England Cardiovascular Disease Study Group with 1-, 5-, and 10-year survival rates significantly reduced in affected patients.<sup>160</sup> Perioperative mortality is similarly increased among those with type 1 injury at over 24%.<sup>281</sup> Type 2 deficits are more difficult to characterize and may be more related to the underlying atherosclerosis than to the bypass operation per se. In one nonrandomized study, there was no evidence that the cognitive test performance of CABG patients differed from that of heart healthy control groups with CAD over a 1-year period.<sup>282</sup>

Just like mortality rates, stroke rates have shown a decrease in incidence over the last decade (1.6% in 2000 vs 1.2 in 2009, a 26.4% decrease).<sup>175</sup> More extensive preoperative imaging of the aorta and its arch vessels via CT scan or ultrasound, as well as liberal usage of axillary cannulation over the last decade may be contributing to this improvement, although there is no published evidence to support this relationship.

Predictors of neurologic deficits included advanced age ( $\geq 70$  years of age), and history or presence of severe hypertension. Independent predictors of type 1 deficits included proximal aortic atherosclerosis, history of prior neurologic disease, need for IABP, diabetes, unstable angina, and perioperative hypotension. Predictors of type 2 deficits included history of alcohol consumption, dysrhythmias, prior CABG, peripheral vascular disease, CHF, and perioperative hypotension. Similar predictors of adverse neurologic outcomes have been observed in other studies.<sup>283</sup>

### DEEP STERNAL WOUND INFECTION

Deep sternal wound infection occurs in 1 to 4% of CABG patients and has historically carried a mortality rate of 25%.<sup>284</sup> These outcomes have dramatically improved over the past 20 years, with the latest meta-analysis reporting a 1.66% risk of mediastinitis when only one ITA is used and 2.64% when both ITAs are used.<sup>285</sup> When skeletonization of the ITAs is performed, these numbers drop to 1.16 and 1.48%.<sup>285</sup> Proven methods to reduce postoperative wound complications include the use of preoperative showers with chlorhexidine gluconate on the evening and morning before the procedure, prophylactic intranasal application of mupirocin given on the evening and the morning before the procedure and twice daily for 5 days postoperatively, hair clipping the morning of surgery, tight glycemic control,

and administration of intravenous prophylactic antibiotics before skin incision.<sup>286-288</sup> Application of a cyanoacrylate-based microbial skin sealant may further reduce surgical site infection.<sup>289</sup>

Obesity and diabetes are strong independent predictors of mediastinitis. Insulin-dependent diabetic patients are especially susceptible to deep sternal wound infection.<sup>290-292</sup> Recent data suggest that tight glycemic control in the postoperative period decreases the risk of mediastinitis in the diabetic population.<sup>293,294</sup> Other preoperative variables independently associated with an increased incidence of deep sternal wound infection include reoperation, longer operative times, reexploration for bleeding, and blood transfusions.<sup>290,291,295</sup>

The use of bilateral ITAs had been implicated as a risk factor for sternal wound complications, especially in diabetics.<sup>296</sup> However, this risk appears to be mitigated in part by using a skeletonized ITA harvesting technique.<sup>297</sup> Bilateral ITA harvest should likely be avoided in obese diabetic women, in cases of repeat sternotomy, and in patients with severe COPD, because they exhibit a higher risk of deep sternal wound infection even with skeletonization of the ITA.<sup>204,298</sup>

## ACUTE RENAL FAILURE

Acute renal failure ensuing after CABG with cardiopulmonary bypass is an ominous event. In a prospective observational study conducted at 24 university centers in the United States, including data on 2222 CABG patients,<sup>299</sup> renal dysfunction not requiring dialysis occurred in 6.3%, and renal dysfunction requiring hemodialysis developed in 1.4%. Mortality was directly related to postoperative renal function. Patients with no renal dysfunction had 0.9% mortality.<sup>299</sup> Postoperative renal dysfunction increased mortality to 19% if no dialysis was needed and increased mortality to 63% if hemodialysis was required. Patients with large creatinine increases (>50%) after CABG surgery also have higher 90-day mortality.<sup>300</sup>

Independent predictors of postoperative renal dysfunction included increasing age, CHF, reoperation, DM, chronic renal insufficiency, prolonged cardiopulmonary bypass time, and low cardiac output.<sup>299</sup> These findings were confirmed in another series of 42,733 patients with similar incidence and mortality associated with postoperative renal dysfunction.<sup>301</sup> One in four patients with preoperative chronic renal insufficiency (creatinine > 1.6 mg/dL) will require renal replacement therapy post-CABG, and patients at highest risk are older than 70 years and have a baseline creatinine > 2.5 mg/dL.<sup>302</sup>

Continuous infusion of low-dose recombinant human B-type natriuretic peptide (nesiritide) from the start of cardiopulmonary bypass has been evaluated as a method to effectively maintain postoperative renal function. In the prospective, randomized, NAPA Trial, 272 patients with EF < 40% undergoing CABG who receive nesiritide experienced a significantly attenuated peak increase in serum creatinine and a greater urine output during the initial 24 hours after surgery. In addition, they had a shorter hospital stay and lower

180-day mortality.<sup>303</sup> Similar renal protective results were noted in a randomized trial using human atrial natriuretic peptide in 251 patients. The treated group had fewer postoperative complications, lower serum creatinine, and higher urinary creatinine and creatinine clearance. The maximum postoperative creatinine level and percent increase of creatinine were also significantly lower in the treatment group. No patient in the natriuretic group required hemodialysis.<sup>304</sup> We are awaiting further study before adopting natriuretic peptides in our routine CABG practice.

## Long-term Outcomes

Long-term outcomes of surgical myocardial revascularization depend on the complex interaction of patient-related and procedure-related factors. Important patient-related factors include anatomic distribution of the CAD, the extent and severity of coronary atherosclerosis, the physiologic impact of ischemia on ventricular function at the time of the original operation, age, gender, overall health status, severity of atherosclerotic burden throughout the body, the presence and severity of associated comorbidities, development of operative complications such as stroke, and need for permanent hemodialysis. The progression rate of native coronary atherosclerosis after surgery and the development of coronary bypass graft failure are of extreme importance in the development of post-CABG angina recurrence, MI, need for reintervention, and cardiac-related mortality. Procedure-related factors that influence long-term outcomes include completeness of revascularization, myocardial protection, and selection of bypass conduits.

Sergeant and colleagues at the Gasthuisberg University Hospital of the Katholieke Universiteit (KU) Leuven, Belgium have provided several reports detailing clinical outcomes after myocardial revascularization.<sup>305-308</sup> From 1971 to 1993, 9600 consecutive CABG patients were prospectively followed with special attention to clinical outcomes after surgical myocardial revascularization; the investigators achieved a 99.9% complete follow-up in this cohort. Clinical outcomes prospectively followed included mortality, return of angina, MI, and coronary reintervention.<sup>305</sup>

Defining the return of angina as the first occurrence of angina of any intensity or duration unless it was associated on the same day with MI or death, and recording the severity of this event, was also recorded. The overall non-risk-adjusted freedom from return of angina was 95% at 1 year, 82% at 5 years, 61% at 10 years, 38% at 15 years, and 21% at 20 years. The data suggest that if followed long enough after CABG, the return of angina is almost inevitable; by 12 years one-half of operated patients had return of angina. The initial episode of recurrent angina was rated as mild in 59% of patients.<sup>306</sup> In the Bypass Angioplasty Revascularization Investigation (BARI) trial of 914 patients with symptomatic multivessel disease randomly assigned to receive CABG, freedom from angina was 84% at 5 and 10 years.<sup>84</sup>

The overall non-risk-adjusted freedom from MI after CABG at the KU Leuven was 97% at 30 days, 94% at 5 years,

86% at 10 years, 73% at 15 years, and 56% at 20 years.<sup>308</sup> The overall non-risk-adjusted freedom from a coronary re-intervention, either PCI or reoperative CABG, was 99.7% at 30 days, 97% at 5 years, 89% at 10 years, 72% at 15 years, and 48% at 20 years (125). In the BARI trial, freedom from subsequent coronary re-intervention at 10 years was 80%.<sup>84</sup>

Overall risk-unadjusted survival after CABG in the KU Leuven experience was 98% at 30 days, 92% at 5 years, 81% at 10 years, 66% at 15 years, and 51% at 20 years. Mortality after CABG was characterized by an initial period of high risk in the first month after surgery, then risk declined to its lowest at 1 year after the operation, and thereafter the mortality risk rose slowly and steadily for as long as the patient was followed. This slow and steady rise in the risk of death over time paralleled that of the general population when matched for sex, age, and ethnicity.<sup>307</sup> In the BARI trial, survival was 89% at 5 years and 74% at 10 years.<sup>84</sup>

The occurrence of ischemic clinical events after CABG negatively influences survival. In the KU Leuven study, overall survival was lessened by return of angina, with an observed survival of 83% at 5 years and 54% at 15 years; the more intense the severity of angina at its return, the greater its influence on survival.<sup>306</sup> The occurrence of MI after CABG has a greater negative effect on survival. Observed long-term survival after post-CABG infarction at the KU Leuven was 80% at 30 days, 65% at 5 years, 52% at 10 years, and 41% at 15 years.<sup>308</sup>

### PROGRESSION OF DISEASE IN NATIVE CORONARY ARTERIES

Progression of atherosclerosis in the native coronary arteries continues after CABG. Bourassa and associates studied the progression of atherosclerosis in the native circulation 10 years after surgery and found that progression of CAD occurs in approximately 50% of nongrafted arteries.<sup>309</sup> The rate of progression of disease in nongrafted arteries was no different from that of grafted arteries with patent grafts; however, progression was more frequent in grafted arteries with occluded grafts. Progression of preexisting stenoses in native coronaries was more frequent than appearance of new stenoses, and it was related to the severity of the preexisting stenosis only in nongrafted arteries.

Progression of native CAD was associated with deterioration in left ventricular function. Native coronary atherosclerosis progressed at a similar rate to that of equally diseased arteries in nonoperated patients.<sup>309</sup> Low levels of high-density lipoprotein cholesterol and elevated levels of plasma low-density lipoprotein cholesterol correlated with native disease progression and development of new atherosclerotic lesions.<sup>310,311</sup> Diabetes has been related to accelerated atherosclerosis.

### VEIN GRAFT FAILURE

Although the use of the saphenous vein helped popularize coronary bypass grafting, the propensity of the SVG to fail over time has been the limiting factor of the procedure. It has been reported that approximately 15% of vein grafts

occlude in the first year after CABG, and by 6 and 10 years after surgery patency rates fall to approximately 75 and 60%, respectively.<sup>197</sup> Three entities are responsible for SVG failure: thrombosis, intimal hyperplasia, and graft atherosclerosis.

Thrombosis accounts for graft failure within the first month after CABG, and graft occlusion is found on angiography in 3 to 12% of all venous grafts. Even when performed under optimal conditions, the harvesting of venous conduits is associated with focal endothelial disruption. In particular, the high pressure distension used to overcome venospasm during harvesting causes prominent endothelial cell loss, medial damage, activation of local factors (ie, fibrinogen) influencing hemostasis. Additionally, the inherent antithrombotic properties of veins are comparatively weak. The propensity for early graft occlusion resulting from these prothrombotic effects may, on occasion, be amplified by technical factors that reduce graft flow, including intact venous valves, anastomotic stricture, or graft implantation proximal to an atheromatous segment.<sup>197</sup>

Intimal hyperplasia, defined as the accumulation of smooth muscle cells and extracellular matrix in the intimal compartment, is the major disease process in venous grafts between 1 month and 1 year after implantation. Nearly all veins implanted into the arterial circulation develop intimal thickening within 4 to 6 weeks, which may reduce the lumen by up to 25%. Intimal hyperplasia rarely produces significant stenosis per se; more importantly, however, is that it may provide the foundation for later development of graft atheroma.<sup>312</sup>

Progression of atherosclerosis in aortocoronary SVGs is frequent and represents the predominant cause of late graft failure after CABG. Vein graft atherosclerosis may begin as early as the first year, but is fully developed only after about 5 years. Ten years after surgery, 50 to 60% of SVGs will be occluded and one-half of still patent grafts will show angiographic evidence of atherosclerosis; two-thirds of these lesions will have a luminal diameter reduction of 50% or greater. Vein graft atherosclerosis is the leading cause for re-intervention following CABG, more so than progression of disease in native coronary arteries.<sup>197</sup>

Although the risk factors predisposing to vein graft atherosclerosis are broadly similar to those recognized for native coronary disease, the pathogenic effects of these risk factors are amplified by inherent deficiencies of the vein as a conduit when transposed into the coronary arterial circulation. A multifaceted strategy aimed at prevention of vein graft disease is emerging, elements of which include continued improvements in surgical technique; more effective antiplatelet drugs; increasingly intensive risk factor modification, in particular early and aggressive lipid-lowering drug therapy; and a number of evolving therapies, such as gene transfer and nitric oxide donor administration, which target vein graft disease at an early and fundamental level. At present, a key measure is to circumvent the problem of vein graft disease by preferential selection of arterial conduits, in particular the internal mammary arteries, for coronary bypass surgery whenever possible.<sup>197</sup>

## Extended Use of Arterial Grafting

### BILATERAL INTERNAL THORACIC ARTERY GRAFT

In contrast to the easily demonstrated survival benefit conferred by an ITA graft to the LAD artery, it was more difficult to demonstrate a survival benefit to a second arterial graft. Buxton and colleagues studied 1243 patients undergoing primary CABG with bilateral ITA grafts compared with 1583 patients with single ITA grafts. This group demonstrated a 15% absolute improvement in actuarial survival rates 10 years after CABG with the use of bilateral ITA grafts, as compared with the use of a single ITA graft (10-year survival for bilateral ITA was  $86 \pm 3\%$  vs  $71 \pm 5\%$  for a single ITA).<sup>312</sup> Lytle and colleagues similarly demonstrated an improvement in survival at 12 years (79 vs 71%) as well as superior reoperation-free survival (77 vs 62%) among 2001 bilateral and 8123 single ITA graft patients.<sup>313</sup> The impact of selection bias in these studies is difficult to control, however, and although some surgeons have embraced bilateral ITA grafting, it still represents a small minority of cases reported to the STS database (3.8%).

### COMPLETE ARTERIAL REVASCULARIZATION

The better long-term results achieved with the use of bilateral ITAs and the well-known time-related attrition in patency of venous conduits encouraged the exclusive use of arterial conduits for myocardial revascularization. Complete arterial revascularization can be achieved by a variety of strategies, including composite grafting using exclusively ITAs or secondary arterial conduits such as the RA and the GEA. The use of sequential anastomotic techniques maximizes the utilization of arterial conduits. Although technically demanding, sequential grafting can be performed safely and with excellent long-term results with reported 96% patency rates of 7.5 years of follow-up on 1150 sequential ITA anastomoses.<sup>314</sup>

Tector has championed complete arterial revascularization using bilateral ITAs in a T configuration with end-to-side anastomosis of one ITA as a free graft to the side of the second ITA, which is left as a pedicled graft, combined with liberal use of sequential anastomoses. In his series of 897 patients overall survival was 75%, and freedom from reintervention was 92%, 8 years after revascularization.<sup>315</sup> Barner has reported similar encouraging results with composite grafting using one ITA and one RA.<sup>316</sup> Data from randomized studies are beginning to emerge supporting improvement in early outcomes with complete arterial revascularization compared with conventional CABG. Muneretto and associates randomized 200 patients to complete arterial revascularization (left ITA to the LAD artery and composite grafts with the right ITA, RA, or both) versus conventional CABG (left ITA to the LAD artery and SVGs). In midterm follow-up (20 months) superior event-free survival (freedom from non-fatal MI, angina recurrence, graft occlusion, need for percutaneous transluminal coronary angioplasty, and late death) was demonstrable in the complete arterial revascularization patients compared to conventional CABG.<sup>317</sup>

The same group conducted a second randomized trial comparing complete arterial revascularization to conventional CABG (ITA to LAD artery and SVG) in 160 patients older than 70 years of age undergoing first time nonemergent CABG. Early mortality was similar, but at  $16 \pm 3$  months, there were significantly fewer graft occlusions and recurrences of angina among the complete arterial revascularization group. Independent predictors of graft occlusion and angina recurrence were use of SVGs, diabetes, and dyslipidemia.<sup>318</sup> At 34 mean months of follow-up in a similar study of diabetics, the total arterial revascularization group had a lower incidence of cardiac-related events and higher graft patency rates.<sup>319</sup>

The most complete retrospective multicenter analysis of complete arterial revascularization versus single ITA supplemented by vein grafts compared long-term outcomes of 384 propensity matched pairs of patients.<sup>320</sup> It demonstrated a statistically significant survival benefit at 15 years (54 vs 41%), suggesting bilateral ITA usage should be encouraged in patients with a reasonable life expectancy.

## KEY POINTS

1. Coronary artery disease (CAD) is the number one killer of Americans.
2. Coronary artery bypass is advantageous over medical therapy in patients with unprotected LMCA stenosis, complex CAD (eg, SYNTAX score > 22), three-vessel disease, two-vessel disease with proximal left anterior descending disease, two-vessel disease without proximal left anterior descending disease but with extensive ischemia, single-vessel proximal left anterior descending disease with use of an ITA graft, and in patients with left ventricular dysfunction.
3. The STS risk model for postoperative morbidity and mortality can be found on the STS web site ([www.sts.org](http://www.sts.org)) and includes 30-day stroke and death rates of 1.6 and 3%, respectively.
4. The left internal mammary to left anterior descending CABG confers a survival advantage to coronary artery bypass patients. In the BARI trial, patency rates at 1 and 4 years were 98 and 91%, respectively.
5. Skeletonization of the internal mammary artery is associated with reduced incidence of sternal wound complications.
6. RA grafts have better 5-year patency (98 vs 86%) than SVGs.
7. Cognitive test performance of patients after CABG is no different from that of heart healthy control groups over a 1-year period.
8. Freedom from angina after CABG in the BARI trial was 84% at 5 and 10 years.
9. Bilateral compared to single internal mammary artery bypass grafting is associated with improved survival, but the benefit is not noted until about 10 years after operation.

# Myocardial Revascularization Without Cardiopulmonary Bypass

Bobby Yanagawa • Michael E. Halkos • John D. Puskas

Despite the increased prevalence of percutaneous coronary intervention (PCI) to treat coronary disease, coronary artery bypass graft (CABG) will continue to have a major role, particularly in patients with complex multivessel disease and diabetes mellitus. Currently, the majority of surgical revascularization is performed with the use of cardiopulmonary bypass (CPB), with most surgeons preferring to perform distal anastomoses on an arrested heart. Advocates of this approach cite low morbidity and mortality with outcomes that have continued to improve despite a surgical patient population with increasing comorbid conditions and more advanced and severe coronary disease.<sup>1-3</sup> However, complications, albeit infrequent, continue to plague a small percentage of patients undergoing CABG including stroke, renal failure, and respiratory failure. These complications occur not only because of the systemic inflammatory activation that occurs with extracorporeal circulation, but also because of the manipulation of the aorta required for cannulation, CPB, and aortic clamping. The interest in off-pump techniques was largely driven by the increased awareness of the deleterious effects of CPB and aortic manipulation.

According to the Society of Thoracic Surgeons Adult Cardiac Surgery Database (STS ACSD), off-pump CABG (OPCAB) use peaked in 2002 (23%) followed by a decline, accounting for approximately 17% of CABG cases in 2012.<sup>4</sup> For most surgeons, the lack of compelling evidence in large randomized controlled trials (RCTs) supporting OPCAB over conventional on-pump coronary artery bypass (ONCAB) and suggestions of more frequent incomplete revascularization have been impediments to implementing this strategy in routine practice.<sup>1-3,5,6</sup> Nonetheless RCTs have almost uniformly demonstrated reduced transfusion requirements, lower postoperative serum myocardial enzyme levels, and shorter length of stay. Moreover, there are many retrospective trials showing a survival benefit as well as reduced morbidity with OPCAB. Retrospective database studies have much larger sample size and include mixed-risk patients. However, inherent selection bias may limit the interpretation of these results, despite advanced statistical methodology. For individual surgeons to

consider implementing an off-pump approach, the following must be demonstrated: (1) equivalent short- and long-term patency rates; (2) complete revascularization; (3) reduced morbidity and even reduced mortality, especially in high-risk patients; and (4) cost efficiency both in the operating room and during the entire hospitalization. For certain high-risk subgroups, it would appear intuitive that avoiding the systemic effects of CPB as well as aortic manipulation would reduce the incidence of specific complications such as stroke and renal failure.

An off-pump approach is more technically challenging, with new risks not familiar to on-pump surgery. Therefore, OPCAB should be considered an advanced technique, not to be performed by all surgeons but by a select few who have trained with experts in OPCAB and who themselves perform large numbers of OPCAB procedures. Finally, there is greater appreciation that OPCAB should be performed in revascularization centers of excellence, incorporated into a comprehensive approach to revascularization, which includes minimally invasive CABG, hybrid, and total arterial revascularization.

## PREOPERATIVE CONSIDERATIONS

### Surgeon Experience

The adoption of OPCAB into clinical practice requires a commitment to learning a unique skill set. This is best achieved by focused training with an established OPCAB surgeon and routine adoption of OPCAB techniques such that the surgeon can employ this approach in patients likely to derive the most benefit. OPCAB surgery poses unique challenges to a surgeon who is accustomed to operating in a motionless and bloodless field. Furthermore, OPCAB requires an adept first and second assistant to provide exposure on a beating heart as well as excellent anesthesia management to maintain hemodynamics and alert the surgical team of potential hemodynamic problems. Thus, the commitment to OPCAB is usually tied to a belief that the technical challenges

inherent in the procedure are worth overcoming so that the patient may benefit from the avoidance of CPB. Although the benefit may be small in low-risk patients, it is becoming apparent that certain high-risk subgroups may benefit from minimizing aortic manipulation as well as avoiding the systemic effects of CPB.

The inexperienced OPCAB surgeon embarking on the learning curve is best advised to choose his or her initial patients carefully and pay close attention to coronary anatomy and confounding patient variables. The surgeon must come to the operating room with an operative plan that is flexible enough to change as operative findings such as hemodynamic fluctuations, ischemia, or arrhythmias. Early in a surgeon's experience, it is probably prudent to exclude patients with difficult lateral wall targets, especially multiple lateral wall targets, severe left ventricular dysfunction, left main disease, or other complex cases (Table 21-1). Ideal early candidates for OPCAB include those undergoing elective primary coronary revascularization with good target anatomy, preserved ventricular function, and one to three grafts with easily accessible or no lateral wall targets. As experience is gained in OPCAB, this technique can be safely and effectively applied to the vast majority of patients requiring coronary artery bypass surgery. Just as important, however, is the experience to know when it is better to use CPB in patients in whom an off-pump approach will be exceedingly difficult, impractical, or poorly tolerated.

### Patient Variables

The preoperative evaluation of patients for OPCAB demands careful planning and consideration for certain risk factors. We routinely perform screening carotid duplex ultrasonography on all patients over the age of 65, smokers, those with a carotid bruit, history of transient ischemic attack or stroke, left main coronary disease, peripheral vascular disease, or history of prior carotid intervention. The remainder of the preoperative evaluation is similar to ONCAB. In patients with a

**TABLE 21-1: Relative Exclusion Criteria during the Early Adoption of OPCAB**

Recent myocardial infarction
More than three grafts required, especially multiple lateral wall targets
Difficult lateral wall targets
Intramyocardial coronary arteries
Left ventricular dysfunction
Small or diffusely diseased coronary arteries
Mild to moderate aortic or mitral regurgitation
Redosternotomy
Hemodynamically unstable
Pulmonary hypertension
Urgent/emergent cases
Left main coronary artery disease

murmur, dyspnea, a history of aortic or mitral regurgitation (MR), or ventricular dysfunction on cardiac catheterization, preoperative echocardiography is warranted. It is important to be aware of right ventricular dysfunction, valvular regurgitation, or pulmonary hypertension as positioning during OPCAB can result in dramatic changes in these parameters. Overall, the clinical condition of the patient, the urgency of the operation, and ventricular function need to be carefully assessed to determine whether an off-pump approach will be tolerated. Patients with left ventricular dysfunction from a recent infarct pose a more difficult challenge than those with chronic ventricular dysfunction, with the former being much more sensitive to cardiac manipulation and displacement and more likely to develop intraoperative arrhythmias.

### Anesthesia

As in other cardiac operations, all patients require invasive monitoring with a pulmonary artery catheter, arterial line, Foley catheter, and central venous line. We use transesophageal echocardiography liberally to provide valuable information about valvular regurgitation, regional myocardial function, and pulmonary hypertension. In our experience, a well-experienced anesthesia team is essential to maintaining stable hemodynamics and ensuring a smooth and uneventful operation. Unlike ONCAB, which requires active coordination among surgeon, anesthesiologist, and perfusionist, the anesthesiologist and surgeon must work especially closely to maintain hemodynamic stability during OPCAB. Subtle changes in hemodynamic status, gradual elevation in pulmonary artery pressures, frequent boluses, or increased requirement of inotropes and vasopressors to maintain hemodynamic stability, and rhythm changes can herald cardiovascular collapse. Such an event can reliably be avoided if these changes are verbalized and discussed between anesthesiologist and surgeon preemptively. When manipulating the heart, it is important for the surgeon to communicate these abrupt maneuvers to the anesthesia team so that appropriate action can be taken and inappropriate reactions (bolusing vasopressors) avoided. Changes in table position (Trendelenburg) can provide dramatic volume changes that affect cardiac output and blood pressure. Autotransfusion of intravascular volume from the lower extremities by Trendelenburg positioning should be the first maneuver to maintain hemodynamic stability. We prefer to avoid giving massive volumes of intravenous fluids, which requires later postoperative diuresis. Instead, aggressive use of Trendelenburg positioning and judicious use of alpha-adrenergic agents provides stable hemodynamics during distal anastomoses. This includes patients with pulmonary hypertension, mild or moderate ischemic MR, or left ventricular dysfunction in which cardiac manipulation and displacement as well as regional myocardial ischemia may be poorly tolerated without inotropic support. If preload conditions have been optimized, then vasopressor agents such as norepinephrine or Neo-Synephrine may be used to assist with maintaining adequate blood pressure during distal anastomoses. In our experience, effective communication with a well-experienced

anesthesiologist is of paramount importance to ensure an uneventful off-pump operation.

Maintaining normothermia is critically important and requires more effort during OPCAB procedures, because the luxury of the CPB circuit for rewarming does not exist. This usually can be accomplished by infusing intravenous fluids through warmers, warming inhalational anesthetic agents, maintaining warm room temperatures before and during the procedure, and using convective forced-air warming systems (Bair Hugger; Arizant Healthcare, Eden Prairie, MN).

Anticoagulation regimens vary according to surgeon preference. For surgeons in their early experience, a full “pump” dose of heparin is reasonable in the event that conversion to CPB becomes necessary. Some surgeons continue to implement a full dose with 400 IU/kg to maintain an activated clotting time (ACT) of greater than 400 seconds; others use a half dose or 180 IU/kg, whereas others start with 10,000 IU and administer additional doses (3000 IU every half-hour) or a heparin infusion of 100 IU/min to maintain an ACT of 300 to 400 seconds. Reversal of anticoagulation with varying doses of protamine is usually administered to facilitate hemostasis.

## SURGICAL TECHNIQUE

### Preparation

After the induction of anesthesia, patients are positioned, prepped, and draped in a standard fashion. At our institution, patients receive an aspirin rectal suppository (1000 mg) after induction. Aspirin 81 mg and clopidogrel (150 mg postoperatively, then 75 mg/day) are routinely administered early in the postoperative period after mediastinal drainage decreases well below 100 cc/h for 4 hours. This has not been associated with an increased risk of mediastinal reexploration.<sup>7</sup> Because of the absence of CPB—related coagulopathy, patients may have a relative hypercoagulable perioperative state, which theoretically may jeopardize early graft patency. For this reason, we administer aspirin preoperatively, aspirin and clopidogrel early postoperatively, and then continue dual antiplatelet therapy in the postoperative period.

Endoscopic radial artery and saphenous vein conduits are harvested simultaneously during internal mammary artery (IMA) harvest. It is our practice to administer 5000 IU of heparin before endoscopic vein harvest to minimize thrombus formation within the conduit. Concern over graft quality with endoscopic vein harvest has prompted increased vigilance in atraumatic harvest technique to ensure adequate conduits for bypass.<sup>8</sup> We routinely harvest skeletonized IMAs using a harmonic scalpel (Harmonic Synergy, Ethicon, Somerville, NJ). Skeletonized harvest of IMA grafts preserves sternal blood flow, leads to less postoperative dysesthesia, and may reduce sternal wound infection in higher risk patients such as those with diabetes mellitus. The Harmonic scalpel uses high-frequency mechanical vibration to cut and coagulate tissues and compared with electrocautery, minimizes surgical trauma to the sternum and reduces the risk of injury to the adjacent IMA.

After single or bilateral IMA harvest, the heparin dose is administered and the arterial conduits divided distally. The pericardium is incised in an inverted T-configuration, and then extended laterally along the diaphragm to facilitate cardiac displacement while avoiding injury to phrenic nerves. It is essential to free the left lateral pericardium from the diaphragm to allow the pericardium to be retracted to displace the heart, exposing the lateral wall of the left ventricle. We routinely dissect the left IMA distally to the bifurcation as the extra length is often necessary to avoid tension on the anastomosis during rightward displacement for lateral or inferolateral wall grafting. Dividing or removing the endothoracic fascia, skeletonizing the IMA during harvest, and dividing the left pericardium vertically toward the left phrenic nerve at the level of the pulmonary artery all provide for extra length and less tension on the anastomosis.

Several pericardial traction sutures are placed to assist with exposure and lateral displacement of the heart. To avoid compression on the right heart during lateral displacement, the right pericardium can be dissected along the diaphragm or the right pleural space opened widely to allow the heart to fall into the right chest during lateral displacement. An important traction suture is the “deep stitch,” which is placed approximately two-thirds of the way between the inferior vena cava and left pulmonary vein at the point where the pericardium reflects over the posterior left atrium (Fig. 21-1). Care should be taken with placement of this suture to avoid the underlying descending thoracic aorta, esophagus, left lung, and adjacent inferior pulmonary vein. This suture should be covered with a soft rubber catheter to prevent laceration of the epicardium during retraction. Furthermore, the manual elevation and compression of the heart required to take this stitch may be poorly tolerated in patients with marginal hemodynamics or significant left main coronary artery disease. In that case,

**FIGURE 21-1** View from surgeon's side of the table. The heart is elevated toward the surgeon and superiorly for placement of the “deep stitch,” which is placed two-thirds of the way between the inferior vena cava and inferior left pulmonary vein. With rightward retraction of the heart, the right-sided pericardial traction sutures should be relaxed to prevent compression of the right atrium and right ventricle.

grafting and reperfusion of the left anterior descending artery (LAD) should be accomplished before placing the deep pericardial traction suture.

## Epiaortic Ultrasound

Epiaortic ultrasonography is used in all of our patients undergoing cardiac surgery, including OPCAB. It is a simple, noninvasive, and inexpensive tool for assessing the extent of atheromatous disease in the ascending aorta in preparation for aortic clamping or selection of an alternative clampless technique.<sup>9</sup> Epiaortic ultrasound has been shown to be superior to transesophageal echocardiography or palpation alone in identifying aortic atheromatous lesions, especially in the mid- to distal ascending aorta.<sup>10-12</sup> The 8.5-MHz linear array probe is placed inside a sterile sleeve filled with sterile saline to act as a medium between the probe and the surface of the aorta (Fig. 21-2). The information allows the surgeon to individualize placement of aortic clamps and proximal anastomotic devices to minimize the risk of atheroembolism. In our practice, for aortic atherosclerosis grades 1 to 2 (Table 21-2), we will use a side-biting clamp or proximal anastomosis device. We will not clamp or manipulate grades 3 to 5, due to the risk of embolization. Rosenberger and coworkers,<sup>13</sup> evaluated greater than 6000 patients with epiaortic ultrasound, suggested that the operative course was changed in 4% of patients because of the finding of aortic pathology, resulting in improved neurologic outcomes. Currently, intraoperative epiaortic ultrasound scanning is performed in only a small minority of centers. More data linking epiaortic ultrasonography to successful intraoperative decision-making and clinical outcomes should help to drive broader adoption of this promising diagnostic modality.

**FIGURE 21-2** Epiaortic ultrasonography is performed in all patients prior to aortic manipulation. The 8.5-MHz linear array probe is placed inside a sterile sleeve filled with sterile saline to act as a medium between the probe and the surface of the aorta.

**TABLE 21-2: Epiaortic Ultrasound Grading System**

Epiaortic ultrasound grade of ascending aorta	Intimal thickness/severity of disease
1	Normal (<2 mm)
2	Mild (2-3 mm)
3	Moderate (3-5 mm)
4	Severe (>5 mm)
5	Mobile plaque, irrespective of thickness

## Exposure

Cardiac positioners and stabilizers have greatly increased the ability to manipulate the heart with minimal hemodynamic compromise. The two systems routinely used in our institution are the Medtronic Octopus Tissue Stabilizer and Starfish or Urchin Heart Positioner (Medtronic Inc., Minneapolis, MN) and the Maquet ACROBAT stabilizer and XPOSE positioner (Maquet, Radstat, Germany). Cardiac positioning devices are frequently placed away from the apex, especially to the left of the apex, to expose the lateral wall and branches of the left circumflex coronary artery (Figs. 21-3 and 21-4). They are generally placed on the apex to expose the anterior wall (LAD territory) and inferior wall (posterior descending territory) of the heart and may be placed on the acute margin to expose the right coronary artery (RCA; Fig. 21-5). The suction-based positioning is well tolerated as the heart is not compressed, thus maintaining its functional geometry. The coronary stabilizer

**FIGURE 21-3** View from head of table. With the cardiac positioning device placed slightly away from the apex, the lateral wall can be exposed. The coronary stabilizers can then be placed to provide exposure and stabilization of obtuse marginal vessels.

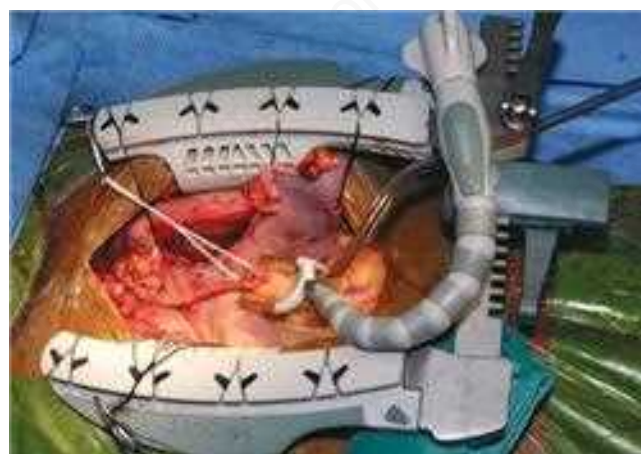

**FIGURE 21-4** View from the head of table. An obtuse marginal artery is prepared for grafting. After positioning the coronary stabilizer, a silastic vessel loop is doubly passed around the proximal coronary artery to allow transient occlusion during the anastomosis.

**FIGURE 21-5** View from the surgeon's side of table. With cardiac positioner placed on the apex, the heart can be easily displaced to expose the inferior wall vessels. Because there is no compression used for displacement, this maneuver is usually accomplished with no hemodynamic sequelae. Note the location of the cardiac positioner and stabilizer on the surgeon's side of the retractor. Alternatively, the stabilizer can be placed on the assistant's side of the retractor. The right pericardial traction sutures are relaxed, and the "deep stitch" is retracted inferolaterally.

devices are placed with minimal tension on the epicardium to allow for an area of mechanical stabilization. The anterior wall vessels often require only the coronary stabilizer for adequate exposure. The stabilizer is positioned along the caudal aspect of the retractor toward the left, with the retractor arm placed out of the way to prevent interference during the anastomosis. For the lateral and inferior wall vessels, the cardiac positioner is usually placed on the surgeon's side at the most cephalad location of the retractor. A general rule is to put the stabilizer in the assistant's way instead of the surgeon's to prevent these devices from obstructing the surgeon's view or interfering with hand positioning during suture placement.

In addition to positioners and stabilizers, manipulating the traction sutures can greatly enhance exposure. When the "deep stitch" is retracted toward the patient's feet, it elevates the heart toward the ceiling and points the apex vertically with remarkably little change in hemodynamics. When retracted toward the patient's left side, the heart rotates from left to right, exposing the lateral wall vessels. Variable tension on this stitch will enhance exposure to both the anterior and lateral wall. The left-sided pericardial sutures should be pulled taut and the right-sided sutures completely relaxed to avoid compression on the right heart during cardiac displacement. Pericardial sutures on both the right and left sides should never be under tension simultaneously. Manipulation of the operating table can also facilitate exposure. Placing the patient in steep Trendelenburg exposes the inferior wall. Turning the table sharply toward the right will aid with exposure of the lateral wall targets. For grafting the anterior wall vessels, the "deep stitch" can be pulled toward the patient's left side and a coronary stabilizer can then be positioned to expose the target coronary artery (Fig. 21-6). Occasionally, a warm moist laparotomy pad can be placed between the heart and the posterolateral pericardium to assist with elevating the heart out of the pericardium.

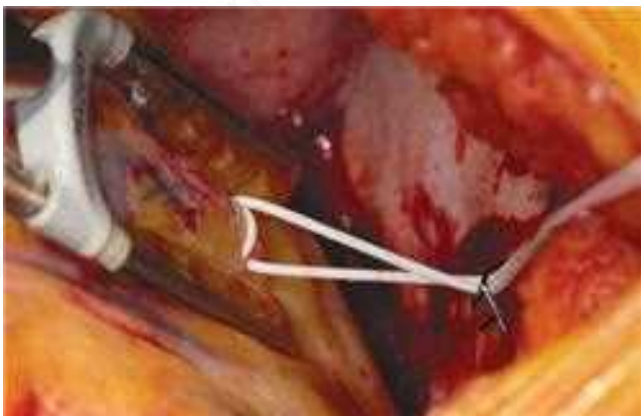

**FIGURE 21-6** View from surgeon's side of table. With LAD grafting, excellent exposure can be obtained with lateral traction of the "deep stitch" and the coronary stabilizer. Note the right pericardial traction sutures are released from the retractor.

In our experience, the most common mistakes leading to suboptimal exposure are

- Incompletely freeing the left pericardium from the diaphragm
- The “deep stitch” too far from the posterior left atrium
- Not loosening the right-sided pericardial sutures during exposure of the left-sided targets
- Compressing the heart against right pericardium, sternum, or retractor
- Kinking the right ventricular outflow tract by excessive cephalad tilt of the vertical heart
- Failing to combine the techniques of deep stitch, positioning device “off-apex”, elevation of the right sternal border on towels, and opening the right pleural space when needed

In preparation for distal anastomosis, a soft silastic retractor tape mounted on a blunt needle (Retract-o-tape, Quest Medical, Inc., Allen, TX) is placed widely around the proximal vessel for transient atraumatic occlusion. For inferior wall vessels, this suture can be displaced posteriorly and caudally by tying a posterior pericardial suture loosely around the retractor tape (Fig. 21-7). The pericardial retraction suture serves as a “pulley” that not only enhances coronary exposure and the surgeon’s view, but also keeps this retraction stitch from interfering with the sutures during the anastomosis. The field is kept free of blood with a humidified CO<sub>2</sub> blower (DLP, Medtronic, Inc.), which is managed by the scrub nurse or second assistant (Fig. 21-8). To avoid injury to the coronary endothelium, the blower should be set at the minimum setting needed for exposure (<5 L CO<sub>2</sub>) and used only when passing the needle through the vessel. Occasionally an epicardial fat retractor can be used to expose the coronary target in patients with a large amount of epicardial fat.

**FIGURE 21-7** View from the surgeon’s side of the table. For inferior vessel exposure (posterior descending or left ventricular branch) the Retract-o-tape is guided out of the surgeon’s way through a “pulley” created by placing a loosely tied superficial suture in the posterior diaphragm. The Retract-o-tape can then be retracted to transiently occlude the artery.

**FIGURE 21-8** View from the head of the table. During the anastomosis, a humidified CO<sub>2</sub> blower managed by the second assistant or scrub nurse is used to expose the LAD.

Although a well-trained first assistant is necessary for providing an effortless anastomosis, the second assistant, often the scrub nurse, also plays a major role in exposure. This assistant usually stands to the right of the surgeon, and controls the CO<sub>2</sub> blower and the Cell Saver (Haemonetics Corp., Braintree, MA). The blower is used to keep the field free of blood and to open the target vessel and graft during suture placement. During the inferior wall or lateral wall targets, the second assistant may provide better exposure by standing to the surgeon’s left. In chronically occluded vessels that have collateral and/or retrograde flow, bleeding into the field can be controlled with another retractor tape distally, a MyOcclude device (United States Surgical Corp., Norwalk, CT), or an intracoronary shunt.<sup>14,15</sup> We use intracoronary shunts selectively rather than routinely, as at least one study demonstrated significant endothelial injury with its use.<sup>16</sup> A final preparatory measure is to place temporary atrial or ventricular pacing cables before positioning the heart, particularly before RCA occlusion. As the heart is rotated toward the right, visualization of the right atrium is more difficult, so it is often prudent to place and test these cables before positioning.

## Coronary Grafting

The current generation of coronary stabilizers relies on epicardial suction rather than compression to maintain epicardial tissue capture. A common mistake is to press down too hard on the epicardium, which will paradoxically cause both increased movement in the target region and impaired hemodynamics. The malleable pods of the stabilizers can be bent or manipulated in any direction to stabilize the target vessel. If there are concerns about hemodynamic stability during regional ischemia, the proximal vessel can be test occluded

for 2 to 5 minutes and then reperfused, providing “preconditioning” of the subtended myocardium. Although not used routinely, preconditioning with two cycles of 2 minutes of LAD occlusion then 3 minutes of reperfusion before the first coronary anastomosis decreased postoperative myocardial enzyme release, heart rate increase, and restored ventricular function.<sup>17</sup> During this time the graft can be prepared. This gives the surgeon some assurance before committing to the anastomosis by creating an arteriotomy. The anastomosis is otherwise performed in a manner identical to on-pump grafting. It is essential to continue communication with the anesthesia team so that adequate steps can be promptly taken if hemodynamic conditions deteriorate. For example, if pulmonary artery pressures begin to rise and mean arterial pressures begin to fall during a lateral wall anastomosis, several steps can be taken to avoid cardiovascular collapse: gently relaxing on the cardiac positioner or coronary stabilizer, steep Trendelenburg positioning, fluid boluses, inotropes, vasopressors, or pacing. If hemodynamic conditions continue to deteriorate, the safe next step is to place an intracoronary shunt, relax the retractor tape, and release both the stabilizer and positioner, allowing the heart to recover.<sup>15</sup> At this point a decision must be made whether to convert “electively” to an on-pump procedure or complete the procedure off-pump. With better preparation (eg, fluids, inotropes, vasopressors, pacing, and shunt), the anastomosis can usually be completed off-pump. Another option for patients at high risk for complications of CPB is the use of intra-aortic balloon counterpulsation for mechanical support during cardiac displacement and positioning.

## Sequence of Grafting

Careful assessment of the cardiac catheterization is imperative. When planning for OPCAB, particular attention needs to be paid to the collateralizing vessel(s), intramyocardial vessels, the size of the distal targets, the degree of stenosis, the complexity of coronary disease, and the number of lateral wall vessels requiring grafting. The sequence of grafting is important as regional myocardial perfusion is temporarily interrupted during anastomosis on the beating heart. As a general rule, the collateralized vessel(s) is grafted first and the collateralizing vessel is grafted last. For example, in patients with an occluded RCA with a posterior descending artery (PDA) supplied by collaterals from the LAD, grafting the LAD first would not only leave the anterior wall ischemic during the anastomosis, but also disrupt flow to the septum, inferior wall, and right ventricle. A more prudent approach would involve grafting the PDA first, then performing a proximal anastomosis to ensure adequate flow to the inferior wall while the proximal LAD is occluded during construction of the IMA-LAD anastomosis. Another scenario that may pose problems is a large moderately stenotic RCA. Not uncommonly, temporary occlusion will result in profound bradycardia and hypotension. The surgeon must be prepared to use an intracoronary shunt or provide temporary epicardial pacing. Additional options include a

“proximals first” approach to allow adequate regional perfusion after completion of each distal anastomosis.

- Perform anastomosis to completely occluded or collateralized vessel first
- If LAD is not a collateralizing vessel, perform LAD-LIMA anastomosis first to allow for anterior wall perfusion during lateral and inferior wall positioning
- Proximal anastomoses can be performed first to allow for perfusion of target vessels after each distal anastomosis. This can be helpful when cardiac positioning is not well tolerated
- Beware of a large RCA with moderated proximal stenosis. Acute occlusion can cause bradycardia and hypotension. Be prepared for intracoronary shunt and epicardial pacing
- Patients with moderate MR may not tolerate prolonged cardiac displacement, which can exacerbate MR, and lead to elevated PA pressures and subsequent hemodynamic deterioration. Grafting the culprit vessel causing papillary muscle dysfunction should be performed early in the procedure.

## Proximal Anastomosis

Proximal anastomoses during OPCAB can be performed with the use of an aortic partial-occluding clamp after epi-aortic ultrasound rules out aortic atherosclerosis or a proximal anastomosis device. In preparation for an aortic clamp, the systolic blood pressure is lowered (eg, <95 mm Hg), the clamp is applied and aortotomies are made with a 4.0-mm aortic punch. Proximal anastomoses are then performed using 5-0 or 6-0 polypropylene suture. Before tying down the most anterior proximal anastomosis, the clamp is released and the aorta is de-aired through the proximal anastomosis with clamps on vein grafts. After the suture is tied down, the vein grafts can be de-aired with a 25-gauge needle and clamps removed. Arterial grafts are not punctured but are allowed to bleed backward before clamp removal.

Unlike ONCAB, OPCAB provides the opportunity to minimize or completely avoid manipulation of the aorta by performing proximal anastomoses to in situ arterial grafts, or using clampless proximal anastomotic devices.<sup>18-21</sup> This is particularly relevant in patients with advanced aortic atheromatous disease detected by epi-aortic ultrasound. Commercially available devices for clampless proximal anastomoses include the Heartstring III (Maquet Cardiovascular LLC, San Jose, CA), the PAS-Port Proximal Anastomosis System (Cardica Inc., Redwood City, CA), and the Enclose II (Vitalitec, Plymouth, MA). The Heartstring and Enclose devices create a near hemostatic seal with the inner surface of the ascending aorta that allows the creation of a hand-sewn anastomosis with a relatively bloodless field (Fig. 21-9). In contrast, the PAS-Port Proximal Anastomosis System is a fully integrated and automated system that attaches the vein graft to the aorta, instantaneously producing a reproducible anastomosis.<sup>21-23</sup>

**FIGURE 21-9** Proximal anastomoses can be performed without the use of an aortic clamp with either a Heartstring III (in these figures) or the PAS-Port device. The Heartstring III device requires a hand-sewn anastomosis, whereas the PAS-Port device is an automated anastomosis.

### Graft Flow Measurement

We routinely quantitate graft flow using an intraoperative transit-time doppler flow meter (Medistim, Oslo, Norway). Acceptable values are flow  $> 15$  mL/min, pulsatility index (the difference of maximum and minimum flow divided by the mean flow)  $< 5$  and diastolic fraction  $> 50\%$  (for left-sided grafts). A post hoc analysis of the Veterans Affairs Randomized On/Off Bypass (ROOBY) Trial found that lower graft patency (non-FitzGibbon grade A) at 1 year was associated with low flow ( $< 20$  mL/min) or high pulsatility index (3-5 and  $> 5$ ) during intraoperative flow probe measurements.<sup>24</sup> Thus, any values outside of this range should alert the surgeon to examine the anastomoses and graft for

potential revision unless unfavorable characteristics of the conduit, native coronary artery or distal run-off can readily account for the suboptimal doppler findings.

### On-Pump Beating Heart Coronary Artery Bypass

Performing beating heart coronary artery bypass with CPB support is especially useful in certain clinical scenarios such as acute coronary syndromes with cardiogenic shock or in patients with severe left ventricular dysfunction where cardiac positioning and displacement will not be tolerated.<sup>25,26</sup> On-pump, beating heart techniques provide hemodynamic support while avoiding aortic clamping and the global ischemic insult associated with cardioplegic arrest.<sup>27,28</sup> However, this is an uncommonly used technique.

### Outcomes

Clinical outcomes have been compared between OPCAB and ONCAB and reported for over a decade. There is a general consensus that either approach yields excellent outcomes in low-risk patients. In select higher-risk patients, it appears in recent studies that OPCAB may reduce both morbidity and mortality. These studies can generally be divided into smaller prospective RCT and larger retrospective analyses. Prospective RCTs provide the most accurate comparison between groups and avoid surgical selection bias and confounding inherent to retrospective and observational analyses. On the other hand, retrospective and observational analyses provide much larger sample sizes with longer duration of follow-up and have included more high-risk patients, but are limited by their retrospective nature and inherent selection bias despite the use of propensity matching or other advanced statistical methodologies designed to control for confounding variables. Because of their larger size, small differences in outcomes can often be detected. Taken together, both types of studies can provide valuable information to guide clinical practice.

### Operative Mortality

In the major prospective randomized large-scale, multicenter OPCAB trials, there have been no differences in operative mortality between on- and off-pump approaches. ROOBY was the first large-scale multicenter RCT comparing OPCAB and ONCAB in 2203 patients at Veterans Affairs Centers.<sup>2</sup> There was no difference in the short term primary composite endpoint of death or major complications before discharge or within 30 days between (OPCAB 7.0 vs ONCAB 5.6%,  $p = .19$ ; Table 21-3). However, OPCAB was associated with higher incidence of the composite endpoint of mortality, myocardial infarction (MI) and repeat revascularization at 1 year (9.9 vs 7.4%,  $p = .04$ ). The major criticisms of this study were insufficient surgeon experience (minimum 20 OPCAB cases; average 120 and median 50 cases), residents/trainees as

**TABLE 21-3: Summary of Large-Scale Randomized Controlled Trials Comparing OPCAB and ONCAB**

Trial	Rooby <sup>2</sup>	Coronary <sup>1,29</sup>	Gopcabe <sup>3</sup>

Major patient characteristics	Patients for CABG-Only	Age $\geq 70$ and 1 RF: PVD, stroke, carotid stenosis $\geq 70\%$ , CKI; Age 60-69 years and 1 RF or age 50-59 and 2 RFs: diabetes, urgent status, LVEF $\leq 35\%$ , recent history of smoking	Age $\geq 75$ years
OPCAB experience requirement	>20 cases	2 years and >100 cases	“Expert”
Median OPCAB experience	50 cases*	—	322 cases
On-pump conversion	12.40%	7.90%	9.70%
Primary outcome	Longterm: Death, MI, stroke AKI requiring dialysis at 1 year	Death, MI, stroke, AKI requiring dialysis at 30 days; death, MI, stroke, AKI requiring dialysis, repeat revascularization at 5 years	Death, MI, AKI requiring RRT, repeat revascularization at 30 days and 1 year
30 days (OPCAB vs ONCAB)	—	9.8 vs 10.3% ( $p = .59$ )	7.8 vs 8.2% ( $p = .74$ )
1 year (OPCAB vs ONCAB)	9.9 vs 7.4% ( $p = .04$ )	12.1 vs 13.3% ( $p = .24$ ) <sup>†</sup>	13.1 vs 14.0% ( $p = .48$ )
Average no. of grafts (OPCAB vs ONCAB)	2.9 vs 3.0 ( $p = .002$ )	3.0 vs 3.2 ( $p < .001$ )	2.7 vs 2.8 ( $p < .001$ )
Incomplete revascularization (OPCAB vs ONCAB)	17.8 vs 11.1% ( $p < .01$ )	11.8 vs 10.0% ( $p = .05$ )	34.0 vs 29.3%
1 Year graft Patency (OPCAB vs ONCAB)	82.6 vs 87.8% ( $p < .01$ )	—	—

AKI and CKI, acute and chronic kidney injury; LVEF, left ventricular ejection fraction; MI, myocardial infarction; PVD, peripheral vascular disease.

\*A resident was the primary surgeon in 64% of OPCAB cases.

<sup>†</sup>Not a prespecified time point for the primary endpoint.

the primary surgeon in 64% of OPCAB cases and a relatively young and healthy male patient population, a subset that one may not expect to benefit greatly from avoidance of CPB.

The ROOBY Trial was followed by two subsequent large RCTs, the CABG Off or On Pump Revascularization Study (CORONARY)<sup>1,29</sup> and the German Off-Pump CABG in Elderly (GOPCABE) Trial.<sup>3</sup> The CORONARY study randomized 4752 high-risk patients to OPCAB versus ONCAB and is the largest international multicenter RCT to date. The co-primary endpoints were death, stroke, MI, or dialysis at 30 days and 1 year, and death, stroke, MI, dialysis, repeat revascularization at 5 years. Surgeons were required to have >2 years experience after residency training and >100 cases of OPCAB; trainees could not be the primary surgeon. The majority of patients had additive EuroSCORE 3 to 5, thus being higher risk. This trial also did not find differences between OPCAB and ONCAB in composite primary endpoint of mortality, MI and stroke neither at 30 days (9.8 vs 10.3%,  $p = .59$ ) nor at 1 year (12.1 vs 13.3,  $p = .24$ ). However,

there was a trend towards benefit with OPCAB for patients in higher EuroSCORE. GOPCABE was a multicenter randomized trial of 2539 high-risk patients (mean logistic EuroSCORE 8.3)  $\geq 75$  years of age comparing OPCAB versus ONCAB. Importantly, OPCAB was “routinely performed at all participating centers” and surgeons had an average 514 cases and median 322 cases with OPCAB. There was no difference in the primary endpoint, a composite risk of death, stroke, MI, repeat revascularization, or new renal replacement therapy at 30 days (7.8 vs 8.2%,  $p = .74$ ) and at 1 year (13.1 vs 14.0%,  $p = .48$ ).

Several registry studies powered by their large sample size were able to detect significant differences in adverse outcomes among a broad population of patients, suggesting that operative mortality may be reduced in patients undergoing OPCAB compared with ONCAB. In a study by Hannan et al,<sup>30</sup> 49,830 patients from the New York State registry underwent risk-adjusted analysis (Cox proportional hazard models and propensity analysis) comparing outcomes after

**FIGURE 21-10** Risk-adjusted odds ratios for major adverse events in all patients undergoing on-pump coronary artery bypass (ONCAB) versus off-pump procedures (OPCAB). MACE = Major adverse cardiac events; MI = myocardial infarction. (Reproduced with permission from Puskas JD, Edwards FH, Pappas PA, et al: Off-pump techniques benefit men and women and narrow the disparity in mortality after coronary bypass grafting. *Ann Thorac Surg.* 2007 Nov;84(5):1447-1454.)

OPCAB versus ONCAB. In this study, OPCAB patients had significantly lower 30-day mortality (adjusted OR 0.81, 95% CI: 0.68 to 0.97,  $p = .0022$ ). A large registry study of CABG outcomes in California demonstrated a significant reduction in propensity-adjusted operative mortality with OPCAB compared with ONCAB (2.59%, 95% CI: 2.52 to 2.67 vs 3.22%, 95% CI: 3.17 to 3.27%).<sup>31</sup> An intention-to-treat retrospective analysis of 42,477 patients from the STS ACSD showed a reduction in risk-adjusted operative mortality (adjusted OR 0.83,  $p = .03$ ) as well as numerous morbidity outcomes favoring patients undergoing OPCAB (Fig. 21-10).<sup>32</sup> However, Chu and associates used an administrative database (Nationwide Inpatient Sample database) of 63,000 patients, and found no difference in hospital mortality between OPCAB and ONCAB (3.0 vs 3.2%,  $p = .14$ ).<sup>33</sup>

### Hospital Mortality in Patients Converted to On-Pump

A major complication of OPCAB is the emergent conversion to CPB support due to profound and acute hemodynamic compromise, either because of regional ischemia, valvular regurgitation from positioning, bradycardia during right-sided or inferior wall grafting, hypotension during cardiac positioning and stabilization, or intractable ventricular tachycardia/fibrillation. Such emergent conversion (“crash on pump”) to ONCAB is associated with significantly higher perioperative morbidity and mortality. Several studies quote mortality specifically for converted patients ranging from 6 to 15%.<sup>34-38</sup> The ROOBY Trial had a 12.4% conversion rate from off- to on-pump CABG, roughly five-fold higher

than the rate reported in the STS ACSD.<sup>32</sup> Of these, 49.3% were elective conversions, mainly for poor visibility, whereas, 50.8% were urgent or emergent, mainly for hemodynamic instability.<sup>39</sup> The 1-year composite outcome of all-cause mortality, MI, and revascularization was significantly worse in the converted versus nonconverted OPCAB patients (21.1 vs 13.7%,  $p = .03$ ). Importantly, 75% of conversions were associated with surgeons with experience of <100 OPCAB cases. Furthermore, a retrospective study of 8077 OPCAB cases used to identify risk factors for on-pump conversion confirmed surgeon experience to be the most significant multivariable predictor.<sup>40</sup> Importantly, there does not appear to be an increased risk of complications in patients who are *electively* converted to ONCAB.

### Mid- and Long-Term Mortality

More recently, mid- and long-term follow-up data has become available in patients undergoing OPCAB.<sup>1,3,41-46</sup> There was no difference in 1-year mortality in the ROOBY (4.1 vs 2.9%,  $p = .15$ ), CORONARY (5.1 vs 5.0%) or GOPCABE Trials (7.0 vs 8.0%,  $p = .38$ ) comparing OPCAB and ONCAB. However, with sensitivity analysis, 1-year death from cardiac causes was slightly higher in the off-pump group compared with the on-pump group (2.7 vs 1.3%,  $p = .03$ ) in ROOBY. The SMART Trial randomized 200 patients to OPCAB versus ONCAB by a single, experienced off-pump coronary surgeon.<sup>46</sup> In this trial, there was no difference in late survival (mean 7.5 years) (Fig. 21-11,  $p = .33$ ), graft patency, recurrent angina nor repeat catheterization. Furthermore, a recent meta-analysis reports a trend towards improved long-term survival with ONCAB (HR 1.06; 95% CI: 1.00 to 1.13,  $p = .05$ ) amongst all studies but there was no difference when analysis was limited to RCTs and propensity-matched studies.<sup>47</sup> Finally, in the observational study by Hannan et al,<sup>30</sup> 3-year survival was equivalent in OPCAB versus ONCAB patients (adjusted hazard ratio 1.01, 95% CI: 0.92 to 1.10,  $p = .89$ ; unadjusted 3-year survival 89.4 vs 90.1%, log-rank test,  $p = .20$ ). Based on these studies, it is reasonable to conclude that long-term survival after CABG is not affected by an on- or off-pump approach for the majority of patients.

### Perioperative Morbidity

Large prospective and retrospective studies have consistently shown reduction in perioperative morbidities with OPCAB. In a meta-analysis of 37 randomized trials comparing OPCAB with ONCAB, OPCAB was associated with a reduced incidence of atrial fibrillation (OR 0.58; 95% CI: 0.44 to 0.77), transfusion requirements (OR 0.43; 95% CI: 0.29 to 0.65), inotrope requirements (OR 0.48; 95% CI: 0.29 to 0.65), respiratory infections (OR 0.41; 95% CI: 0.23 to 0.74), ventilation time (weighted mean difference, -3.4 hours; 95% CI: -5.1 to -1.7 hours), intensive care unit stay (OR weighted mean difference, -0.3 days; 95% CI: -0.6 to -0.1 days), and hospital stay (weighted mean difference, -1.0 days; 95% CI: -1.5 to -0.5 days).<sup>48</sup> Similarly, in a propensity score analysis of 548 patients,

**FIGURE 21-11** No difference in long-term survival comparing on-pump CABG versus OPCAB in the SMART randomized controlled trial. (Reproduced with permission from Puskas JD, Williams WH, O'Donnell R, et al: Off-pump and on-pump coronary artery bypass grafting are associated with similar graft patency, myocardial ischemia, and freedom from reintervention: long-term follow-up of a randomized trial, *Ann Thorac Surg*. 2011 Jun;91(6):1836-1842.)

OPCAB was associated with significantly lower in-hospital mortality (0.5 vs 2.9%;  $p = .001$ ), incidence of stroke (0 vs 0.9%;  $p = .02$ ), postoperative renal dysfunction (4.9 vs 10.8%;  $p = .001$ ), pulmonary complications (10.2 vs 16.6%;  $p = .002$ ), and infections (3.5 vs 6.2%;  $p = .03$ ).<sup>49</sup>

## Neurologic Outcomes

Stroke remains a significant cause of morbidity and mortality after CABG, occurring in approximately 1 to 14% of patients.<sup>50,51</sup> In addition, long-term survival after stroke post-CABG is negatively impacted with reductions in 1- and 5-year survival to 66% and 44% compared with 94% and 81% without stroke.<sup>51</sup> Recently, more attention is being focused on the observation that a large proportion of strokes is embolic in nature and occurs at the time of clamp removal.<sup>52</sup> Other potential sources of emboli include carotid artery disease, particulate matter aspirated from cardiectomy suction, delayed thromboembolism from clamp injuries to the ascending aortic intima or proximal anastomotic sites, or left atrial thrombi secondary to postoperative atrial fibrillation. Additional iatrogenic causes of emboli (gaseous) may include aggressive use of carbon dioxide blower devices to facilitate visualization during construction of proximal anastomoses.

It is clear that less aortic manipulation results in fewer stroke events.<sup>53,54</sup> Studies utilizing transcranial Doppler ultrasonography have confirmed the production of aortic emboli associated with cannulation, CPB, and application of aortic clamps.<sup>55-57</sup> Bowles<sup>58</sup> et al used transcranial Doppler ultrasonography to demonstrate production of large quantities of aortic emboli during CPB, even without manipulation of the aorta. Furthermore, Kapetanakis and colleagues<sup>59</sup> and Calafiore and associates<sup>54</sup> concluded that aortic manipulation is independently associated with an increased risk of postoperative stroke. Approaches used to decrease this embolic load include avoidance of aortic cannulation using off-pump techniques, avoidance of multiple aortic clamping, use of

clampless anastomotic devices, and a completely no-touch aortic technique.<sup>60-62</sup> Kim and associates<sup>63</sup> reported a lower incidence of postoperative stroke in patients undergoing OPCAB without any manipulation of the aorta compared with patients undergoing OPCAB with partial clamping and patients undergoing ONCAB. In 12,079 patients undergoing OPCAB, Moss et al<sup>53</sup> found progressively lower rates of stroke in no-touch aortic (0.6%), versus clampless facilitating device (1.2%) versus side-biting clamp (1.5%) (Fig. 21-12). Emmert et al<sup>64</sup> report a significantly lower incidence of stroke for OPCAB with partial occlusion clamp versus ONCAB (1.1 vs 2.4%; OR 0.35; CI: 95%: 0.17 to 0.72;  $p < .005$ ) and even lower rates for OPCAB using a proximal occlusion device versus partial occlusion clamp (0.7 vs 2.3%; OR 0.39; CI: 95%: 0.16 to 0.90;  $p = .04$ ) which approached that of the no-touch group (0.8%).

Large retrospective analyses<sup>30,32,43,65-68</sup> have demonstrated that OPCAB may be associated with a reduced incidence of stroke compared with ONCAB, but this has not been borne out in the large-scale RCTs. Hannan et al<sup>30</sup> reported a risk-adjusted decrease in postoperative stroke with OPCAB compared with ONCAB (adjusted OR 0.70, 95% CI: 0.57 to 0.86,  $p = .0006$ ). A meta-analysis of 59 randomized trials of OPCAB versus ONCAB (N = 8961) report a 30% reduction in stroke (RR: 0.70, 95% CI: 0.49 to 0.99; Fig. 21-13).<sup>68</sup> Of 2468 patients in the CREDO-Kyoto Registry that underwent surgical revascularization, ONCAB was associated with higher stroke (OR 8.30, 95% CI: 2.25 to 30.7;  $p = .01$ ) but only in the highest risk patient tertile (logistic EuroSCORE  $\geq 6$ ).<sup>69</sup> The observed reduction in postoperative stroke is likely due to lack of aortic cannulation and CPB, and possibly due to lack of aortic manipulation during proximal anastomoses. However, as mentioned, there was no difference in the rates of stroke in the large RCTs.<sup>1-3,29</sup> Notably, the method of construction of proximal anastomosis was left up to the surgeon and was not reported. Thus, if a significant number were performed with a side-biting clamp versus a minimal or no-touch

**FIGURE 21-12** Stroke rate for OPCAB procedure using no-touch aortic, clampless facilitating device (CFD) and side-biting clamp. (Reproduced with permission from Moss E, Puskas JD2, Thourani VH, et al: Avoiding aortic clamping during coronary artery bypass grafting reduces postoperative stroke, *J Thorac Cardiovasc Surg.* 2015 Jan;149(1):175-180.)

**FIGURE 21-13** Forest plot for stroke. Forty-nine strokes were observed among 3605 off-pump coronary artery bypass patients compared with 76 among 3589 conventional coronary artery bypass patients, representing a 30% relative risk reduction. (Reproduced with permission from Afilalo J, Rasti M, Ohayon SM, et al: Off-pump versus on-pump coronary artery bypass surgery: an updated meta-analysis and meta-regression of randomized trials, *Eur Heart J.* 2012 May;33(10):1257-1267.)

aortic approach, the potential benefits of OPCAB with regard to postoperative stroke may have been attenuated.

## Renal Failure

Preoperative renal insufficiency is a significant predictor of postoperative renal failure and mortality in patients undergoing CABG.<sup>70</sup> In multiple studies, OPCAB has been shown to reduce morbidity and mortality in patients with normal renal function,<sup>71,72</sup> those with renal dysfunction not yet on hemodialysis<sup>73</sup> as well as those with end-stage renal failure on dialysis.<sup>74</sup> In a prospective randomized trial of 116 diabetic patients with preoperative nondialysis-dependent renal insufficiency, the use of CPB was associated with a significant increase in adverse renal outcomes.<sup>73</sup> Two retrospective analyses, however, reported equivalent renal outcomes with either OPCAB or ONCAB.<sup>74,75</sup> Thus, the advantages of OPCAB to minimize or avoid renal dysfunction remain controversial.

## High-Risk Patients

Several studies have documented improved outcomes in higher-risk patients undergoing OPCAB. Specifically, such higher-risk groups include women<sup>32</sup> and patients with left ventricular dysfunction,<sup>77,78</sup> ST-elevation MI,<sup>79</sup> prior stroke,<sup>67</sup> advanced age,<sup>80</sup> renal insufficiency,<sup>74,81</sup> reoperative cardiac surgery,<sup>82,83</sup> cirrhosis,<sup>84</sup> at the extremes of the BMI (<25 or >35) spectrum,<sup>85</sup> and in the patients with high Society of Thoracic Surgeon's predicted risk scores.<sup>86,87</sup> In such patients, improved end-organ perfusion, myocardial protection, limited aortic manipulation, and avoidance of systemic inflammation may explain the observed difference in major morbidity and mortality. A study of patients with left ventricular dysfunction (ejection fraction < 30%) in the STS ACS/SCD report lower adjusted risk of death (OR 0.82), stroke (OR 0.67), major adverse cardiac events (OR 0.75), and prolonged intubation (OR 0.78) with OPCAB versus on-pump CABG.<sup>85</sup> Furthermore, Puskas and colleagues<sup>87</sup> reported that patients in the highest risk quartile had a significant reduction in hospital mortality with OPCAB compared with ONCAB (3.2 vs 6.7%,  $p < .0001$ , OR 0.45 95% CI: 0.33 to 0.63,  $p < .0001$ ; Fig. 21-14). Also, as mentioned, the CORONARY Trials results showed a trend in improved outcomes for those patients in the highest EuroSCORE tertile.<sup>1</sup>

There is some evidence that OPCAB confers improved survival with emergent revascularization for acute coronary syndrome.<sup>88-91</sup> Although the safety and feasibility of OPCAB in select emergency situations has been confirmed, most surgeons today would argue against OPCAB in unstable patients.

## Completeness of Revascularization, Graft Patency, and Need for Repeat Revascularization

Completeness of revascularization is critical for the success and durable benefit of CABG.<sup>92,93</sup> The index of completeness

**FIGURE 21-14** Regression curve comparison of observed mortality rates for off-pump coronary artery bypass grafting (OPCAB) and coronary artery bypass grafting (CABG) on cardiopulmonary bypass (CPB) across all levels of predicted risk. STS = The Society of Thoracic Surgeons. (Reproduced with permission from Puskas JD, Thourani VH, Kilgo P, et al: Off-pump coronary artery bypass disproportionately benefits high-risk patients, *Ann Thorac Surg*. 2009 Oct;88(4):1142-1147.)

of revascularization is defined as number of grafts performed divided by number deemed necessary preoperatively (number of graftable vessels with angiographically significant stenoses), which is more important than the absolute number of grafts.<sup>94</sup> The choice to perform a procedure off-pump should not compromise the completeness of revascularization unless the use of CPB poses obvious and significant risk for postoperative complications or mortality, which may be the case in patients with severe atherosclerotic disease of the ascending aorta. In centers that routinely perform the large majority of coronary operations without CPB, complete revascularization, even in the more difficult lateral wall territory, is routinely accomplished.

The ability to provide complete revascularization with equivalent graft patency OPCAB techniques has been challenged, to provide complete revascularization with OPCAB techniques with equivalent graft patency has been challenged, although the majority of evidence from randomized trials suggests near-equivalent revascularization.<sup>1-3,5,6,95-97,46</sup> In the ROOBY Trial, there were more patients with fewer grafts completed overall (2.9 vs 3.0,  $p = .002$ ) and fewer than originally planned in the OPCAB group (17.8 vs 11.1%).<sup>2</sup> In the CORONARY Trial, there were also fewer grafts (3.0 vs 3.2,  $p < .001$ ) and a trend towards higher rates of incomplete revascularization (11.8 vs 10.0%,  $p = .05$ ) in the OPCAB compared to ONCAB group.<sup>1,29</sup> Again, in the GOPCAB Trial, OPCAB was associated with fewer grafts (2.7 vs 2.8,  $p < .001$ ) and higher incomplete revascularization (34.0% vs 29.3%).<sup>3</sup> The DOORS Trial was a multicenter randomized trial of 900 patients  $\geq 70$  years of age, which compared OPCAB versus ONCAB with the same heparinization protocol. They also report statistically fewer grafts being performed

with OPCAB (3.1 vs 2.9%,  $p = .007$ ).<sup>5,6</sup> A meta-analysis of randomized trials has consistently shown a lower number of grafts per patient in off-pump versus on-pump CABG (2.6 vs 2.8,  $< .0001$ ).<sup>98</sup> Even analysis of later trials in which surgeon experience was greater still showed fewer grafts performed off-pump versus on-pump (2.7 vs 2.9 grafts).<sup>99</sup> In a study of the STS ACSD by Puskas and colleagues,<sup>32</sup> OPCAB patients had a slightly lower index of complete revascularization than ONCAB patients. Thus, OPCAB is consistently associated with a statistically significant but small difference in absolute number of grafts performed. Given equivalent survival between OPCAB and ONCAB, whether the difference in revascularization is clinically significant is unknown.

Graft patency has been evaluated in several randomized trials, demonstrating that in experienced centers, graft patency can be equivalently excellent with either technique.<sup>46,100</sup> However, Shroyer et al<sup>2</sup> found that the overall rate of graft patency (driven by vein graft patency) was lower in the OPCAB group compared with the ONCAB group (82.6 vs 87.8%,  $p < .001$ ). A further blinded follow-up angiographic analysis in 685 OPCAB and 685 ONCAB patients in ROOBY revealed that OPCAB was associated with lower FitzGibbon A patency for arterial conduits (85.8 vs 91.4%;  $p = .003$ ) and saphenous vein grafts (72.7 vs 80.4%;  $p < .001$ ).<sup>101</sup> As expected, ineffective revascularization was associated with greater 1-year nonfatal MI and repeat revascularization. In the DOORS Trial, OPCAB was associated with a greater incidence of graft stenosis (9 vs 5%) and occlusion (12 vs 9%) ( $p = .01$ ), which was primarily seen in vein grafts at 6-month angiography.<sup>5,6</sup> Again, this may be an issue of experience. In the SMART trial, Puskas et al<sup>46</sup> randomized patients to either OPCAB versus on-pump CABG and demonstrated similarly excellent 1-year graft patency (93.6% for OPCAB vs 95.8% for ONCAB,  $p = .33$ ) as well as clinical outcomes of death, stroke, MI, and reintervention. There was an increase in the rate of repeat revascularization (0.7 vs 0.2%,  $p = .01$ ) in the CORONARY Trial, although whether this is a result of lower graft patency or greater incomplete revascularization alone is unknown.<sup>1</sup> A meta-analysis of 12 RCTs comparing OPCAB versus on-pump CABG showed an increased risk of graft occlusion (RR 1.35; 95% CI: 1.16 to 1.57), driven by saphenous vein graft occlusion (RR 1.41; 95% CI: 1.24 to 1.60) but not occlusion of IMA nor radial artery grafts.<sup>102</sup>

The New York registry data from Hannan et al<sup>30</sup> report that OPCAB was associated with lower in-hospital mortality and morbidity and equivalent long-term outcomes than ONCAB but greater need for repeat revascularization (93.6 vs 89.9%). However, because this was a retrospective analysis, this study was unable to differentiate whether this difference was a result of incomplete revascularization during OPCAB, reduced graft patency, or unrecognized confounding variables.

## Guidelines

The 2011 ACCF/AHA Guideline for Coronary Artery Bypass Graft Surgery included two recommendations regarding OPCAB<sup>103</sup>: OPCAB to reduce bleeding and blood

transfusion (Class IIa, Level of Evidence A) and OPCAB for patients with renal dysfunction (Class IIb, Level of Evidence B). More recently, the strength of data in support of OPCAB is recognized in the 2014 European Society of Cardiology/European Association of Cardio-Thoracic Surgery Guidelines on Myocardial Revascularization.<sup>104</sup> Here the recommendation is that OPCAB be performed in high-risk patients in experienced off-pump centers (Class IIa, Level of Evidence B) and in patients with ascending aortic atherosclerosis (Class I, Level of Evidence B). Furthermore, these guidelines recommend routine use of intraoperative graft flow measurements (Class IIa, Level of Evidence C).

## Minimally Invasive, Robotic, and Hybrid Approaches

Widespread familiarity with off-pump techniques has facilitated the development and application of sternal-sparing minimally invasive cardiac surgery (MICS) revascularization procedures for highly selected patients. There are several different variations. A small thoracotomy has been used to accomplish LIMA harvest and off-pump bypass on the anterior wall under direct vision, known as single vessel small thoracotomy (SVST), or for multivessel, known as multivessel small thoracotomy (MVST). Thoracoscopic or robotic-assisted left IMA dissection and harvest can be followed by a direct off-pump anastomosis to the LAD (Fig. 21-15) or by a total endoscopic LIMA-LAD anastomosis; the latter is referred to as totally endoscopic CABG (TECAB). Hybrid coronary revascularization (HCR) combines a minimally invasive LIMA to LAD graft with percutaneous intervention to non-LAD targets.<sup>105,106</sup> The feasibility of these alternative minimally invasive approaches has been demonstrated. The use of minimally invasive techniques has generated enthusiasm in the surgical and interventional communities, and its use is expanding beyond a few select centers.

For patients with anterior single vessel disease, a SVST offers a sternal-sparing incision with the long-term patency benefit

**FIGURE 21-15** After endoscopic or robotic-assisted IMA harvest, a direct hand-sewn anastomosis can be performed off-pump via a left anterolateral non-rib spreading minithoracotomy.

of the LIMA graft. Blazek et al<sup>107</sup> show equivalent 7-year survival in 130 patients with single vessel LAD disease randomized to MIDCAB versus DES-PCI. There was no difference in the composite primary endpoint of all-cause mortality, MI, and repeat revascularization but with significantly higher repeat revascularization after PCI (HR 13.50, 95% CI: 1.76 to 103.29;  $p < .001$ ). Moreover, a single center propensity score-matched minimally invasive direct coronary artery bypass (MIDCAB) versus DES-PCI comparison found at 10 years that DES-PCI was associated with a 2.2-fold increased risk of mortality as well as a 2.0-fold increased risk of repeat revascularization.<sup>108</sup> Multivessel small thoracotomy CABG offers complete revascularization with lower blood transfusion, incidence of chest wound infection, and improved postoperative physical recovery.<sup>109</sup> In their series of direct MVST CABG of which 75% were performed off-pump, Ruel and colleagues<sup>110</sup> report 92% and 100% 6-month graft patency for all grafts and for LIMA grafts, respectively.

Several experienced groups have reported successful outcomes using a robotic CABG approach.<sup>111-113</sup> Halkos et al<sup>111</sup> report 1.3% 30-day mortality, 5.2% conversion to sternotomy and 2.3% reexploration for bleeding for 307 consecutive robotic CABG procedures. For the 199 patients with pre-discharge follow-up angiography, LIMA-LAD patency was 95.0% and anastomotic lesions were found in only three patients. Srivastava et al<sup>112</sup> describe robotic multivessel CABG with bilateral IMA off-pump distal anastomoses constructed with the U-Clip Anastomotic Device (Medtronic, Minneapolis, MN). Bonaros et al<sup>113</sup> also present the largest experience of 500 cases of single and multivessel robotic CABG with on-pump distal anastomoses, reporting excellent results.

As described by Harskamp et al,<sup>114</sup> the concept of HCR stems from the hypothesis that (1) the LIMA-LAD is superior to coronary stenting and (2) contemporary DES-PCI is noninferior to venous bypass grafts used for non-LAD disease. Thus, patients with multivessel disease with a complex LAD lesion and noncomplex non-LAD lesions suitable for PCI, may be considered. Those patients with impediments to conventional CABG such as those with advanced age, frailty, obesity, lack of conduits, poor non-LAD target vessels, and porcelain aorta may be particularly suited for HCR. In the 2011 ACCF/AHA Guideline for Coronary Artery Bypass Graft Surgery, HCR is considered reasonable in patients with limitations to traditional CABG, such as heavily calcified proximal aorta or poor target vessels for CABG; lack of conduits; or unfavorable LAD artery for PCI (Class IIa, Level of Evidence B).<sup>103</sup> Furthermore, HCR may be reasonable as an alternative to multivessel PCI or CABG in an attempt to improve the overall risk-benefit ratio (Class IIb, Level of Evidence C). The 2014 European Society of Cardiology/European Association of Cardio-Thoracic Surgery Guidelines on Myocardial Revascularization suggests HCR for redo revascularization when lack of conduit poses a limitation to a conventional surgical approach (Class IIb, Level of Evidence C).<sup>104</sup>

In experienced minimally invasive revascularization centers, the major clinical outcomes of HCR are equivalent to

traditional CABG.<sup>115</sup> Halkos et al<sup>116</sup> performed a propensity-matched study comparing patients with multivessel coronary disease who underwent endoscopic-assisted or robotic LIMA harvest with SVST direct LIMA-LAD grafting versus OPCAB. There was no difference in 5-year survival but there were fewer blood transfusions ( $p < .001$ ) and more repeat revascularizations with HCR (12.2 vs 3.7%,  $p < .001$ ). A meta-analysis of six retrospective studies found that HCR was associated with no difference in freedom from MACCE at 1 year when compared with CABG but a greater incidence of repeat revascularization (Fig. 21-16).<sup>114</sup> Considering that the major weakness of HCR is in-stent restenosis or thrombosis requiring repeat revascularization, young, healthy patients may benefit more from conventional CABG. In the STS ACSD, there are 950 HCR cases (0.5% of all CABG cases) between 2011 and 2013, performed in 1/3 of all cardiac centers.<sup>117</sup> Patients who underwent HCR had higher cardiovascular risk profiles compared with traditional CABG and after adjustment, there was no differences in the composite of in-hospital mortality and major morbidity.

## Surgical Revascularization Centers of Excellence

A recurring issue in evaluation of data from RCTs comparing OPCAB versus ONCAB continues to be that of surgeon expertise. There is no doubt that OPCAB is more technically challenging for the surgeon and surgical team. Mastery of this procedure requires experience and team commitment. A review of the Nationwide Inpatient Sample Database reported a 5% decrease in the absolute probability of mortality with OPCAB between the highest and lowest volume surgeon cohorts, with the threshold for the largest improvement occurring after 50 cases/year and the lower mortality above 150 cases/year.<sup>118</sup> Notably, in this study, surgeons performed 105 OPCAB procedures per year (mean), which is significantly higher than the STS reported average.

As mentioned, ROOBY was criticized for lack of surgeon experience with off-pump procedures. In CORONARY and GOPCABE Trials, surgeons were considerably more experienced with off-pump procedures and in both trials, there were no differences in the primary composite endpoints. The difference in expertise was also highlighted by an OPCAB-to-ONCAB crossover rates of 12.4% for ROOBY versus 7.9% and 9.7% for CORONARY and GOPCABE, respectively.<sup>1-3</sup> Finally, a meta-analysis of >100,000 patients comparing OPCAB versus ONCAB by Takagi et al<sup>119</sup> found an increase in long-term all-cause mortality with OPCAB. But in the two largest RCTs in which expertise was defined as >2 years of experience and the completion of >100 OPCAB procedures, there was no difference in mid-term outcomes.

As such, there is increasing appreciation that OPCAB should be performed not by all surgeons at all surgical centers, but by experts in surgical revascularization at centers of excellence. To meet the technical challenges of performing successful OPCAB, young surgeons must train with established experts in surgical revascularization. Training in advanced

**FIGURE 21-16** Forest plot for the major clinical outcomes comparing HCR versus coronary artery bypass surgery: a meta-analysis of 1190 patients. (Reproduced with permission from Harskamp RE, Bagai A, Halkos ME, et al: Clinical outcomes after hybrid coronary revascularization versus coronary artery bypass surgery: a meta-analysis of 1,190 patients, *Am Heart J*. 2014 Apr;167(4):585-592.)

surgical revascularization may include OPCAB, hybrid, total arterial, minimally invasive, and robotic revascularization. Complex revascularization cases should be referred to revascularization centers of excellence. This is a model that is well-established for cardiac surgical treatment of heart failure as well as complex valvular and aortic disease.

## KEY POINTS

- The choice of OPCAB versus ONCAB requires careful attention to preoperative and intraoperative patient variables that may influence operative circumstances as well as short- and long-term morbidity and mortality.
- With the appropriate use of modern stabilizers and heart positioning devices, adequate surgeon experience and careful patient selection, equivalent completeness of revascularization and graft patency can be achieved with OPCAB.
- The quality of the anastomosis and the completeness of revascularization should not be compromised when performing off-pump anastomoses unless CPB poses excessive risk to the patient.
- Urgent or emergent conversion from OPCAB to ONCAB is associated with higher in-hospital morbidity and mortality but preemptive controlled conversion is not.

- Randomized trials have shown equivalent mortality outcomes between OPCAB and ONCAB techniques.
- In particular, low-risk patients undergoing surgical revascularization can be safely revascularized with either OPCAB or ONCAB.
- Certain high-risk groups may have better in-hospital morbidity and mortality outcomes when revascularized without the use of CPB likely due to avoidance of CPB and minimizing aortic manipulation.
- Long-term survival outcomes are equivalent in patients undergoing ONCAB or OPCAB.
- There is an improvement in resource utilization with OPCAB, including reduced transfusion requirements, shorter length of stay, less intensive care and ventilator time, and reduced cost.

# Myocardial Revascularization after Acute Myocardial Infarction

Deane E. Smith III • Mathew R. Williams

Acute myocardial infarction (MI) affects approximately 1.5 million individuals each year in the United States.<sup>1</sup> Of these patients, 30% die before reaching the hospital and another 5% die during their hospital admission.<sup>1</sup> Since 1998, the death rate from cardiovascular disease has declined 30.6%; however, cardiovascular disease remains the leading cause of death in the United States.<sup>2</sup> Prompt medical attention including transport to the hospital, diagnosis, and treatment of the MI is critical to patient survival. Over the past 40 years, many developments have led to a decrease in the overall morbidity and mortality associated with acute MI. These developments include new pharmacologic agents, advancement in interventional cardiology procedures, modifications of coronary artery bypass surgical techniques, and the development of treatment algorithms and guidelines. Despite these advances, mechanical and electrical complications such as cardiogenic shock, rupture of the ventricular septum or free wall, acute mitral regurgitation, pericarditis, tamponade, and arrhythmias continue to challenge the medical community caring for patients presenting with acute MI on a daily basis.<sup>3</sup> Of these complications, cardiogenic shock complicating acute MIs has the most significant impact on in-hospital mortality and long-term survival. The loss of more than 40% of functioning left ventricular mass and its accompanying systemic inflammatory response are the major causes of cardiogenic shock. Factors that impact the development of cardiogenic shock include the degree of pre-infarct ventricular dysfunction, the size of the infarcted vessel, and pathologic level of inflammatory mediators.<sup>4,5</sup> Revascularization of threatened myocardium offers the best chance of survival following acute coronary occlusion, but the technique and timing of revascularization continue to evolve. The available therapies that can decrease the mortality associated with acute MIs include thrombolytics, percutaneous coronary intervention (PCI), and coronary artery bypass graft (CABG) surgery.

## **PATHOGENESIS OF ACUTE OCCLUSION**

Myocardial ischemia resulting from coronary occlusion causes ischemic zone changes from a state of active systolic shortening to one of passive systolic lengthening within 60 seconds of onset of ischemia.<sup>6</sup> Occlusions for less than 20 minutes usually cause reversible cellular damage and depressed function with subsequent myocardial stunning. Furthermore, reperfusion of the infarct results in variable amounts of salvageable myocardium. After 40 minutes of ischemia followed by reperfusion, 60 to 70% of the ultimate infarct is salvageable, but this decreases to approximately 10% after 3 hours of ischemia.<sup>7,8</sup> Evidence from animal model has also demonstrated that 6 hours of regional ischemia produces extensive transmural necrosis.<sup>9</sup> The exact timing in humans is more difficult to analyze because of collateral flow, which is a major determinant of myocardial necrosis in the area at risk in humans.<sup>8</sup> The collateral blood supply is extremely variable, especially in patients with long-standing coronary disease. In addition, collateral flow is jeopardized with arrhythmias, hypotension, or the rise of left ventricular end-diastolic pressure above tissue capillary pressure.<sup>7</sup> Thus, loss of collateral flow to the infarct area may lead to the cellular death of salvageable myocardium, and control of blood pressure and prevention of arrhythmias are vital during this time immediately after infarction.

Table 22-1 outlines the effects of anatomic, physiologic, and therapeutic variables on the evolution of final infarct size.

## **STATES OF IMPAIRED MYOCARDIUM**

### **Infarcted Myocardium**

Disruption of coronary perfusion can result in three states of impaired myocardium: infarcted, hibernating, and stunned. Each state has a unique cause of injury and carries different prognostic implications (Table 22-2). Infarcted myocardium

has suffered irreversible myocardial cell death owing to prolonged ischemia and will not benefit from revascularization.

## Hibernating Myocardium

Hibernating myocardium is a state of impaired myocardial and left ventricular function at rest resulting from reduced coronary blood flow and impaired coronary vasodilator reserve that can be restored to normal if a normal myocardial oxygen supply-demand relationship is reestablished.<sup>10</sup> Hibernating myocardium is defined as contractility-depressed myocardial function secondary to severe chronic ischemia that improves clinically immediately after myocardial revascularization. This may be acute or chronic. Carlson and associates<sup>11</sup> showed that hibernating myocardium was present in up to 75% of patients with unstable angina and 28% with stable angina. The entity also occurs after MI. Angina after MI commonly occurs at a distance from the area of infarction.<sup>12</sup>

**TABLE 22-2: States of Myocardial Cells after Periods of Ischemia**

Condition	Viability of cells	Cause of injury	Return of function
Infarcted	Nonviable	Prolonged ischemia	No recovery
Stunned viable	Limited ischemia	Delayed with reperfusion	Recovery
Hibernating	Viable	Ongoing ischemia	Prompt, sometimes unpredictable recovery

In fact, mortality is significantly higher in patients with ischemia at a distance (72%) compared with ischemia adjacent to the infarct zone (33%).<sup>12</sup> It is the hibernating myocardium that may be in jeopardy and salvageable, although its presence is usually incidental to the occurrence of the acute infarction. By distinguishing between hibernating myocardium and irreversibly injured myocardium, a more focused approach to restoring or improving blood flow to the area at risk is possible. Ventricular function often improves immediately after revascularization of appropriately selected regions.

## Stunned Myocardium

Stunned myocardium is left ventricular dysfunction without cell death that occurs following restoration of blood flow after an ischemic episode. The phrase was initially coined by Braunwald and Kloner in 1982.<sup>13</sup> If a patient survives the insult resulting from a temporary period of ischemia followed by reperfusion, the previously ischemic areas of cardiac muscle eventually demonstrate improved contractility. Stunning can be a fully reversible process despite the severity and duration of the insult if the cells remain viable. Within 60 seconds of coronary occlusion, the ischemic zone changes from a state of active shortening to one of passive shortening. Coronary occlusions lasting less than 20 minutes provide the classic model of the stunning phenomenon.<sup>14</sup> The most likely mechanisms of myocardial stunning are listed in Table 22-3.<sup>14,15</sup>

Stunned myocardium can occur adjacent to necrotic tissue after prolonged coronary occlusion and can be associated with demand-induced ischemia, coronary spasm, and cardioplegia-induced cardiac arrest during cardiopulmonary bypass. Pathologically, these regions are edematous, and even hemorrhagic, and can clinically present as both systolic and diastolic dysfunction.<sup>16</sup> They also have a propensity for arrhythmias, which can lead to more extensive stunning and hypotension with subsequent infarction of these regions.

The primary distinction between stunned and hibernating myocardium is that in the former blood flow has been re-established after total occlusion whereas in the latter, coronary artery obstruction and reduced blood flow are still present.<sup>7</sup>

## DIAGNOSIS OF VIABLE MYOCARDIUM

Mechanisms to identify patients with myocardial stunning and hibernation include electrocardiogram (ECG) findings, radionuclide imaging, positron emission tomography (PET), dobutamine echocardiography, and more recently magnetic resonance imaging (MRI). Thallium identifies perfusion-related defects of the myocardium and can distinguish between viable and scarred myocardium as well. However, early redistribution of thallium does not distinguish between hibernating and scarred myocardium because many segments with irreversible defects by thallium improve after reperfusion. Redistribution imaging and reinjection imaging improve the predictive value of thallium imaging in distinguishing hibernating myocardium.

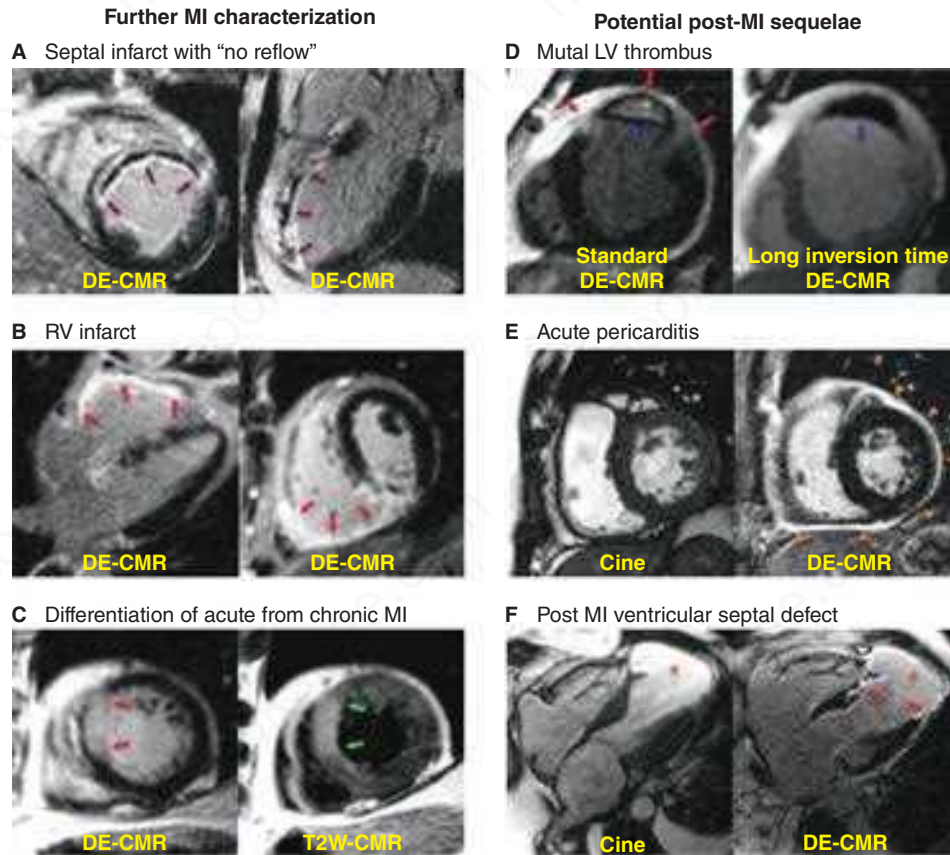

PET measures the metabolic activity of myocardial cells. It has high positive and negative predictive values. It is now regarded as the best method to determine myocardial

viability, particularly in patients with severe left ventricular dysfunction in whom other modalities are less accurate.<sup>17</sup>

Dobutamine echocardiography identifies hibernating and stunned myocardium by monitoring changes in segmental wall motion while the heart is stressed inotropically and chronotropically by dobutamine infusion. It has high specificity, sensitivity, and more importantly, positive predictive value.<sup>18</sup>

MRI has also been established as an effective method to assess hibernating myocardium.<sup>19</sup> It has been proven to accurately diagnose the degree of both acute and chronic MI and predict functional recovery.<sup>20,21</sup> A number of advantages exist with cardiac MRI, such as superior image resolution allowing accurate identification of transmural infarction (Fig. 22-1). By providing morphologic, functional, and metabolic information, it may ultimately supplant other modalities for the diagnosis of cardiac injury and recovery.

Finally, multislice computed tomography has been used to measure hibernating myocardium, and early data suggest it

**FIGURE 22-1** Cardiovascular MRI (CMR) characterization of myocardial infarction (MI) and post-myocardial infarction sequelae. Examples are shown of patients with myocardial infarction complicated by the presence of (A) microvascular damage (no reflow, purple arrows), and (B) right ventricular involvement (red arrows). (C) Acute infarcts (red arrows) can be differentiated from chronic infarcts by the use of T2-weighted imaging, which can show increased signal in areas of acute necrosis (green arrows). (D) Post-MI sequelae such as mural thrombus (blue arrows) can be identified by delayed-enhancement-CMR. Long-inversion-time imaging may improve detection because the image intensity of viable myocardium is gray rather than black. Thrombus is often immediately adjacent to infarcted myocardium (red arrows). (E) Acute pericarditis can be diagnosed by the presence of hyperenhanced pericardium (orange arrowheads). (F) CMR image may be used to define ventricular septal defect location (orange stars), extent of associated infarction (red arrows), and severity of shunting. (Reproduced with permission from Kim HW, Farzaneh-Far A, Kim RJ: Cardiovascular magnetic resonance in patients with myocardial infarction: current and emerging applications, *J Am Coll Cardiol*. 2009 Dec 29;55(1):1-16.)

may be a reliable and sensitive method compared with MRI, although its use in clinical practice is limited.<sup>22</sup>

## MEDICAL MANAGEMENT OF MYOCARDIAL INFARCTION

Initial management of patients presenting with acute MI requires rapid diagnosis and assignment into the appropriate treatment algorithm. Treatment strategies should be directed toward reducing myocardial oxygen demand, maintaining circulatory support, and protecting the threatened myocardium before irreversible damage and expansion of the infarct occur.

Patients presenting with ongoing chest pain and ST-segment elevation in two contiguous leads or new left bundle branch block or anterolateral ST depression are classified as having ST-segment elevation myocardial infarction (STEMI). These patients are referred for primary revascularization, typically with fibrinolytics or percutaneous intervention in the cardiac catheterization suite, as immediately as possible assuming no contraindications exist. The other group of patients, those with non-ST-segment elevation myocardial infarction (NSTEMI), present with chest pain at rest for 10 minutes or more and ST-segment depression greater than 0.5 mm or ST-segment elevation 0.6 to 1 mm or T-wave inversions greater than 1 mm or positive troponin levels. Alternatively, there is a history of unstable angina in a patient with coronary artery disease risk factors. The initial management of these patients includes a combination of antiplatelet therapy, intravenous heparin, and other medications with a less urgent plan for cardiac catheterization. Both clinical and basic science research have demonstrated that reperfusion is the main treatment option for acute MI. Unfortunately, the majority of patients with MI receive only conservative medical management; only 40% of patients having an acute MI receive thrombolytic therapy, the most common means of reperfusion.<sup>23</sup>

Patients who present with STEMI can be further categorized by the presence or absence of cardiogenic shock. This distinction is important as it clearly predicts patient outcome, and it will impact treatment strategy. Cardiogenic shock can be defined as a systolic blood pressure of less than 90 mm Hg that is secondary to myocardial dysfunction. Clinically, it is associated with signs of hypoperfusion including decreased urine output, altered mental status, and peripheral vasoconstriction with cool extremities. Hemodynamic parameters consistent with cardiogenic shock include a cardiac index less than 2.2 L/min/m<sup>2</sup>, stroke volume index less than 20 mL/m<sup>2</sup>, mean pulmonary capillary wedge pressure greater than 18 mm Hg, and a systemic vascular resistance of over 2400 dyn-s/cm<sup>5</sup>. These patients are defined as type IV by the Killip classification system, a widely used system to classify MIs.<sup>24</sup>

Shock is the most common cause of in-hospital mortality after MI.<sup>25</sup> The in-hospital mortality associated with cardiogenic shock has remained unchanged at approximately 80% despite the development of new treatment modalities.<sup>26</sup> Since 1975, the incidence of cardiogenic shock complicating

**FIGURE 22-2** Relationship between time to treatment and 1-year mortality, as a continuous function, was assessed with a quadratic regression model. Dotted lines represent 95% confidence intervals of predicted mortality. (Reproduced with permission from De Luca G, Suryapranata H, Ottervanger JP, et al: Time delay to treatment and mortality in primary angioplasty for acute myocardial infarction: every minute of delay counts, *Circulation*. 2004 Mar 16;109(10):1223-1225.)

acute MIs has remained constant at 7.5%, ranging between 5 and 15% (Fig. 22-2).<sup>25</sup> The progressive reduction in time delay from symptom onset to treatment may account for these constant figures. Previously, patients with excessive time delays would have died before reaching the hospital or soon thereafter, as treatment delays increase 1-year mortality exponentially (Fig. 22-2).<sup>27</sup>

Shock is directly related to the extent of the myocardium involved, and infarctions resulting in loss of at least 40% of the left ventricle have been found on autopsy in patients with cardiogenic shock.<sup>4,28</sup> Autopsy findings also revealed marginal extension of the recent infarct and focal areas of necrosis in patients with cardiogenic shock.<sup>4</sup> Extensive three-vessel disease is usually found in individuals with cardiogenic shock, and extension of the infarct is an important determinant in those individuals.<sup>4,28</sup> Thus, limiting the size of the infarct and preventing its extension are the primary goals of therapeutic interventions in patients with MI.

## RATIONALE FOR AGGRESSIVE MANAGEMENT OF MYOCARDIAL INFARCTION-REPERFUSION

Randomized trials have shown beneficial effects of early reperfusion within 12 hours and possibly up to 24 hours after acute MI.<sup>11,24,26,29</sup> Early reperfusion clearly reduces infarct size in the major areas at risk, and controlled reperfusion may even be superior. The arguments are more difficult to make for patients outside the 24-hour window; however, patients with ongoing ischemia often have ischemic border regions that are prone to arrhythmias and necrosis. In addition, these patients are at risk for prolonged periods of hypotension with resulting end-organ injury and further left ventricular dysfunction. The benefit to early revascularization may be

greatest in those patients with cardiogenic shock. Even if revascularization does not appear critical, ventricular unloading with intra-aortic balloon pump (IABP) or left ventricular assist device (LVAD) may provide the bridge to recovery needed in patients dying after MI. The primary factors limiting an aggressive surgical approach are major comorbidities, which make continuation of life undesirable or unlikely, and an unclear neurologic status, especially after a period of cardiopulmonary arrest.

Although restoration of blood flow to ischemic regions is essential, the accompanying reperfusion injury initially can worsen rather than improve myocardial dysfunction. The area at risk is affected not only by reperfusion but also by the conditions of reperfusion and the composition of the reperfusate.<sup>30</sup> Thus, controlling reperfusion itself may aid in reducing myocardial infarct size and ventricular injury. At the cellular level, myocardial ischemia results in a change in energy production from aerobic metabolism to anaerobic metabolism. The consequences of ischemia vary from decreased adenosine triphosphate production and increased intracellular calcium to decreased amino acid precursors such as aspartate and glutamate. These changes can be reversed only by reperfusion. However, as oxygen is reintroduced into an ischemic region, oxygen free radical generation ensues with resulting cellular damage. Cellular swelling and/or contracture can lead to a “no-reflow phenomenon” that limits the recovery of some myocytes and possibly results in irreversible injury of others. The production of oxygen free radicals during ischemia, and at the time of reperfusion, is the leading mechanism proposed to explain cellular injury. Four basic types of reperfusion injury have been described: lethal cell death, microvascular injury, stunned myocardium, and reperfusion arrhythmias (Table 22-4).

Buckberg and coworkers<sup>31-36</sup> conducted studies of controlled reperfusion after ischemia and produced a clinical application for controlled reperfusion. The surgical strategy of controlled reperfusion includes several elements. First, extracorporeal circulation is established as expeditiously as possible with venting of the left ventricle as required. Initially, antegrade cardioplegia is delivered using either a warm Buckberg solution to rebuild adenosine triphosphate stores or

cold high-potassium cardioplegia to achieve rapid diastolic arrest. Retrograde cardioplegia can be added to ensure global cooling, even in areas of active ischemia. The temperatures of the anterior and inferior walls of the ventricle are measured to ensure adequate cooling. After each distal anastomosis, cold cardioplegia is infused into each graft and the aorta at 200 mL/min over 1 minute. This is followed by retrograde infusion through the coronary sinus for 1 minute. After completion of the final distal anastomosis, warm substrate-enriched blood cardioplegia is given at 150 mL/min for 2 minutes into each anastomosis and the aorta. After removal of the aortic cross-clamp, regional blood cardioplegia is given at 50 mL/min into the graft supplying the region at risk for 18 minutes. This controlled rate of reperfusion minimizes cellular edema and myocyte damage. The proximal vein grafts are then completed, followed by reestablishment of normal blood flow. To decrease oxygen demand, the heart is allowed to beat in an empty state for 30 minutes. After this time, the patient is weaned off bypass.

Application of the Buckberg solution and technique has been shown to be effective in improving mortality rates and myocardial function after acute coronary occlusion. With ischemic times averaging 6 hours, a prevalence of multivessel disease, and cardiogenic shock, the overall mortality in patients with acute coronary occlusion who underwent surgical revascularization applying this method of reperfusion was 3.9%. Postoperative ejection fraction averaged 50%.<sup>37</sup> Surgical revascularization in this manner using controlled reperfusion compared favorably with percutaneous transluminal coronary angioplasty (PTCA) in several large series. These principles are reflected primarily in the surgical management of acute MI and will be outlined more specifically later in the chapter.

## METHODS OF REPERFUSION

Once a patient who is a candidate for reperfusion therapy has been identified there are essentially three options available to the practitioner. They include thrombolytic therapy, primary PCI, and CABG. The intervention chosen for any particular patient will undoubtedly reflect the services that are available at the time of presentation, but they should also conform to the recommendations outlined by the ACCF/AHA guidelines including its most recent update in 2013.<sup>38</sup> The following is a review of the available therapies, their roles, and the data that exist to support their use.

### Role of Thrombolytic Therapy

Because myocardial salvage depends on reperfusion of occluded coronary arteries, rapid dissolution of an occluding thrombus with thrombolytic therapy is an appealing intervention. Intracoronary streptokinase in patients with acute MI demonstrated that thrombolytic therapy is a safe and efficient way to achieve the desired early reperfusion.<sup>39</sup> Following this study, a number of multi-institutional meta-analyses showed the effectiveness of thrombolytic therapy in

**TABLE 22-4: Potential Types of Reperfusion Injury**

Lethal	Cell death secondary to reperfusion
Vascular	Progressive damage causes an expanding zone of “no reflow” and deterioration of coronary flow reserve during the phase of reperfusion
Reperfusion arrhythmias	Arrhythmias, mainly ventricular, that occur shortly after reperfusion
Stunned myocardium	Postischemic ventricular dysfunction

treating acute MIs. The trial of the Italian Group for the Study of Streptokinase in Myocardial Infarction (Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardio [GISSI])<sup>40</sup> and the Second International Study of Infarct Survival [ISIS-2]<sup>41</sup> found a reduced hospital mortality in patients treated with streptokinase. The effectiveness of tissue-type t-PA also has been evaluated in randomized studies. The Thrombolysis in Myocardial Infarction (TIMI) study<sup>42</sup> and the European Cooperative Study Group<sup>43</sup> demonstrated the effectiveness of t-PA for the treatment of acute MI. When streptokinase and t-PA were compared, two studies failed to demonstrate any difference in mortality.<sup>44,45</sup> A third study, however, the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial, supported the use of t-PA by demonstrating a more rapid and complete restoration of coronary flow that resulted in improved ventricular performance and reduce mortality.<sup>46,47</sup>

Although thrombolysis improves survival and ventricular function the patency of infarct-related arteries is reported to be between 50 and 85%.<sup>40-47</sup> Normal flow should be achieved in 60% of patients by today's standards. Thrombolytic therapy works well but is not without complications, including bleeding and intracranial hemorrhage.<sup>48</sup> Bleeding is usually minor and occurs mostly at the sites of vascular puncture. Intracranial hemorrhage and stroke rates are approximately 1%. The relative benefits of thrombolytic therapy appear to decrease as patient age increases, and a higher risk of intracranial hemorrhage in the elderly may partially account for these findings.<sup>46,49,50</sup> Careful selection of patients suitable for fibrinolytic therapy is warranted, especially in an increasingly older population.

Thrombolytic therapy for patients presenting in cardiogenic shock or heart failure does not appear to improve survival in this population but may decrease the incidence of patients developing heart failure after MI.<sup>51</sup>

In summary, studies evaluating the effectiveness of thrombolytic therapy have demonstrated several useful points. First, survival is improved by decreasing time to reperfusion. The GUSTO trial showed that patients treated within the first hour had the greatest improvement in survival, with a 1% reduction in mortality for each hour of time saved.<sup>46,47</sup> Thrombolytic therapy is easy to administer in the community by trained personnel, although a significant risk of bleeding exists in certain patients. Because the time to reperfusion is a critical element in preserving myocardium, thrombolytic therapy is ideal for most communities without percutaneous interventional capabilities. The importance of these elements is evidenced by two points made in the updated ACCF/AHA guidelines. First, in the absence of contraindications, fibrinolytic therapy should be administered to patients with STEMI at non-PCI-capable hospitals when the anticipated first medical contact (FMC)-to-device time at a PCI-capable hospital exceeds 120 minutes because of unavoidable delays.<sup>38</sup> Second, when fibrinolytic therapy is indicated or chosen as the primary reperfusion strategy, it should be administered within 30 minutes of hospital arrival.<sup>38</sup>

## Role of Percutaneous Coronary Intervention

Since the first reported PTCA by Gruntzig and associates<sup>52</sup> in 1979, the efficacy of this percutaneous intervention in the treatment of coronary artery disease has been well recognized. A number of studies have evaluated the efficacy of primary PTCA in the treatment of acute MI. The overall PTCA hospital mortality rates range from 6 to 9%.<sup>53-56</sup> Initial experience utilizing only balloon angioplasty was termed PTCA. One of the areas of technological advancement has been the development of new percutaneous therapies. These options include not only implantation of intracoronary stents, but also rotational atherectomy, directional atherectomy, extraction atherectomy, and laser angioplasty. In the current era, these techniques collectively are referred to as PCI. Here, we will use the term PTCA to relate data from studies limited to angioplasty, and the term PCI to accurately describe trials and studies that involve one or more of these additional techniques. This is consistent with the approach taken by the authors of 2001 ACCF/AHA Guidelines for PCI, which was a revision of the 1993 PTCA Guidelines.<sup>57</sup>

Several different strategies employing PCI for acute MI have been developed and examined through clinical trials. Primary, rescue, immediate, delayed, and elective PCI are options for the treatment of acute MI. Primary PCI uses percutaneous intervention as the method of reperfusion in patients presenting with acute MI. Rescue, immediate, delayed, and elective PCI are all done in conjunction with or following thrombolytic therapy. Rescue PCI is performed for recurrent angina or hemodynamic instability after thrombolytic therapy. Immediate PCI is performed in conjunction with thrombolytic therapy, and delayed PCI occurs during the intervening hospitalization. Finally, elective PCI is done following thrombolytic therapy and medical management when a positive stress test is obtained during the same hospitalization or soon thereafter.

Several studies evaluated the role of PTCA compared with thrombolytic therapy. The first study, the Primary Angioplasty in Myocardial Infarction Study Group trial in 1993, concluded that immediate PTCA without thrombolytics reduced occurrence of reinfarction and death and was associated with a lower rate of intracranial hemorrhage.<sup>53</sup> Since then, more than 20 studies have compared PTCA to thrombolysis. The results from these studies have consistently and conclusively demonstrated the superiority of PTCA to thrombolysis, regardless of the thrombolytic agent used. The findings include a lower short-term mortality rate, lower rates of reinfarction, reduced stroke and intracranial hemorrhage rates, and a decreased composite end point of death, reinfarction, and stroke.<sup>58</sup> These findings have been reconfirmed on long-term follow-up. A higher overall rate of bleeding was observed, likely because of vascular access complications. Myocardial salvage is similar for PTCA and thrombolytic therapy. However, primary PTCA may be slightly less costly than thrombolytic therapy.<sup>54</sup>

The use of intracoronary stents after MI has expanded as PTCA has become more prevalent. Benefits of stenting

include lowered rates of restenosis and abrupt closure, and a reduced need for target revascularization after PTCA. Although the STENT-PAMI trial in 1999 using first-generation stents showed lower restenosis rates compared with thrombolysis, a trend toward higher mortality was seen, and its effectiveness as first-line therapy was questioned.<sup>59</sup> Composite end points of death, reinfarction, and urgent target vessel revascularization at 30 days have now been shown to be lower in subsequent studies, such as the CADILLAC, ISAR-2, and ADMIRAL trials, which employed newer-generation stents.<sup>60-62</sup> In these trials, a glycoprotein (GP) IIb/IIIa inhibitor, abciximab, was added to primary stenting. A significant reduction in restenosis rates with stenting plus abciximab versus PTCA alone was evident at 12-month follow-up in the CADILLAC study (41 vs 22%).<sup>60</sup> More recent data suggest that stenting combined with antiplatelet therapy provides superior benefit to PTCA alone. Drug-eluting stents offer the potential to lower restenosis rates even further through the use of anti-inflammatory medication delivered via the stent. More recently, patients in the STRATEGY trial treated with drug-eluting stents after acute STEMI had a significantly lower composite end point of death, reinfarction, stroke, and angiographic evidence of restenosis at 8-month follow-up compared with bare-metal stenting plus abciximab (50 vs 19%).<sup>63</sup> Using propensity score matching, retrospective analysis of patients post-acute MI in Massachusetts has shown a slight 2-year mortality benefit for drug-eluting stents when compared with bare-metal stents (10.7 vs 12.8%), as well as a lower need for repeat revascularization.<sup>64</sup> Further prospective studies are under way to determine if long-term data confirm these findings.

The optimal pharmacotherapy for these patients continues to be debated and is an area of ongoing investigation. Initial experience with heparin was believed to be improved by the addition of GP IIb/IIIa inhibitors.<sup>65</sup> However, routine use of GP IIb/IIIa inhibitors has fallen out of favor, and current guidelines recommend limiting their use to high-risk situations. The HORIZONS-AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial<sup>66,67</sup> compared bivalirudin, a direct thrombin inhibitor, with heparin plus a GP IIb/IIIa inhibitor for use after primary PTCA with or without stenting. The data disclosed decreased 30-day major bleeding events, death from cardiac causes, and death from all causes, despite a higher 24-hour risk of stent thrombosis in the bivalirudin cohort. Interestingly the mortality benefit persisted after 3-year follow-up. Since this trial, there have been several changes in management strategy including newer antiplatelets, increased radial access, and decreased use of GPIIb/IIIa inhibitors. A similar trial comparing bivalirudin to heparin plus GP IIb/IIIa inhibitors, the EUROMAX trial, demonstrated a decrease in incidence of major bleeding at 30 days but no difference in mortality or reinfarction.<sup>68</sup> More recently, results of the HEAT PPCI (How Effective are Antithrombotic Therapies in Primary PPCI) trial were released. This was an open-label, randomized trial of STEMI patients which compared heparin with bivalirudin and used GP IIb/IIIa inhibitors only in

**FIGURE 22-3** Revascularization rates in patients with cardiogenic shock at presentation ( $n = 7356$ ). (Reproduced with permission from Babaev A, Frederick PD, Pasta DJ, et al: Trends in management and outcomes of patients with acute myocardial infarction complicated by cardiogenic shock, *JAMA* 2005 Jul 27;294(4):448-454.)

bail out situations. Heparin was associated with a significant reduction in the major cardiovascular end points of all-cause mortality, cerebrovascular accidents, reinfarction, and target vessel revascularization (5.7 vs 8.7%,  $p = .01$ ).<sup>69</sup> In addition, there was no significant difference in the rate of major bleeding (3.5 vs 3.1%,  $p = .59$ ). This study, along with others (NAPLES III, BRAVE IV), have raised significant questions regarding the benefit to using bivalirudin as opposed to heparin.<sup>70,71</sup>

Primary PCI may play a greater role in patients presenting in cardiogenic shock, as percutaneous interventions have become more common over the past 10 years (Fig. 22-3). The GISSI-1 and GISSI-2 trials demonstrated no benefit from intravenous thrombolysis, with mortality rate of 70%.<sup>40,44</sup> In patients presenting in or developing cardiogenic shock after acute MI, PTCA improved survival to 40 to 60%.<sup>72</sup> This improvement was even greater when angioplasty was successful, as in-hospital survival rates increased to 70%. In most of these series an IABP was used in conjunction with PTCA. The SHOCK trial showed that revascularization by PTCA or CABG within 12 hours of the onset of cardiogenic shock results in improved 1- and 6-year survival rates versus medical stabilization followed by delayed revascularization (32.8 for PTCA/CABG vs 19.6% for initial medical stabilization, 6-year follow-up) in this high-risk group, particularly for those under the age of 75 years (Fig. 22-4).<sup>11,26,29</sup> Subgroup analysis in patients undergoing successful PTCA or with TIMI Grade 3 coronary flow after PTCA in the SHOCK trial revealed that 1-year survival was even higher, at 61%.<sup>73</sup> Independent predictors of mortality include age, hypotension, lower TIMI flow, and multivessel PTCA.

In conclusion, specialized centers that have 24-hour catheterization facilities can provide primary PCI as a first-line therapy for patients with acute MI. Patients with established or developing cardiogenic shock should be revascularized early by PCI rather than initial medical stabilization with thrombolytic therapy. Rescue PCI after failed thrombolytic

**FIGURE 22-4** Survival estimates for early revascularization ( $n = 152$ ) and initial medical stabilization ( $n = 150$ ) groups in the SHOCK trial. Log-rank test,  $p = .03$ . therapy for patients with ongoing ischemia or clinical compromise is also recommended. Finally, elective PCI should be performed on patients who have recurrent or provokable angina before hospital discharge.

### Role of Coronary Artery Bypass Grafting

The role of surgical revascularization in the treatment of acute MI has changed considerably over the past 30 years. During the 1980s, reports appeared recommending surgical revascularization in preference to medical therapy for acute MI.<sup>74,75</sup> Mortality rates under 5% were reported. Critics argued that these studies lacked randomization or consecutive entry of patients, preoperative stratification was absent, and enzyme levels were not included. Inherent bias that favored surgery in low-risk patients was believed to be the reason for the excellent outcomes.<sup>76</sup> At the time these reports surfaced, thrombolytic therapy and interventional cardiology were emerging as alternative options for patients with acute infarctions. With the availability of thrombolytics and PCI, large multicenter trials began looking at the efficacy and usefulness of these two techniques. Randomized trials using CABG were not done, and thus this option was never established as an alternative for acute MI. Despite this, several centers continued to use surgical revascularization to treat acute MI with excellent results. However, practical, logistic, and economic constraints relegate surgical revascularization to a third option behind thrombolytics and PCI for the primary treatment of acute MI.

There continue to be several scenarios that require emergent or urgent surgical revascularization. Failure of thrombolytics or PCI with acute occlusion may require surgical intervention. Additionally, CABG for post-infarction angina has become a critical step in the pathway of treating acute MI. Finally, surgical revascularization may be indicated in

patients with multivessel disease or left main coronary artery disease developing cardiogenic shock after MI.

### Timing after Infarction

If surgical revascularization within 6 hours after the onset of symptoms is feasible, the mortality rate is improved over that of medically treated, nonrevascularized patients.<sup>74,75</sup> Although these early studies were not controlled and were criticized for selection bias,<sup>76</sup> they did demonstrate that surgical revascularization may be performed with an acceptable mortality in the presence of acute MI with improved myocardial protection, anesthesia, and surgical techniques. However, with the advent of thrombolytic therapy, PCI, and an aging population, the surgical patient we encounter today bears little resemblance to the patient population represented in these early studies.

Previous analyses of the New York State Cardiac Surgery Registry, which included every patient undergoing a cardiac operation over more than a decade in the state of New York, resulted in valuable information regarding the optimal timing of CABG in acute MI. In this large and contemporary patient population, there is a significant correlation between hospital mortality and time interval from acute MI to time of operation, particularly if CABG was performed within 1 week of acute MI. In addition, patients with transmural and nontransmural acute MI have different trends in mortality when the time course is taken into consideration. Mortality for the nontransmural group peaked if the operation was performed within 6 hours of acute MI, and then decreased precipitously (Table 22-5).<sup>77</sup> On the other hand, mortality for the transmural group remained high during the first 3 days before returning to baseline.<sup>78</sup> Multivariate analyses confirmed that CABG within 6 hours for the nontransmural group and 3 days for the transmural group were independently associated

**TABLE 22-5: Comparison of Hospital Mortality with Respect to Time of Surgery—Transmural versus Nontransmural Myocardial Infarction**

Time between CABG and MI	Mortality	
	Transmural MI (%)	Nontransmural MI (%)
<6 h	14	13
6-23 h	14*	6*
1-7 days	5	4
>7 days	3	3

with increased in-hospital mortality.<sup>77,78</sup> Optimal timing of CABG in patients with acute MI remains a controversial subject. Early surgical intervention has the advantage of limiting the infarct expansion and ventricular remodeling that may result in possible ventricular aneurysm and rupture.<sup>79</sup> However, there is the theoretical risk of reperfusion injury, which may lead to hemorrhagic infarction resulting in extension of infarct size, poor infarct healing, and scar development.<sup>80</sup> The data from these studies caution against early surgical revascularization, particularly within 3 days of onset, among patients with acute transmural MI.

Some have advocated the use of mechanical support to stabilize the patient and allow elective rather than emergent surgery.<sup>81,82</sup> Delaying CABG with “prophylactic” mechanical support in an effort to improve outcome, however, may result in placement of such support in some situations where it is unnecessary. If revascularization cannot be delayed, aggressive mechanical support (such as an LVAD) should be available because mortality is most likely a result of pump failure. Furthermore, mechanical circulatory support (MCS) has been shown to be efficacious as a bridge to ventricular recovery or transplantation for this patient cohort.<sup>82</sup> This approach is supported by results from a multicenter study, in which overall survival at 6 and 12 months was higher in patients who underwent direct LVAD implantation rather than revascularization followed by LVAD, in patients suffering cardiogenic shock (Fig. 22-5).<sup>83</sup> Although emergent cases such as structural complications and ongoing ischemia clearly cannot be delayed, nonemergent cases, particularly patients with transmural acute MI, may benefit from delay of surgery. Early surgery after transmural acute MI has a significantly higher risk and surgeons should be prepared to provide aggressive cardiac support including LVADs in this ailing population.

### Risk Factors

In addition to timing of surgery as discussed, risk factors include urgency of the operation, increasing patient age, renal insufficiency, number of previous MIs, hypertension,<sup>84</sup>

**FIGURE 22-5** Outcomes of direct left ventricular assist device (LVAD) implantation versus coronary artery bypass graft (CABG) followed by LVAD implantation for cardiogenic shock. (Reproduced with permission from Dang NC, Topkara VK, Leacche M, et al: Left ventricular assist device implantation after acute anterior wall myocardial infarction and cardiogenic shock: a two-center study, *J Thorac Cardiovasc Surg.* 2005 Sep;130(3):693-698.)

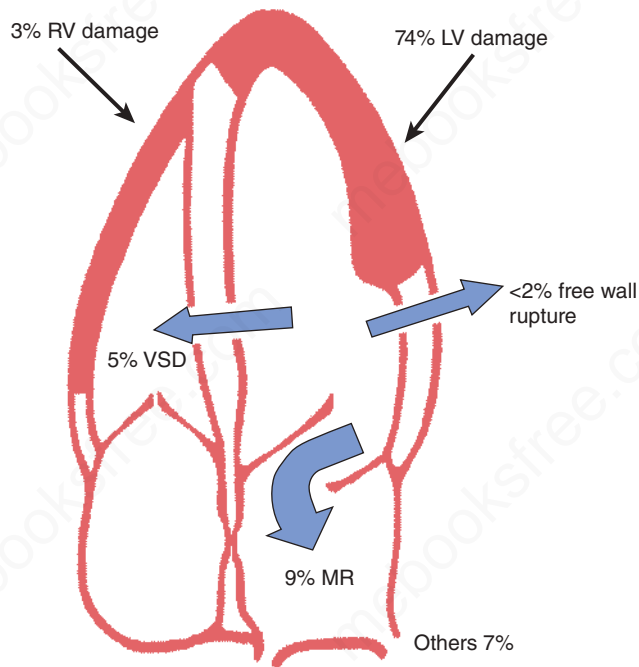

reoperation, cardiogenic shock, depressed left ventricular function, and the need for cardiopulmonary resuscitation, left main disease, female gender, left ventricular wall motion score, need for IABP, and transmural infarction.<sup>85</sup> Characteristics associated with better early outcome after MI include preservation of left ventricular ejection fraction, male gender, younger patients, and subendocardial versus transmural MI.

### Cardiogenic Shock

Surgical revascularization in acute MI complicated by cardiogenic shock has been shown to improve survival. Cardiogenic shock is accompanied by 80 to 90% mortality rates. The various mechanisms of cardiogenic shock in acute MI are shown in Fig. 22-6. DeWood and colleagues<sup>86</sup> were the first to demonstrate improved results with revascularization in patients with cardiogenic shock complicating acute MI. Patients who were stabilized with an IABP and underwent emergent surgical revascularization had survival rates of 75%. Early surgical revascularization was associated with survival rates of 40 to 88% in patients in cardiogenic shock from nonmechanical causes. Guyton and coworkers<sup>87</sup> reported an 88% in-hospital survival and a 3-year survival of 88%, with no late deaths reported.

Furthermore, the SHOCK trial demonstrated survival benefit in early revascularization by CABG or PTCA within 12 hours of the diagnosis of cardiogenic shock for patients of all ages.<sup>11,29</sup> Patients comprising the CABG cohort in the SHOCK trial had more severe disease, with higher rates of three-vessel disease, left main coronary artery disease, diabetes, and elevated mean coronary jeopardy scores than the PTCA cohort.<sup>88</sup> Despite this, 87.2% of these patients achieved successful and complete revascularization with CABG, compared with successful revascularization in 77.2% with PTCA and only 23.1% with complete revascularization with PTCA. Overall,

**FIGURE 22-6** Mechanisms of cardiogenic shock. Apical four-chamber echo view with relative incidence of the mechanisms responsible for cardiogenic shock in the SHOCK and MILIS 4 registries. LV = left ventricle; MR = mitral regurgitation; RV = right ventricle; VSD = ventricular septal defect. (Reproduced with permission from Davies CH: Revascularization for cardiogenic shock, *QJM*. 2001 Feb;94(2):57-67.)

mortality was no different between groups at 1 year (Fig. 22-7). On subgroup analysis, patients older than age 75 years, with left main coronary disease or three-vessel disease, or with diabetes had trends toward better survival at 30 days and 1 year after CABG compared to PTCA. Thus, for patients in cardiogenic shock, surgical revascularization remains an established and viable option for select patient groups.

### Advantages of Coronary Artery Bypass Grafting

Reported survival rates are similar for CABG and PCI in the treatment of acute MI. To date, there have been no large, randomized clinical trials comparing CABG with PCI and thrombolytics after MI. For patients with stable angina and elective revascularization for ischemic heart disease, a number of trials have been conducted comparing CABG with stenting.<sup>89-92</sup> In these studies, trends favoring CABG for multivessel disease were seen after 2 years in composite cardiac event end points, rate of reinfarction, and mortality; revascularization rates were five times higher in the stenting group.<sup>93</sup> Most notably, survival after CABG for two or more diseased vessels was significantly higher than stenting with 2-year follow-up in a retrospective study of the New York Cardiac Surgery Reporting System and Percutaneous Coronary Intervention Reporting System.<sup>94</sup> These results must be interpreted with

**FIGURE 22-7** Kaplan-Meier survival estimates at 96 hours (A), 30 days (B), and 1 year (C) in patients treated with emergency percutaneous coronary intervention (PCI) versus emergency coronary artery bypass graft (CABG) in the SHOCK trial. (Reproduced with permission from White HD, Assmann SF, Sanborn TA, et al: Comparison of percutaneous coronary intervention and coronary artery bypass grafting after acute myocardial infarction complicated by cardiogenic shock: results from the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) trial, *Circulation*. 2005 Sep 27;112(13):1992-2001.)

caution; however, as patients with acute infarctions less than 24 hours pretreatment were excluded. Because of the lack of prospective, randomized trials, recommendations must be based on retrospective and observational studies.

CABG does offer a few potential advantages. First, surgical revascularization is the most definitive form of treatment of the occlusion. CABG offers the longest patency of revascularized stenotic and occluded arteries; in elective cases, more than 90% of internal mammary artery grafts are patent at 10 years.

Second, CABG also offers more complete revascularization, because all vessel lesions are treated. This concept becomes especially important in patients with multivessel disease or those in cardiogenic shock, in whom remote myocardium may continue to be comprised with only “culprit vessel” revascularization and inadequate restoration of collateral flow.<sup>95</sup> A complete revascularization restores global myocardial perfusion to normal levels and offers the best chance for myocardial salvage. Finally, there is the opportunity for controlled reperfusion to reverse ischemic injury and reduce reperfusion injury.

## Summary

Surgical revascularization following acute MI can be performed with excellent results when the timing and patient cohort are appropriate. Most patients do not need such measures and would not benefit from this aggressive form of therapy. However, patients with mechanical complications, those in cardiogenic shock, and those with post-infarction angina are likely to benefit from early CABG.

## OPERATIVE TECHNIQUES FOR ACUTE MYOCARDIAL INFARCTION

### Anesthesia

Anesthesia is provided by a rapid narcotics-based regimen with perfusion and surgical teams prepared to respond to catastrophic hypotension or cardiac arrest. Transesophageal echo probes are placed in these patients if possible.

### Bleeding

Bleeding is a significant complication of emergency CABG and can result in further myocardial depression and pulmonary hypertension. Cytokine release induced by infusion of blood products and thromboxane A<sub>2</sub> released as a result of cardiopulmonary bypass stimulate pulmonary hypertension, which can be catastrophic in the setting of right ventricular ischemia. Use of antifibrinolytics, such as aminocaproic acid, for re-operative, emergency, or high-risk CABG is common in many institutions.

The use of clopidogrel deserves special mention, and its expanding administration can pose unique problems for the cardiac surgeon. Clopidogrel, an oral, irreversible antagonist of the 5'-adenosine diphosphate that inhibits platelet activation and aggregation, is used extensively in patients with acute coronary syndromes and has been shown to lower cardiovascular risk by up to 20% and reduce reinfarction and stroke rates.<sup>96,97</sup> In addition, it is commonly given before percutaneous interventions and after intracoronary stenting to prevent thrombosis. Higher loading doses have been used with increasing efficacy against ischemic complications, which will likely expand its use in the future.<sup>98</sup> However, patients frequently require surgical revascularization after medical therapy or cardiac catheterization while taking

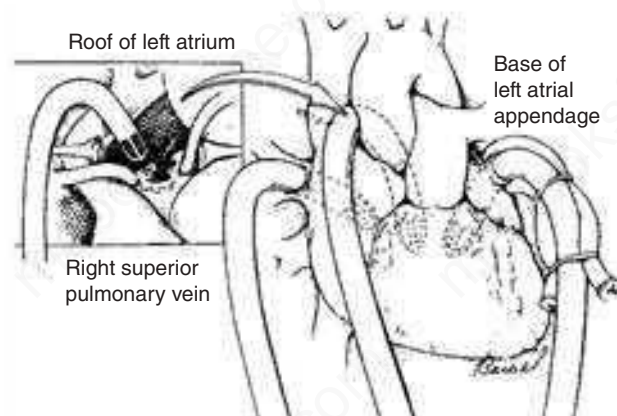

clopidogrel. The risk of bleeding after clopidogrel and cardiac surgery can be substantial. In multiple reports, the risk of reoperation for hemorrhage in patients receiving clopidogrel within 7 days of cardiac surgery was six times higher, and patients required more blood, platelet, and fresh-frozen plasma transfusions.<sup>99,100</sup> Because of these complication rates and the inability to reverse the drug's effect on platelets, surgery is often delayed until platelet function is restored, which may take up to 7 days, or the life of the platelets. Emergent surgery while taking clopidogrel often necessitates blood product transfusions and confers significant morbidity, and possibly mortality. Ongoing work continues in an effort to determine if current dosing regimens after acute MI can be reduced to lessen bleeding complications.

### Choice of Conduits

For emergency cases, the choice of conduit should usually not differ from elective cases in most circumstances. The internal mammary artery is not associated with a higher number of complications compared with saphenous vein grafting in emergent situations and can be used in most circumstances.<sup>101,102</sup>

### Intraoperative Considerations

Decompression of the ventricle during revascularization after acute coronary occlusion decreases muscle damage and improves functional outcome by decreasing wall tension and reducing oxygen consumption (Figs. 22-8 and 22-9).<sup>36</sup> In fact, ventricular decompression reduces metabolic energy consumption by 60%. Diastolic basal arrest, by avoiding the energy of contraction, is the second most important means of minimizing oxygen consumption and further reduces metabolic energy consumption by 30%. Cooling of the patient and heart has an impact on the final 10% of basal energy requirements. Reduction of myocardial energy consumption is best

**FIGURE 22-8** The inflow cannula for short-term left ventricular assist device support can be placed through the right superior pulmonary vein, the dome of the left atrium, or the left atrial appendage. Lighthouse tip cannulas allow improved venous return.

**FIGURE 22-9** (A) Myocardial oxygen uptake ( $MvO_2$ ), measured in milliliters per 100 grams per minute, in beating and working, beating and empty, and arrested hearts. Values after cardioplegia were determined both during cardiopulmonary bypass (cardioplegia) and during regional cardioplegic reperfusion in the working heart (dyskinetic muscle). Note (1) marked fall in  $MvO_2$  with cardioplegia in the decompressed heart and (2) oxygen requirements of dyskinetic muscle increase fivefold over cardioplegia alone, and equal almost 55% of beating, working needs. (B) Regional oxygen uptake during selective cardioplegic reperfusion in dyskinetic and vented cardiac muscle. Stippled areas show requirements in working heart (8.5-10.5 mL/100 g/min). Note (1) high oxygen demands of dyskinetic muscle and (2) marked reduction in demands when noncontracting muscle is decompressed by venting. (Reproduced with permission from Allen BS, Rosenkranz ER, Buckberg GD, et al: High oxygen requirements of dyskinetic cardiac muscle, *J Thorac Cardiovasc Surg*. 1986 Sep;92(3 Pt 2):543-552.)

achieved by early institution of cardiopulmonary bypass to maintain a high perfusion pressure. If a coronary salvage catheter has been placed across a tight coronary lesion, the catheter is left in place until just before cross-clamping. Antegrade and retrograde cardioplegia catheters are placed before cross-clamping to allow quick instillation of retrograde cardioplegia and protection of the territory supplied by the occluded or

compromised vessel. The standard Buckberg protocol is followed, including warm induction to allow regeneration of depleted adenosine triphosphate stores. If the territory at risk is to be grafted by saphenous vein, this anastomosis is performed first to allow direct instillation of cardioplegia into the territory at risk. The proximal anastomoses should be performed before removal of the cross-clamp to allow complete perfusion of the entire heart upon removal of the cross-clamp.

Although large ventricular aneurysms are treated by resection and patch, debate surrounds smaller aneurysm. If an aneurysm is resected, the defect is repaired with a patch of bovine pericardium sewn to the fibrotic rim of the endoaneurysm surface. The native left ventricular wall is closed over the patch.

Utilization of the Dor procedure (endoventricular circular patch plasty repair) in the post MI setting is another controversial subject. Some data have shown that surgical remodeling improves systolic function, ejection fraction, and intraventricular dyssynchrony, whereas other data suggest no additional benefit when the Dor procedure is added to CABG.<sup>103-106</sup> Further investigation is needed to definitively answer this question.

## Postoperative Care

A higher incidence of complications in shock patients compared with non-shock emergencies has been reported. Guyton and associates<sup>87</sup> report a 47% complication rate associated with cardiogenic shock compared with 13% for patients with non-shock emergencies. This increase in complications probably reflects the preoperative condition of the patients as much as the treatment itself. Long-term follow-up in patients after emergency surgical revascularization shows that survival rates are closely correlated with postoperative ejection fraction and left ventricular size.<sup>107,108</sup>

## USE OF THE INTRA-AORTIC BALLOON PUMP

The early use of aortic counterpulsation with an IABP demonstrated the safety but not efficacy of this device for patients in cardiogenic shock following acute MI.<sup>109</sup> Although survival was not improved, aortic counterpulsation did improve the myocardial oxygen requirements and myocardial energetics were reduced in patients in shock.

Over the last several decades, multiple studies have been performed to help define the role for IABP in acute MI. Early reports demonstrated that aortic counterpulsation decreased the reocclusion rate, recurrent ischemia, and need for emergency PCI in patients who had coronary patency reestablished by emergency cardiac catheterization after acute MI.<sup>110</sup> Prophylactic counterpulsation for 48 hours sustained patency in these patients without increasing vascular or hemorrhagic complications.<sup>110</sup> However, additional randomized trials have been performed which have questioned the advantage of IABP in cardiogenic shock secondary to MI.<sup>111</sup> Recently, the ACC/AHA guidelines have downgraded the recommendation for IABP use in cardiogenic shock from a Class I to Class IIa

recommendation.<sup>38</sup> The IABP-Shock II Trial randomized patients with cardiogenic shock complicating acute MI who were undergoing early revascularization and optimal medical therapy to IABP versus control.<sup>112</sup> The 30-day outcomes showed no survival benefit with IABP support. In addition, these patients were subsequently followed for 6-month and 12-month follow-up to determine the long-term impact of IABP support. There was no significant difference in mortality, reinfarction, repeat revascularization or stroke.<sup>113</sup>

For patients who undergo early revascularization, the empiric addition of aortic counterpulsation with an IABP will not improve the patient's outcome; however, the IABP remains a useful adjunct for patients who are awaiting revascularization or continue to show signs of ischemia after revascularization. Placement of an IABP is also reasonable in patients who remain in cardiogenic shock despite adequate revascularization and optimal medical management if it may aid in stabilizing a patient for more definitive therapy, that is, mechanical circulatory support (MCS). The use of IABP is also effective for temporary hemodynamic stabilization in complications of acute MI, such as ventricular septal rupture, acute mitral valve insufficiency,<sup>114</sup> post-infarct angina,<sup>115</sup> ventricular arrhythmias,<sup>116</sup> and acute heart failure following infarction.<sup>117</sup>

## ROLE OF MECHANICAL CIRCULATORY SUPPORT

One area of ongoing development involves the use of MCS for cardiogenic shock. Mechanical assist devices augment systemic perfusion and prevent end-organ damage while resting the stunned ventricle with complete or partial pressure-volume unloading.<sup>118</sup> Early studies of implantable LVADs have shown that end-organ function is an early predictor of mortality. Treatment of patients before end-organ deterioration is essential to improving the odds for long-term survival. In addition to affecting end-organ function, assist devices promote "reverse remodeling" by improving myocardial contractility and calcium handling, altering the extracellular matrix, and decreasing myocardial fibrosis.<sup>119,120</sup> Recent studies have shown that circulatory support early after MI improves survival and offers a feasible bridge to recovery or transplantation.<sup>82,121</sup> Although still in its early stages, many institutions are working to develop the optimal strategy for adding MCS to their treatment algorithms for ACS. There are essentially three categories of MCS available, and the choice of type of support depends on a number of variables.

VA-ECMO is one option available for MCS in acute MI patients. Its primary use is in cardiogenic shock or cardiac arrest after acute MI, as it can often be placed rapidly and without moving the patient. There may be additional benefits to inserting cannulas under fluoroscopic-guidance while the patient is in the cath lab. Because it can be performed expeditiously, it is a useful first-line MCS therapy for these patients.

Another option available in this situation is percutaneous VADs. These include the Impella 2.5, CP or 5.0 (Abiomed

Europe GmbH, Aachen, German), the TandemHeart (Cardiac Assist, Pittsburgh, PA, USA), and the Hemopump (Johnson & Johnson, Racho Cordova, CA, USA). These are also devices that can be implanted percutaneously in the cath lab to augment cardiac output in patients undergoing post-infarct PCI. The TandemHeart provides up to 4 L/min of support, producing a higher mean blood pressure and cardiac output, and lowering pulmonary capillary wedge pressure.<sup>122</sup> Likewise, the Impella device can provide between 2.5 L/min and 5 L/min depending on the model, and in small series, may offer superior hemodynamic support when compared with an IABP.<sup>123</sup>

Finally, another more invasive option for mechanical support in post-MI patients involves implantable VADs. Again, there are multiple reports utilizing different types of VADs in this particular situation. These include ABIOMED ventricular support system (Abiomed, Inc., Danvers, MA, USA), the Thoratec paracorporeal system (pVAD), the Thoratec Centrimag Blood Pump (Thoratec Corp., Pleasanton, CA, USA), and the Syncardia ventricular support system (Syn Cardia Systems, Inc., Tucson, AZ, USA). An important consideration when selecting a device is whether there is likely to be recovery of adequate ventricular function or not. If there is an expectation of recovery, or if the plan is for surgical revascularization at the time of ventricular support, then a temporary LVAD would be the more reasonable approach. If the patient is unable to be weaned from their temporary LVAD, then a long-term device remains an option. Likewise, if the patient's ventricular function is not expected to recover, and in particular, if there are no plans for revascularization, then proceeding with a long-term LVAD may be the best course. Another factor that is part of this algorithm is whether the patient is potentially a transplant candidate or not. There are many variables which may impact the feasibility of this strategy, and some of them are exclusive of the patient's overall condition. For example, the patient's gender, size, blood type, and local allocation limitations will all impact the expected waiting times, and may preclude transplant as a viable option without long-term mechanical support. The decision-making in these instances involves a multidisciplinary team to optimize resource utilization for these patients. Enthusiasm for using mechanical support to help patients survive their acute infarcts is growing at many institutions across the country. With the development and refinement of these techniques and the ability to fit the right strategy to the right patient, we expect outcomes to improve for this group of critically ill patients. A full discussion of short-term and long-term MCS is reported in Chapters 18 and 66.

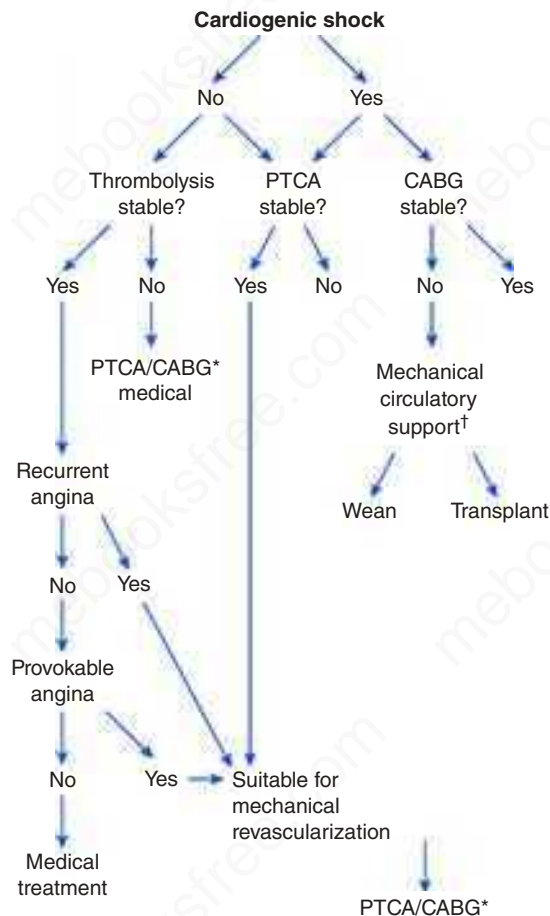

## SURGICAL MANAGEMENT

The use of MCS in the setting of an acute MI is continuing to evolve. Many patients with an acute MI requiring consideration for mechanical support are in a state of uncertainty. They are by definition, unstable, and many will have already received, or will be in the process of receiving CPR. The status of their end-organ function and their neurologic

function is unclear. In these situations, one option is to utilize peripheral VA-ECMO in an attempt to stabilize the patient. This can usually be done in the catheterization lab either via a percutaneous or cut-down technique. Femoral artery and venous cannulas are placed and the patient is connected to the ECMO circuit. Flow is initiated to provide as much cardiac output as possible. With adequate flow to maintain a normal cardiac output, vasoactive medications, including pressors and inotropes, can be weaned. There are several advantages to this approach. First, it allows clinicians the opportunity to assess the patient's neurologic function before embarking on a more invasive procedure or long-term support. The patient can wake up and undergo a complete neurologic evaluation while on VA-ECMO support. This is most important for patients who have received CPR prior to initiation of MCS. Second, VA-ECMO preserves, and in some cases, allows recovery of the end-organ function as patients can typically be weaned off of inotropes and pressors entirely. Again, this is an important part of the algorithm as preserved end-organ function will greatly improve the likelihood that a patient will survive the additional steps needed to bridge the patient to recovery, a long-term LVAD, or transplantation. Initiation of peripheral VA-ECMO can also decompress the heart and allow an opportunity for recovery. With the heart decompressed, there is less wall tension and stress, primarily, on the right ventricle. Although there is increased afterload on the left ventricle with VA-ECMO, there are several strategies designed to decompress the left side and allow the myocardium to recover. An in-depth discussion regarding options to assist in decompressing the left ventricle on VA-ECMO is beyond the scope of this chapter, but these options include inotropes, IABP, Impella, and surgical vents.

If patients have survived the initial event with VA-ECMO support, then they can proceed to the next step which is an evaluation for signs of myocardial recovery and a determination of the need for long-term mechanical support (Fig. 22-10). The patients have usually already received a coronary angiogram, and if feasible, an attempt at PCI. If the myocardium has recovered the patients can be weaned from ECMO and decannulated. However, if they fail to wean, then a determination of their candidacy for a long-term LVAD or transplant is made. The decision to place a long-term LVAD is influenced by many factors, but can be summarized by their score on a screening scale designed for this purpose (Table 22-6). These scores were selected to identify end-organ dysfunction (lung, liver, or kidney) and operative constraints (right-sided heart failure and bleeding). Excellent results have been reported with nearly a 90% survival if the summed scores are less than 5 points, versus 30% survival with summed scores greater than 5 points.<sup>124</sup> For this reason, if the total score is greater than 5 points, an attempt is made to improve end-organ function before attempting long-term LVAD insertion.

These algorithms continue to be refined as experience with mechanical support grows. Utilizing a short-term option such as VA-ECMO or a nonimplantable LVAD to stabilize the

\*PTCA = percutaneous transluminal coronary angioplasty; CABG = coronary artery bypass grafting. Choice of therapy is made based on the lesion(s) and comorbid factors.

patient, preserve their end-organs, and ensure adequate neurologic function has been an important advancement in the care of these critically ill patients. Identifying which patients will benefit most from implantation of long-term devices is an area of ongoing investigation.

## CONSENSUS GUIDELINES

The initial evaluation and management of a patient suffering from a MI begins before the patient arrives to the hospital. First responders in the field are trained to perform the initial ECG, and initiate treatment algorithms based upon these findings and the overall condition of the patient. Throughout the literature, this point of contact marks the time of FMC, which will impact the steps that follow.

Based upon the definitions as previously stated, patients are categorized as either STEMI or NSTEMI. Patients who meet criteria for STEMI are evaluated for urgent or immediate reperfusion. Again, the approach for reperfusion will depend upon the patient's location and the medical resources available to them at their destination hospital.

The recent executive summary update to the STEMI guidelines has attempted to outline these issues (regional systems of STEMI care, reperfusion therapy, and time-to-treatment goals) with the following Class I recommendations<sup>38</sup>:

1. Performance of a 12-lead electrocardiogram (ECG) by emergency medical services personnel at the site of first medical contact (FMC) is recommended in patients with symptoms consistent with STEMI
2. Reperfusion therapy should be administered to all eligible patients with STEMI with symptom onset within the prior 12 hours
3. Primary PCI is the recommended method of reperfusion when it can be performed in a timely fashion by experienced operators
4. Emergency medical services transport directly to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI, with an ideal FMC-to-device time system goal of 90 minutes or less
5. Immediate transfer to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI who initially arrive at or are transported to a non-PCI-capable hospital, with an FMC-to-device time system goal of 120 minutes or less
6. In the absence of contraindications, fibrinolytic therapy should be administered to patients with STEMI at non-PCI-capable hospitals when the anticipated FMC-to-device time at a PCI-capable hospital exceeds 120 minutes because of unavoidable delays
7. When fibrinolytic therapy is indicated or chosen as the primary reperfusion strategy, it should be administered within 30 minutes of hospital arrival

An additional class IIa recommendation is as follows:

1. Reperfusion therapy is reasonable for patients with STEMI and symptom onset within the prior 12 to 24 hours who have clinical and/or ECG evidence of ongoing ischemia. Primary PCI is the preferred strategy in this population

These strategies are outlined in Fig. 22-10.

In summary, the initial decision making involves a determination of the expected time from FMC to revascularization

by PCI. If the FMC-to-device time is expected to be greater than 120 minutes, then it is recommended that patients receive fibrinolytics. The next step in the algorithm was evaluated by the TRANSFER-AMI trial.<sup>125</sup> Here, patients who had received fibrinolytics were randomized to either standard treatment (which included rescue PCI, if required) or a strategy of immediate transfer to another hospital and PCI within 6 hours of fibrinolysis. At 30 days, patients assigned to routine early PCI had a statistically significant reduction in the incidence of the primary end point which was the composite of death, reinfarction, recurrent ischemia, new or worsening congestive heart failure, or cardiogenic shock (11.0 vs 17.2%).<sup>125</sup> Thus, this trial supports an aggressive approach to transferring patients for PCI even after receiving thrombolytics for an acute MI.

The same Executive Summary of STEMI Guidelines included recommendations regarding surgical therapy.<sup>38</sup>

Class I recommendations include:

1. Urgent CABG is indicated in patients with STEMI and coronary anatomy not amenable to PCI who have ongoing or recurrent ischemia, cardiogenic shock, severe heart failure, or other high-risk features
2. CABG is recommended in patients with STEMI at time of operative repair of mechanical defects

Class IIa recommendations include:

1. The use of mechanical circulatory support is reasonable in patients with STEMI who are hemodynamically unstable and require urgent CABG

Class IIb recommendations include:

1. Emergency CABG within 6 hours of symptom onset may be considered in patients with STEMI who do not have cardiogenic shock and are not candidates for PCI or fibrinolytic therapy

## FUTURE THERAPIES AND TRENDS

Improving outcomes in patients suffering acute MI can occur through pharmacologic advances, optimization of existing practices, and application of new technology. Various medications have been described that reduce ischemic-reperfusion injury and limit infarct size in animal models, such as oxygen-derived free radical scavengers, folic acid, nitric oxide inhibitors, and others<sup>126</sup>; clinical study of these promising drugs will determine their efficacy. Reducing transport time to the hospital after the onset of symptoms and implementation of clinical guidelines have been the focus of many hospitals and emergency services. The increased number of local hospitals able to perform primary percutaneous interventions has meant quicker revascularization and thus improved outcomes.<sup>27</sup> In addition, the technology used to treat these patients continues to improve. New wires, catheters, balloons, and stents continue to be developed and improved upon compared with previous generations. Furthermore, the optimization of the medical treatment of these patients is an

area of ongoing research and development. Improved antiplatelet and anticoagulation strategies are just one example. With more experience, widely available guidelines have been developed and published in an effort to standardize care for all patients across the country, regardless of where they present. This will also allow for better data collection and assessment and comparisons, and ultimately improvement in strategies.

Surgically, we continue to develop and improve our techniques for surgical revascularization. This includes advances in myocardial protection, and refinements in the cardiopulmonary bypass circuit to limit the physiologic insult of surgery. MCS has advanced greatly over the past 10 years, and pumps have become smaller, safer, less invasive, easier to use, and easier to implant. In addition, patients who remain in cardiogenic shock despite inotropes and revascularization are being identified as candidates for MCS. There is likely to be continuing review of the role of intra-aortic balloon counterpulsation in the management of STEMI with cardiogenic shock. Another area for investigation includes the optimal timing for surgical revascularization should percutaneous options fail or be unavailable. The availability of MCS backup, may allow for successful surgical revascularization and recovery in patients previously deemed not operative candidates because of their high surgical risk.

Finally, the rapidly emerging field of cellular therapy holds great promise for repair of damaged myocardium. A number of cell types, such as endothelial progenitor cells, mesenchymal stem cells, skeletal myoblasts, resident cardiac stem cells, and embryonic stem cells, are being investigated<sup>127</sup>; the optimal cell type, mode of delivery (intracoronary artery infusion, intravenous infusion, transendocardial injection, and transepical injection), and timing of administration have yet to be determined. Nevertheless, early clinical trials suggest that cellular therapy may offer benefits. One-year follow-up of 59 patients suffering acute MI in the TOPCARE-AMI trial who received either circulating progenitor cells or bone marrow-derived progenitor cells demonstrated increased cardiac function and reduced ventricular dimensions, without adverse events.<sup>128</sup> Precultured mesenchymal cells also offer great promise by allowing cells from an unrelated donor to be administered without the complications of an individual tissue harvest. The safety of these cells given intravenously after percutaneous revascularization in acute MI was recently published, and efficacy studies are ongoing.<sup>129</sup> Numerous other clinical trials are underway to address questions regarding mechanisms of benefit, cell viability, and dosing. Further randomized clinical trials will be required to establish outcome benefit.

Effective management of acute MI requires a well-coordinated plan that starts with first medical contact. Rapid diagnosis and transport to the appropriate institution in the first step. If the diagnosis is an ST-elevation MI, then the priority is reperfusion. Depending on the available resources, this will require transport to a facility with emergency-PCI capabilities. If this is not possible, then thrombolytics should be administered if there are not contraindications. If either of these options are not available, or are unsuccessful, the patient should undergo an evaluation for emergency CABG.

The initial management is the same in patients who are in cardiogenic shock; however, facilities managing these patients should have available means of providing additional support. If a reperfused patient remains in shock despite inotropes, pressors, and an IABP, consideration should be given to pursuing MCS.

# Minimally Invasive Myocardial Revascularization

Piroze M. Davierwala • David M. Holzhey • Friedrich W. Mohr

The term *minimally invasive coronary artery bypass grafting* (CABG) is not well defined. According to one definition, avoidance of cardiopulmonary bypass (CPB) is considered essential in decreasing the morbidity associated with conventional CABG.<sup>1</sup> Other authors consider median sternotomy as a potential source for morbidity, due to increased risk of deep sternal wound infection and mediastinitis and delayed return to daily activities.<sup>2</sup> Accordingly, a number of surgical strategies have evolved to avoid the need for extracorporeal circulation and minimize surgical access. Furthermore, eluding aortic manipulation and complete arterial revascularization are operative strategies that focus on improving short and long-term results. Likewise, it was widely recognized that conventional harvesting techniques for bypass grafts are often associated with wound-healing problems, especially in diabetic patients. As a consequence, endoscopic harvesting techniques for both, venous and radial artery grafts have been developed.

## OFF-PUMP CORONARY ARTERY BYPASS (OPCAB) GRAFTING

Conventional CABG has been performed with CPB under cardioplegic arrest for decades. An empty, arrested heart, a bloodless surgical field, and an excellent exposure of all epicardial vessels have been considered to be the key factors for the success of this procedure. Excellent results and constantly declining mortality despite the ever-increasing risk profile of patients (Davierwala) have made standard CABG the “bread and butter” of our profession.<sup>3</sup> Anecdotal reports on the deleterious effects of CPB and systematic reports that examined the pathophysiology of extracorporeal circulation began questioning the dogma, “the pump is your friend.” CPB is associated with (1) a systemic inflammatory response, (2) release of cytokines, (3) activation of the clotting cascade, (4) metabolic disturbances, and (5) microembolization among numerous other adverse effects. Although well tolerated by most patients, these effects alone or in combination may cause substantial morbidity, thus negatively affecting the results of the procedure. With an ever-aging population and increasing comorbidity, surgeons all over the world sought to

further minimize the risk of CABG, and it seemed logical to question the role of CPB in CABG.

The evolution of *off-pump coronary artery bypass* (OPCAB) grafting is closely linked to the development of stabilizers that became available in the early 1990s. Initially, only pressure stabilizers were developed, but it soon became obvious that exposure of vessels on the posterolateral and inferior walls of the heart would require additional means of support. Hence, OPCAB gained greater popularity when vacuum-assisted stabilizers were introduced by the Utrecht group, which facilitated localized myocardial immobilization for all territories. Additionally, it was also recognized that OPCAB requires a team approach between the surgeon and anesthesiologist so as to prevent sudden hemodynamic changes during the procedure and to manage the same when they do occur.

## Anesthesia Requirements

OPCAB is performed under general anesthesia in most centers. Incidental reports in literature demonstrate that OPCAB can also be performed under high epidural anesthesia in an awake patient breathing spontaneously.<sup>4</sup> Standard monitoring is used. In addition, some centers prefer continuous cardiac output measurement using the PICCO or similar methods.<sup>5</sup> A Swan-Ganz catheter is not always beneficial and contrarily can potentially cause arrhythmias when the heart is manipulated during the procedure. It is of utmost importance that the patient is kept warm at all times during the operation. Temperature management includes the use of a warming blanket and warm infusions, and maintaining higher room temperatures. Volume management is essential because it is generally the preferred means to counterbalance hemodynamic changes. Exposure of the posterior wall results in severe hemodynamic compromise due to some degree of right ventricular compression under the right hemisternum, but can be treated adequately by increasing venous return by tilting the operating room table to the right in a Trendelenburg position. Excessive infusion of fluids should be avoided, especially in patients with end-stage renal disease (ESRD), as hemofiltration is not possible during surgery due to the absence of

CPB. The use of inotropes should be preferably reserved only in patients with severe hemodynamic alterations, because they invariably increase the heart rate and make grafting more difficult. A review of human factors associated with manual control and tracking revealed that a human operator can, at his or her best, track a three-dimensional motion (such as the beating heart) only up to a frequency of 1 Hz, which corresponds to a heart rate of 60 beats per minute.<sup>6</sup> Higher frequencies cannot be tracked; therefore the preferred heart rate should be maintained between 50 and 70 beats per minute to simplify anastomotic suturing. In case of atrial fibrillation (AF), pharmacologic reduction in the heart rate and temporary ventricular pacing using epicardial pacing wires may facilitate grafting. The use of a Cell Saver is recommended to minimize the risk of blood transfusion, which is rarely necessary. If less than 500 mL is accumulated, the blood is usually discarded in the Cell Saver.

### Surgical Technique

Single or bilateral internal thoracic arteries (ITA) are harvested following a standard median sternotomy. The patient is heparinized (150-200 units/kg, ie, about half of CPB dosage). An activated clotting time (ACT) greater than 300 seconds is maintained. It may be necessary to open the right pleura in patients with severely dilated hearts, although some surgeons do it routinely to give the heart enough space during manipulation for exposure of the posterolateral wall. It avoids excessive compression of the right ventricle. Following pericardiectomy, it is advisable to hitch the left side of the pericardium onto the left sternal edge. Thereafter, the two edges of the sternum are spread out with the sternal retractor. This helps not only in rightward rotation of the heart, but also elevates the heart to a certain degree, which additionally facilitates exposure of vessels on the posterolateral wall. Subsequently, deep pericardial stay sutures are placed to further aid in exposure and manipulation of the heart. Numerous methods have been proposed for placing these sutures. Ideally, two sutures are placed deep into the pericardium (deeper than the level of the atrioventricular groove), one just medial to the inferior vena cava and the other just inferior to the left inferior pulmonary vein (Fig. 23-1). To avoid damage to the myocardium due to shearing, the sutures should be covered by plastic tubing; sponges may be used alternatively. Placement of the stay sutures should be done slowly because abrupt changes in positioning of the heart may cause undesired hemodynamic alterations or arrhythmias.

The sequence in which the grafting should be performed depends largely on the coronary anatomy and the grafting techniques used. The left anterior descending (LAD) artery is considered to be the most important target vessel and can be easily grafted without too much manipulation of the heart. Therefore, revascularization should start with an ITA graft to the LAD in most cases. A slight pull on the stay sutures easily brings the LAD into the operative field. The stabilizer is placed at the desired site of the anastomosis

**FIGURE 23-1** Setup for off-pump coronary artery bypass grafting. Placement of pericardial stay sutures.

so as to ensure adequate distance between the pods of the stabilizer and the vessel for suturing. The anterior surface of the vessel is exposed by dissecting it free from the overlying tissue. If the vessel is covered by excessive fat or muscle, low-energy cautery and clipping of epicardial veins may help to minimize bleeding from the surrounding tissue. Mechanical compression of large diagonal branches should be avoided. Vacuum stabilizers should be locked only after vacuum is applied and the stabilizer firmly holds on to the surface. Only minimal pressure will then be required to immobilize the heart. The greater the pressure exerted by the stabilizer, the greater the force with which the heart beats against it, resulting in increasing wall motion and hence the difficulty in anastomosis. Temporary occlusion of the target vessel can be achieved in many ways. Complete or partially encircling 4-0 polypropylene sutures with or without pledgets or silastic tapes are commonly used widely. The occlusion tapes or sutures should be placed at a distance of at least 5 to 10 mm from the anastomosis to avoid compression and distortion of the target vessel at the level of the anastomosis, thus allowing for safe and comfortable suturing. The suture needs to be placed deep enough in the tissue to avoid damage of the target vessel. Injury to the accompanying coronary vein should be avoided to prevent bleeding at and around the anastomotic site. Distal coronary artery occlusion should be avoided and is rarely necessary even in occluded vessels with strong backflow. A shunt can be used in the latter case. Care must be taken to avoid occluding vessels in stented areas because the occlusion sutures/tapes may bend or kink an implanted stent. The incision is usually made before the occlusion suture is tightened to ensure that the vessel is full, as it will minimize the risk of back wall injury while opening the vessel. The suture then is tightened gently until the bleeding stops. This may not be necessary in totally occluded vessels with minimal coronary blood flow. A CO<sub>2</sub> blower-mister is used to maintain a clear field of vision during the anastomosis by blowing

away the blood flowing retrograde from septal branches or the distal coronary artery. The CO<sub>2</sub> flow rate should not exceed 5 L/min. Excessive blowing can produce dissection or injury to the intima of both, the graft and the coronary artery, or cause air embolism. The use of coronary artery shunts is controversial because they also may cause endothelial damage. If shunts are used, care must be taken to ensure atraumatic placement. Another option is the use of a transparent reverse thermosensitive gel (LeGoo™, Pleuromed Inc., Woburn, MA) injected at the anastomotic site after incising the coronary artery, which temporarily blocks the blood flow allowing an almost bloodfree anastomotic site. The anastomosis can then be performed without a blower-mister, shunt, or occlusion snares. The gel completely dissolves with time (after approximately 15 minutes) or with the local application of a cold sponge or gauze.<sup>7,8</sup>

The circumflex artery and its branches are usually grafted next, especially when a composite Y/T-grafting technique is used. Grafting the distal circumflex artery is considered to be the most challenging during OPCAB because exposure may be difficult. In patients with cardiomegaly and more importantly in those with right ventricular dilatation and dysfunction, it may be necessary to open the right pleura and divide the right-sided pericardium at the diaphragm up to the level of the inferior vena cava. This allows displacement of the heart under the right sternal edge into the right pleural cavity, thus preventing the compression of the right ventricle. Thereafter, the right coronary artery (RCA) and its branches are grafted. If the RCA is the dominant vessel and has a stenosis less than 80%, it may be necessary to use a shunt because loss of blood flow in the atrioventricular (AV) nodal artery during occlusion of the RCA can cause acute total AV block. It is therefore advisable to place and connect a temporary pacing wire before occluding such vessels.

To maximize both the short- and long-term benefits of an OPCAB procedure, composite arterial grafting is preferred. This will obviate the need for aortic clamping, which is another source for emboli and an independent predictor of stroke.<sup>9</sup> In fact, some authors believe that avoiding aortic manipulation is the key factor in reducing the stroke risk following CABG below that after percutaneous coronary intervention (PCI).

If aortocoronary vein or radial grafts are used, the proximal or distal anastomosis can be performed first. However, in patients with critical ischemia or hemodynamic instability, it would be beneficial to perform the proximal anastomosis initially, as it can be performed without manipulating the heart and the myocardium is revascularized as soon as the distal anastomosis is completed. It is of utmost importance to reduce the systemic blood pressure during partial clamping of the aorta to minimize the risk of embolization and aortic dissection. This can be achieved pharmacologically or mechanically by briefly compressing the inferior vena cava. This maneuver should also be repeated prior to declamping. Intraoperative graft patency control using transient-time Doppler or other imaging techniques is recommended. If the operative field is dry, heparin usually is not completely antagonized.

Postoperatively, aspirin is administered on the day of surgery, provided the patient does not bleed to muchion.

## Special Situations

In patients with unstable angina, acute cardiogenic shock, or low ejection fraction (EF < 20%), the preoperative implantation of an intra-aortic balloon pump (IABP) may be useful. Alternatively, these patients can be operated on CPB without cardioplegic arrest (on-pump beating heart) to combine the advantages of preserved native coronary blood flow, decompression of the heart, and adequate organ perfusion.<sup>13,14</sup> Patients with AF have an irregular contraction pattern that may distract the surgeon while suturing (regular-motion patterns allow the development of coping strategies such as the “wait and see” strategy that are less effective when motion is unpredictable<sup>5</sup>). It may, therefore, be helpful to reduce the heart rate pharmacologically and temporarily pace the patient in a VVI mode. If AF is paroxysmal, epicardial ablation may be used for pulmonary vein isolation on the beating heart before grafting.

## Results

Bakaeen et al reported recently that the number of OPCABs performed in the United States peaked in 2002 (23%) and 2008 (21%), followed by a steady decline to 17% in 2012. The last 5 years has witnessed a reduction in OPCAB rates not only in intermediate-volume centers performing between 50 and 200 cases a year, but also in high-volume centers performing >200 cases a year. They further reported that 84% of centers performed fewer than 50 off-pump cases per year, 34% of surgeons performed no off-pump operations, and 86% of surgeons performed fewer than 20 off-pump cases per year.<sup>17</sup> However, in some countries, especially those with limited medical and financial resources, OPCAB still accounts for almost 80% of CABG procedures. Some units almost exclusively perform OPCAB with no patient selection. One of the major reasons for this decline is the results of several randomized controlled trials that have been unfavorable for OPCAB. The ROOBY trial reported a worse composite outcome of death and complications (9.9 vs 7.4%,  $p = .04$ ), higher rate of incomplete revascularization (17.9 vs 11.1%;  $p < .0001$ ), and a lower graft patency rate (82.6 vs 87.8%,  $p < .01$ ) for OPCAB than on-pump CABG at 1 year. The Danish off-pump versus on-pump randomization study (DOORS) which included 900 patients > 70 years of age found no difference in the compound clinical endpoints between the two techniques at 30 days and 6 months.<sup>16</sup> However, the DOORS study group recently published a subanalysis, which revealed significantly inferior graft patency rates after OPCAB than after on-pump CABG at 6 months (79 vs 86%;  $p = .01$ ).<sup>17</sup> Nevertheless, both these trials were not sufficiently powered to determine clinically relevant differences between the two techniques of surgical revascularization with respect to death, myocardial infarction, stroke, or renal failure. Sergeant and colleagues as well as Puskas and coworkers have pointed out that large

cohorts of patients would be required to reveal a significant statistical difference in these outcomes between the two operative techniques.<sup>18,19</sup> Hence, the CORONARY trial was conducted, which randomized 4752 patients to OPCAB (2375) and on-pump CABG (2377). No differences in composite outcomes were found between groups at 30 days, 30 days to 1 year, and at 1 year after surgery.<sup>20</sup> Similarly, the German Off-Pump Coronary Artery Bypass Grafting in Elderly Patients (GOPCABE) study, which involved 2539 patients > 75 years of age randomized to OPCAB or on-pump CABG, showed no difference in clinical composite or individual components of death, stroke, MI, or renal replacement therapy at 30 days and 12 months between the two groups.<sup>21</sup> However, patients undergoing OPCAB required significantly more repeat revascularization at 30 days, which nonetheless evened out at 12 months. This finding was keeping in lieu with those of Khan et al, who reported reduced graft patency in OPCAB patients three months postoperatively.<sup>22</sup> Contrary to this, other studies like the SMART and Prague IV study that provide angiographic data on graft patency reveal equal patency rates for on- and off-pump bypass surgery.<sup>23-25</sup> This controversy concerning OPCAB has remained unresolved ever since the first reports on OPCAB regarding higher rates of incomplete revascularization<sup>26-29</sup> and lower graft patency<sup>21</sup> were published.

OPCAB does play an important role in stroke prevention, especially in patients at higher risk. A meta-analysis that involved all major randomized controlled trials comparing OPCAB with on-pump CABG between 2011 and 2010 revealed a significant 30% reduction in the occurrence of postoperative stroke with OPCAB [risk ratio (RR): 0.70]. There was no significant difference in mortality (RR: 0.90) or myocardial infarction (pooled RR: 0.89).<sup>30</sup> There is growing evidence that neurocognitive outcome is better and stroke rate is lower after OPCAB.<sup>31-33</sup> Several studies have proven CPB to be an independent predictor of adverse neurologic outcomes.<sup>34</sup> The embolic burden that is measured by transit-time Doppler of the medial cerebral artery is reduced significantly during OPCAB.<sup>35-37</sup> Neurological complications can be further reduced during OPCAB by performing the operation without aortic manipulation. In a recent retrospective analysis of 12,079 CABG patients, Moss and colleagues reported that the ratio of observed to expected stroke rate increased as the degree of aortic manipulation increased, from 0.48 in the no-touch group, to 0.61 in the clampless facilitating device group, and to 0.95 in the clamp group. Aortic clamping was independently associated with an increase in postoperative stroke compared with a no-touch technique (adjusted odds ratio (OR), 2.50;  $p < .01$ ).<sup>38</sup> OPCAB has also been associated with a reduced risk of acute renal failure,<sup>39-41</sup> especially in high-risk patients with preoperative renal insufficiency.<sup>42,43</sup> A meta-analysis of 22 randomized studies involving 4819 patients affirmed these findings. OPCAB was associated with a 40% lower odds of postoperative acute kidney injury (OR 0.60; 95% confidence interval (CI) 0.43 to 0.84;  $p = .003$ ) and a nonsignificant 33% lower odds for dialysis requirement (OR 0.67;

95% CI 0.40 to 1.12;  $p = .12$ ) than on-pump CABG.<sup>44</sup> The kidney function substudy of the CORONARY trial, which enrolled 2932 patients, revealed that OPCAB reduced the risk of acute kidney injury when compared to on-pump CABG (17.5 vs 20.8%,  $p = .01$ ); however, there was no significant difference between the two groups in the loss of kidney function at 1 year (17.1 vs 15.3%,  $p = .23$ ).<sup>45</sup>

Furthermore, the incidence of postoperative AF<sup>43,46</sup> and blood levels of biochemical markers for myocardial injury (eg, creatinine kinase and troponin) are also reduced after OPCAB.<sup>47-49</sup> Blood loss is less, and transfusion rate is reduced.<sup>19</sup> Overall, OPCAB reduces hospital costs by 15 to 35%,<sup>50,51</sup> possibly owing to a decrease in the length of hospital stay and resource utilization.<sup>50</sup>

Most studies favor OPCAB with respect to operative and short-term mortality. A retrospective analysis of 17,969 OPCAB patients (8.8% of total) in the Society of Thoracic Surgeons database for the years 1999 and 2000 identified a significant survival advantage for OPCAB compared to on-pump CABG, as was demonstrated by risk-adjusted multivariate logistic regression analysis (OR 0.76, 95% CI 0.68 to 0.84) and conditional logistic regression of propensity-matched groups (OR 0.83, 95% CI 0.73 to 0.96).<sup>52</sup> Similar results have been reported from another multicenter analysis by Mack and colleagues, which included 7283 patients. Following propensity score matching and multivariate regression analysis, the use of CPB was identified as an independent predictor of mortality (OR 2.08, 95% CI 1.52 to 2.83,  $p < .001$ ).<sup>53</sup> OPCAB seems to offer a survival benefit especially in high-risk populations (eg, the elderly, those with EF < 30%, and obese patients).<sup>19,50,54,55</sup> The International Society for Minimally Invasive Cardiac Surgery Consensus Group, in a thorough meta-analysis, published that OPCAB reduces mortality and length of stay and the incidence of postoperative myocardial infarction (MI), renal failure, AF, and transfusion rate in mixed-risk and high-risk patients<sup>19</sup> (Fig. 23-2). Few reports on mid-term survival showed similar outcomes for OPCAB and on-pump CABG at 2 and 4 years.<sup>26,56</sup>

There are limited reports comparing the long-term outcomes of OPCAB and on-pump CABG. Three major publications in the last 5 years have produced different results. The long-term follow-up of patients enrolled in the Beating Heart Against Cardioplegic Arrest Study (BHACAS 1 and 2) showed a similar likelihood of graft occlusion between OPCAB (10.6%) and on-pump CABG (11.0%) groups (OR: 1.00;  $p > .99$ ). Similarly, no differences were noted in the hazard of death (hazard ratio (HR): 1.24) or major adverse cardiac-related events or death (HR: 0.84) between the two groups.<sup>57</sup> Contrarily, a large propensity-matched analysis of 5203 patients showed a similar risk of death at 30 days (OR: 0.70;  $p = .31$ ) and up to 1 year (HR: 1.11;  $p = .62$ ) for OPCAB and on-pump CABG, but a higher risk of death for the former at a median follow-up duration of 6.4 years (HR: 1.43;  $p < .0001$ ).<sup>58</sup> A recent meta-analysis of 32 studies comparing the long-term outcomes of OPCAB and on-pump CABG concluded that OPCAB has similar mid-term

mortality and morbidity to on-pump CABG in a low-risk population. When observational studies were excluded a comparable long-term mortality was observed between the two surgical revascularization techniques.<sup>59</sup> To summarize, OPCAB is a technically challenging operation, which requires a prolonged learning curve compared to conventional bypass graft surgery. Some surgeons perform OPCAB almost exclusively, whereas others never use it at all. OPCAB may not be the best option for every patient or for all cardiac surgeons. It is, however, an important alternative and must be mastered with the same technical precision as conventional CABG.<sup>60</sup> True comparisons between OPCAB and on-pump CABG are extremely difficult even by randomized controlled trials as there are many factors such as quality of the coronary vessels anastomosed, type of conduits used, grafting techniques

(sequential, composite total arterial, venous grafts, etc), and competency and experience of the surgeons to perform OPCAB that cannot be accounted for. All the same, we have to wait for the results of long-term follow-up of large-scale, multi-institutional RCTs.

### MINIMALLY INVASIVE DIRECT CORONARY ARTERY BYPASS (MIDCAB)

One of the goals of minimally invasive cardiac surgery has been to avoid sternotomy to reduce the amount of surgical trauma and avoid wound complications. Therefore, coronary artery bypass techniques on the beating heart without

sternotomy were developed. The operation was termed *minimally invasive direct coronary artery bypass* (MIDCAB), and since its introduction in the mid-1990s,<sup>61-65</sup> it has found a widespread application. In some centers, MIDCAB is the preferred method of surgical revascularization for isolated LAD disease. In addition, MIDCAB is a valuable alternative to standard CABG or OPCAB in selected high-risk patients with multivessel disease and extensive comorbidity, who are at a prohibitively high risk for sternotomy and CPB.

## Anesthesia

Standard monitoring techniques are applied, and temperature management is as described previously for OPCAB procedures. Single-lung ventilation is achieved by using a double-lumen tube or bronchus blocker to provide selective right lung ventilation. Short-acting anesthetics are used to allow early extubation.

## Surgical Technique

Standard MIDCAB is usually performed through a left anterolateral minithoracotomy with the patient in a 10 to 30° right lateral position. Following a 5 to 6 cm skin incision at the level of the fifth intercostal space or the inframammary fold in females, the pectoralis muscle is displaced bluntly with minimal division of its muscle fibers (muscle-sparing approach). This decreases the likelihood of developing a lung hernia that has been sometimes reported with this approach. The chest is then usually entered one intercostal space higher than the actual incision. Excessive rib spreading must be avoided at all times to prevent dislocation or fracture. Excision of a rib is almost never necessary. LITA harvest is usually performed under direct vision, but endoscopic harvest utilizing a harmonic scalpel or telemanipulation systems has also been reported.<sup>65-67</sup>

The intrathoracic fascia is divided to facilitate LITA harvest, which can be performed in a pedicled or skeletonized manner, from the fifth intercostal space to the origin of the subclavian artery. Using a skeletonized technique offers the advantage of gaining more graft length, but is, of course, more time-consuming. Additional length can also be gained by dividing the mammary vein at its junction with the subclavian vein. Side branches are clipped or cauterized based on the preference of the surgeon. Heparin is administered prior to distal transection of the graft. As in a sternotomy OPCAB, the ACT is maintained at a level greater than 300 seconds. The pericardium should be opened at a point approximately corresponding to the course of the LAD and extended to the groove between the aorta and the pulmonary artery. This will facilitate location of the target vessel in the presence of excessive epicardial fat or an intramuscular course. The target vessel is identified. To enhance exposure, one or two pericardial stay sutures may be used to position the heart. It is of utmost importance to have the anastomotic site in direct vision. Standard

**FIGURE 23-3** Minimally invasive direct coronary artery bypass. Through a muscle-sparing incision, the left anterior descending artery is easily exposed; standard pressure stabilizers are used. (Data from 1483 patients undergoing MIDCAB at the Heartcenter Leipzig.)

reusable pressure stabilizers are then used to immobilize the target vessel (Fig. 23-3). Vacuum stabilizers in general are too bulky and not required for a single anastomosis to the LAD. Proximal LAD occlusion is performed using a 4-0 pledgeted suture or vessel loops. Ischemic preconditioning is not helpful, but some surgeons use it to feel more comfortable knowing that ischemia is well tolerated. The use of shunts is rarely necessary, but they may be used based on surgeon preference, presence of significant retrograde coronary flow or evidence of ischemia or hemodynamic instability. Distal occlusion should be avoided whenever possible (99% of patients). A blower-mister is used in all cases to achieve a bloodless field. The anastomosis then is performed in a standard manner using a 7-0 or 8-0 polypropylene running suture. Finally the LITA pedicle can be fixed to the epicardial tissue. Graft patency assessment is performed routinely using transit-time Doppler flow measurements. A single chest tube is inserted into the left pleural space, and intercostal nerve blockade is applied using local anesthetics. Before closing the chest with one or two strong rib sutures, the single-lung ventilation is stopped and the left lung is inflated under direct vision of the surgeon to prevent it from causing an avulsion of the LITA and also confirm that the LITA lies perfectly without undue tension. This is facilitated by holding the LITA close to the mediastinum using the suction tip or long forceps. Extubation can be performed in the operating room or a few hours postoperatively. Antiplatelet therapy is usually administered on the day of surgery.

## Results

Many papers have reported excellent results with the use of this approach. Immediate angiographic patency rates range between 94 and 98% and are thus similar to those following conventional CABG.<sup>64,68</sup> At 6 months, 94% patency has been

reported.<sup>69</sup> The mid-term results published recently by Reser et al demonstrated an overall survival of  $92.4 \pm 0.2\%$  and MACCE-free survival of  $96.1 \pm 1.7\%$  at 24 months.<sup>70</sup> In our own series of 1768 patients, who underwent MIDCAB from 1996 to 2009, in-hospital mortality was 0.8% (predicted mortality by Euroscore 3.8%), and stroke rate was 0.4%. Conversion to sternotomy was necessary in 1.7%. A total of 712 patients underwent routine postoperative angiogram demonstrating a 95.5% early patency rate. Short-term target-vessel reintervention was required in 3.3% of patients. At 6-month follow-up, graft patency was 95.2% ( $n = 423$ ). The 5- and 10-year survival was 88.3% (95% CI 86.6 to 89.9%) and 76.6% (95% CI 73.5 to 78.7%) (Fig. 23-4A). The corresponding freedom from MACCE and angina was 85.3% (95% CI 83.5 to 87.1%) and 70.9% (95% CI 68.1 to 73.7%) (see Fig. 23-4B).<sup>71</sup> These results are comparable to those of other groups.<sup>69,72,73</sup>

In-hospital mortality after MIDCAB is <1% and compares favorably with 1.4% mortality following off-pump single-vessel bypass and 3.6% mortality after on-pump single-vessel bypass reported in the registry of the German Society for Thoracic and Cardiovascular Surgery.<sup>74</sup> It is also lower than the 2.4% mortality reported from the STS database.<sup>75</sup> A propensity score adjusted comparison of MIDCAB versus full sternotomy revealed similar operative mortality, late survival, and need for repeat revascularization

at a mean follow-up of 6.2 years, but a lower rate of surgical site infection (2.8 vs 0.7%;  $p = .04$ ).<sup>76</sup> Another smaller study from the UK also found MIDCAB comparable to OPCAB with regard to operative mortality, MI, stroke, reinterventions, and ICU stay. However, hospital stay was significantly lower for MIDCAB patients.<sup>77</sup> In general, rates of perioperative major complications such as MI and the need for target-vessel reintervention are low and comparable with standard CABG. However, due to anaortic surgery perioperative stroke is rare and considerably lower compared to conventional techniques. A few randomized trials comparing the LIMA-LAD with the MIDCAB approach to bare metal stenting for isolated proximal LAD disease have demonstrated better early patency and superior freedom from target-vessel reintervention and angina up to 5 years of follow-up in patients undergoing MIDCAB.<sup>78-83</sup> The 10-year results of the randomized trial conducted by our group comparing MIDCAB with bare metal stents for proximal LAD disease showed no differences in the primary composite endpoint of death, MI, and reintervention (47 vs 36%;  $p = .12$ ) and hard endpoints (death and infarction) between the two revascularization modalities. However, a higher target vessel revascularization rate in the PCI group (34 vs 11%;  $p < .01$ ) was observed.<sup>84</sup> Similar results were also reported when drug-eluting stents were compared to MIDCAB.<sup>85</sup> These results have been further confirmed not only by meta-analyses<sup>86,87</sup> but also propensity-matched data from large registries.<sup>88</sup>

Some studies have pointed out that the lateral approach is associated with more pain than sternotomy chiefly due to excessive rib spreading required for visualizing the LITA during harvest.<sup>65</sup> Rib dislocation or fracture has been reported infrequently with this approach. Direct harvesting of the LITA is regarded as being technically challenging and has been one of the main arguments used by surgeons to disregard MIDCAB as the primary operation for patients who require surgical revascularization of the LAD. Limited working space and incomplete vision are blamed for insufficient graft length, incomplete mobilization, and the occasional reports of LITA or subclavian vein injury.

MIDCAB is technically a highly demanding procedure that should be performed by surgeons who have sufficient experience in conventional and off-pump surgery. It has been shown that the complication rate of MIDCAB (viz. conversion to sternotomy, reexploration for bleeding, and reintervention on the target vessel) is significantly reduced following 100 to 150 MIDCAB procedures.<sup>89</sup> Therefore, it can be recommended that this operation should be performed by experienced surgeons dedicated to this technique.

Even in the era of improved outcomes following interventional procedures and lower in-stent restenosis rates with the use of drug-eluting stents,<sup>90</sup> MIDCAB, based on its very good long-term results,<sup>91</sup> will always remain an alternative revascularization strategy to PCI, especially for patients with complex ostial lesions, chronic occlusions, and in-stent restenosis of the LAD.

**FIGURE 23-4** Kaplan-Meier (including 95% confidence interval) five-year survival curve (A) and event-free survival curve (freedom from death, myocardial infarction, stroke, freedom from angina, freedom from reintervention) (B) after minimally invasive direct coronary artery bypass. ## TOTAL ENDOSCOPIC CORONARY ARTERY BYPASS GRAFTING

*Total endoscopic coronary artery bypass grafting* (TECAB) on the beating heart is conceivably the least invasive approach for surgical revascularization. It has been well known for a long time that working through ports limits the available space to perform motions, substantially decreases the dexterity of the operator, and alters the hand-eye coordination.<sup>92</sup> Active assistance, an indispensable component of open surgery, is difficult in thoracoscopic procedures. The transition from limited-access cardiac surgery to endoscopic cardiac surgery therefore complicates the procedure manifold and has rendered previous attempts at endoscopic CABG using conventional endoscopic instruments impossible. To overcome some of the instrument-related limitations, computer-enhanced instrumentation systems have been developed.

### Principles of Telescopically-Assisted Cardiac Surgery

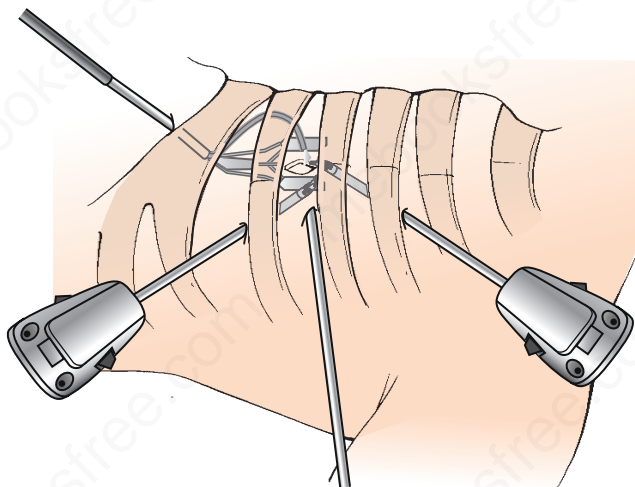

With the use of telescopically devices, the operator involved in the surgery is physically away but not necessarily remote from the operation table. He sits at an *input manipulator* (surgical console, master console), from which he steers the *executing manipulator* (slave console), which is situated at the patient site. The slave console consists of all the necessary electromechanical equipment needed to operate two to three exchangeable endoscopic instruments in addition to a high definition three-dimensional endoscopic camera. Both tactile and visual information is fed back to the master console. In this way a virtual three-dimensional operative field is created, wherein the surgeon can manipulate steering handles with a perfect hand-eye coordination. The introduction of telescopically technology to endoscopic surgery was able to address the key performance limitations of conventional endoscopic surgery, namely, reduced articulation, monocular vision, and loss of hand-eye coordination.

### Surgical Technique

Standard monitoring for cardiac surgery is used. Defibrillator pads are placed on the back and the right side of the chest. Single-lung ventilation using a double-lumen endotracheal tube or a bronchus blocker is used to ventilate only the right lung. Temperature management principles remain the same as for OPCAB surgery. After draping the instrument and camera arms, the camera and scope are calibrated, and the endostabilizer is prepared. A holding arm for the endostabilizer is mounted onto the operating table on the patient's right side, and the operating table is rotated 10 to 15° to raise the patient's left side.

After single right-lung ventilation is initiated, the camera port is inserted through the fifth intercostal space 2 cm medial to the anterior axillary line. CO<sub>2</sub> insufflation is used

for adequate visualization and to create working space that is hemodynamically tolerated (usually 10-12 mm Hg of insufflation pressure). A 30° scope that is angled up is used for LITA harvest. The right instrument port is inserted through the third intercostal space medial to the anterior axillary line, and the left instrument port is inserted through the seventh intercostal space medial to the anterior axillary line. The instrument arms are centered for optimal range of motion by adjusting the respective setup joints, and the instruments are inserted. LITA harvest starts by division of the intrathoracic fascia covering it with low-power monopolar cautery. The LITA is dissected bluntly off the chest wall moving from the lateral to the medial aspect as a pedicle, preserving the lateral veins. Side branches are cauterized or clipped. Dissection is performed from the first intercostal space to the level of the bifurcation. The pedicle is not detached from the chest wall until the anastomosis is finally performed in order to avoid torsion of the graft. The distal end of the graft is skeletonized to facilitate suturing of the anastomosis. The pericardial fat is removed, and the mediastinal and diaphragmatic attachments to the pericardium are dissected bluntly to widen the available space. The pericardiectomy is performed through a longitudinal incision in the pericardium over the probable course of the LAD. The ideal anastomotic site is identified by the absence of visible atheromatous plaques and avoidance of proximity to bifurcations. At this point, angling the endoscope downwards may enhance visualization. After heparinization (an ACT of 300 seconds is recommended), a vascular clamp is placed across the LITA approximately 2 cm proximal to the transection site. The LITA is clipped distally, transected, and spatulated in preparation for the anastomosis. Flow in the graft is confirmed by briefly releasing the vascular clamp. The LITA pedicle is still left attached to the chest wall in order to maintain orientation of the graft until the anastomosis is performed. A 12 mm subxyphoid cannula is inserted under endoscopic vision. Before introduction of the endostabilizer, temporary silastic occlusion tapes and a 7 cm 7-0 double-armed polypropylene suture are introduced through this port and retained in the mediastinum. Some surgeons prefer Gore-Tex sutures to avoid the memory effect of polypropylene. Alternatively, nitinol clips (U-clips) may be used. The endostabilizer then is introduced under endoscopic vision by the surgeon at the operating table (Fig. 23-5). Vacuum and saline irrigation lines are connected, and the multilink irrigator is advanced into the field of vision. The console surgeon then positions the stabilizer feet parallel to the LAD target site. After suction is applied, the feet are locked into position. After blunt dissection of the anastomotic target site, the silastic tapes are placed proximal and distal to the anastomotic site, and the LAD is temporarily occluded. After a 5 to 6 mm arteriotomy is performed, transection of the LITA is completed, and the graft is brought in close proximity of the target site. The anastomosis is best performed by beginning in the middle of the medial edge of the incision (12 o'clock position), suturing inside-out on the LITA and out-side-in on the LAD toward and around the heel. Care has to be taken to maintain tension on the suture

**FIGURE 23-5** Setup for total endoscopic coronary artery bypass grafting. Two instrument ports, one central camera port, and a subxyphoid port for the endostabilizer are required.

continuously. After the needles are broken off, an instrument knot is tied. The occlusion tapes and vascular clamp are released and brought out through an instrument port. The pedicle may be fixed to the epicardium by stay sutures. Graft patency can be checked by transient time Doppler flow measurements endoscopically, if a probe without a handle is available. This probe can be advanced through the stabilizer port. Alternatively, intraoperative angiography has been performed using a mobile angiography unit or modern C-arm systems when TECAB operation is performed in a hybrid suite. After the pleural space is drained under vision, the stabilizer and instruments are withdrawn, and the left lung is ventilated. A chest tube is inserted through one of the port holes. In case a four-arm system is used, the fourth arm is introduced after LITA harvest through the third intercostal space in the anterior axillary line. It may be used to provide counter traction during pericardial fat excision and pericardiotomy and to hold the pedicle during the anastomosis. The new version of the da Vinci system also allows the use of a remotely controlled stabilizer that is placed on the fourth arm and thus can be adjusted from the console.

## Results

Initially, TECAB was performed on an arrested heart using the Port-Access platform with femoro-femoral CPB, endoaortic balloon clamping, and cardioplegic arrest. CPB time and cross-clamp times were in the range of 80 to 120 and 40 to 60 minutes, respectively. The reported patency rate for the TECAB procedures on an arrested heart ranged from 95 to 100% prior to discharge and 96% at the 3-month follow-up angiography.<sup>93-96</sup> In addition to reporting good overall results and patency rates after TECAB, a large single-center study including 100 patients also revealed anastomotic times of 10 to 30 minutes after a long learning curve. They further acknowledged that the learning curve continues beyond 100

operations, which is even more pronounced than in MID-CAB procedures (see above).<sup>97</sup>

Endoscopic CABG on the beating heart is even more challenging.<sup>93,98,99</sup> Based on an intention-to-treat basis, the conversion rate (elective conversion to a MIDCAB procedure) in a five-center registry was 33% (37 of 117). Conversions were mostly due to calcified target vessels or the inability to locate or dissect the LAD and rarely due to other conditions such as arrhythmias or hemodynamic instability. The patency rates for completed beating-heart TECAB procedures are in the range of 92 to 94%.<sup>75</sup>

TECAB can be performed safely, but is currently restricted to a few indications (eg, single-vessel bypass grafting of the LAD and occasionally double-vessel grafting), but has the potential for endoscopic multivessel grafting as well.<sup>100,101</sup> A more commonly applied technique is an endoscopic harvesting of both ITAs and direct coronary anastomosis via a mini-thoracotomy. This yields excellent results and very short recovery times for the patients.<sup>101,102</sup>

Despite the use of advanced telemanipulator technology, the TECAB procedure remains technically demanding and is infrequently performed worldwide. Long operation times, extensive use of material, and operation room capacity combined with a stretched learning curve and well-established alternative minimally invasive techniques have confined TECAB to few centers and single dedicated surgeons.

## MULTIPLE BYPASS GRAFTING USING MINIMALLY INVASIVE TECHNIQUES

Talking about minimally invasive surgical revascularization almost always means revascularization of the anterior wall with the left internal mammary artery. The classical MID-CAB operation is only rarely extended to graft a diagonal or even an intermediate branch as well, typically with a Y-graft using a vein or radial artery.

Recent reports have proven the feasibility of complete revascularization for multivessel disease. Bilateral internal thoracic artery harvest is possible through small incisions under direct vision or endoscopically with the help of a telemanipulator.<sup>103</sup> For proximal anastomoses the aorta can be mobilized and partially clamped or the internal thoracic arteries serve as sources of inflow for a radial artery or saphenous vein.

Accessibility of all areas of the heart is made possible by special stabilizers and suction retractors that allow distal anastomoses even on the beating heart. As an alternative the Heartport system for endoaortic clamping and cardioplegia can be used.

These techniques are not yet routinely used. However, the published series of patients show excellent results oftentimes superior to conventional CABG or OPCAB.<sup>103</sup> Lemma and coworkers reported 137 patients operated with this technique with a 1.4% incomplete revascularization and revision for bleeding. There were no conversions to sternotomy nor

were there wound complications. Only two deaths occurred at a mean follow-up of 26 months. A positive stress test was reported in 4.3% of patients.<sup>104</sup> An angiographic patency study involving 91 patients who were prospectively enrolled to undergo minimally invasive multivessel CABG revealed a 100% patency for the LIMA-LAD graft and 92% patency for all grafts.<sup>105</sup> It can be assumed that these operations are performed by dedicated, experienced surgeons on selected patients. Only a more widespread application of these procedures and the treatment of a broader variety of patients together with randomized studies would bring light to their significance in the future.

## HYBRID REVASCULARIZATION

The hybrid approach for patients with multivessel coronary artery disease seeks to combine the advantages of PCI and minimally invasive CABG. The principle was first described by Angelini in 1996.<sup>106</sup> The goal is to minimize the surgical trauma but still gain complete revascularization. The rationale is that the excellent long-term results of LIMA to LAD grafting<sup>91,107</sup> cannot be extended to other grafts and areas of myocardium. This is particularly true for the still commonly used venous grafts to non-LAD targets. Here PCI can potentially achieve similar long-term results, though with higher rates of reintervention. Although recent studies underline the superiority of complete surgical revascularization,<sup>108</sup> the avoidance of sternotomy seems to be very appealing to both patients and treating cardiologists.

However, combining the benefits of two different procedures also means adding risks inherent to each type of procedure. The drawbacks of a surgical procedure including the risk of general anesthesia and artificial ventilation are combined with an increased risk of inferior long-term outcomes after PCI resulting in higher rates of reinterventions and the possibility of eventual redo surgical multiple bypass grafting. Therefore the indication for hybrid revascularization should be discussed and agreed upon by the treating cardiologist, cardiac surgeon and, most importantly, the patient himself.

## Indications for the Hybrid Approach

Current recommendations for coronary artery revascularization do not include hybrid procedures. This is due to limited availability of outcome data and a lack of randomized trials. Thus, choosing a hybrid approach is usually based on an individual decision. In all cases, the patients with multivessel disease including the proximal LAD need to be informed that the best evidence-based treatment is a sternotomy CABG procedure. However, the different reasons for choosing a hybrid approach can be summarized as follows:

- *Multimorbid or high-risk patients:* This is probably the best accepted indication and includes patients with a high risk for sternotomy such as those with skeletal anomalies like

osteogenesis imperfecta, severe osteoporosis, etc., those who are crutches- or wheel-chair-dependent, and those with a history of deep sternal wound infections following previous sternotomy. Patients with reduced life expectancy such as advanced malignancies, end-stage cardiomyopathy, advanced liver, and renal failure not amenable for transplant could also benefit from a hybrid procedure. Additionally, comorbidities that could be considered risk factors for a sternotomy and occurrence of other post-operative complications such as diabetes, severe obesity, COPD, end-stage peripheral vascular disease, porcelain aorta, and history of stroke with paraplegia might also be candidates for the hybrid approach.

- *Primary PCI of Circumflex/RCA:* Patients with acute coronary syndromes presenting with a culprit lesion in the circumflex or RCA and an additional stenosis of the LAD may undergo primary emergency PCI of the culprit lesion by the referring cardiologist. A MIDCAB procedure involving a LITA-LAD can be performed four to six weeks later. A preoperative angiogram confirming the patency of the stents should be performed prior to surgery. In the presence of an in-stent restenosis the patient can be scheduled for a standard bypass procedure.
- *Patient preference:* Some well-informed patients want to avoid a sternotomy and opt for a hybrid approach. Patients need to be informed that they might require future reinterventions including repeat target vessel revascularization or bypass surgery. Because the choice of the hybrid revascularization in these patients is not based on medical grounds, it deserves a formal discussion between the patient, interventional cardiologist, and cardiac surgeon.

## Timing of the Procedures

The optimal timing and the sequence of revascularization is still controversial.<sup>109</sup> All three possible scenarios have inherent benefits and drawbacks:

- *PCI before CABG:* Performing PCI first is usually associated with an increased risk of bleeding at the time of surgery because of dual antiplatelet therapy. This can be avoided in stable patients who received a bare metal stent by postponing the CABG procedure for more than 4 weeks. When the interval between the two procedures is even longer, performing a preoperative check-angiogram is reasonable to exclude early in-stent restenosis.

The PCI-first strategy is most commonly used in an emergency situation, when a non-LAD culprit lesion requires primary PCI.<sup>110</sup>

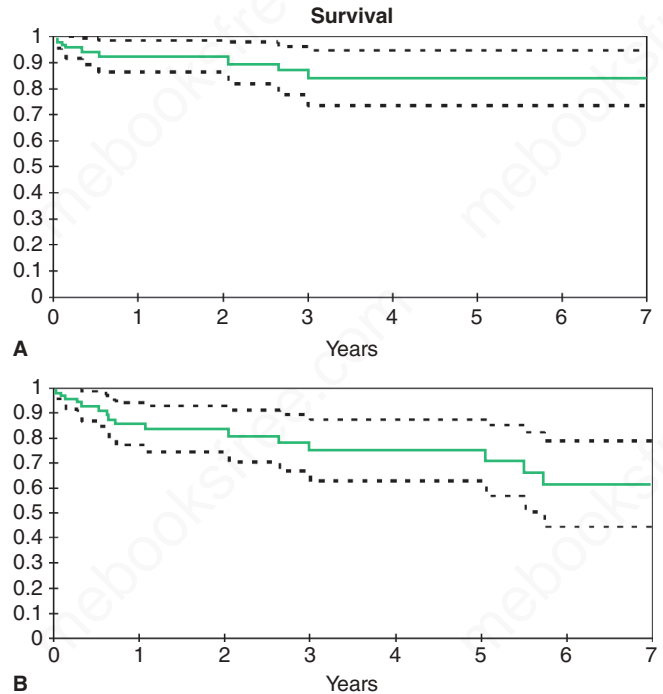

- *CABG before PCI:* This is the most frequently used option. PCI is performed after the patient has recovered from surgery. After protection of the anterior wall the percutaneous approach for the other coronary arteries, including the left main coronary artery, is safer.<sup>111</sup> Additionally, the LITA-LAD graft can also be assessed.

- *Simultaneous revascularization:* The growing number of novel operating suites that provide true integration of surgical and fluoroscopic capabilities allow for complete hybrid revascularization in one session without moving the patient. After performing a standard MIDCAB/TECAB procedure the quality and patency of the bypass graft is verified and PCI of the remaining vessels is undertaken with the patient still under general anesthesia. In the rare case of a failed PCI easy and safe conversion to conventional bypass surgery is possible. Patient acceptance for this approach is high, however, good coordination and synchronization of the schedules of the cardiologist and the cardiac surgeon is required.

## Results

Hybrid coronary revascularization (HCR) as a concept has been applied for almost 15 years and provides an additional approach to revascularization for patients with multivessel coronary disease. The general consensus is that hybrid integrated revascularization is feasible and safe.<sup>112-116</sup> Friedrich and colleagues reviewed the results of 18 studies in literature, which included 367 patients. At 6 months the LIMA stenosis rate was 2% and in-stent restenosis was 12%.<sup>112</sup> The large single-center series published by our group revealed a survival of 92.5% (95% CI 86.5 to 98.4%) at 1 year and 84.8% (95% CI 73.5 to 94.9%) at 5 years.<sup>110</sup> Eight patients died during follow-up (208 patient-years). A total of 23 patients had an angiogram for recurrent angina. One patient had an occluded LIMA bypass. Five patients showed significant in-stent-restenosis with the need for reintervention. At 1 year freedom from MACCE and angina was 85.5% (95% CI 76.9 to 94.1%) and 75.5% (95% CI 62.7 to 87.3%), respectively (Fig. 23-6).

The short-term results have been excellent.<sup>117</sup> Before a new therapeutic approach is routinely used, it has to be compared to well-proven standard modalities of treatment. Several controlled studies comparing the safety, feasibility, and efficacy of HCR with OPCAB have been published in the last 5 years.<sup>118-121</sup> However, the number of patients undergoing HCR in these studies was small and hence, conclusions drawn from such studies do not carry too much weight. A recently published meta-analysis, which included 422 patients undergoing HCR and >5000 patients undergoing OPCAB, revealed no differences in in-hospital mortality [relative risk (RR) 0.57, 95% CI 0.13 to 2.59,  $p = .47$ ] or MACCE rates (RR 0.63, 95% CI 0.24 to 1.64,  $p = .34$ ) between groups. Nevertheless, HCR was associated with significantly lesser length of hospitalization (RR 0.55, 95% CI 0.13 to 0.97,  $p = .01$ ), length of ICU stay (RR 0.45, 95% CI 0.10 to 0.80,  $p < .05$ ), intubation time (RR 0.48, 95% CI 0.13 to 0.84,  $p < .01$ ) and need for red blood transfusion (RR 0.67, 95% CI 0.56 to 0.82,  $p < .001$ ).<sup>122</sup> With regard to mid-term outcomes, Shen et al reported that mortality, MI, and stroke at 3 years after HCR were comparable to both, CABG and PCI in patients with multivessel disease.<sup>123</sup> However, the cumulative MACCE rate in the hybrid group (6.4%) was significantly lower than that in the PCI group (22.7%;  $p < .001$ ), but similar to that in the

**FIGURE 23-6** Kaplan-Meier (including 95% confidence interval) 5-year survival curve (A) and event-free survival curve (freedom from death, myocardial infarction, stroke, freedom from angina, freedom from reintervention) (B) after minimally invasive hybrid revascularization in 117 patients.

CABG group (13.5%;  $p = .14$ ). This was chiefly driven by a higher incidence of repeat revascularization in the PCI group. But interestingly, compared with the hybrid group, repeat revascularization in the PCI group was mainly concentrated in the LAD (2 vs 10 events;  $p = .029$ ), and PCI with DES for non-LAD offered a similar repeat revascularization rate in the hybrid and PCI groups (4 vs 8 events;  $p = .307$ ). This clearly proves the benefit of surgical revascularization of the LAD with the LIMA. Although HCR appears to be an attractive option, especially in the elderly and those at a higher risk due to comorbidities,<sup>124</sup> one must keep in mind the potentially higher rate of target vessel revascularization for non-LAD vessels, especially in diabetic patients Repossini.

No randomized controlled trial comparing HCR to CABG or PCI exist, which is mandatory in the current era of evidence-based medicine. Large, multicenter RCTs are needed to compare HCR with OPCAB to identify patient populations that would benefit most from HCR. Furthermore, the strategy or the order of revascularization should also be determined through such trials.

## ENDOSCOPIC CONDUIT HARVEST

To minimize the overall trauma and wound healing problems of a CABG procedure, conduit harvest should be performed endoscopically or through small incisions. There is a body of evidence indicating that while the quality of the conduit is

not impaired by an endoscopic harvest, wound infections and other complications of the harvesting procedure are decreased substantially. The cosmetic advantage is obvious.

## Endoscopic Saphenous Vein Harvesting

Despite the fact that arterial grafting yields better long-term results than venous grafting, and despite the increased use of the ITA and other arterial grafts, the greater saphenous vein is still frequently used for CABG. The standard longitudinal open harvesting technique of the greater saphenous vein is associated with a 2 to 25% wound complication rate (eg, dehiscence, delayed healing, infection, cellulitis, sepsis, and occasionally, limb amputation), delaying ambulation of patients, prolonging hospitalization, and causing an enormous economic burden.<sup>125-128</sup> In addition, open saphenous vein harvest is associated with increased postoperative and long-term pain, swelling, neuropathy, and scarring resulting in patient dissatisfaction.

Various techniques using 1 to 2 cm incisions have been described for endoscopic vein harvest. The single-incision technique involves identification of the greater saphenous vein through a 2 cm longitudinal incision at the crease of the knee posterior to the medial femoral condyle. The vein is layered free circumferentially, following which, a subcutaneous retractor or dissection cannula is introduced. An endoscope is inserted into the subcutaneous tissue. Exposure can be enhanced by insufflating CO<sub>2</sub>. The vein is further mobilized circumferentially, and side branches are either clipped, coagulated using bipolar endoscopic cautery scissors, or vaporized using a harmonic scalpel. Whenever bipolar cautery is applied, a distance of at least 2 mm between the scissors and the vein should be maintained in order to avoid thermal damage to the graft. Proximal and distal control of the greater saphenous vein is accomplished with endoscopic application of clips or polypropylene sutures or ligation loops. With this technique, the entire length of the vein can be harvested from the sapheno-femoral junction to the medial malleolus through a single incision. The wound is closed in a standard manner, and the leg is wrapped circumferentially with crepe bandages. In experienced hands, the procedure takes between 15 and 30 minutes.<sup>129</sup> As with all endoscopic techniques, a learning curve is associated with endoscopic vein harvesting as well, and entails approximately 30 patients and a conversion rate ranging from 0 to 22%.

## Results

The ISMICS Consensus Group reviewed the results of 1319 randomized and 8023 nonrandomized patients. In this meta-analysis, the risk of wound complications was reduced significantly by 69% with endoscopic vein harvesting compared with the open technique (OR 0.31, 95% CI 0.23 to 0.43;  $p < .0001$ ).<sup>130</sup> The need for surgical intervention for wound infection also was reduced significantly (OR 0.29, 95% CI 0.12 to 0.70;  $p = .007$ ). With regard to the incidence of moderate to severe postoperative pain, endoscopic vein harvesting

was associated with a 74% reduction when compared with the open technique (OR 0.26, 95% CI 0.12 to 0.55;  $p < .0001$ ), and this reduction reached 90% at 4 to 6 weeks follow-up (OR 0.10, 95% CI 0.03 to 0.37;  $p < .0001$ ). The incidence of disturbance in mobility at discharge was reduced by 69% (OR 0.31, 95% CI 0.15 to 0.65;  $p = .002$ ).

One recent study reported worse angiographic and clinical outcomes in patients after endoscopic vein harvest.<sup>131</sup> Most studies, however, found no difference in the rates of myocardial infarction, recurrence of angina or reintervention, and death over the short- and mid-term follow-up.<sup>130,132</sup> However, the number of trials evaluating cardiac outcomes and providing angiographic data on patency rates is too limited to allow for any meaningful conclusion to be made. The few trials that assessed vascular integrity and vessel wall trauma did not find any difference between the two techniques.<sup>133,134</sup>

## Endoscopic Radial Artery Harvest

Use of the radial artery for CABG has regained popularity over the last decade and a half. Conventional radial artery harvest involves an incision that extends from approximately 1 cm distal to the antecubital fossa up to the wrist joint, along the medial border of the brachioradialis muscle. While wound complications are reported infrequently, delayed healing of the forearm can cause severe discomfort.<sup>135</sup> Objective sensory loss in 10% of patients and forearm scar discomfort in 33% undergoing open radial artery harvest have been reported.<sup>136,137</sup> Endoscopic techniques for graft harvest have been developed subsequently.<sup>138</sup>

### SURGICAL TECHNIQUE

Collateral circulation from the ulnar artery to the palmar arch has to be verified pre- or intraoperatively using either the standard Allen's test or modification of the test by using an arterial Doppler or pulse oximetry, especially in patients in whom the signs of visual reperfusion are doubtful. In order to prevent brachial plexus injury, the arm should not be overextended ( $>90^\circ$ ). A 2 to 3 cm incision is made 1 cm superior to the radial styloid prominence and the radial artery is identified and dissected. A subcutaneous retractor and a 5 mm, 30° endoscope are inserted into the incision. The radial artery is visualized by bluntly advancing the retractor through the subcutaneous tissue. Side branches and surrounding tissue are divided using an ultrasonic harmonic or thermowelding scalpel that is placed underneath the retractor. The fascia between the brachioradialis and flexor carpi radialis muscles is divided anterior to the radial artery with the scalpel to increase the space for insertion of the subcutaneous retractor.<sup>139</sup> After division of all side branches, a vessel retractor is advanced from the distal incision to verify complete isolation of the conduit. The proximal radial artery is occluded using an Endolooop<sup>®</sup> or clipped distal to the origin of the ulnar artery branch and transected with endoscopic scissors. The graft is recovered through the distal incision, and the distal end is ligated. The incision is closed in a standard manner.

## RESULTS

The reported incidence of neurologic complications after standard open technique of radial artery harvest vary in the literature between 2.4 and 30% and can be related to injury of the superficial radial or the lateral antebrachial cutaneous nerves. The latter is usually not encountered in the endoscopic technique because the dissection is performed deep to the brachioradialis muscle. Superficial radial nerve injury, however, still may occur during distal dissection.<sup>139</sup> Endoscopic radial artery harvest is associated with a lower rate of wound infection (0–2.7%) as compared to the open technique.<sup>129,140</sup>

Graft patency, clinical outcomes, histological integrity, and in vitro vasoreactivity are similar to open graft harvest techniques.<sup>141–143</sup> Thus, endoscopic radial artery harvesting can be recommended for better patient satisfaction and fewer wound healing complications.<sup>144</sup>

# Coronary Artery Reoperations

Bruce W. Lytle • George Tolis, Jr.

Coronary artery reoperations are more complicated than primary operations. Patients undergoing reoperations have distinct, more dangerous pathologies; reoperations are technically more difficult to perform; and the risks are greater.<sup>1-12</sup> Vein graft atherosclerosis, present in most reoperative candidates, is a unique and dangerous lesion. Reoperative candidates commonly have severe and diffuse native-vessel distal coronary artery disease (CAD), a problem that has had the time to develop only because these patients did not die from their original proximal coronary artery lesions. Aortic and noncardiac atherosclerosis are also often far advanced in many reoperative candidates. Some technical hazards, including the presence of patent arterial grafts and sternal reentry, are unique to reoperations, and others, such as lack of bypass conduits and difficult coronary artery exposure, are common.

## INCIDENCE OF REOPERATION

After a primary bypass operation, the likelihood of a patient undergoing a reoperation depends on patient-related variables, primary operation-related variables, adherence to strict medical control of risk factors for disease progression after bypass surgery, the possibility of alternative treatments, physician opinion about the feasibility of reoperation, and time. Studies from the Cleveland Clinic demonstrated a cumulative incidence of reoperation of 3% by 5 years, 10% by 10 years, and 25% by 20 postoperative years<sup>13</sup> (Fig. 24-1). Factors associated statistically with an increased likelihood of reoperation have been variables predicting a favorable long-term survival (eg, young age, normal left ventricular function [LVF], and single- or double-vessel disease), variables designating an imperfect primary operation (eg, no internal thoracic artery [ITA] graft and incomplete revascularization), and symptom status (eg, class III or IV symptoms at primary operation). Young age at primary operation and incomplete revascularization are also markers of a severe atherogenic diathesis.

Over recent decades the proportion of isolated coronary artery operations that are reoperations has decreased. In 1990, about 37% of coronary artery revascularization

operations were reoperative interventions, whereas in 2002 this figure was 30%<sup>14</sup> (Fig. 24-2). Compared to that year, a much more dramatic decrease in reoperative coronary bypass surgery occurred during the most recent decade, with reoperative procedures representing only 4.6% of all isolated coronary bypass operations. This decrease is related in part to the more aggressive use of coronary artery interventions for patients with previous bypass surgery and probably to more effective risk factor control. Also, surgery has changed in directions that will decrease the rate of reoperation. Use of the left internal thoracic artery (LITA) to graft the left anterior descending (LAD) coronary artery decreases the risk of reoperation compared with the strategy of using only vein grafts, and the LITA-LAD graft has become a standard part of operations for coronary artery revascularization.<sup>15</sup> Furthermore, it now appears that use of bilateral ITA grafts decreases the likelihood of death and reoperation when compared with the single LITA-LAD strategy<sup>16</sup> (Fig. 24-3). The use of other arterial conduits such as the radial artery and the gastroepiploic artery in the context of total arterial revascularization may decrease the risk of reoperation further, but as yet the long-term data are insufficient to answer this question.

The patient population of reoperative candidates has evolved. Cleveland Clinic Foundation studies have shown that in the early years of bypass surgery (1967-1978), only 28% of patients underwent reoperation solely because of graft failure, and that graft failure often occurred early after the primary operation (mean postoperative interval of 28 months after primary operation). Reoperation because of the progression of atherosclerosis in nongrafted coronary arteries was common in the 1967 to 1978 time period (55% of patients).<sup>1,2</sup> Between 1988 and 1991, almost all patients had graft failure as at least part of the indication for reoperation (92%), but that graft failure occurred late after the primary operation at a mean interval of 116 months.<sup>3</sup> Today, patients undergoing reoperation usually had a successful primary operation at least 10 years previously for the treatment of multivessel CAD, and the angiographic indications

**FIGURE 24-1** Study of 4000 patients who underwent bypass surgery from 1971 to 1974 showed that 25% of patients had undergone a reoperation within a period of 20 years after primary operation. (Data from Cosgrove DM, Loop FD, Lytle BW, et al: Predictors of reoperation after myocardial revascularization, *J Thorac Cardiovasc Surg.* 1986 Nov;92(5):811-821.)

for reoperation are progression of native-vessel distal CAD in combination with late graft failure caused by vein graft atherosclerosis.

### GRAFT FAILURE

An understanding of the pathology and causes of saphenous vein graft (SVG) failure is important not only for an understanding of the causes of the need for reoperation, but also for understanding the dangers inherent in either the interventional or the conservative treatment of patients with previous bypass surgery. Saphenous vein to coronary artery

**FIGURE 24-3** Comparison of survival and reoperation hazard function curves in the propensity-matched patients undergoing bilateral (BITA, n = 1989) or single ITA (SITA, n = 4147) CABG. grafts exhibit different pathologies at different intervals after operation.<sup>17-20</sup> Within a few months, they often have diffuse endothelial disruptions with associated mural thrombus. The mural thrombus usually is not obstructing, and when grafts do become occluded early after operation owing to thrombosis, it may not be a result of these intimal changes, but rather may be related to hemodynamic factors. Most saphenous vein grafts examined more than 2 to 3 months after operation have developed a proliferative intimal fibroplasia. This is a concentric cellular process, and it is diffuse, extending the entire length of the graft (Fig. 24-4). It evolves with time to a more fibrous lesion. It is not friable, and although

**FIGURE 24-2** Study of 21,568 patients who underwent bypass surgery from 1990 to 2003 showed a steady decrease in the number of patients undergoing redo coronary artery operations. (Data from Sabik JF, Blackstone EH, Houghtaling PL, et al: Is reoperation still a risk factor in coronary artery bypass surgery? *Ann Thorac Surg.* 2005 Nov;80(5):1719-1727.)

**FIGURE 24-4** Pathology of (A) native coronary artery atherosclerosis, (B) vein graft intimal fibrosis, and (C) severe vein graft atherosclerosis. (Reproduced with permission from Lytle BW, Cosgrove DM: Coronary artery bypass surgery, *Curr Probl Surg* 1992 Oct;29(10):743-807.)

intimal fibroplasia involves most vein grafts, it causes stenoses or occlusions of only a few.

Vein graft atherosclerosis is a distinct pathologic process that often is recognized as early as 3 to 4 years after operation and is characterized by lipid infiltration of areas of intimal fibroplasia (Fig. 24-5). The distribution of vein graft

**FIGURE 24-5** Patients with late stenoses in vein grafts to the LAD coronary artery had worse survival when compared with either patients with native coronary LAD stenoses or patients with no stenotic vein grafts. (Reproduced with permission from Lytle BW, Loop FD, Taylor PC, et al: Vein graft disease: the clinical impact of stenoses in saphenous vein bypass grafts to coronary arteries, *J Thorac Cardiovasc Surg*. 1992 May;103(5):831-840.)

atherosclerosis mimics that of intimal fibroplasia in that it is concentric and diffuse, although as vein graft atherosclerosis progresses, stenotic lesions may become eccentric. In addition, vein graft atherosclerosis is a superficial lesion, it is very friable, and it is often associated with overlying mural thrombus. These characteristics make it different from native-vessel coronary atherosclerosis, a process that is segmental and proximal, eccentric, encapsulated, usually not friable, and usually not associated with overlying mural thrombus. Vein graft atherosclerosis is seen in a majority of grafts explanted more than 10 years after surgery whether or not those grafts are stenotic, and atherosclerotic lesions appear to account for almost all late SVG stenoses. The extreme friability of vein graft atherosclerosis creates a substantial risk of distal coronary artery embolization during percutaneous interventions to treat stenotic lesions and during reoperations for patients with atherosclerotic vein grafts. It is also probable that spontaneous coronary artery embolization may occur from atherosclerotic grafts. In addition, atherosclerotic stenoses in vein grafts appear to predispose to graft thrombosis. Vein graft atherosclerosis appears to be an “active” event-producing lesion.

The exact incidence of late SVG stenoses and occlusions is difficult to determine even with prospective studies because death and reoperation are nonrandom events that remove patients from prospective populations available for late coronary artery angiography. However, it appears that by 10 years after operation, approximately 30% of vein grafts are totally occluded, and 30% of patent grafts exhibit some degree of stenosis or intimal irregularities characteristic of vein graft atherosclerosis.<sup>21,22</sup> Although vein graft atherosclerosis is not the only factor related to late SVG occlusion, it is an important one. Native-vessel stenoses distal to the insertion site of vein grafts may decrease SVG graft outflow and contribute

to graft failure, but late graft occlusion usually occurs in the presence of vein graft atherosclerosis. Furthermore, when stenotic vein grafts are replaced at reoperation, the late patency rate of the new vein grafts is good.<sup>2</sup>

Progress has been made toward decreasing the rate of vein graft failure. The early patency rates of SVGs have been improved by the use of perioperative and long-term platelet inhibitors,<sup>23-25</sup> but the best data involving patients receiving platelet inhibitors indicate that the 10-year vein graft failure rate is approximately 35%. Some studies now indicate that lipid-lowering regimens decrease late vein graft disease and the risk of late cardiac events.<sup>26,27</sup> However, the overall level of improvement has been small.<sup>26,27</sup> So far, the only way known to avoid vein graft atherosclerosis is to avoid using vein grafts.

ITA grafts rarely develop late atherosclerosis, and the late attrition rate of patent ITA grafts is extremely low. Left ITA to LAD grafts have a very high late (20 years) patency rate, and for most patients, the LAD is a profoundly important coronary artery.<sup>21,28</sup> These factors account for the impact of the LITA-LAD graft not only in decreasing the rate of late death after primary bypass surgery, but also in decreasing the rate of reoperation.<sup>15</sup> Multiple ITA grafts provide incremental benefit in decreasing the risk of reoperation.<sup>16</sup> It is also important that ITA grafts do not develop graft atherosclerosis, and therefore do not create the risk of coronary artery embolization during reoperation. The presence of patent arterial grafts may create other technical problems during repeat surgery, but embolization is not among them.

## INDICATIONS FOR REOPERATION

The randomized trials of bypass surgery versus medical management that were initiated in the 1970s provided a framework of information concerning the indications for bypass surgery, and subsequent observational studies have added substance to that framework. However, no randomized trials of medical versus surgical management pertain to patients with prior surgery. The coronary pathology of patients with previous bypass surgery is different from that of patients with only native-vessel stenoses, and we cannot assume that the natural history of, for example, triple-vessel disease based on atherosclerotic vein grafts, is equivalent to that of triple-native-vessel disease.

Two nonrandomized, retrospective studies of patients who had angiograms after bypass surgery addressed the issue of late survival.<sup>29,30</sup> One study showed that patients with early (fewer than 5 years after operation) stenoses in vein grafts and patients with no stenotic vein grafts had approximately the same outcomes and that these outcomes were relatively good.<sup>29</sup> However, the presence of late (5 years or more after operation) stenoses in vein grafts predicted poor long-term outcomes, particularly if a stenotic vein graft supplied the LAD coronary artery. When late stenoses in LAD vein grafts were combined with other high-risk characteristics, the late survival rate was particularly dismal. For example, patients with a 50 to 99% stenosis in an LAD vein graft combined with abnormal LVF

and triple-vessel or left main stenoses had only a 46% 2-year survival without reoperation. Patients with late stenoses in an LAD vein graft had significantly worse long-term outcomes than did patients with the LAD jeopardized by a native lesion (see Fig. 24-5). This study showed that the difference in the pathology of early (intimal fibroplasia) and late (vein graft atherosclerosis) vein graft stenoses is associated with a difference in clinical outcome and that late stenoses in vein grafts are dangerous lesions.

A second study compared the outcomes of patients with stenotic vein grafts treated with reoperation (REOP group) versus those treated with medical treatment (MED group).<sup>30</sup> Again, this was a nonrandomized, retrospective study, and the patients in the REOP group were older and more symptomatic, had worse LVF, and had fewer patent grafts than the patients in the MED group.

The survival of patients with early (fewer than 5 years) SVG stenoses was not different in the two groups. The operative risk for the REOP group was low (no deaths among the 59 patients) and the long-term survival was good, but late survival was just as good for the patients treated medically (Fig. 24-6). It is important to note that the patients in the REOP group were more symptomatic to start with, and at late follow-up, they were less symptomatic than the patients in the MED group. Thus, reoperation for patients with early vein graft stenosis was an effective way of relieving symptoms of angina, but it appears that patients without symptoms can be treated medically with safety, at least over the short term.

However, the overall outcomes were worse for patients with late stenoses in vein grafts, and many subgroups had improved survival rates with reoperation. By multivariate testing (Table 24-1), a stenotic (20-99%) LAD vein graft predicted late death, and performing a reoperation increased

**FIGURE 24-6** The survival of patients with early (<5 years after operation) stenoses in vein grafts was favorable with and without reoperation ( $p = NS$ ). (Reproduced with permission from Lytle BW, Loop FD, Taylor AC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts, *J Thorac Cardiovasc Surg.* 1993 Apr;105(4):605-612.)

late survival for these patients. Multivariate testing of smaller subgroups showed that the survival advantage for the REOP group was true even for patients with only class I or class II symptoms, and that reoperation still improved survival for the remaining patients when patients with stenoses in LAD vein grafts were excluded from the analysis.

Univariate comparisons for the REOP and MED subgroups of patients with stenotic LAD grafts are shown in Fig. 24-7, demonstrating the improved survival for the REOP group. When patients with stenotic LAD vein grafts were

**FIGURE 24-7** If patients had late (≥5 years after operation) stenoses in LAD vein grafts, they had a better survival rate ( $p = .004$ ) with immediate reoperation than if they received initial nonoperative treatment. (Reproduced with permission from Lytle BW, Loop FD, Taylor AC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts, *J Thorac Cardiovasc Surg.* 1993 Apr;105(4):605-612.)

**FIGURE 24-8** Patients with late stenoses in LAD vein grafts (*top*) had immediate improvement in their survival rate. Patients with moderate (20-49%) stenoses in LAD vein grafts had equivalent survival with or without reoperation for approximately 2 years, but after that point, the patients who did not have reoperation did poorly. (Reproduced with permission from Lytle BW, Loop FD, Taylor AC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts, *J Thorac Cardiovasc Surg.* 1993 Apr;105(4):605-612.)

subgrouped on the basis of severity of the stenotic lesions (Fig. 24-8), the patients with severely stenotic (50-99%) vein grafts obviously benefited from surgery, exhibiting a decreased risk of death even early in the follow-up period. For patients with moderate stenoses (20-49%) in LAD vein grafts, the survivals of the MED and REOP groups were equivalent for about 2 years, but after that point survival of the patients in the MED group became rapidly worse, so that by 3 to 4 years of follow-up, the survival benefit of reoperation became apparent. Although the patients in these studies did not have consistent functional testing, there is evidence that myocardial perfusion and functional studies can help to identify patients likely to benefit from reoperation. Lauer and colleagues studied 873 symptom-free postoperative patients with symptom-limited exercise thallium-201 studies and found that patients with reversible perfusion defects were more likely to die or experience major cardiac events during a 3-year follow-up.<sup>31</sup> Impaired exercise capacity also was strongly predictive of unfavorable outcomes.

Anatomical indications for reoperation to improve survival prognosis include: (1) atherosclerotic (late) stenoses in vein grafts that supply the LAD artery; (2) multiple stenotic vein grafts that supply large areas of myocardium; and (3) multivessel disease with a proximal LAD lesion and/or abnormal LVF based on either native-vessel lesions or stenotic vein grafts or a combination of the two pathologies. Reoperation is also effective in other anatomical situations in which severe symptoms are the indication for invasive treatment, including patients with a patent ITA to LAD graft combined with other ischemia-producing pathology and multiple early vein graft stenoses. The combination of the anatomical characteristics just noted and reversible ischemia and/or worsening LVF during stress constitutes a particularly strong indication for reoperation.

## PERCUTANEOUS TREATMENT OF POSTOPERATIVE PATIENTS

Percutaneous treatments (PCTs) represent alternative anatomical treatments for postoperative patients and often are useful. The effectiveness of PCTs is related to the vascular pathology to be treated and the clinical implications of treatment failure. Today, native coronary artery stenoses often can be treated with a low restenosis rate as long as those vessels are large enough to allow intracoronary stenting. Unfortunately, many postoperative patients have very diffuse native coronary atherosclerosis that makes PCT difficult or ineffective. Also, PCT has not been as effective in the treatment of diabetic native CAD.

The rate of technologic change in interventional cardiology has been rapid, and multiple percutaneous technologies have been used to treat stenotic vein grafts. Balloon angioplasty, first-generation PCT, was relatively dangerous to perform and produced ineffective long-term revascularization, particularly when used to treat older (atherosclerotic) vein grafts.<sup>32</sup> Direct coronary atherectomy (DCA) increased the risk of coronary embolization at the time of the procedure without improving the restenosis rate.<sup>33</sup> It has been hoped that the use of intracoronary stents, particularly covered stents and drug-eluting stents (DESs), in stenotic vein grafts might provide better outcomes, and stenting does represent an improvement over balloon angioplasty.<sup>32</sup> The Randomized Evaluation of Polytetrafluoroethylene Covered Stent in Saphenous Vein Grafts (RECOVERS) trial, a randomized study designed to compare rates of SVG restenosis between coronary artery bypass graft (CABG) patients treated with covered stents and with bare stents, showed identical restenosis rates at 6 months of follow-up (24.2 vs 24.8%;  $p = .24$ ).<sup>34</sup> In a nonrandomized retrospective study comparing the effects of DESs with those of bare metal stents in treating SVG stenosis, Ge and colleagues reported significant differences in in-stent stenosis between groups at 6 months of follow-up (10 vs 26%;  $p = .03$ ).<sup>35</sup> However, other reports comparing DES with bare metal stents showed that the use of DES lowered the rate of restenosis but increased the risk of death.<sup>36</sup>

The kinetics of treatment failure after PCT for vein grafts are different from those for native coronary vessels. Restenosis and new stenotic lesions in vein grafts continue to appear with time, and the shoulder on the adverse outcome curve that appears at 6 months to 1 year after PCT for native vessels does not appear for vein grafts. Thus, there is still some uncertainty about the clinical impact of PCTs of stenotic vein grafts. Patients with previous bypass surgery are an extremely heterogeneous group; some subgroups are at low risk without any anatomical treatment at all, and some subgroups are at high risk without effective therapy. To date, the reported studies of PCT of SVG lesions have not included clinical risk stratifications that would allow comparison of patient survival rates.

Despite persistently high restenosis rates after percutaneous interventions, there are still many indications for their use in the treatment of patients with previous bypass surgery. Realistically, the ideal uses of PCTs are in situations in which failure of the anatomical treatment is not likely to be catastrophic as the impact of stenting on survival is unclear. These situations include symptomatic patients with: (1) early vein graft stenoses; (2) native coronary stenoses; or (3) focal late SVG stenoses in vein grafts not supplying the LAD artery. There are many patients with previous surgery who will fall into a middle ground where it is not clear whether percutaneous transluminal coronary angioplasty (PTCA) or reoperation is likely to yield the best outcome, and judgments must be made on the specific advantages and disadvantages of the treatments for those particular patients. Factors making PTCA more attractive than reoperation are listed in Table 24-2.

There are patients with postsurgical repeat ischemic syndromes and very unfavorable coronary anatomy for whom good options for anatomical treatment do not exist. For reoperative coronary surgery to be of benefit there must be bypass conduits available to construct new grafts to graftable coronary arteries that subtend substantial areas of ischemic but viable myocardium. If these conditions do not exist, surgery may not be in the interest of even a symptomatic patient. Studies of diabetic patients undergoing

**TABLE 24-2: Reoperation versus PTCA for Patients with Stenotic Vein Grafts**

Factors favoring reoperation	Factors favoring PTCA
Late ( $\geq 5$ years) stenoses	Early ( $< 5$ years) stenoses
Multiple stenotic vein grafts	Single stenotic vein graft
Diffusely atherosclerotic vein grafts	Other patent vein grafts
Stenotic LAD vein graft	Focal graft lesions
No patent ITA graft	Patent ITA-LAD graft
Abnormal left ventricular function	Normal left ventricular function

postsurgical repeat revascularization with PCT or surgery have shown unfavorable 10-year-survival rates.<sup>37</sup> Unless good coronary targets to receive bypass grafts are available, PCT may be the best choice for marginal candidates because of lower initial costs and, in some settings, lower initial mortality.

## TECHNICAL ASPECTS OF CORONARY REOPERATIONS

Reoperations are more complicated than primary operations. The specific technical challenges that surgeons must recognize and solve that are unique to or more common during coronary reoperation are:

1. Sternal reentry
2. Stenotic or patent vein or arterial bypass grafts
3. Aortic atherosclerosis
4. Diffuse native-vessel coronary artery disease
5. Coronary arteries located amid old grafts and epicardial scarring
6. Lack of bypass conduits

The overall problem of myocardial protection is more difficult during reoperations, with perioperative myocardial infarction still being the most common cause of in-hospital death.<sup>3,6</sup> The metabolic concepts of myocardial protection in use today are valid, but the reasons that myocardial protection sometimes fails during reoperation are related to anatomical causes of myocardial infarction. These anatomical causes of perioperative myocardial infarction include injury to bypass grafts, atherosclerotic embolization from vein grafts or the aorta to distal coronary arteries, myocardial devascularization secondary to graft removal, hypoperfusion through new grafts, failure to deliver cardioplegic solution, early vein graft thrombosis, incomplete revascularization, diffuse air embolization, and technical error.<sup>3,38–42</sup> To be consistently successful, coronary reoperations must be designed to avoid these causes of myocardial infarction.

### Preoperative Assessment

A complete understanding of the patient's native coronary and bypass graft anatomy is essential. Achieving this goal is sometimes not as easy as it sounds, particularly if the patient has had multiple previous coronary operations. If bypass grafts, venous or arterial, are not demonstrated by a preoperative coronary angiogram, it usually means that they are occluded, but it is also possible that the angiogram simply has failed to demonstrate their location. Examination of old angiograms performed before previous operations and review of previous operative records often help to illustrate the patient's coronary anatomy.

It is also important to know that graftable stenotic coronary arteries supply viable myocardium. Myocardial scar and viability can be differentiated by thallium scanning, positron-emission tomography, and stress (exercise or

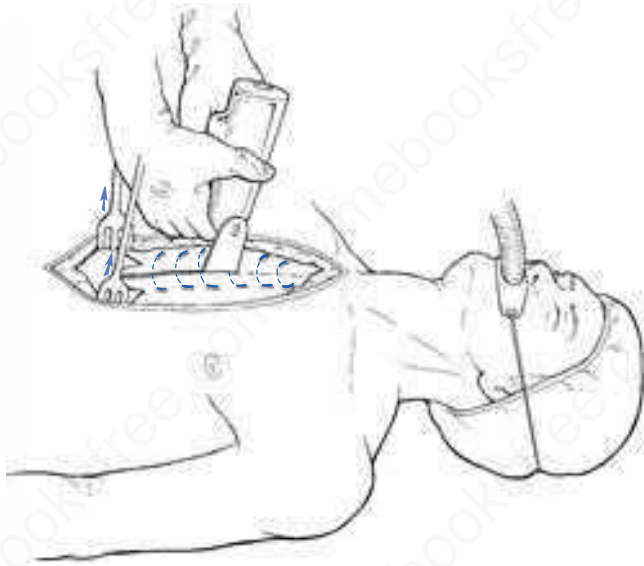

dobutamine) echocardiography. The intricacies of establishing myocardial viability are beyond this discussion, but it is an important issue. Before embarking on a reoperation, it makes sense to be reasonably sure that there is a matchup between the patient's graftable arteries and some viable myocardium such that grafting those arteries will provide some long-term benefits.

It is also wise to have a preoperative plan for bypass conduit selection and to document that potential bypass conduits are available. ITA angiography often is helpful. Venous Doppler studies can be used to assess the presence of greater and lesser saphenous vein segments, and arterial Doppler studies can assess the radial and inferior epigastric arteries and establish the adequacy of flow to the digits during radial artery occlusion.

### Median Sternotomy Incision, Conduit Preparation, and Cannulation

Most coronary reoperations are performed through a median sternotomy. Situations associated with increased risk during a repeat median sternotomy include right ventricular or aortic enlargement, a patent vein graft to the right coronary artery, an in situ right ITA graft patent to a left coronary artery branch, an in situ left ITA graft that curls under the sternum, multiple previous operations, and difficulty reopening the sternum during a previous reoperation. In such situations, vessels for arterial (via the femoral or axillary artery) and venous access for cardiopulmonary bypass may be dissected out before sternal reentry. Alternatively, given the cannulae currently available for percutaneous access, wire access of the femoral artery and vein may be accomplished with little morbidity while providing a safety net for emergent institution of bypass if necessary. All bypass grafts except for the internal thoracic arteries may be prepared before sternal reentry in high-risk cases. Preparation of radial artery and greater and lesser saphenous vein segments can be carried out simultaneously. The most common structure injured during reentry is a bypass graft.<sup>4</sup>

When reopening a median sternotomy, the incision is made to the level of the sternal wires; the wires are cut anteriorly and bent back but are not removed (Fig. 24-9). An oscillating saw is used to divide the anterior table of the sternum. When the anterior table has been divided, ventilation is stopped, and the assistants elevate each side of the sternum with rake retractors while the posterior table of the sternum is divided in a caudal-cranial direction. The sternal wires that have been left in place posterior to the sternum help to protect underlying structures. Once the posterior table of the sternum has been divided with the saw, the wires are removed, and sharp dissection with scissors is used to separate each side of the sternum from underlying structures. Once the sternum has been divided, it is important that the assistants retract in an upward direction, not laterally. The right ventricle is injured more often by lateral retraction while it is still adherent to the underside of the sternum than it is by a direct saw injury.

**FIGURE 24-9** Leaving the sternal wires in place posteriorly helps to protect underlying structures while the posterior table of the sternum is divided with an oscillating saw. The direction of retraction with rake retractors should be anterior, not lateral.

In high-risk situations, it can be helpful to perform a small anterolateral right thoracotomy before the repeat median sternotomy. Underlying structures, such as the aorta, patent bypass grafts, and the right atrium and ventricle, can be dissected away from the sternum via this approach, and thus, with the surgeon's hand placed behind the sternum, reentry is safe. This small additional incision contributes little morbidity.

Another technique for sternal reentry in high-risk patients is to heparinize, cannulate, and initiate cardiopulmonary bypass before median sternotomy. The advantages of this strategy are that the heart can be emptied and allowed to fall away from the sternum, and cardiopulmonary bypass already has been initiated for protection if an injury does occur. The disadvantages of this approach are that extensive mediastinal dissection must be carried out in a heparinized patient, including dissection of the right internal thoracic artery if that is to be used. We rarely employ this approach except in situations in which adherence of an aortic aneurysm to the sternum or a patent right ITA-to-LAD graft creates a specific danger.

Once the sternum has been divided, the pleural cavities are entered. A general principle of dissection during reoperation is that starting at the level of the diaphragm and proceeding in a cranial direction is usually the safest approach. At the level of the diaphragm, few critical structures are injured if the wrong plane is entered. Therefore, at this point in the operation we usually dissect along the level of the diaphragm to the patient's right side until we enter the pleural cavity and then detach the pleural reflection from the chest wall in a cranial direction to the level of the innominate vein. The innominate vein is dissected away from both sides of the

sternum with scissors, a maneuver that prevents a "stretch" injury to that vein.

Once the right side of the sternum is separated from the cardiac structures, it is usually possible to prepare a right ITA graft. Once the right ITA dissection is completed to the superior border of the first rib, an incision is made in the parietal pleura to separate the proximal ITA from the area of the phrenic nerve. Thus, if the right ITA needs to be converted to a "free" graft during aortic cross-clamping, it makes division at that point easier because the proximal ITA is clearly identifiable. Although intrapericardial dissection of the left side of the heart is left until later, freeing the left side of the anterior chest wall from the underlying structures (which may include a patent ITA graft) is undertaken now. This is difficult only if there is a patent ITA graft that is densely adherent to the chest wall. Again, it is best to enter the left pleural cavity at the level of the diaphragm and proceed in a cranial direction.

The most difficult point of dissection is usually at the level of the sternal angle, where a patent ITA graft may approach the midline and be adherent to the sternum or the aorta. There are no tricks for dissecting out a patent ITA graft except for being careful. The danger to a patent left ITA graft during sternal reentry and mediastinal dissection is entirely related to the location of the graft at the time of the primary operation. Ideally, the pericardium should be divided at a primary operation, and the left ITA graft should be allowed to run posterior to the lung through the incision in the pericardium and to the LAD or circumflex artery (Fig. 24-10). When this is done, the lung will lay anterior to the left ITA, and that graft will not become adherent to the aorta or to the chest wall.

Once the left side of the chest wall is free, the left internal mammary artery (IMA) is prepared (if it has not been used at a previous operation), the sternal spreader is inserted, and the intrapericardial dissection of the aorta and right atrium is accomplished. Again, in most cases it is safest to find the correct dissection plane at the level of the diaphragm and then to continue around the right atrium to the aorta. The one situation in which this strategy may be dangerous is if an atherosclerotic vein graft to the right coronary artery lies over the right atrium. Manipulation of atherosclerotic vein grafts can cause embolization of atherosclerotic debris into coronary arteries, and it is best to employ a "no touch" technique with such grafts. If a vein graft to the right coronary artery lies in an awkward position over the right atrium, it is best to leave the right atrium alone and use the femoral vein and superior vena cava cannulation to establish venous drainage (Fig. 24-11). Once cardiopulmonary bypass has been established, the aorta has been cross-clamped, and cardioplegia has been given, the atherosclerotic vein graft then can be disconnected.

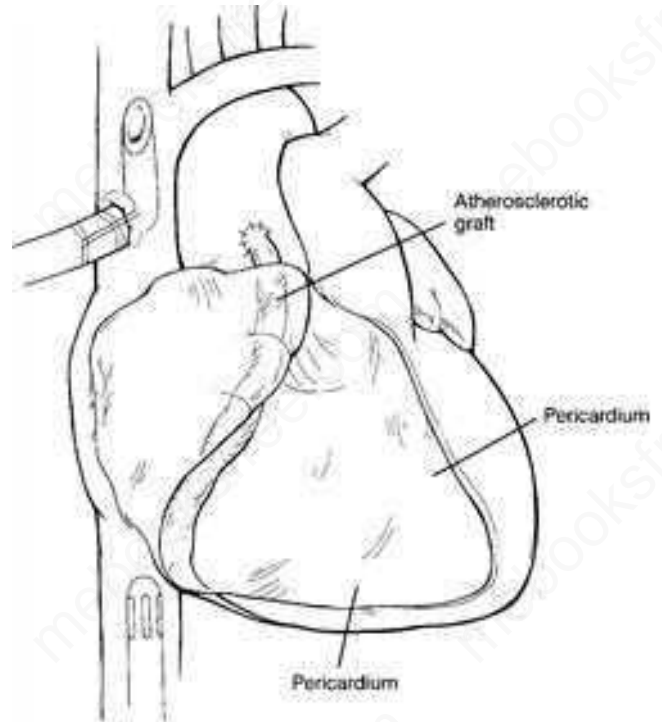

The goal of dissection of the ascending aorta is to obtain enough length for cannulation and cross-clamping and to avoid the most common error, aortic subadventitial dissection. The correct level of dissection on the aorta usually is found either by following the right atrium to the aorta in a

**FIGURE 24-10** A patent left ITA-to-LAD graft should not pose a threat during reoperation. At a primary operation, the pericardium should be divided in a posterior direction, and the ITA graft should be placed in that incision. The ITA graft then will lie posterior to the lung and will not be pushed toward the midline by the lung or become adherent to the sternum.

caudal-to-cranial direction or by identifying the innominate vein and leaving all the tissue beneath the innominate vein on the aorta. At the level of the innominate vein, the pericardial reflection on each side of the aorta will be identifiable. Division of the pericardial reflection on the left side in a posterior direction will lead to the plane between the aorta and the pulmonary artery. Once the left side of the aorta is identified, the surgeon then may dissect posteriorly on the medial aspect of the left lung toward the hilum. The segment of tissue between these two dissection planes usually will include a patent left ITA graft, if present, and clamping that tissue will produce occlusion of the ITA graft.

When the aorta has been dissected out, heparin is given, and cannulation is undertaken. Cannulation of an atherosclerotic ascending aorta may cause atherosclerotic embolization leading to stroke, myocardial infarction, or multiorgan failure, so the ascending aorta should be studied with palpation and echocardiography to detect atherosclerosis before cannulation. Although the most widely used alternative arterial cannulation site is the femoral artery, arteriopathic patients often have severe femoral artery atherosclerosis. The axillary artery is an alternative arterial cannulation site that we have used with increasing frequency because atherosclerotic disease is usually not

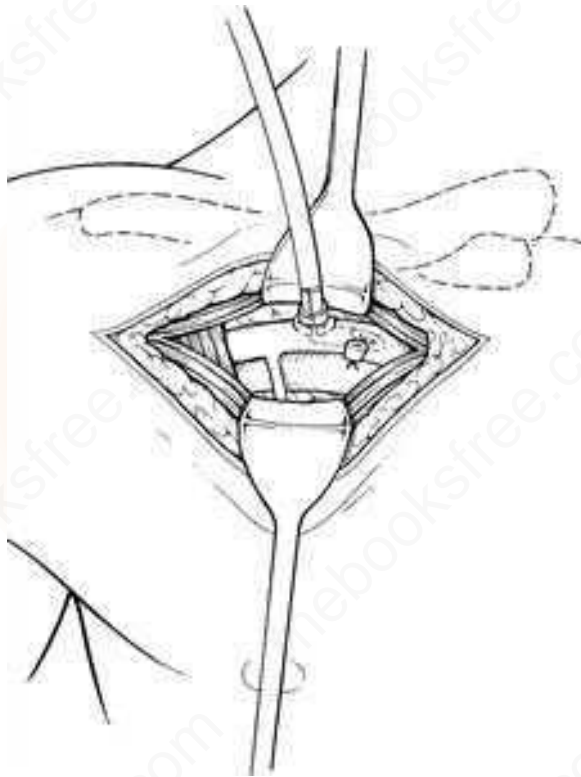

**FIGURE 24-11** Manipulation of patent but atherosclerotic vein grafts should be avoided. If an atherosclerotic right coronary vein graft blocks access to the right atrium, femoral vein, and direct superior vena cava, cannulation is safer than mobilizing the vein graft so as to achieve right atrial cannulation.

present in that vessel, and its cannulation allows antegrade perfusion<sup>44</sup> (Fig. 24-12). If atherosclerotic disease or calcification of the aorta makes any aortic occlusion hazardous, the options are off-pump bypass surgery (see Other Options) or replacement of the aorta with axillary artery cannulation, hypothermia, and circulatory arrest. Venous cannulation usually is accomplished with a single two-stage right atrial cannula. A transatrial coronary sinus cardioplegia cannula is inserted via a right atrial purse string with the aid of a stylet, and a needle is placed in the ascending aorta for delivery of antegrade cardioplegia and for use as a vent (Fig. 24-13).

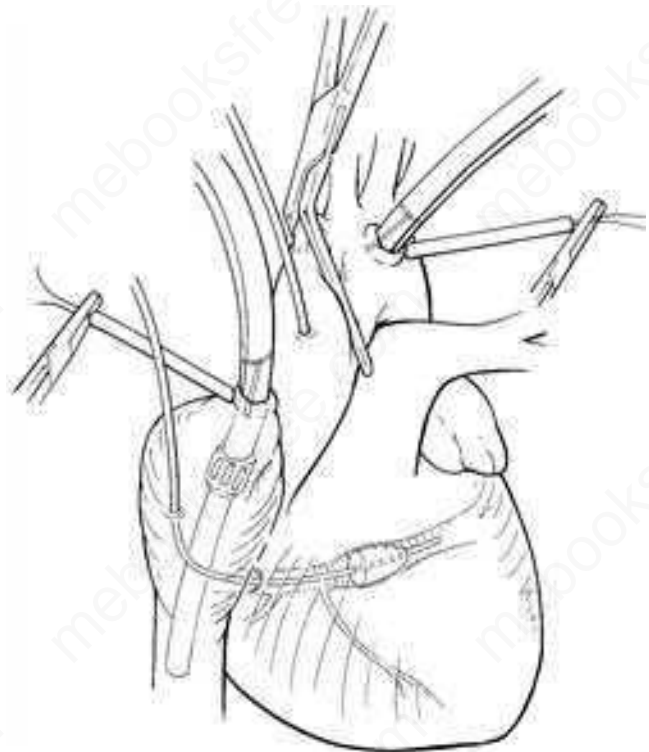

## Myocardial Protection

The myocardial protection strategy used by us during most coronary artery reoperations is a combination of antegrade and retrograde delivery of intermittent cold blood cardioplegia combined with a dose of warm reperfusion cardioplegia (“hot shot”) given before aortic unclamping, principles developed by Buckberg and colleagues.<sup>45</sup> Multiple types of cardioplegic solutions have been described, and most appear to provide a metabolic environment that effectively protects the myocardium. Because of the

**FIGURE 24-12** The axillary artery is an important alternative arterial cannulation site for patients with aortic and femoral artery atherosclerosis. A 21-gauge cannula will fit the axillary artery in most patients.

potential anatomical challenges to cardioplegic myocardial protection during reoperations, the details of how the cardioplegic solution is delivered are very important. In most primary bypass operations, antegrade cardioplegia works well by itself. During reoperations, however, antegrade cardioplegia may not be effective for areas of myocardium that are supplied by patent in situ arterial grafts and may be dangerous because of the risk of embolization of atherosclerotic debris into the coronary arteries from old vein grafts. The delivery of cardioplegia through the coronary sinus and through the cardiac venous system to the myocardium (retrograde cardioplegia) has been a step forward in myocardial protection during reoperations.<sup>46,47</sup> Retrograde cardioplegia delivery avoids atheroembolism from vein grafts, can be helpful in removing atherosclerotic debris and air from the coronary artery system, and can deliver cardioplegia to areas supplied by in situ arterial grafts. The biggest disadvantage of retrograde cardioplegia is that it is not always possible to place a catheter in the coronary sinuses that will deliver cardioplegia consistently. It is important to monitor the adequacy of cardioplegia delivery by measuring the pressure in the coronary sinus, noting the distention of cardiac veins with arterial blood, the cooling of the myocardium, and the return of desaturated blood from open coronary arteries.

**FIGURE 24-13** Standard cannulation for coronary artery reoperation includes aortic arterial cannulation, an aortic needle for antegrade delivery of cardioplegia and aortic root venting, a single two-stage venous cannula, and a transatrial coronary sinus catheter with a self-inflating balloon for delivery of retrograde cardioplegia. Cannulation is accomplished before dissection of the left ventricle.

Cardiopulmonary bypass is begun, the perfusionist empties the heart and produces mild systemic hypothermia ( $34^{\circ}\text{C}$ ), and the aorta is cross-clamped. We usually initiate cardioplegia induction with aortic root cardioplegia. To induce and maintain cardioplegic protection, it is helpful to be able to occlude patent arterial grafts. If it has not yet been possible to dissect out a patent arterial graft so that it can be clamped, the systemic perfusion temperature may be decreased to  $25^{\circ}\text{C}$  until control of the graft is achieved. After antegrade cardioplegia has been given for 2 to 3 minutes, we shift to retrograde induction for another 2 to 3 minutes. Giving any antegrade cardioplegia does risk embolization from atherosclerotic vein grafts, but if these grafts have not yet been manipulated, that danger is relatively small. Once the adequacy of retrograde cardioplegia delivery has been established, it is often possible to use that route predominantly for maintenance doses.

### Intrapericardial Dissection

When the heart has been arrested completely, intrapericardial dissection of the left ventricle is undertaken, starting at the diaphragm and extending out to the left of the apex of the heart. After the apex is identified, the surgeon divides the pericardium in a cranial direction on the left side of the LAD

**FIGURE 24-14** Division of the pericardium along the diaphragm allows the surgeon to reach a point to the left of the cardiac apex. From that point, the pericardium can be divided in a cranial direction to the left of the LAD artery, leaving a patent ITA graft in the strip of tissue overlying the LAD artery. Atherosclerotic vein grafts that are going to be replaced may be divided once a dose of antegrade cardioplegia is given.

artery (Fig. 24-14). A patent LITA-to-LAD graft will be contained within the strip of pericardium that lies over the LAD artery. Dissection of this pedicle from the anterior aspect of the pulmonary artery will allow an atraumatic clamp to be placed across the patent ITA graft and also will allow the passage of new bypass grafts from the aorta underneath the patent ITA graft to left-sided coronary arteries. The advantages of waiting until after aortic clamping and arrest to dissect out the left ventricle are that dissection is more accurate, there is less damage to the epicardium and less bleeding, manipulation of atherosclerotic vein grafts is less likely to cause coronary embolization, and the dissection of patent ITA grafts is safer.

After the heart is dissected out completely, the coronary arteries to be grafted can be identified, the lengths that bypass conduits need to reach those vessels may be assessed, and the final operative plan can be established. The old grafts and epicardial scarring that are present during reoperations make the preoperative prediction of the lengths of conduits needed for bypass grafts quite difficult, particularly the lengths of arterial grafts, and it is wise to have some flexibility in the operative plan. Before the construction of the anastomoses, those patent but atherosclerotic vein grafts that are going to be disconnected are identified and are disconnected with a scalpel. The order of anastomosis construction that is used by the authors

is: (1) distal vein graft anastomoses; (2) distal free arterial graft anastomoses; (3) distal in situ arterial graft anastomoses; and (4) proximal (aortic) anastomoses.

### Stenotic Vein Grafts

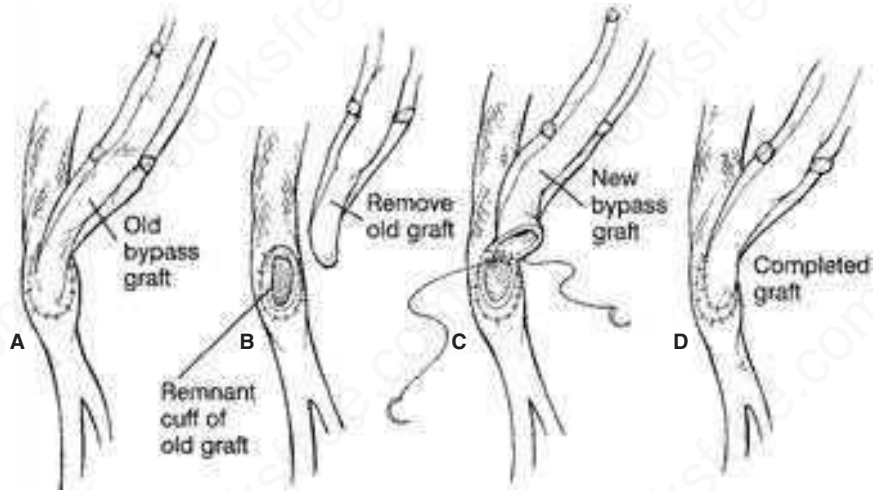

When should patent or stenotic vein grafts be replaced, and with what should they be replaced? Atherosclerosis in vein grafts is common if those grafts are more than 5 years old, and leaving them in place risks embolization of atherosclerotic debris at the time of reoperation and subsequent development of premature graft stenoses or occlusions after reoperation. On the other hand, replacement of all vein grafts extends the operation and may use up available bypass conduits.

In the past, our general rule has been to replace all vein grafts that are more than 5 years old at the time of reoperation, even if those grafts are not diseased angiographically. However, this strategy assumes that conduits are available that can replace these old grafts. Today, many patients have very limited conduits at reoperation because of the large numbers of vein grafts used at primary surgery or because of multiple previous operations. Thus, graft replacement must be individualized. Inspection of vein grafts at reoperation occasionally will identify a graft that looks normal angiographically and does not appear to have any thickening or atherosclerosis on visual inspection. Such grafts are thought to be “privileged” and often will be left alone.

Replacing old vein grafts with new vein grafts may often be accomplished by creating the new vein-to-coronary-artery anastomosis at the site of the previous distal anastomosis, leaving only 1 mm or so of the old vein in place (Fig. 24-15). If significant native-vessel stenoses have developed distal to the old vein graft, it is often best to place a new graft to the distal vessel in addition to replacing the vein graft. Many reoperative candidates have proximal occlusions of the native coronary artery system and multiple stenoses throughout the vessel, and if only new distal grafts are constructed, the proximal segments of coronary arteries and their branches that are supplied by atherosclerotic vein grafts may be jeopardized. More than one graft to a major coronary artery may be desirable during reoperation (Fig. 24-16).

Sequential vein grafts often are very helpful during reoperation because they allow more distal anastomoses and fewer proximal anastomoses. Sites for proximal anastomoses are often at a premium in the scarred reoperative aorta.

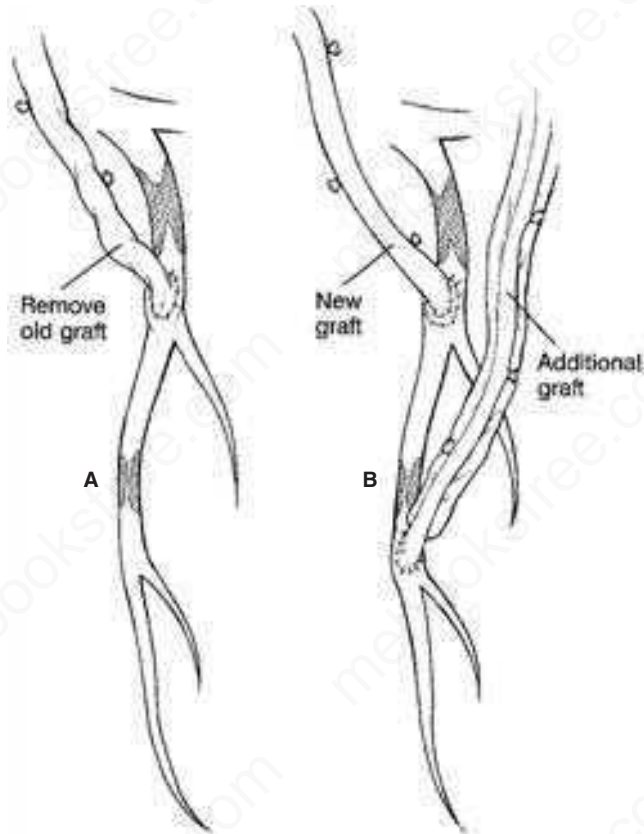

Artery-to-coronary-artery bypass grafts have many advantages during reoperations. First, they are often available. Second, the tendency of arteries to remain patent even when used as grafts to diffusely diseased coronary arteries makes them particularly applicable to reoperative candidates. Third, in situ arterial grafts do not require a proximal anastomosis. If the left ITA has not been used as a graft at a previous operation, a strong attempt should be made to use it as an in situ graft to the LAD artery. During primary operations, the right ITA usually can be crossed over as an in situ graft to left-sided vessels, but such a plan is more difficult during repeat surgery, so the right ITA is often used as a free graft.

**FIGURE 24-15** For patients with extensive native coronary atherosclerosis, the distal anastomotic site of an old vein graft is often the best spot for the distal anastomosis of a new graft. Only a small rim of the old graft should be left in place.

Arterial graft proximal anastomoses are a problem at reoperation because the scarring and thickening of the reoperative aorta often make direct anastomoses of arterial grafts to the aorta unsatisfactory. However, when old vein grafts

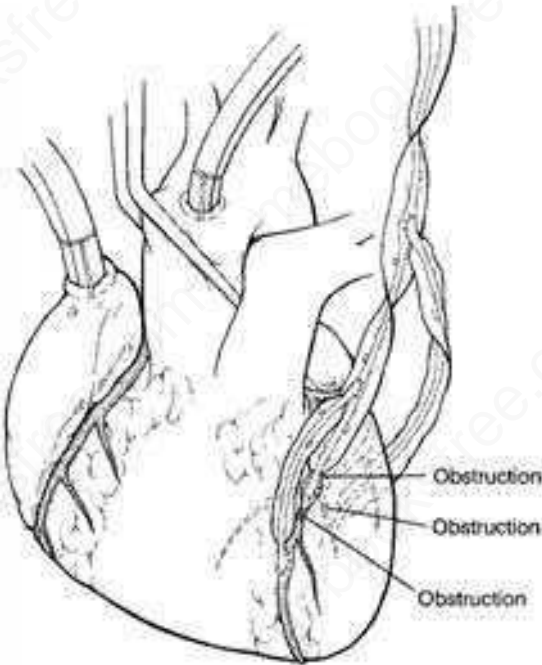

become occluded, there is usually a “bubble” of the hood of the old vein graft that is not atherosclerotic and that often is a good spot for construction of a free (aorta-to-coronary-artery) arterial graft anastomosis (Fig. 24-17). In addition, if new vein grafts are performed, the hood of that new vein graft represents a favorable location for an arterial graft

**FIGURE 24-16** Extension of native-vessel coronary artery disease may indicate the placement of new distal grafts as well as replacement of diseased vein grafts supplying proximal coronary artery segments.

**FIGURE 24-17** The hood of new or old vein grafts is often the best spot for the aortic anastomosis of free arterial grafts. Atherosclerosis rarely occurs in that “bubble” of vein.

**FIGURE 24-18** Composite arterial grafts can be constructed using a new or old left ITA graft as the inflow source. With its proximal anastomosis to the left ITA, a right ITA graft will easily reach the circumflex branches. Furthermore, a shorter segment of inferior epigastric artery or radial artery can be used to reach the distal LAD artery if intervening native LAD stenoses have limited the effectiveness of an old ITA graft.

anastomosis. Late angiographic data regarding this strategy are not available, but the relative freedom of the hood of vein grafts from the development of atherosclerosis means these grafts are likely to be successful.

Another effective strategy is to use either an old arterial graft or a newly constructed arterial graft for the proximal anastomosis of a free arterial graft (Fig. 24-18). Composite arterial grafts, usually using a new *in situ* left ITA graft at the proximal anastomotic site for a free right ITA graft, have been employed with increasing frequency, and early outcomes have been favorable.<sup>48,49</sup> This method is particularly useful during reoperations because it may avoid an aortic anastomosis, and less right ITA graft length is needed to reach distal circumflex arteries. Other advantages of using a previously performed patent ITA graft for the proximal anastomosis of a new arterial graft are that the old left ITA graft often has increased in size, and the preoperative angiogram has demonstrated its integrity. In situations in which the effectiveness of an LITA-to-LAD graft has been jeopardized by a distal LAD lesion, a short segment of a new arterial graft can be used to bridge that stenosis from the old arterial graft to the distal LAD artery (see Fig. 24-17).

Can an ITA graft be used to replace a vein graft during reoperation? When faced with replacing a stenotic or patent vein graft during reoperation, the surgeon has a number of options, all of which have some potential disadvantages:

1. The surgeon may leave the old vein graft in place and add an arterial graft to the same coronary vessel. The dangers of this approach are that atherosclerotic embolization from the old vein may occur during the reoperation, and competitive flow between the vein graft and the arterial graft may jeopardize the ITA graft after reoperation.
2. The surgeon may remove the old vein graft and replace it with an ITA graft. This decreases the likelihood of atherosclerotic embolization and competitive flow but risks hypoperfusion during reoperation if the arterial graft cannot supply all the flow that had been generated previously by the vein graft.
3. The surgeon may replace the old vein graft with a new vein graft. The disadvantage of this approach is a long-term one. The coronary vessel is left dependent on a vein graft.

When we examined these choices in a retrospective study of operations for patients with atherosclerotic vein grafts supplying the LAD artery, we found that the worst outcomes resulted from removing a patent (although stenotic) vein graft and replacing it with only an ITA graft.<sup>39</sup> This strategy was associated with a significant incidence of hypoperfusion and severe hemodynamic difficulties during reoperation that were treated effectively only by adding a vein graft to the same coronary artery. The incidence of myocardial infarction associated with leaving a stenotic vein graft in place was low. Thus, atherosclerotic embolization from an atherosclerotic vein graft is a danger, but it appears that with the use of retrograde cardioplegia, it is not commonly a major catastrophe.

Another potential disadvantage of the strategy of adding an ITA graft to a stenotic vein graft is that competition in flow from the stenotic vein graft may lead to failure of the new ITA graft. However, this is unlikely to occur as long as the stenosis in the SVG is severe.<sup>50</sup> Our usual approach, therefore, is to remove atherosclerotic vein grafts when replacing them with a new vein graft but leave stenotic vein grafts in place when grafting the same vessel with an arterial graft (Fig. 24-19).

Alternative arterial grafts often are very useful during reoperation. The radial artery has particular advantages during repeat surgery because it is larger and longer than other free arterial grafts. These qualities increase the range of coronary arteries that can be grafted. Early studies of radial artery grafts have shown favorable patency rates, but few long-term data currently exist. If the high patency rates that have been documented by early studies are confirmed by the tests of time, the radial artery will be used extensively during reoperations. The inferior epigastric artery often is too short to function as a separate aorta-to-coronary-artery graft during reoperation but can be extremely useful as a short composite arterial graft, as illustrated in Fig. 24-18.

The right gastroepiploic artery (RGEA) has established a good midterm graft patency rate record and often is useful during reoperation because it is an *in situ* graft.<sup>51</sup> Furthermore, it can be prepared before the median sternotomy. It is effective most often as an *in situ* graft to the posterior

**FIGURE 24-19** In this example, an atherosclerotic right coronary artery vein graft is disconnected and is replaced with a new vein graft. However, the stenotic vein graft to the LAD artery is left in place to avoid hypoperfusion, and a new ITA graft is added to the LAD artery.

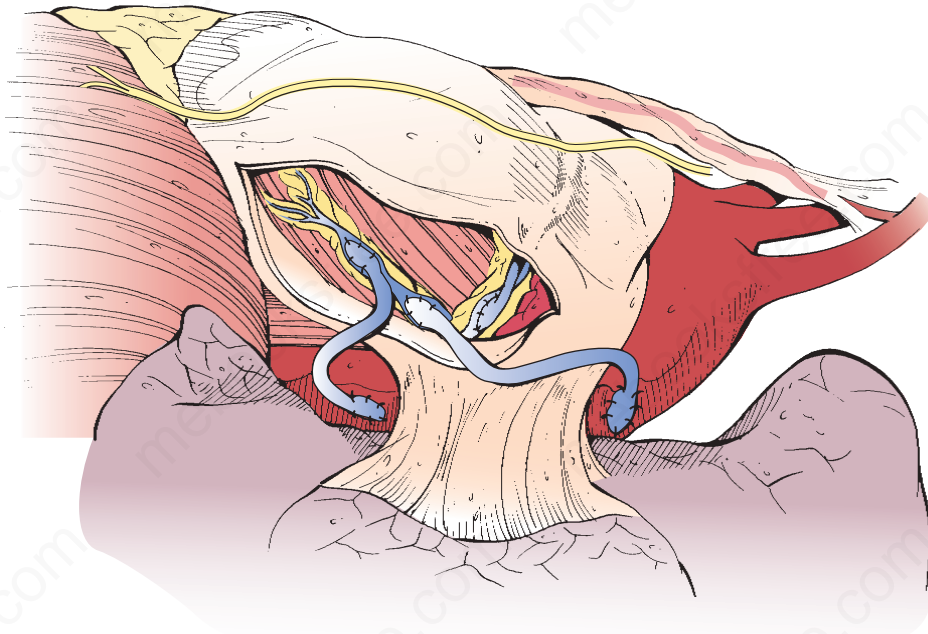

descending branch of the right coronary artery or the distal LAD artery (Fig. 24-20).

The aortic anastomoses of the vein and arterial grafts are performed last during the single period of aortic cross-clamping. Sites for aortic anastomoses are often at a premium owing to previous scarring, atherosclerotic disease, or the use of Teflon felt during the primary operation, and often the locations of the previous vein graft proximal anastomoses are the best locations for the new ones. The advantages of constructing aortic anastomoses during a single period of aortic cross-clamping are that it minimizes aortic trauma and allows excellent visualization of the proximal anastomoses. In addition, if patent or stenotic vein grafts have been removed and replaced, reperfusion is not accomplished by aortic declamping until the aortic anastomoses have been completed.

The disadvantage of this approach is that it prolongs the period of aortic cross-clamping. However, our strategies for reoperation are not based on trying to minimize myocardial ischemic time. If cardioplegia can be delivered effectively, its metabolic concepts are valid, and myocardial protection is secure. Failure of myocardial protection usually is caused by anatomical events, not by metabolic failure. Once the proximal anastomosis has been constructed, a “hot shot” of substrate-enhanced blood cardioplegia is given, and the aortic cross-clamp is removed.

### Other Options

Although most reoperations are performed through a median sternotomy with the use of cardiopulmonary bypass, the

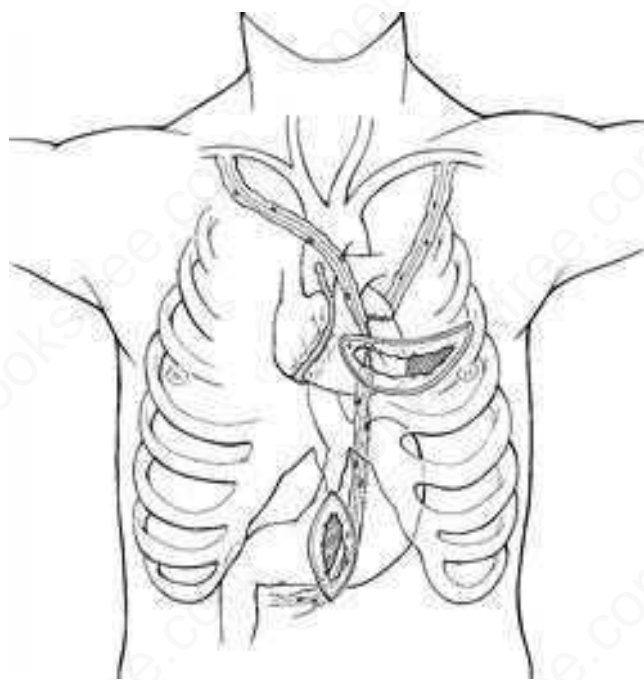

**FIGURE 24-20** Circumflex vessels may be grafted through a left thoracotomy incision without cardiopulmonary bypass.

strategies of small-incision surgery and off-pump surgery that have been gaining increasing use for primary coronary artery operations also can be helpful during reoperations. Reoperations in situations in which a limited area of myocardium needs revascularization often can be accomplished through a limited incision and without the use of cardiopulmonary bypass (known as the *minimally invasive direct coronary artery bypass* [MIDCAB] operation). The distal LAD artery may be exposed with a small anterior thoracotomy, and the LAD or diagonal artery may be grafted with a left ITA graft. A stabilizing device usually is employed for anastomotic construction, although the intrapericardial adhesions provide some stability during reoperations. If the left ITA is not available, a segment of saphenous vein can be anastomosed to the subclavian artery and routed in a transthoracic path to the LAD artery. If the right ITA is to be used as an in situ graft to the LAD artery, a median sternotomy is indicated, but if this is the only graft, off-pump surgery usually is possible.

The lateral wall of the heart can be exposed through a left lateral thoracotomy (Fig. 24-21), and the circumflex and distal right coronary artery branches can be grafted with this approach. Often the LITA already has been used for a graft, but the descending thoracic aorta may be used as a site for the proximal anastomosis of a vein graft or a radial artery graft using a partial occluding clamp. The disadvantages of this approach are that the right ITA is difficult to use as an in situ graft, and if the circumflex vessels are deeply intramyocardial, they may be difficult to expose and isolate with the off-pump strategy.

In addition to avoiding potential complications of cardiopulmonary bypass, the “limited-area, off-pump” approach also

**FIGURE 24-21** An in situ gastroepiploic artery (GEA) graft may be used for an on- or off-pump anastomosis to the distal LAD artery.

avoids extensive dissection of the heart and possible manipulation of atherosclerotic vein grafts. The disadvantage of this approach is that most patients who are candidates for reoperation need grafts to multiple vessels in multiple myocardial areas.

Use of a median sternotomy and the off-pump strategy to graft multiple myocardial areas is now a standard approach to primary coronary revascularization and also can be used during reoperation. However, because of the need to access all areas, extensive dissection sometimes is necessary for lysis of adhesions to be able to mobilize the heart. If patients have atherosclerotic vein grafts, dissection and manipulation create the dangers of embolization of atherosclerotic debris and myocardial infarction. This problem was encountered during the early years of bypass surgery when the risks of atherosclerotic embolization were less recognized. Another disadvantage of off-pump reoperative strategies is that reoperative candidates often have very distal and diffuse CAD, which leaves intramyocardial segments as the best areas for grafting. These characteristics stress off-pump isolation and immobilization techniques. In addition, the aortic anastomoses of vein or free arterial grafts may be difficult because of aortic atherosclerosis, adhesions, or previous aortic anastomoses that may limit the application of a partial occluding clamp. On the other hand, the use of off-pump techniques may minimize aortic trauma, particularly if in situ arterial grafts can be employed to provide inflow to new grafts.

In an individual case, the disadvantages of off-pump surgery may be important or irrelevant. Surgeons who perform reoperative coronary artery surgery in a wide spectrum of situations will find both on- and off-pump strategies helpful.

## RESULTS OF CORONARY ARTERY REOPERATIONS

### Early Results

Coronary artery reoperations are riskier than primary operations. A study from the Society of Thoracic Surgeons (STS) database reported an in-hospital mortality rate of 6.95% associated with reoperations for the years 1991 to 1993, and in a multivariate analysis of all isolated coronary artery bypass surgery, “previous operation” was identified as a factor that increased the mortality rate.<sup>12</sup> At the Cleveland Clinic Foundation, the in-hospital mortality rate of a first reoperation ranged between 3 and 4% from 1967 through 1991, and the rate was 3.7% for 1663 patients having repeat surgery from 1988 through 1991.<sup>1-3</sup> Progress during the last decade has continued to lower this risk. In a recent report by Sabik and colleagues, the hospital mortality rate for patients undergoing reoperative CABG was reduced to 2.5% in 2002, and risk adjustment identified the comorbidity burden carried by reoperative patients as a factor that increased risk, not reoperative status itself.<sup>14</sup>

In the 1990s and 2000s, mortality rates from other large series range from 4.2 to 11.4%, most being around 7%.<sup>4-9,52</sup> In 2013, among all STS database participants the mortality rate was 3.5%, while the mortality rate for primary operations was 1.5%.

All these figures are two to five times higher than the rates we would expect for the risk of primary CABG. Coronary artery reoperations have been associated with a higher in-hospital mortality mostly because of an increased risk of perioperative myocardial infarction. In the Cleveland Clinic Foundation series, the cause of perioperative death was cardiovascular in 85% of cases in the most recent cohort of patients undergoing reoperation, a figure that contrasts with recent studies of primary operations, in which noncardiac causes of death have been increasingly important.<sup>3,15</sup> Furthermore, in the reoperative series, in-hospital mortality was associated with new perioperative myocardial infarction in 67% of cases. Multiple causes of myocardial infarction have been identified, including incomplete revascularization owing to distal CAD, vein graft thrombosis, ITA graft failure, atherosclerotic embolization from vein grafts, injury to bypass grafts, hypoperfusion from arterial grafts, preoperative myocardial infarction, and complications of PTCA.

Sternal reentry still creates risk. In a study of 1847 patients undergoing reoperation, 7% were associated with an adverse event and only previous radiation and the number of previous operations could be identified as predictors of injury. Of the 127 patients sustaining an injury, 24 (19%) experienced a major adverse outcome (stroke, myocardial infarction, or death) compared with a risk of 6.2% for those without an injury.<sup>43</sup>

Multiple studies of patients undergoing reoperation have identified increased age, female gender, and emergency operation as clinical variables that have a high association with in-hospital mortality. Emergency operation is a particularly strong factor. Although there is not a standard definition of *emergency*, mortality rates after emergency reoperations that have been reported range from 13 to 40%.<sup>3,5-8</sup> Data from the STS for the year 1997 documented a risk of 5.2% for elective reoperations, 7.4% for urgent reoperations, 13.5% for emergency reoperations, and 40.7% for "salvage" reoperations. There is clearly a major increment in risk associated with emergency reoperations, a larger increment than has existed for patients undergoing primary surgery.

Advanced age, by itself, does not increase the risk of reoperation substantially but does so when combined with other variables. In a review of 739 patients aged 70 years or older undergoing reoperation, we noted an overall in-hospital mortality rate of 7.6% and identified emergency operation, female gender, left ventricular (LV) dysfunction, creatinine concentration greater than 1.6  $\mu\text{g}/\text{dL}$ , and left main coronary artery stenosis as specific factors increasing risk. For patients with none of these characteristics, the in-hospital mortality rate was only 1.5%.<sup>53</sup>

Specific anatomical situations, in particular, the presence of patent ITA grafts and atherosclerotic vein grafts, can increase the risk of reoperation, but with experience, these technical factors largely have been neutralized. We have never documented an increased mortality rate for patients with patent ITA grafts but have noted that the risk of ITA damage has dropped from 8% in our early experience to 3.7% more recently, an improvement almost entirely related to

increased surgical experience. With proper positioning of an ITA graft at primary operation, a patent LITA-to-LAD-artery or LITA-to-circumflex-artery graft should not represent an impediment to reoperation. Situations in which a patent in situ right ITA graft crosses the midline to supply the LAD or circumflex system are more difficult and require extreme care in reoperating using a median sternotomy incision. Although these situations are uncommon and provide difficult technical challenges, the risks for these patients have not been increased.

Studies from the past noted that the presence of atherosclerotic vein grafts did increase perioperative risk. Perrault and colleagues documented mortality rates of 7, 17, and 29% for patients with one, two, or three stenotic vein grafts, respectively, and in a previous study of patients with atherosclerotic vein grafts, we noted that the presence of an atherosclerotic vein graft to the LAD artery increased in-hospital risk.<sup>30,36</sup> However, in our more recent study we found that atherosclerotic vein grafts did not increase mortality, although there was a nonsignificant trend toward increased risk for patients with multiple stenotic grafts.<sup>3</sup> The favorable results for these patients have been based on a combination of improved technology, the use of retrograde cardioplegia delivery, and increased surgeon experience.

Although arterial grafts may offer advantages at reoperation, their use may prolong an already complex operation, and the influence of arterial grafting on perioperative risk has been a concern. However, we have specifically studied this issue and found that the use of single or double ITA grafts at reoperation does not increase perioperative risk, and in fact, not having an ITA graft at either the first or second operation appeared to be a factor associated with increased in-hospital mortality.<sup>3</sup> Graft selection in that study was not randomized, and it is certainly possible that the increased risk for patients receiving only vein grafts was related to patient-related variables rather than surgical strategy. It does appear, however, that the use of arterial grafts does not increase risk. Except for an increased incidence of perioperative myocardial infarction, in-hospital morbidity does not seem to be increased for patients undergoing reoperation. One important observation relates to wound complications. Multiple groups, including ours, have noted an increased risk of wound complications when diabetic patients have received bilateral (simultaneous) ITA grafts. However, there does not appear to be an increased risk of wound complications for diabetic patients who receive staged ITA grafts, one at the first and another at a second operation.

Among all STS participants in 2013, when compared to primary coronary bypass, reoperative procedures appeared to be associated with an increased of major complications (17.3 vs 12.8%), risk of reoperation within 30 days (5.0 vs 3.6%). Interestingly, no additional risk of mediastinitis (0.3 vs 0.2%) or permanent cerebrovascular accident (1.2 vs 1.3%) was demonstrated.

It is important to note that only the variables that can be identified and quantified are included in studies consistent enough to be identified as risk factors. For example,

experience and logic dictate that severe atherosclerosis of the ascending aorta is a major risk factor, but this is rarely identified in large studies because patients do not routinely undergo echocardiography to identify the presence of aortic atherosclerosis.

## Late Results

Patients who are undergoing reoperation are at a later stage in the progression of their native coronary atherosclerosis compared with the point when they underwent primary surgery, and the anatomical corrections achieved at reoperation are less perfect. Although the definition of *complete revascularization* varies widely, few reoperative candidates undergo an operation in which all diseased segments of all arteries receive bypass grafts. It is not surprising that the long-term results of reoperation have not been as favorable as the long-term results of primary operations.

The likelihood of recurrent angina after any bypass operation is related to time, but angina symptoms are more common after repeat surgery than they are after primary operation. Follow-up of our reoperative patients at a mean interval of 72 months after reoperation showed that 64% of patients were in New York Heart Association (NYHA) functional class I, although only 10% of patients had class III or class IV symptoms.<sup>2</sup> Weintraub and colleagues also noted at a 4-year follow-up that 41% of reoperative patients had experienced some angina.<sup>6</sup>

Late survival rates after reoperation are also inferior to those after primary surgery. Weintraub and colleagues noted 76% 5-year- and 55% 10-year survival rates, and our most recent follow-up study found a 10-year survival rate of 69% for in-hospital survivors (Fig. 24-22).<sup>2,6</sup> The predictors of late survival have varied among studies, but LV dysfunction, advanced age, and diabetes consistently have been associated with a decreased late survival rate. The variables identified by

**FIGURE 24-22** For 2429 hospital survivors who underwent reoperation between 1967 and 1987, the 10-year survival was 69%, and event-free survival was 41%. multivariate testing as decreasing the late survival for 2429 hospital survivors of a first reoperation are listed in Table 24-3. The influence of ITA grafts on late survival has been difficult to determine for reoperations. We found a positive influence of a single ITA graft on late survival, as have others,<sup>54</sup> but the effect was not as dramatic as has been noted after primary operations. Weintraub and colleagues did not document an improved survival associated with ITA grafting.<sup>6</sup> However, there is clear evidence that usage of ITA grafts has at least partially contributed to a dramatically lower number of reoperations<sup>55</sup>, and this could be potentially extrapolated to a positive effect of ITA grafts on late survival.

## Multiple Coronary Artery Reoperations

Patients who have had more than one previous coronary artery operation are like patients undergoing first reoperations, only more so. Many patients undergoing multiple reoperations had their first procedure more than 15 years ago, and severe native-vessel disease and lack of bypass conduits are a common combination of problems. Selection criteria vary widely among institutions, but in-hospital mortality rates are increased relative to first reoperations.<sup>10,11</sup> Through 1993, we reoperated on 392 patients who had more than one previous bypass operation, with an in-hospital mortality rate of 8%. Over the next 10 years, this mortality rate has decreased to 5.8%.<sup>14</sup> Follow-up of the in-hospital survivors in the former group found late survival rates of 84% at 5 and 66% at 10 postoperative years. Thus, although the in-hospital risks were increased for these patients, the long-term outcome has been relatively favorable. Age was a major determinant of outcome. Recently, in-hospital mortality for patients younger than 70 years of age has decreased to 1 to 2%, but for patients greater than age 70, it has remained higher than 10%. Furthermore, patients greater than age 70 who did survive operation in our series had only a 50% 5-year late survival.

## KEY POINTS

1. Make certain the end justifies the means before performing a coronary reoperation
2. Avoid cardiac injury
3. Do not replace a patent or stenotic vein graft with an ITA graft
4. Dissect out the left side of the heart with the heart arrested
5. Use the axillary artery as an alternative cannulation site

# Surgical Treatment of Complications of Myocardial Infarction, Ventricular Septal Defect, Myocardial Rupture, and Left Ventricular Aneurysm

Donald D. Glower

Acute myocardial infarction can require surgical intervention for many reasons. Most commonly, patients may have coronary artery stenosis that may be amenable to coronary artery bypass grafting, either to halt the progress of the acute infarction, or to prevent subsequent angina, reinfarction, or death (see Chapters 20 to 25). Myocardial infarction can also result in refractory congestive heart failure and/or circulatory shock due to inability of the left and/or right ventricles to maintain the cardiovascular circulation. These patients may benefit from ventricular replacement therapy that include cardiac transplantation (see Chapter 61), extracorporeal membrane oxygenation (see Chapter 19) or placement of left and/or right ventricular assist devices (see Chapter 63). Acute myocardial infarction can have a number of other mechanical consequences that may need to be addressed surgically. These can include acute and chronic ischemic mitral regurgitation and even papillary muscle rupture (see Chapter 38) and functional tricuspid regurgitation (see Chapter 44). Three final and potentially catastrophic mechanical complications of acute myocardial infarction are addressed in this chapter and include postinfarction ventricular septal defect, cardiac rupture, and left ventricular aneurysm.

## POSTINFARCTION VENTRICULAR SEPTAL DEFECT

Postmortem description of a postinfarction ventricular septal defect was first made in 1845 by Latham.<sup>1</sup> The first antemortem clinical diagnosis of a postinfarction ventricular septal defect was made in 1923 by Brunn.<sup>2</sup> Sager<sup>3</sup> in 1934 established specific clinical criteria for diagnosis and

associated postinfarction septal rupture with coronary artery disease.

The first successful surgical repair of a postinfarction ventricular septal defect was made in 1956 by Cooley in a patient 9 weeks after the diagnosis of septal rupture.<sup>4</sup> The approach used was a right ventriculotomy similar to that used in patients with congenital ventricular septal defects. Thereafter the surgical mortality was sufficiently high that the strategy was to limit operation to those patients surviving for more than a month after acute septal perforation.<sup>5</sup> Delayed surgery also had the advantage of allowing septal healing to facilitate more secure closure of the septal rupture.<sup>6</sup> Heimbecker<sup>6</sup> described septal defect repair through a left ventriculotomy in the zone of infarction combined infarctectomy and aneurysmectomy.<sup>7</sup> Approaching the septal defect through the left ventricular infarct had distinct advantages of providing better exposure of the apical and inferior septum than did a right ventriculotomy. The left ventriculotomy also did not unnecessarily injure the otherwise critical right ventricle and allowed surgical remodeling of the infarcted portion of the left ventricle. Daggett et al<sup>8</sup> in 1977 first reported a large series of 43 patients with improved surgical outcomes using a combination of infarctectomy and prosthetic patch material. In addition to the improved results overall, Daggett et al were able to successfully treat inferoposterior septal defects that previously had been problematic.<sup>9-11</sup> In 1995 David described 44 patients treated with infarct excluding patches with excellent mortality of 19% and unusually low incidence of right ventricular dysfunction in two of 44 patients.<sup>12</sup> Today, percutaneous septal defect closure devices are evolving to have a role in selected patients,<sup>13</sup> and ventricular replacement

therapy is finding use in some septal defect patients with extensive ventricular damage and inability to maintain end organ perfusion.<sup>14</sup>

## Incidence

Ventricular septal defect occurs in 1 to 2% of all acute myocardial infarctions, typically 3 to 5 days after the onset of symptoms.<sup>15</sup> Rupture of the interventricular septum with resultant ventricular septal defect can occur as early as hours after infarction or as late as 2 weeks.<sup>16,17</sup> This timing correlates well with the maximal tissue necrosis from acute myocardial infarction with minimal healing having occurred. Patients with postinfarction ventricular septal defect are most likely to be men; but because women are less likely to present with transmural infarction, some suggest that women with transmural infarction are actually at somewhat higher risk of developing postinfarction ventricular septal defect. Older age and total occlusion of the infarct vessel with minimal collateralization are also associated with postinfarction ventricular septal defect. The onset of early coronary reperfusion using thrombolytics or angioplasty may have shortened the time between infarction and septal rupture in some patients, perhaps due to hemorrhagic reperfusion of the infarct. However, the overall incidence of postinfarction ventricular septal defect appears to have declined in the last two decades with the increased prevalence of early coronary perfusion and the decreased number of large, nonreperfused infarctions.<sup>18</sup> In the GUSTO I trial of thrombolysis for infarction due to total occlusion of a coronary vessel,<sup>19</sup> the median age of patients with postinfarction ventricular septal defect was 72 years with 43% of septal defect patients versus 75% of remaining patients being male, and a higher incidence of hypertension and diabetes in the septal defect group. Infarctions were anterior in 70% of septal defect patients, with 29% being inferior and 1% presenting other cardiac zones. Single vessel coronary disease was present in 50% of septal defect patients, and 57% had total occlusion of the infarct vessel with the median restenosis being 100%. Shock was present in 67% of patients, and 89% had heart failure. Thirty-day mortality was 74%, and 1-year mortality was 76% with 33% of patients undergoing bypass surgery. Survival was significantly higher for anterior infarctions (20/39 (51%)) versus inferior infarction being survival being two of 22 (9%).

## Pathophysiology

Postinfarction ventricular septal defect generally involves transmural infarction of the interventricular septum with subsequent dissection of ventricular blood into the septal myocardium, resulting in a ventricular septal defect. Patients with postinfarction septal defects generally have larger infarcts involving 26% of the left ventricular wall as opposed to only 15% of the left ventricular wall in other infarction,<sup>15</sup> and most have single vessel disease.<sup>20</sup> Patients with acute postinfarction septal defect tend to have greater right ventricular infarction than other patients with acute infarction.<sup>21</sup> The

interventricular septal defect may be large and single, as is commonly seen with anterior infarctions. On the other hand, there may be multiple defects in the septum and a serpiginous course through the septum, as is more common with inferior infarctions producing ventricular septal defects. Because of the large volume of myocardial infarction in patients with postinfarction ventricular septal defects, roughly half of septal defect patients who survive the acute phase develop ventricular aneurysms, as opposed to only 12% of acute infarction patients without ventricular septal defects developing ventricular aneurysms.<sup>22</sup> Roughly one-third of postinfarction ventricular septal defect patients will have some degree of mitral regurgitation due to left ventricular dilation and altered papillary and annular geometry.<sup>23</sup>

Once the ventricular septal defect occurs, shunting of blood from the left ventricle to the right ventricle occurs with subsequent development of left and/or right ventricular heart failure. The combination of left to right shunting along with impairment of right and/or left ventricular contractility can produce low cardiac output and cardiogenic shock with end organ malperfusion progressing to death within days to weeks. In patients with postinfarction ventricular septal defect, left ventricular muscle loss is significant enough that one-third or more of all patients may not have a survivable amount of remaining myocardium without ventricular replacement therapy.<sup>18</sup> Heart failure and shock are the primary causes of ultimate death. Right ventricular failure leading to shock and death is more common with inferior than anterior infarction due to more extensive right ventricular infarction along with left to right shunting.

## Natural History

Without surgical intervention, the natural history of postinfarction ventricular septal defect is that nearly 25% of patients will be dead within 24 hours, 50% in one week, 65% in 2 weeks, and 80% within four weeks, with 1-year survival being 5 to 20%.<sup>24</sup> Those who survived the initial few days to 2 weeks tend to have smaller degrees of shunting and smaller infarctions. Spontaneous closure of the postinfarction ventricular septal defect has been seen but is quite rare.

## Clinical Presentation

The typical patient with a postinfarction ventricular septal defect initially presents with a large transmural anterior myocardial infarction. Most will appear to be convalescing in the initial few days, whereupon a new systolic murmur is noted, recurrent chest pain may develop, and hemodynamics may deteriorate with onset of dyspnea, tachycardia, hypotension, and oliguria.

## Diagnosis

On clinical examination, 90% of patients with postinfarction ventricular septal defect will have a new, harsh, pansystolic murmur at the left lower sternal border, usually with

a palpable thrill. Chest radiographic will commonly show progressive pulmonary edema and cardiomegaly. The electrocardiogram will continue to reflect transmural myocardial infarction in the appropriate zone, with occasional transient partial atrioventricular conduction block occurring around the time of rupture. Unfortunately, no electrocardiographic findings are highly predictive or diagnostic of septal rupture itself.

The differential diagnosis of postinfarction ventricular septal defect in a patient with acute onset of congestive heart failure and a new systolic murmur several days after transmural myocardial infarction importantly involves acute ischemic mitral regurgitation with or without papillary muscle rupture. While echocardiography is the definitive means of distinguishing between these two entities, several clinical associations might lead to early suspicion of one versus the other. Septal rupture occurs most commonly in anterior infarctions, while papillary muscle rupture is more common with inferoposterior infarctions. The murmur of septal rupture tends to be greatest at the left lower sternal border with a palpable thrill in more than half of patients, while the murmur of mitral regurgitation tends to radiate towards the left axilla.

Today, echocardiography is the definitive means of making the diagnosis of postinfarction ventricular defect and differentiating it from other complications such as acute mitral regurgitation.<sup>25</sup> Echocardiography can also provide reasonably accurate information in terms of the location and size of the septal defect and associated ventricular wall motion abnormalities. Mitral and/or tricuspid regurgitation can be quantified along with an assessment of left ventricular and right ventricular size and contractility.

In the absence of diagnostic echocardiography, right heart catheterization or placement of a Swan-Ganz pulmonary artery catheter can be diagnostic of a significant left to right shunt inherent (1.4:1 to 8:1 or more) due to postinfarction ventricular septal defect. Right heart catheterization can provide cardiac output, central venous pressure, and pulmonary artery pressure for prognostic value and to optimize medical management. Preoperative right heart catheterization may not be needed if the diagnosis is firm based on echocardiography.

Today, many patients with postinfarction ventricular septal defect already had left heart catheterization on presentation with transmural infarction and may have already had reperfusion of the infarct vessel. If this has not been done at the time of presenting with a septal defect, then the decision to perform left heart catheterization prior to correcting the septal defect is controversial. Left heart catheterization can identify or even treat residual coronary stenoses. However, the mortality benefit from reperfusion of the infarct vessel diminishes rapidly once the patient is more than several hours into the infarction. Moreover, the relatively high incidence of single vessel disease in postinfarction ventricular septal defect patients and the risk of volume overload and nephrotoxicity from dye all suggest that the decision to perform coronary angiography after the onset of septal rupture needs to be made on a case-by-case basis.

## Indications for Operation

Because of the high mortality of postinfarction ventricular septal defects and because of the progressive volume overload due to left to right shunting, postinfarction ventricular septal defects should ideally be corrected in any patient who appears to be viable. Correction of the septal defect should also be performed as soon as possible to minimize subsequent end organ damage due to heart failure and hypoperfusion. Some patients may have sufficiently poor likelihood of surviving an operation that medical and/or percutaneous therapy might be more attractive. The timing of surgery may be emergent, urgent, or delayed depending upon the patient's situation. The main reasons for delay might be to optimize the patient hemodynamically, to obtain adequate diagnostic information, and to optimize volume status as best possible in a very short period of time. Once these goals have been accomplished in a period of no more than 12 to 24 hours, further delay of surgery tends to only result in a sicker patient going to operation.<sup>18</sup> Exceptions might be patients with relatively small shunts and/or other overriding surgical contraindications where the septal defect might reasonably be closed on a delayed basis once the other acute conditions are sufficiently corrected. In the past, significant delays in operation simply selected out those patients likely to survive long term in either event, with many otherwise potentially salvageable patients succumbing in the interim.

## Preparation for Operation

Because of the rapidly life-threatening nature of postinfarction ventricular septal defects with 50 to 60% of patients having severe congestive heart failure or low cardiac output, these patients should be managed in an intensive care setting.<sup>26</sup> Preoperative management has three important goals: (1) to maintain cardiac output and arterial pressure for adequate end organ perfusion, (2) to reduce systemic vascular resistance to decrease the left to right shunt, and (3) to maintain adequate coronary blood flow.<sup>27</sup> The surgical team should be involved immediately upon making the diagnosis of a postinfarction ventricular septal defect. Placement of an intra-aortic balloon pump should be an early intervention to achieve some of these goals by improving coronary blood flow and decreasing the left to right shunt by decreased left ventricular outflow resistance.<sup>28</sup>

Pharmacologic therapy for postinfarction ventricular septal defect patients includes inotropic agents to improve end organ perfusion in the face of impaired right and/or left ventricular function. In addition, intravenous diuretics are generally needed early on to treat pulmonary edema. Intravenous vasodilators such as sodium nitroprusside, nitroglycerin, or calcium-channel blockers can occasionally be helpful, but most patients are sufficiently hypotensive to not tolerate significant doses of these agents. Because these patients all have significant ventricular dysfunction that may not improve with surgery, some patients may need evaluation for mechanical ventricular replacement therapy on an acute basis. This could

include extracorporeal membrane oxygenation or right and/or left ventricular assist devices. In general, those patients receiving this type of support before operation are those who are poor candidates for surgical closure of the septal defect at the time of evaluation but in whom the end organ dysfunction is felt to be reversible. Preoperative support over a period of time could allow some healing of infarct tissue and some recovery of stunned myocardium, in addition to allowing recovery of other end organs, at the expense of the multiple risks of cardiac assist devices.<sup>29</sup> Postinfarction ventricular septal defect patients have an inherent risk of right to left shunting from an isolated left ventricular assist device alone. As a result, many patients might need biventricular support or at most partial left heart support.

## Operative Techniques

### OVERVIEW

Repair techniques for a postinfarction ventricular septal defect and can be classified based on the location of the infarct and on whether the approach of infarct excision versus exclusion is used. Infarctectomy with or without patch closure of the infarct is a technique applicable to some septal infarctions and some apical infarctions to ensure suturing to viable myocardium that will heal. Table 25-1A lists the principles of the infarctectomy as stated by Daggett.<sup>30</sup> Infarct exclusion potentially allows less distortion of ventricular geometry but still requires suturing to viable myocardium. Table 25-1B lists the principles of infarct exclusion as stated by David.<sup>12</sup> Septal defects due to apical infarction are amenable either

**TABLE 25-1A: Principles of Infarctectomy Repair of Postinfarction VSD**

Transinfarct approach to ventricular septal defect

1. Thorough trimming of the left ventricular margins of the infarct back to viable muscle to prevent delayed rupture of the closure
2. Conservative trimming of the right ventricular muscle as required for complete visualization of the margins of the defect
3. Inspection of the left ventricular papillary muscles and concomitant replacement of the mitral valve only if there is frank papillary muscular rupture
4. Closure of the septal defect without tension, which in most instances will require the use of prosthetic material
5. Closure of the infarctectomy without tension with generous use of prosthetic material as indicated, and epicardial placement of the patch to the free wall to avoid strain on the friable endocardial tissue
6. Buttressing of the suture lines with pledgets or strips of Teflon felt or similar material to prevent sutures from cutting through friable muscle

Data from Heitmiller R, Jacobs ML, Daggett WM: Surgical management of postinfarction ventricular septal rupture, *Ann Thorac Surg.* 1986 Jun;41(6):683-691.

**TABLE 25-1B: Principles of Exclusion Repair of Postinfarction VSD**

Transinfarct approach to ventricular septal defect

1. No infarctectomy unless necrotic muscle along ventriculotomy is sloughing during closure
2. Bovine pericardial patch in either an oval (anterior defect) or triangular (posterior defect) shape is sutured securely with continuous Prolene around the defect to exclude it from the LV cavity
3. Where necessary, full-thickness bites are taken to the epicardial surface and anchored by strips of pericardium or Teflon (see text for details)
4. An anterior patch is anchored to noninfarcted septum below the defect, then the noninfarcted endocardium of the anterolateral ventricular wall. If the infarct involves the base of the anterior muscle, full thickness anchoring bites are used
5. A posterior patch is anchored to the mitral annulus, noninfarcted septum, and through the infarcted posterior wall along a line corresponding to the medial margin of the posteromedial papillary muscle (with full thickness anchoring)
6. Closure of the infarctectomy using strips of pericardium or Teflon
7. When possible, infarcted right ventricular free wall is left undisturbed during closure

Data from David TE, Dale L, Sun Z: Postinfarction ventricular septal rupture: repair by endocardial patch with infarct exclusion, *J Thorac Cardiovasc Surg.* 1995 Nov;110(5):1315-1322.

infarctectomy or exclusion techniques. Septal defects due to anterolateral infarction generally require an exclusion patch on the septum, often with primary closure of the left ventriculotomy. Septal defects due to inferior infarction generally require an exclusion patch on the septum and patch closure of the ventriculotomy.

### INTRAOPERATIVE CONSIDERATIONS

Patients with postinfarction ventricular septal defects are often in cardiogenic shock, intolerant of vasodilation and needing inotropic support during the induction of anesthesia. If not already present, an intra-aortic balloon pump may be placed to ensure stability during induction. Pulmonary vasodilators and venous vasodilators should be avoided to minimize left-to-right shunting. A Swan-Ganz pulmonary artery catheter should be placed to assist postoperative inotropic management.

Median sternotomy is the incision of choice. Cardio-pulmonary bypass should be accomplished with bicaval venous drainage and bicaval isolation to avoid entraining air into the venous line given that the right heart will be open through the septal defect. Postinfarction septal defects are best repaired in the arrested heart with careful attention to good myocardial protection given the already impaired by ventricular performance in these patients.

The use of concurrent coronary bypass grafting depends upon surgical philosophy and the coronary anatomy of the each patient. Some groups argue that concurrent coronary bypass grafting and left heart catheterization can delay surgery, add unnecessary risks, and is unlikely to benefit already infarcted myocardium. The incidence of late, clinically significant, untreated coronary disease in patients receiving isolated repair of postinfarction ventricular septal defects has in fact been low in several series.<sup>31</sup> Others argue that concurrent bypass grafting could potentially improve myocardial protection and reduce late myocardial ischemia.

In weaning from cardiopulmonary bypass, an intra-aortic balloon pump should be used if possible. Multiple inotropes will be needed, and intravenous milrinone and inhaled nitric oxide may be of particular value. In patients who cannot be weaned from cardiopulmonary bypass using standard techniques, the use of the left and/or right ventricular assist device could be considered (see Chapter 63).<sup>14</sup> In postinfarction ventricular septal defect patients, one particularly needs to be cognizant of potential residual right to left shunting with resultant hypoxemia when an isolated left ventricular assist device is used.

Postoperative hemostasis can be a problem in these critically ill patients. Routine use antifibrinolytic agents such as  $\epsilon$ -aminocaproic acid (Amicar) can be helpful. Seguin and others have recommended application of a fibrin sealant to the ventricular septum around the septal defect before formal repair,<sup>32</sup> followed by biological glue applied to bleeding suture lines after repair. Transfusion of appropriate blood products and isolated clotting factors may be needed, given the tissue fragility along with intolerance of ongoing bleeding or any degree of postoperative tamponade.

### REPAIR OF APICAL SEPTAL RUPTURE

Daggett described the technique of apical amputation in 1970<sup>8</sup> where necrotic apical myocardium is resected back to left ventricle, right ventricle, and septum (Figs. 25-1A and B). The remaining apical defect is then closed using interrupted mattress sutures of 1-0 Tevdek securing the left and right ventricular walls to the interventricular septum with strips of Teflon felt outside the left ventricular wall, outside the right ventricular wall, and on either side of the interventricular septum (Figs. 25-2A and B).<sup>8,27</sup> After all sutures have been tied, the closure is reinforced with running suture, to ensure hemostasis.

### ANTERIOR REPAIR WITH INFARCTECTOMY

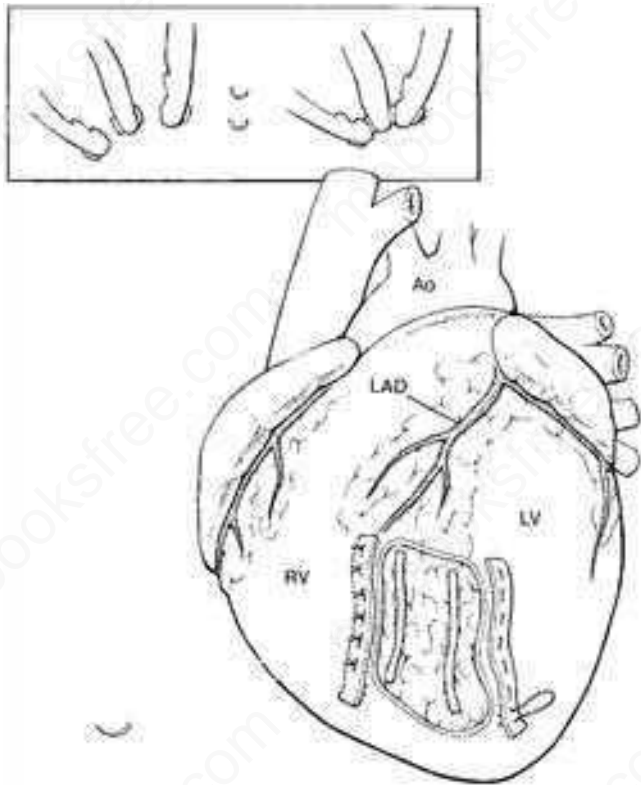

Postinfarction septal defects due to anterior infarction are generally approached through a linear incision in the anterior infarct parallel to the left anterior descending artery, with infarctectomy or debridement of nonviable tissue as described by Daggett<sup>27</sup> (Fig. 25-3). Shumacker<sup>33</sup> described a plication closure of small anterior septal defects by the free anterior edge of the debrided septum to the right ventricular free wall using mattress sutures of 1-0 Tevdek over strips of felt (Fig. 25-4A).

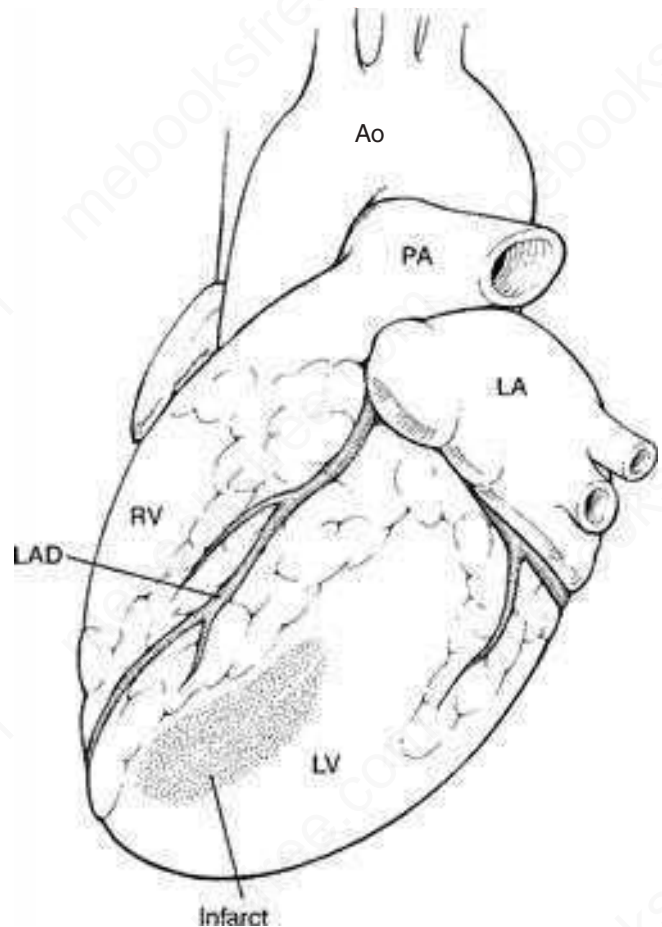

**FIGURE 25-1** (A) Apical postinfarction ventricular septal defect. (B) View of the apical septal rupture, which is exposed by amputating the apex of the left and right ventricles. Ao, aorta; LAD, left anterior descending coronary artery; LV, left ventricle; RV, right ventricle; stippled region, infarcted myocardium.<sup>27</sup>

The transinfarct left ventriculotomy is then closed with a second row of mattress sutures buttressed with strips of Teflon felt (see Figs. 25-4B-D), followed by an outer hemostatic running suture line for ventriculotomy closure.<sup>27,34</sup>

In septal defects that are not small and anteriorly located, the debrided septal defect should be closed with a prosthetic patch of Dacron or bovine pericardium to reduce tension on the repair as described by Daggett<sup>27,34</sup> (see Fig. 25-5). After debridement of necrotic septum and left ventricular muscle, a series of pledgeted interrupted mattress sutures are placed around the perimeter of the defect (see Fig. 25-5A). Along the posterior aspect of the defect, sutures are passed through the septum from right to left. Along the anterior edge of the defect, sutures are passed from the epicardial surface of the right ventricle to the endocardial surface. All sutures are placed before the patch is inserted, and then passed through the edge of a synthetic patch, which is seated on the left side of the septum (see Fig. 25-5B). Each suture is then passed through an additional pledget and all are tied. We use additional pledgets on the left ventricular side overlying the patch (see Fig. 25-5C) to cushion each suture as it

**FIGURE 25-2** (A) The necrotic infarct and the apical septum have been debrided back to healthy muscle. Repair is made by approximating the left ventricle, apical septum, and right ventricle using interrupted mattress sutures of 1-0 Tevdek with buttressing strips of Teflon felt. Felt strips are used within the interior of the left and right ventricles as well as on the epicardial surface of each ventricle. (B) All sutures are placed before any are tied. A second running over-and-over suture (not shown) is used, as in left ventricular aneurysm repair, to ensure a secure hemostatic ventriculotomy closure. Ao, aorta; LAD, left anterior descending coronary artery; LV, left ventricle; RV, right ventricle.

**FIGURE 25-3** Transinfarct left ventricular incision to expose an anterior septal rupture. An incision (dashed line) is made parallel to the anterior descending branch of the left coronary artery (LAD) through the center of the infarct (stippled area) in the anterior left ventricle (LV). Ao, aorta; LA, left atrium; PA, pulmonary artery; RV, right ventricle.<sup>27</sup>

is tied down to prevent cutting through the friable muscle. The edges of the ventriculotomy are then approximated by a two-layer closure consisting of interrupted mattress sutures passed through buttressing strips of Teflon felt or bovine pericardium and a final outer running suture.<sup>27</sup>

#### POSTERIOR/INFERIOR REPAIR WITH INFARCTECTOMY

Postinfarction defects of the inferoposterior septum after inferolateral infarction have been the most challenging to repair because geometry does not lend itself to simple plication.<sup>10,11</sup> Daggett in 1974 described the technique of infarctectomy and patch closure which for the first time yielded reliably good results.<sup>10</sup> However, today many surgeons feel that the inferoposterior septal defects are particularly better suited to an exclusion technique as opposed to infarctectomy.<sup>27</sup> With the heart arrested and the left ventricle vented,

the heart is retracted out of the pericardial to expose the posterior descending coronary artery and the inferior infarction which may involve both ventricles (Fig. 25-6A). As described by Daggett<sup>27,35</sup> a transinfarct incision is made in the left ventricle, and the left ventricular portion of the infarct is excised (see Fig. 25-6B), exposing the septal defect. The left ventricular papillary muscles are inspected. If indicated, mitral valve replacement is performed through a separate conventional left atrial incision, to avoid trauma to the friable ventricular muscle. After all the infarcted left ventricular muscle has been excised, a less aggressive debridement of the right ventricle is accomplished, with the goal of resecting only as much muscle as is necessary to afford complete visualization of the defect(s). Using this technique, delayed rupture of the right ventricle has not been a problem. If the posterior septum has cracked or split from the adjacent ventricular free wall without loss of a great deal of septal tissue, then the septal rim of the posterior defect may be approximated to the edge of

**FIGURE 25-4** (A) Repair of an anterior septal rupture by plicating the free anterior edge of the septum to the right ventricular free wall with interrupted 1-0 Tevdek mattress sutures buttressed with strips of Teflon felt. (B, C, and D) The left ventriculotomy is then closed as a separate suture line, again with interrupted mattress sutures of 1-0 Tevdek buttressed with felt strips. A second running suture (not shown) is used to ensure a secure left ventriculotomy closure. Ao, aorta; LAD, left anterior descending coronary artery; LV, left ventricle; PA, pulmonary artery; RV, right ventricle. (Adapted with permission from Cohn LH (ed): *Modern Techniques in Surgery: Cardiac/Thoracic Surgery*. Mt. Kisco, NY: Futura; 1983.)

the diaphragmatic right ventricular free wall using mattress sutures buttressed with strips of Teflon felt or bovine pericardium (see Figs. 25-6C and D).<sup>27,35</sup>

Larger posterior defects require patch closure (Fig. 25-7).<sup>27,35</sup> Pledged mattress sutures are placed from the right side of the septum and from the epicardial side of the right ventricular free wall (Fig. 25-7B). All sutures are passed through the perimeter of the patch and then through additional pledgets, and are then tied (Fig. 25-7C). Thus, as in closure of large anterior defects, the patch is secured on the left ventricular side of the septum. Because direct closure of the remaining infarctectomy is rarely possible due to tension on the edges of the large defect, a Dacron prosthetic patch is generally required. Pledged mattress sutures are passed out through the margin of the infarctectomy (endocardium to epicardium) and then through the patch (Fig. 25-7D), which is seated on the epicardial surface of the heart. After each suture is passed through an additional pledget, all sutures are

tied (Fig. 25-7E). The cross-sectional view of the completed repair (Fig. 25-8) illustrates the restoration of relatively normal ventricular geometry, which is accomplished by the use of appropriately sized prosthetic patches.<sup>27</sup>

#### ANTERIOR AND INFEROPOSTERIOR REPAIR BY INFARCT EXCLUSION

The work of Dor and others led to the concept of ventricular endoaneurysmorrhaphy<sup>36</sup> or placing an intracavitary endocardial patch to exclude infarcted myocardium while maintaining ventricular geometry and thus preserving left ventricular function. David,<sup>7</sup> Cooley,<sup>37</sup> Ross<sup>38</sup> and others applied the infarct exclusion endocardial patch technique to repair of postinfarction ventricular septal defects, with good results in some centers but mixed results in others. The endocardial patch technique described by David<sup>7</sup> was felt by Daggett and others to be particularly helpful in some patients with

**FIGURE 25-5** (A) Larger anterior septal defects require a Dacron patch, which is sewn to the left side of the ventricular septum with interrupted mattress sutures, each of which is buttressed with a pledget of Teflon felt on the right ventricular side of the septum and anteriorly on the epicardial surface of the right ventricular free wall. All sutures are placed before the patch is inserted. (B and C) Additional pledgets are placed on the left ventricular side overlying the patch to cushion each suture as it is tied down to prevent cutting through the friable muscle. Ao, aorta; LAD, left anterior descending coronary artery; LV, left ventricle; PA, pulmonary artery; RV, right ventricle. (Adapted with permission from Cohn LH (ed): *Modern Techniques in Surgery: Cardiac/Thoracic Surgery*. Mt. Kisco, NY: Futura; 1983.)

inferoposterior septal defects.<sup>27</sup> For anterior septal rupture, Daggett described the technique of David<sup>12,39</sup> as follows.<sup>27</sup>

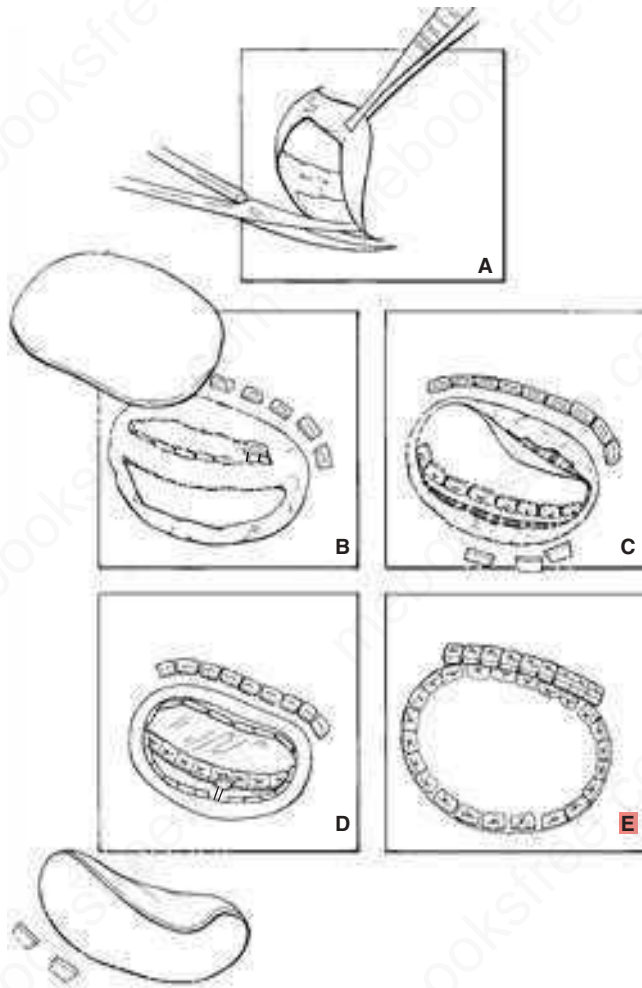

The interventricular septum is exposed via a left ventriculotomy made through the infarct starting at the apex and extending proximally parallel to, but 1 to 2 cm away from, the anterior descending artery (Fig. 25-9A).<sup>27,39</sup> Stay sutures are passed through the margins of the ventriculotomy to aid in the exposure of the infarcted septum. The septal defect is located and the margins of the infarcted muscle identified. A bovine pericardial patch is tailored to the shape of the left ventricular infarction as seen from the endocardium but 1 to 2 cm larger. The patch is usually oval and measures approximately 4 × 6 cm in most patients. The pericardial patch is then sutured to healthy endocardium all around the infarct (see Fig. 25-9B). Suturing begins in the lowest and most proximal part of the noninfarcted endocardium of the septum with a continuous 3-0 polypropylene suture. Interrupted mattress sutures with felt pledgets may be used to reinforce the repair.<sup>38,40</sup> The patch

is also sutured to the noninfarcted endocardium of the anterolateral ventricular wall. The stitches should be inserted 5 to 7 mm deep in the muscle and 4 to 5 mm apart. The stitches in the patch should be at least 5 to 7 mm from its free margin so as to allow the patch to cover the area between the entrance and exit of the suture in the myocardium. This technique minimizes the risk of tearing muscle as the suture is pulled taut. If the infarct involves the base of the anterior papillary muscle, the suture is brought outside of the heart and buttressed on a strip of bovine pericardium or Teflon felt applied to the epicardial surface of the left ventricle. Once the patch is completely secured to the endocardium of the left ventricle, the left ventricular cavity becomes largely excluded from the infarcted myocardium. The ventriculotomy is closed in two layers over two strips of bovine pericardium or Teflon felt using 2-0 or 3-0 polypropylene sutures, as illustrated in Fig. 25-9C. No infarctectomy is performed unless the necrotic muscle along the ventriculotomy is sloughing at the time of its closure, and

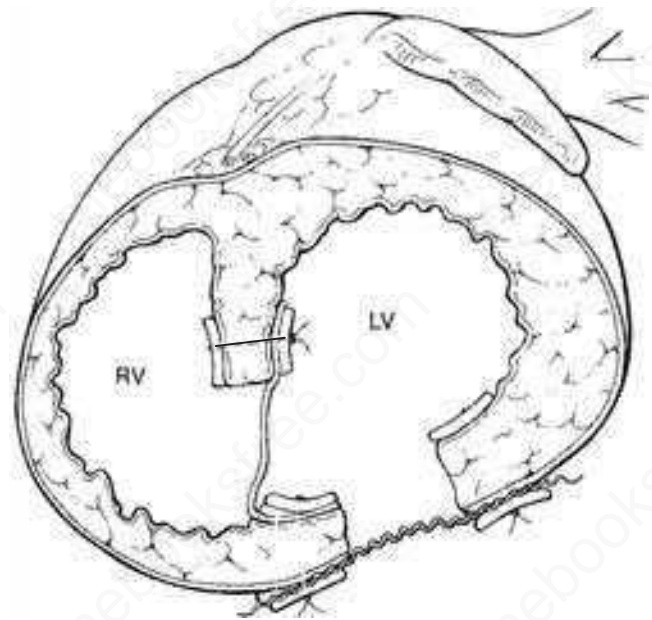

**FIGURE 25-6** (A) View of an inferior infarct (stippled area) associated with posterior septal rupture. The apex of the heart is to the right. Exposure at operation is achieved by dislocating the heart up and out of the pericardial sac, and then retracting its cephalad, as in the performance of distal vein bypass and anastomosis to the posterior descending artery. (B) The inferoposterior infarct is excised to expose the posterior septal defect. Complete excision of the left ventricular portion of the infarct is important to prevent delayed rupture of the ventriculotomy repair. The free edge of the right ventricle is progressively shaved back to expose the margins of the defect clearly. (C and D) Repair of the posterior septal rupture is accomplished by approximating the edge of the posterior septum to the free wall of the diaphragmatic right ventricle with felt-butressed mattress sutures. The repair is possible when the septum has cracked or split off from the posterior ventricular wall without necrosis of a great deal of septal muscle. The surgeon can perform repair of posterior septal rupture to best advantage by standing at the left side of the supine patient. The left ventriculotomy is then closed as a separate suture line, again with interrupted mattress sutures of 1-0 Tevdek buttressed with felt strips. A second running suture is used to ensure a secure left ventriculotomy closure (not shown). LV, posterior left ventricle; PDA, posterior descending artery; RV, diaphragmatic surface of the right ventricle. (Adapted with permission from Daggett WM: Surgical technique for early repair of posterior ventricular septum rupture, *J Thorac Cardiovasc Surg.* 1982;Aug;84(2):306-312.)

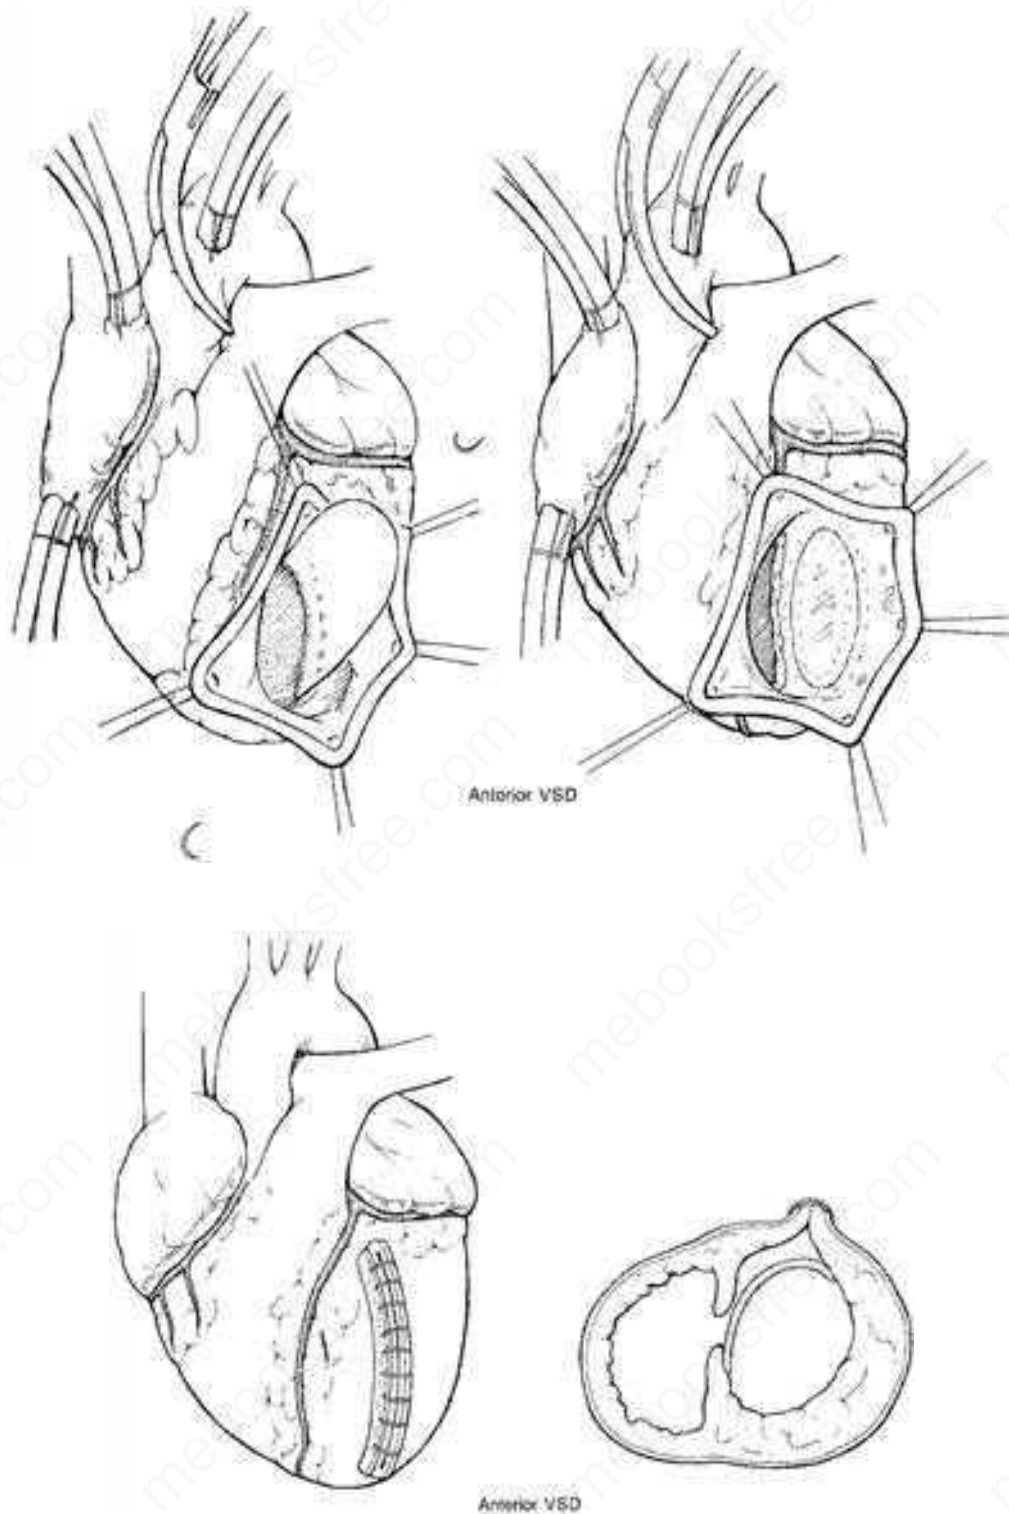

**FIGURE 25-7** (A) Repair of posterior septal rupture when necrosis of a substantial portion of the posterior septum requires the use of patches. (B) Interrupted mattress sutures of 2-0 Tevdek are placed circumferentially around the defect. These sutures are buttressed with felt pledgets on the right ventricular side of the septum and on the epicardial surface of the diaphragmatic right ventricle. (C) All sutures are placed and then the Dacron patch is slid into place on the left ventricular side of the septum. The patch sutures are tied down with an additional felt pledget placed on top of the patch (left ventricular side) as each suture is tied, to cushion the tie and prevent cutting through the friable muscle. These maneuvers are viewed by Daggett et al.<sup>27</sup> as essential to the success of early repair of the posterior septal rupture. (D) Remaining to be repaired is the posterior left ventricular free wall defect created by infarctectomy. Mattress sutures of 2-0 Tevdek are placed circumferentially around the margins of the posterior left ventricular free wall defect. Each suture is buttressed with a Teflon felt pledget on the endocardial side of the left ventricle. With all sutures in place, a circular patch, fashioned from a Dacron graft, is slid down onto the epicardial surface of the left ventricle. An additional pledget of Teflon felt is placed under each suture (on top of the patch) as it is tied to cushion the tie and prevent cutting through the friable underlying muscle. This onlay technique of patch placement prevents the cracking of friable left ventricular muscle that occurred with the eversion technique of patch insertion. (E) Completed repair. (Adapted with permission from Daggett WM: Surgical technique for early repair of posterior ventricular septum rupture, *J Thorac Cardiovasc Surg.* 1982;Aug;84(2):306-312.)

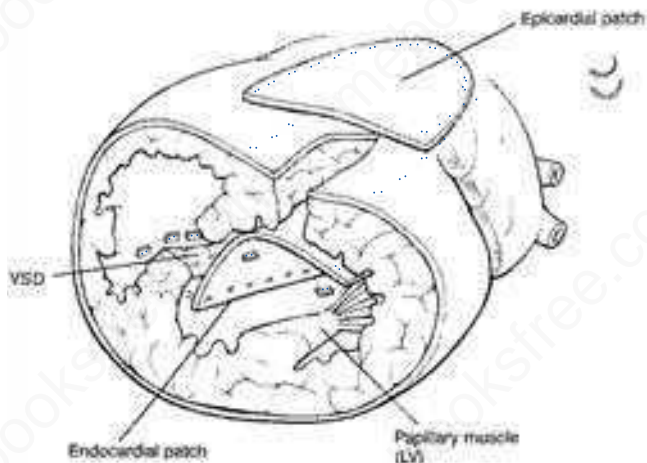

**FIGURE 25-8** Cross-sectional view of the completed repair of posterior septal rupture with prosthetic patch placement of the posterior left ventricular free wall defect created by infarctectomy. LV, left ventricular cavity; RV, right ventricular cavity. (Adapted with permission from Daggett WM: Surgical technique for early repair of posterior ventricular septum rupture, *J Thorac Cardiovasc Surg.* 1982;Aug;84(2):306-312.)

even then it is minimized, because infarcted muscle will not be exposed to left ventricular pressures when the heart begins to work (see Fig. 25-9D). Alternatively, sutures can be passed through the ventricular free wall and through a tailored external patch of Teflon or pericardium (Fig. 25-10).<sup>27</sup>

In patients with inferoposterior septal defects, an incision is made in the inferior wall of the left ventricle 1 or 2 mm from the posterior descending artery (Fig. 25-11A).<sup>27,39</sup> This incision is started at the midportion of the inferior wall and extended proximally toward the mitral annulus and distally toward the apex of the ventricle. Care is taken to avoid damage to the posterolateral papillary muscle. Stay sutures are passed through the fat pad of the apex of the ventricle and margins of the ventriculotomy to facilitate exposure of the ventricular cavity. In most cases, the rupture is found in the proximal half of the posterior septum, and the posteromedial papillary muscle is involved by the infarction. A bovine pericardial patch is tailored in a triangular shape of approximately 4 × 7 cm in most patients. The base of the triangular-shaped patch is sutured to the fibrous annulus of the mitral valve with a continuous 3-0 polypropylene suture starting at a point corresponding to the level of the posteromedial papillary muscle and moving medially toward the septum until the noninfarcted endocardium is reached (see Fig. 25-11B). At that level, the suture is interrupted and any excess patch material trimmed. The medial margin of the triangular-shaped patch is sewn to healthy septal endocardium with a continuous 3-0 or 4-0 polypropylene suture taking bites the same size

**FIGURE 25-9** Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (A) The standard ventriculotomy is made in the infarcted area of left ventricular free wall. An anterior patch of Dacron, polytetrafluoroethylene, or glutaraldehyde-fixed pericardium is fashioned to replace and/or cover the diseased areas (ventricular septal defect [VSD], septal infarction, or free wall infarction). (B) The internal patch is secured to normal endocardium with a continuous monofilament suture, which may be reinforced with pledgeted mattress sutures. There is little, if any, resection of myocardium and no attempt is made to close the septal defect. Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (C) The ventriculotomy, which is outside the pressure zone of the left ventricle, may be repaired with a continuous suture. (D) On transverse section, one can see that the endocardial patch is secured at three levels: above and below the septal rupture and beyond the ventriculotomy. (Adapted with permission from David TE, Dale L, Sun Z: Postinfarction ventricular septal rupture: repair by endocardial patch with infarct exclusion, *J Thorac Cardiovasc Surg.* 1995;Nov;110(5):1315-1322.)

**FIGURE 25-10** Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion with external patching of the ventricular free wall with tailored Teflon or pericardium. LV, left ventricle; VSD, ventricular septal defect. (Adapted with permission from Cooley DA: Repair of postinfarction ventricular septal defect, *J Card Surg*. 1994;July;9(4):427-429.)

as those described for anterior defects. In this area of the septum, reinforcing pledged sutures may be required. The lateral side of the patch is sutured to the posterior wall of the left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. Because the posterior wall of the left ventricle is infarcted, it is usually necessary to use full-thickness bites and anchor the sutures on a strip of pericardium or Teflon felt applied on the epicardial surface of the posterior wall of the left ventricle right at the level of the posteromedial papillary muscle insertion, as shown in Fig. 25-11B. Once the patch is completely sutured to the mitral valve annulus, the endocardium of the interventricular septum, and the full thickness of the posterior wall (see Fig. 25-11C), the ventriculotomy is closed in two layers of full-thickness sutures buttressed on strips of pericardium or Teflon felt (see Fig. 25-11D). The infarcted right ventricular wall is left undisturbed. If the posteromedial papillary muscle is ruptured, mitral valve replacement is necessary.<sup>27</sup>

Daggett and others<sup>27</sup> feel that the theoretical advantages in the technique of infarct exclusion are: (1) It does not require resection of myocardium; excessive resection results in depression of ventricular function and insufficient resection predisposes to recurrence of septal rupture; (2) it maintains ventricular geometry, which enhances ventricular function; and (3) it avoids tension on friable muscle, which may diminish postoperative bleeding.

#### OTHER TECHNIQUES

Many have minor variants to the endocardial infarct exclusion technique have been described utilizing the principles

stated above.<sup>41-43</sup> Asai<sup>44</sup> described an approach through the right ventricle which may be appropriate for some patients but which has all of the issues with the original right ventricular approached use by Cooley and others years earlier.<sup>4</sup>

#### PERCUTANEOUS CLOSURE

Percutaneous closure of postinfarction ventricular septal defects has been performed with a number of devices, including those used to close congenital atrial or ventricular septal defects.<sup>45-47</sup> These devices can be placed through the systemic venous circulation into the right ventricle to access the septal defect, or through the arterial system and the left ventricle to approach the septal defect, or both. Calvert<sup>47</sup> reported 53 cases with percutaneous closure of postinfarction ventricular septal defects with complete shunt reduction in 23%, partial shunt reduction in 62%, and a 5-day post procedure length of stay. Percutaneous devices certainly have the theoretical advantage of avoiding cardiopulmonary bypass and the morbidity of open-heart surgery in an otherwise sick patient. However, technical issues exist with current devices, both in delivering the device to the defect (which may occur at most any location in the interventricular septum) and in obtaining a durable closure of large defects in a thick septum with poorly defined, necrotic edges. Problems have been reported with recurrent septal defects due to continued necrosis of septal tissue<sup>48</sup> and device migration or embolization.<sup>46</sup>

Results of percutaneous closure may be somewhat better 2 weeks or more after infarction, but surgical results are also better in those patients who are able to delay intervention.<sup>45,49</sup> Hybrid approaches have been reported where percutaneous devices were placed intraoperatively using open exposure on cardiopulmonary bypass to avoid a ventriculotomy.<sup>50</sup> To date, the best application of percutaneous catheter-based devices for postinfarction ventricular septal defects may be in those with recurrent or residual defects after surgical therapy.<sup>47,51</sup> If percutaneous closure of postinfarction ventricular septal defects can be obtained safely, even on a partial basis, the approach may have some role in palliating critically ill patients who might ultimately tolerate more definitive surgical intervention at a later date.

#### HIGHLIGHTS OF POSTOPERATIVE CARE

Impaired biventricular performance with low cardiac output is frequent in these patients and may require gradual weaning of inotropic support and the intra-aortic balloon pump over several days. Intravenous milrinone and inhaled nitric oxide may benefit some patients. Correction of hypoxia, hypercarbia, and acidosis can be important to maintain normal right ventricular afterload (see Chapters 12 and 18). Acute renal insufficiency and pulmonary edema are also frequent and require careful volume management, early postoperative diuresis, and the use of positive end-expiratory pressure ventilation (see Chapter 18). Ventricular and atrial arrhythmias can be poorly tolerated and can often be managed with intravenous amiodarone.

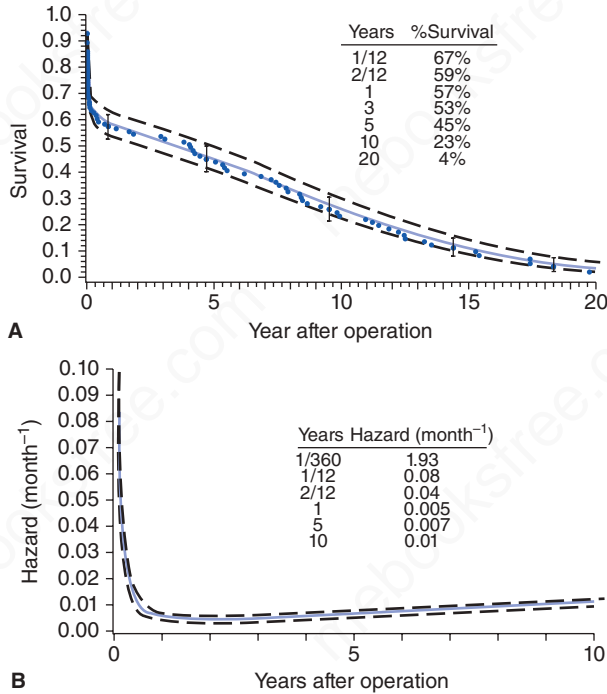

**FIGURE 25-11** Endocardial repair of a posterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (A) An incision is made in the inferior wall of the left ventricle 1 or 2 mm from the posterior descending artery starting at the midportion of the inferior wall and extended proximally toward the mitral annulus and distally toward the apex of the ventricle. Care is taken to avoid damage to the posterolateral papillary muscle. (B) A bovine pericardial patch is tailored in a triangular shape. The base of the triangular-shaped patch is sutured to the fibrous annulus of the mitral valve with a continuous 3-0 polypropylene suture starting at a point corresponding to the level of the posteromedial papillary muscle and moving medially toward the septum until the noninfarcted endocardium is reached. (C) The medial margin of the triangular-shaped patch is sewn to healthy septal endocardium with a continuous 3-0 or 4-0 polypropylene suture. The lateral side of the patch is sutured to the posterior wall of the left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. At this point, it is usually necessary to use full-thickness bites and anchor the sutures on a strip of pericardium or Teflon felt applied on the epicardial surface of the posterior wall of the left ventricle. (D) Once the patch is completely sutured to the mitral valve annulus, the endocardium of the interventricular septum, and the full thickness of the posterior wall, the ventriculotomy is closed in two layers of full-thickness sutures buttressed on strips of pericardium or Teflon felt. The infarcted right ventricular wall is left undisturbed. (Adapted with permission from David TE, Dale L, Sun Z: Postinfarction ventricular septal rupture: repair by endocardial patch with infarct exclusion, *J Thorac Cardiovasc Surg.* 1995;Nov;110(5):1315-1322.)

## Early Results

### HOSPITAL MORTALITY

Operative mortality defined as death before discharge or within 30 days of operation, ranged from 30 to 50%.<sup>27,40,52-55</sup> In the Massachusetts General Hospital experience of 114 patients, Daggett reported an operative mortality of 37% (Fig. 25-12A) with the risk of death falling rapidly after 1 year

(see Fig. 25-12B).<sup>27</sup> The independent risk factors for early death were: older age, higher blood urea nitrogen (BUN), emergency surgery, higher right atrial pressure, and preoperative uses of catecholamines.<sup>27</sup> Inferoposterior location of the septal rupture has been associated with an increased operative mortality.<sup>21</sup> This has been attributed to a more technically difficult repair, the increased risk of associated mitral regurgitation, and associated right ventricular dysfunction

**FIGURE 25-12** (A) Time-related survival after repair of postinfarction ventricular septal defect at the Massachusetts General Hospital (n = 114). Note that the horizontal axis extends to 20 years. Circles represent each death, positioned on the horizontal axis at the interval from operation to death, and actuarially (Kaplan-Meier method) along the vertical axis. The vertical bars represent 70% confidence limits ( $\pm 1$  SD). The solid line represents the parametrically estimated freedom from death, and the dashed lines enclose the 70% confidence limits of that estimate. The table shows the nonparametric estimates at specified intervals. (B) Hazard function for death after repair of postinfarction ventricular septal defect (n = 114). The horizontal axis is expanded for better visualization of early risk. The hazard function has two phases, consisting of an early, rapidly declining phase, which gives way to a slowly rising phase at about 6 months. The estimate is shown with 70% confidence limits.<sup>27</sup>

that is an independent predictor of early mortality after posterior infarction. A short time interval between infarction and operation selects for sicker patients unable to be managed medically.

Daggett reviewed the Massachusetts General Hospital experience and concluded that patients cover a wide range of risk determined most notably by hemodynamic instability (emergency surgery and use of inotropes) (Figs. 25-13 and 25-14).<sup>27</sup> Daggett also concluded that a small group of high-risk patients dramatically affected the overall mortality rate, possibly explaining the tremendous variability in mortality rates between institutions with different patient selection and referral patterns, independent of surgical technique.

**IN-HOSPITAL COMPLICATIONS**

Daggett et al reported that the most common cause of death after repair of acute postinfarction ventricular septal defect was low cardiac output syndrome (52%), with technical failures

**FIGURE 25-13** Nomograms (specific solutions to the multivariate equation) depicting the effect of age on risk in two different hypothetical patients. In both curves the patient was considered to have no left main disease, a blood urea nitrogen of 30 mg/dL, creatinine of 1.5 mg/dL, and no history of previous myocardial infarction. The curve for “low-risk” was solved for a patient who was not emergent and not on catecholamines. The curve for “high-risk” was for an emergent patient on inotropes. The vertical axis represents the calculated survival at 1 year.<sup>27</sup>

such as recurrent or residual septal defect and bleeding in 23%, sepsis (17%), recurrent infarction (9%), cerebrovascular complications (4%), and intractable ventricular arrhythmias.<sup>27</sup>

**Late Results**

**SURVIVAL**

Despite the very high early mortality rate with repair of postinfarction ventricular septal defect, mortality rates

**FIGURE 25-14** Nomograms (specific solutions of the multivariate equation) depicting the predicted survival in three hypothetical 65-year-old patients who present with ventricular septal defect. Each solution is for a patient who has no history of myocardial infarction and without left main coronary artery disease, blood urea nitrogen of 20 mg/dL, and creatinine of 0.8 mg/dL. The “low-risk” patient is nonemergent and not on inotropes with right atrial pressure (RAP) of 8 mm Hg. The “intermediate risk” patient is emergent and not on inotropes with RAP of 12 mm Hg. The “high-risk” patient is emergent and on inotropes with RAP of 20 mm Hg. Confidence limits have been eliminated to improve clarity.<sup>27</sup>

**FIGURE 25-15** Survival in patients who were discharged after repair of postinfarction ventricular septal defect (Massachusetts General Hospital,  $n = 72$ ). The horizontal axis is expanded and represents the time from hospital discharge to death. The depiction is otherwise similar to that seen in Fig. 25-12A.<sup>27</sup>

stabilized at a much lower level after about 1 year. Actuarial survival at 5 years series ranged between 40 and 60% (Fig. 25-12).<sup>27,40,52-54</sup> For hospital survivors, 1-, 5-, and 10-year survival have been reported at 91, 70, and 37%, respectively (Fig. 25-15).<sup>27</sup> The multivariable predictors of late death were: older age, previous myocardial infarction, higher creatinine, higher right atrial pressure, and the presence of left main coronary disease.<sup>27</sup>

### SYMPTOMATIC IMPROVEMENT

Ultimately survivors also can have good functional status with Daggett reporting that 75% were in New York Heart Association functional class I, and 12.5% were class II.<sup>9</sup>

### RECURRENT VENTRICULAR SEPTAL DEFECTS

Using echocardiography, recurrent or residual septal defects have been observed to occur in 10 to 25% of patients.<sup>56</sup> Large residual septal defects with a Qp:Qs > 2.0 should undergo a repair while smaller defects may be managed medically and may occasionally close spontaneously. Percutaneous approaches for these small residual septal defects have been preferred when possible. Surgical closure of late postoperative particular septal defects have been reported via a right atrial approach.<sup>57,58</sup>

## ACUTE VENTRICULAR FREE WALL RUPTURE

### Definition

Left ventricular free wall rupture is similar to rupture of the interventricular septum, except for the location of the rupture. Acute left ventricular free wall rupture is a life-threatening complication of myocardial infarction that requires early intervention. In those unusual patients who survive the initial acute, 2-week phase of ventricular free wall rupture without

diagnosis and/or therapy, this entity will ultimately evolve into a pseudoaneurysm of the left ventricular free wall. These later-phase patients have generally undergone some pericardial healing at the site of infarction, and their management more resembles that of patients with chronic true aneurysms of the left ventricle (see Chapter 26).

### History

The first known case of left ventricular free wall rupture after myocardial infarction was described by William Harvey in 1647.<sup>59</sup> In 1765, Morgagni reported 11 postmortem cases of myocardial rupture<sup>60</sup> and ultimately himself later died of myocardial rupture. The first successful surgical treatment of free wall rupture of the right ventricle was reported by Hatcher in 1970.<sup>61</sup> FitzGibbon<sup>62</sup> in 1971 and Montegut<sup>63</sup> in 1972 reported the first successful repairs of postinfarction left ventricular free wall rupture.

### Incidence

Left ventricular free wall rupture is a relatively common finding in an autopsy series of patients expiring early after acute myocardial infarction, occurring in 10 to 30% of such patients.<sup>64,65</sup> In clinical series of early death after acute myocardial infarction, ventricular rupture may be the second cause of death after cardiogenic shock. Postinfarction ventricular free wall rupture may be more common in elderly patients, and women, and in patients suffering their first infarction.<sup>66</sup> The peak incidence of postinfarction left ventricular free wall rupture occurred at a median of 5 days after infarction.<sup>67</sup> However, thrombolysis and early coronary perfusion may have resulted in an increased number of ventricular ruptures occurring at earlier times, as early as hours after the onset of infarction.<sup>68</sup> In a recent series of 1290 acute myocardial infarction patients, most of whom were reperfused, left ventricular free wall rupture occurred in 1.3%.<sup>69</sup> Because anterolateral infarctions are more common than inferior infarction in general, some series report the anterolateral wall as the most common site of rupture.<sup>64</sup> Other series suggest that a posterolateral or inferior infarction is itself more likely to result in free wall rupture than is anterior infarction.<sup>65</sup>

### Etiology

Acute left ventricular free wall rupture is most commonly due to acute myocardial infarction, with either blunt or penetrating trauma being another common etiology. Prior cardiac surgery, such as mitral valve replacement or transapical aortic valve replacement, can result in acute left ventricular free wall rupture.<sup>70,71</sup> However, once postoperative pericarditis is mature 2 weeks or more postoperatively, prior cardiac surgery is more likely to produce chronic left ventricular pseudoaneurysms instead of acute free wall rupture with tamponade. Other etiologies such as pericardial infection or cardiac tumor have rarely resulted in left ventricular free wall rupture. The treatment of acute left ventricular free wall rupture not

due to infarction will be similar to that of postinfarction rupture, except that underlying coronary disease and myocardial infarction will generally be absent.

## Pathophysiology

Postinfarction left ventricular free wall rupture can present on an acute, subacute, or chronic basis. *Acute* ventricular free wall rupture, in generally, results in acute pericardial tamponade, followed by shock, electromechanical dissociation, and death within a few minutes. *Subacute* rupture may initially involve a smaller ventricular wall tear which becomes partially sealed by clot and pericardial adhesions. *Chronic* left ventricular free wall rupture is by definition a left ventricular pseudoaneurysm which results when pericardial adhesions are sufficient to prevent free rupture for 2 weeks or more. Chronic left ventricular pseudoaneurysms generally have a narrow neck, contain no myocardial cells in the wall, and have a high propensity to convert to an acute rupture. On rare occasion, left ventricular free wall rupture can present with simultaneous rupture of the interventricular septum, right ventricular rupture, or rupture of a papillary muscle head.<sup>72,73</sup> Risk factors associated with left ventricular pseudoaneurysm in 290 patients included older age, female gender, hypertension, and inferolateral myocardial infarction.<sup>74</sup> The most common location for left ventricular pseudoaneurysm in these 290 patients was posteroinferior, in contrast to true left ventricular aneurysms which are more common in the anterolateral region.<sup>74</sup>

The pathophysiology of left ventricular free wall rupture involves initial transmural myocardial infarction followed by expansion and thinning of the infarcted wall until the elastic strength of the free wall is exceeded by the forces generated by left ventricular systole.<sup>22,75</sup> Transmural myocardial infarction is, in turn, associated with lack of collateral blood flow.<sup>76</sup> This infarct expansion and thinning results from slippage between muscle bundles and tearing of the surrounding protein matrix. Ventricular rupture may be associated with systemic hypertension which can increase infarct thinning and wall stress.<sup>77</sup> Thrombolysis has not had any clear positive or negative effect on the incidence of left ventricular rupture,<sup>68,78,79</sup> although early coronary reperfusion is associated with less transmural infarction which in turn should prevent some infarctions from turning into rupture.

## Natural History

Acute left ventricular free wall rupture generally results in death within minutes of the onset of recurrent chest pain.<sup>67,80</sup> In an autopsy series, most patients dying from left ventricular free wall rupture died acutely.<sup>81-83</sup> Subacute rupture of the left ventricular free wall, in one series, was associated with a median survival time of 8 hours,<sup>81</sup> while another study showed that 69% of such patients died within minutes of the onset of symptoms.<sup>84</sup> Chronic rupture or pseudoaneurysm of the left ventricular free wall has a less well-defined prognosis. While rare patients may present with pseudoaneurysm of the

left ventricular free wall years after myocardial infarction,<sup>85</sup> postinfarction left ventricular pseudoaneurysm is clearly associated with a high probability of early rupture.<sup>83,86</sup>

## Clinical Presentation

The patient with acute or subacute rupture of the left ventricular free wall generally presents with recurrent chest pain followed by a rapid, severe hemodynamic instability due to development of cardiac tamponade and resultant low cardiac output, often followed ultimately by ventricular fibrillation and/or electromechanical dissociation. Clinically these phenomena may manifest as sudden death or syncope with physical findings of hypotension, distended neck veins, pulsus paradoxus, and cardiogenic shock from the underlying cardiac tamponade. Subacute left ventricular rupture may clinically resemble infarct extension or right ventricular failure.<sup>80</sup> Chronic left ventricular rupture or pseudoaneurysm presents most commonly with congestive heart failure.<sup>72,74</sup>

## Diagnosis

The primary means of diagnosing postinfarction left ventricular rupture is echocardiography. Echocardiography may show definitive evidence of a ventricular wall defect systolic and/or systolic blood flow outside the wall of the ventricle. Highly suggestive but less definitive echocardiographic findings associated with left ventricular rupture include the presence of pericardial effusion over 10 mm, echo-dense masses in a pericardial effusion, and signs of tamponade such as early diastolic collapse of the right atrium and right ventricle and increased respiratory variation in transvalvular blood flow velocities.<sup>81,87</sup> Aspiration of uncoagulated blood on pericardiocentesis can be suggestive of left ventricular rupture but has an incidence of false-positive and false-negative results. Aspiration of clear fluid on pericardiocentesis definitively excludes cardiac rupture.<sup>87</sup> Oliva<sup>64</sup> reported several factors associated with postinfarction left ventricular rupture in 70 consecutive patients. Some predictive value has been reported for the development of pericarditis, repetitive emesis, restlessness and agitation, recurrent or persistent ST segment elevation, and persistent T-wave changes after 48 to 72 hours.<sup>65</sup>

## Indications for Operation

Because most patients with acute or subacute rupture of the left ventricular free wall expire within minutes to hours of onset, the diagnosis or even a high suspicion of acute left ventricular free wall rupture is itself an indication for emergent operation. At present, no acute interventional procedure is reliable in treating this catastrophic event. Chronic pseudoaneurysm of the left ventricular free wall has a significant risk of rupture and should be treated surgically.<sup>73,88-91</sup> Alapati<sup>92</sup> reported that less than 0.1% of all myocardial infarctions resulted in left ventricular pseudoaneurysm but that death occurred in the 48% patients with chronic pseudoaneurysm of the left ventricular free wall with medical therapy.

## Preparation for Operation

Acute postinfarction rupture of the left ventricular wall requires a high index of suspicion and emergent surgery for survival.<sup>84</sup> One report suggested that emergent percutaneous intrapericardial injection of fibrin glue immediately after pericardiocentesis<sup>93,94</sup> may allow some patients to get to surgery. Subacute postinfarction rupture of the left ventricle similarly requires emergent surgery once the diagnosis is made without further delay for coronary angiography.<sup>68,72</sup> Volume resuscitation, inotropic support, intra-aortic balloon pump, and possibly pericardiocentesis may temporize the pericardial tamponade on the way to surgery.

## Operative Techniques

### ACUTE OR SUBACUTE FREE WALL RUPTURE

Patients being operated for postinfarction rupture of the left ventricular free wall are generally quite unstable with pericardial tamponade and recent transmural myocardial infarction. Much of the patient preparation in the operating room may be conducted while the patient is awake and minimally sedated to avoid hypotension. One should consider exposure of the femoral artery and femoral vein in the groin for rapid institution of cardiopulmonary bypass, even before median sternotomy.

Median sternotomy is the incision of choice with rapid institution of cardiopulmonary bypass, preferably from the femoral vessels. Opening the pericardium can quickly result in significant hemorrhage from the ventricular tear that may be difficult to control manually without further hemodynamic compromise until on cardiopulmonary bypass. Just a few minutes of inadequate brain perfusion can result in a poor neurologic outcome. In exceptional cases where there are no other indications for cardiopulmonary bypass such as posterior wall rupture, mitral regurgitation, ventricular septal rupture, or graftable coronary disease, good short-term results have been reported for repairing ventricular rupture without cardiopulmonary bypass<sup>80,88</sup> or without aortic clamping. Once on cardiopulmonary bypass, having an arrested heart with venting of the left ventricular cavity can facilitate obtaining a dry and motionless field for manipulation of friable tissue.

For repairing an acute or subacute for left ventricular free wall rupture, surgical techniques resemble those for left ventricular pseudoaneurysm repair, with the exception that the acutely or subacutely infarcted tissue is much more friable and has not had time to develop any fibrous content. Standard linear closure with large horizontal mattress sutures buttressed by two strips of Teflon felt has been reported but is limited by myocardial friability. Better results have been reported using linear closure between strips of Teflon felt, if the entire ventricular tear and surrounding infarct is covered with a plastic patch secured to the surrounding normal myocardium using a continuous polypropylene suture (Fig. 25-16).<sup>27</sup> A more radical approach would be to perform infarct excision and closure of the defect with either pledgeted sutures or a Dacron patch,<sup>95</sup> but this technique might

**FIGURE 25-16** Technique to repair rupture of the free wall of the left ventricle. (A) Left ventricular free wall rupture. (B) A limited infarctectomy is closed with horizontal mattress sutures buttressed with two strips of Teflon felt. (C) Then the whole area is covered with a Teflon patch sutured to healthy epicardium with a continuous polypropylene suture. Alternatively, the Teflon patch can be glued to the ventricular tear and the infarcted area using a biocompatible glue. (Reproduced with permission from Buxton BF, et al: *Ischemic Heart Disease Surgical Management*. Philadelphia, Mosby 1999.)

best be reserved for specific indications such as the presence of a postinfarction ventricular septal defect.

Frequent reports have described using one of many biological glues to attach a patch of either Teflon felt or bovine pericardium to the ventricular tear, with or without running a polypropylene suture around the edge of the patch secured to the surrounding normal myocardium.<sup>88</sup> This technique has the advantage of avoiding cardiopulmonary bypass but has been reported to have some risk of late pseudoaneurysm formation.<sup>96</sup>

## Results

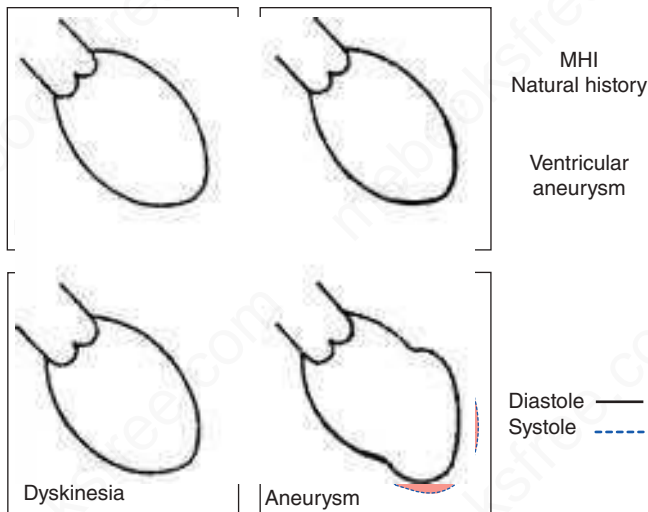

The literature only contains several small series of surgical repair of acute or subacute left ventricular free wall rupture. Padró<sup>88</sup> reported 13 survivors and a mean follow up of 26 months using a biological glue and Teflon patch technique, without cardiopulmonary bypass in most patients. Other series have reported an operative mortality around 50%.<sup>84,97,98</sup>

## LEFT VENTRICULAR ANEURYSM

### Definition

*Left ventricular aneurysm* has been strictly defined as a distinct area of abnormal left ventricular diastolic contour with systolic dyskinesia or paradoxical bulging (Fig. 25-17).<sup>99,100</sup> Yet, a growing number of authors favor defining left ventricular aneurysm more loosely as any large area of left ventricular akinesia or dyskinesia that reduces the left ventricular ejection fraction.<sup>101-103</sup> This broader definition has been justified by data suggesting that the pathophysiology and treatment may

**FIGURE 25-17** Diagrammatic distinction between aneurysm and other states of the left ventricle. (Reproduced with permission from Grondin P, Kretz JG, Bical O, et al: Natural history of sacular aneurysm of the left ventricle, *J Thorac Cardiovasc Surg.* 1979 Jan;77(1):57-64.)

be the same for ventricular akinesia and for ventricular dyskinesia.<sup>102,104</sup> However, recent studies suggest that the optimal treatment and outcomes of patients with akinetic segments versus dyskinetic segments might be different.<sup>105,106</sup> Intraoperatively, a left ventricular aneurysm may also be identified as an area that collapses upon left ventricular decompression.<sup>101,104,107</sup> True left ventricular aneurysms involve bulging of the full thickness of the left ventricular wall, whereas a false aneurysm of the left ventricle is, in fact, a rupture of the left ventricular wall contained by surrounding pericardium.

## History

Left ventricular aneurysms have long been described at autopsy, but left ventricular aneurysm was not recognized to be a consequence of coronary artery disease until 1881.<sup>108</sup> The angiographic diagnosis of left ventricular aneurysm was first made in 1951.<sup>108</sup> A congenital left ventricular aneurysm was first treated surgically by Weitland in 1912 using aneurysm ligation. In 1944, Beck<sup>109</sup> described fasciae latae plication to treat left ventricular aneurysms. Likoff and Bailey<sup>110</sup> successfully resected a left ventricular aneurysm through a thoracotomy in 1955 using a special clamp without cardiopulmonary bypass. The modern treatment era began in 1958 when Cooley et al<sup>111</sup> successfully performed a linear repair of a left ventricular aneurysm using cardiopulmonary bypass. More geometric ventricular reconstruction or surgical ventricular restoration (SVR) techniques were subsequently devised by Stoney et al,<sup>112</sup> Daggett et al,<sup>113</sup> Dor et al,<sup>36</sup> Jatene,<sup>114</sup> and Cooley et al.<sup>115,116</sup> In 2009, the results of the randomized STICH trial comparing coronary bypass grafting with or without surgical ventricular restoration were published, casting some doubt on the value of repairing small aneurysms or small akinetic segments.<sup>105</sup>

## Incidence

The incidence of left ventricular aneurysm in patients suffering from myocardial infarction has varied between 10 and 35%, depending on the definition and the methods used. Of patients undergoing cardiac catheterization in the CASS study, 7.6% had angiographic evidence of left ventricular aneurysms.<sup>117</sup> The absolute incidence of left ventricular aneurysms may be declining because of the increased use of thrombolytics and revascularization early after myocardial infarction.<sup>118,119</sup>

## Etiology

More than 95% of true left ventricular aneurysms reported in the English literature result from coronary artery disease and myocardial infarction. True left ventricular aneurysms also may result from trauma,<sup>120</sup> Chagas' disease,<sup>121</sup> or sarcoidosis.<sup>122</sup> A very small number of congenital left ventricular aneurysms also have been reported and have been termed *diverticula* of the left ventricle.<sup>123</sup>

False aneurysms of the left ventricle result most commonly from contained rupture of the ventricle 5 to 10 days after myocardial infarction and often occur after circumflex coronary arterial occlusion. False aneurysm of the left ventricle also may result from submitral rupture of the ventricular wall, a dramatic event that generally occurs after mitral valve replacement with resection of the mitral valve apparatus.<sup>124</sup> Left ventricular pseudoaneurysm may also result from septic pericarditis<sup>125</sup> or any prior operation on the left ventricle, aortic annulus, or mitral annulus. Pseudoaneurysm can occur after transapical or transfemoral transcatheter aortic valve replacement (TAVR).<sup>126</sup>

## Pathophysiology

The development of a true left ventricular aneurysm involves two principal phases: early expansion and late remodeling.

### EARLY EXPANSION PHASE

The early expansion phase begins with the onset of myocardial infarction. Ventriculography can demonstrate left ventricular aneurysm formation within 48 hours of infarction in 50% of patients who develop ventricular aneurysms. The remaining patients have evidence of aneurysm formation by 2 weeks after infarction.<sup>127</sup>

True aneurysm of the left ventricle generally follows transmural myocardial infarction because of acute occlusion of the left anterior descending or dominant right coronary artery.

Lack of angiographic collaterals is strongly associated with aneurysm formation in patients with acute myocardial infarction and left anterior descending artery occlusion,<sup>128</sup> and absence of re-formed collateral circulation is probably a prerequisite for formation of a dyskinetic left ventricular aneurysm (Table 25-2). At least 88% of dyskinetic ventricular aneurysms result from anterior infarction, and the remainder follow inferior infarction.<sup>108</sup> Posterior infarctions that

**TABLE 25-2: Factors Contributing to Left Ventricular Aneurysm Formation**

Transmural infarction
Lack of collateral circulation
Lack of reperfusion
Preserved contractility of surrounding myocardium
Elevated wall stress
Hypertension
Ventricular dilation
Wall thinning

produce a distinct dyskinetic left ventricular aneurysm are relatively unusual.<sup>129</sup>

In experimental transmural infarction without collateral circulation, myocyte death begins 19 minutes after coronary occlusion. Infarctions that result in dyskinetic aneurysm formation are almost always transmural and may show gross thinning of the infarct zone within hours of infarction. Within a few days, the endocardial surface of the developing aneurysm becomes smooth with loss of trabeculae and deposition of fibrin and thrombus on the endocardial surface in at least 50% of patients. Because most myocytes within the infarct are necrotic, viable myocytes often remain within the infarct zone. In a minority of patients, extravascular hemorrhage occurs in the infarcted tissue and may further depress systolic and diastolic function of involved myocardium. Inflammatory cells migrate into the infarct zone by 2 to 3 days after infarction and contribute to lysis of the necrotic myocytes by 5 to 10 days after infarction. Electron microscopy demonstrates disruption of the native collagen network several days after infarction. Collagen disruption and myocyte necrosis produce a nadir of myocardial tensile strength between 5 and 10 days after infarction, when rupture of the myocardial wall is most common. Left ventricular rupture is relatively rare after the ventricular aneurysmal wall becomes replaced with fibrous tissue.

Loss of systolic contraction in the large infarcted zone and preserved contraction of surrounding myocardium cause systolic bulging and thinning of the infarct. By Laplace's law ( $T = Pr/2h$ ), at a constant ventricular pressure (P), increased radius of curvature (r) and decreased wall thickness (h) in the infarcted zone both contribute to increased muscle fiber tension (T) and further stretch the infarcted ventricular wall.

Relative to normal myocardium, ischemically injured or infarcted myocardium displays greater *plasticity* or *creep*, defined as deformation or stretch over time under a constant load.<sup>130</sup> Thus increased systolic and diastolic wall stress in the infarcted zone tends to produce progressive stretch of the infarcted myocardium (termed *infarct expansion*)<sup>131</sup> until healing reduces the plasticity of infarcted myocardium.

Transmural infarction without significant hibernating myocardium within the infarct region is necessary for

subsequent development of a true left ventricular aneurysm. Angiographic ventricular aneurysms with evidence of hibernating myocardium (lack of Q waves or presence of uptake on technetium scan, Takotsubo cardiomyopathy, for example) may resolve over days to weeks and thus do not represent true left ventricular aneurysms by strict criteria.<sup>132,133</sup>

Because of increased diastolic stretch or preload and elevated catecholamines, remaining noninfarcted myocardium may demonstrate increased fiber shortening and, ultimately, myocardial hypertrophy in the presence of a left ventricular aneurysm.<sup>134</sup> This increased shortening and increased wall stress increase oxygen demand for noninfarcted myocardium and for the left ventricle as a whole.

In addition to increased regional wall stresses, left ventricular aneurysm can increase ventricular oxygen demand and decrease net forward cardiac output by producing a ventricular volume load because a portion of the stroke volume goes into the aneurysm instead of out of the aortic valve. Net mechanical efficiency of the left ventricle (external stroke work minus myocardial oxygen consumption) is decreased by reducing external stroke work (volume times pressure) and increasing myocardial oxygen consumption.

Left ventricular aneurysms can produce both systolic and diastolic ventricular dysfunction. Diastolic dysfunction results from increased stiffness of the distended and fibrotic aneurysmal wall, which impairs diastolic filling and increases left ventricular end-diastolic pressure.

#### LATE REMODELING PHASE

The remodeling phase of ventricular aneurysm formation begins 2 to 4 weeks after infarction when highly vascularized granulation tissue appears. This granulation tissue is subsequently replaced by fibrous tissue 6 to 8 weeks after infarction. As myocytes are lost, ventricular wall thickness decreases as the myocardium becomes largely replaced by fibrous tissue. In larger infarcts, the thin scar is often lined with mural thrombus.<sup>135</sup>

After acute myocardial infarction, animal studies show that ventricular load reduction with 8 weeks of nitrate therapy may reduce expected infarct thinning, decrease infarct stretch, and lessen hypertrophy of noninfarcted myocardium.<sup>136</sup> Interestingly, nitrate therapy for only 2 weeks after infarction does not prevent aneurysm formation. This observation emphasizes the importance of late remodeling from 2 to 8 weeks after infarction. Angiotensin converting-enzyme (ACE) inhibitors also reduce infarct expansion and subsequent development of ventricular aneurysm.<sup>137</sup> Because animal studies show that ACE inhibitors nonspecifically suppress ventricular hypertrophy, it is not clear whether suppression of the compensatory hypertrophy of surrounding myocardium is ultimately beneficial or harmful. Intravenous administration of atrial natriuretic factor for 4 weeks has improved ventricular function, dimensions, and fibrosis in rats.<sup>138</sup>

Lack of coronary reperfusion is probably a prerequisite for development of left ventricular aneurysm. In humans, reperfusion of the infarct vessel either spontaneously,<sup>132</sup> by thrombolysis,<sup>139</sup> or by angioplasty<sup>140</sup> has been associated with

a lower incidence of aneurysm formation. It is speculated that coronary reperfusion as late as 2 weeks after infarction prevents aneurysm formation by improving blood flow and fibroblast migration into the infarcted myocardium. The role of delayed infarct healing in aneurysm development is supported by observations that steroids after myocardial infarction may increase the likelihood of aneurysm formation.<sup>141</sup>

Arrhythmias such as ventricular tachycardia may occur at any time during the development of a ventricular aneurysm, and all these patients have the substrate for reentrant conduction pathways within the heterogeneous ventricular myocardium. These pathways tend to involve border zones surrounding the ventricular aneurysm (see Chapter 57).

## Natural History

The excellent prognosis of asymptomatic patients with dyskinetic ventricular aneurysms who were treated medically was demonstrated in a series of 40 patients followed for a mean of 5 years.<sup>100</sup> Of 18 initially asymptomatic patients, six developed class II symptoms and 12 remained asymptomatic. The 10-year survival was 90% for these patients but was only 46% at 10 years in patients who presented with symptoms (Fig. 25-18).<sup>100</sup>

Although an earlier autopsy series reported relatively poor survival in patients with medically managed left ventricular dyskinetic aneurysms (12% at 5 years), most recent studies report 5-year survival from 47 to 70%.<sup>100,117,142-144</sup> Causes of death include arrhythmia in 44%, heart failure in 33%, recurrent myocardial infarction in 11%, and noncardiac causes in 22%.<sup>100</sup> The natural history of patients with akinetic rather than dyskinetic left ventricular aneurysms is less well documented.<sup>105</sup>

Factors that influence survival with medically managed left ventricular dyskinetic aneurysm include age, heart failure score, extent of coronary disease, duration of angina, prior infarction, mitral regurgitation, ventricular arrhythmias, aneurysm size, function of residual ventricle, and left ventricular end-diastolic pressure.<sup>100,144</sup> Early development of

**FIGURE 25-18** Survival in medically treated patients with left ventricular aneurysm based on presence (group B) or absence (group A) of symptoms. (Data from Grondin P, Kretz JG, Bical O, et al: Natural history of saccular aneurysm of the left ventricle, *J Thorac Cardiovasc Surg.* 1979 Jan;77(1):57-64.)

aneurysm within 48 hours after infarction also diminishes survival.<sup>127</sup>

In general, the risk of thromboembolism is low for patients with aneurysms (0.35% per patient-year),<sup>142</sup> and long-term anticoagulation is not usually recommended. However, in the 50% of patients with mural thrombus visible by echocardiography after myocardial infarction, 19% develop thromboembolism over a mean follow-up of 24 months.<sup>145</sup> In these patients, anticoagulation and close echocardiographic follow-up may be indicated. Atrial fibrillation and large aneurysmal size are additional risk factors for thromboembolism.

The natural history of left ventricular pseudoaneurysm is not well documented. Frank rupture of chronic left ventricular pseudoaneurysms is less common than one might expect.<sup>89</sup> Rupture of left ventricular pseudoaneurysms may be most likely in the acute phase or in large-sized pseudoaneurysms.<sup>90</sup> Left ventricular pseudoaneurysms tend to behave similarly to true aneurysms in that they may present a volume load to the left ventricle or may be a source of embolization or endocarditis. Left ventricular pseudoaneurysms after prior cardiac surgery have also been reported to compress adjacent structures such as the pulmonary artery or esophagus.

## Clinical Presentation

Angina is the most frequent symptom in most series of operated patients with left ventricular aneurysm. Given that three-vessel coronary disease is present in 60% or more of these patients, the frequency of angina is not surprising.<sup>91</sup>

Dyspnea is the second most common symptom of ventricular aneurysm and often develops when 20% or more of the ventricular wall is infarcted. Dyspnea may occur from a combination of decreased systolic function and diastolic dysfunction.

Either atrial or ventricular arrhythmias may produce palpitations, syncope, or sudden death, or aggravate angina and dyspnea in up to one-third of patients.<sup>91</sup> Thromboembolism is unusual but may produce symptoms of stroke, myocardial infarction, or limb or visceral ischemia.

## Diagnosis

The electrocardiogram frequently demonstrates Q waves in the anterior leads along with persistent anterior ST-segment elevation (Fig. 25-19). The chest radiograph may show left ventricular enlargement and cardiomegaly (Fig. 25-20), but the chest radiograph is not usually specific for left ventricular aneurysm.

Left ventriculography is the gold standard for diagnosis of left ventricular aneurysm. The diagnosis is made by demonstrating a large, discrete area of dyskinesia (or akinesia), generally in the anteroseptal-apical walls. Occasionally, left ventriculography also may demonstrate mural thrombus. Quantitative definition of left ventricular aneurysms has been accomplished using a centerline analysis of left ventricular wall motion on left ventriculography in the 30° right anterior oblique view.<sup>5</sup> Hypocontractile segments contracting more than two standard

**FIGURE 25-19** Electrocardiogram showing persistent ST-segment elevation with pathologic Q waves in a 72-year-old man with left ventricular aneurysm.

deviations out of normal range have also been defined as aneurysmal (Fig. 25-21).<sup>92,102</sup> Outward motion is termed *dyskinetic*, and remaining aneurysmal segments are termed *akinetic*. The fraction of total left ventricular circumference that is aneurysmal can thus be computed as the value %A.<sup>103</sup>

Two-dimensional echocardiography is also a sensitive and specific means of diagnosing left ventricular aneurysm. Echocardiography can detect mural thrombus or mitral valve regurgitation, and echocardiography can often distinguish false aneurysm from true aneurysm by demonstrating a defect in the true ventricular wall.

Magnetic resonance imaging (MRI) is the most reliable means of assessing left ventricular volume in the presence of left ventricular aneurysm<sup>146,147</sup> (Fig. 25-22). Magnetic

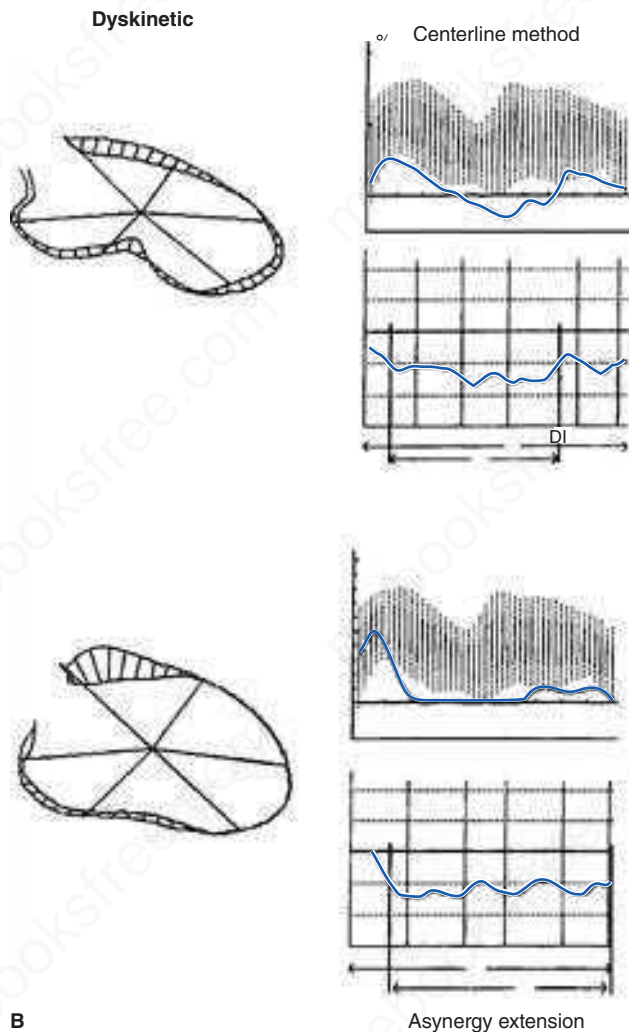

resonance imaging (MRI) can accurately define left ventricular aneurysms and can detect mural thrombus.<sup>146</sup> Yet, distinguishing true aneurysms from pseudoaneurysms remains difficult, even with magnetic resonance imaging.<sup>148</sup> Gated radionuclide angiography reliably detects left ventricular aneurysms, and thallium scanning or positron emission tomography (PET) can be helpful early after infarction to differentiate a true aneurysm from hibernating myocardium with reversible dysfunction.

### Indications for Operation

Because of the relatively good prognosis for asymptomatic left ventricular aneurysm,<sup>100</sup> no indications for repairing chronic,

**FIGURE 25-20** Posteroanterior and lateral chest radiograph in a patient with an anteroapical left ventricular aneurysm with calcification (arrows).

**FIGURE 25-21** Examples of preoperative centerline analysis in dyskinctic (A) and akinetic (B) LV aneurysms. Vertical lines indicate the extent of asynergy. AB, anterobasal; AL, anterolateral; AP, apical; DI, diaphragmatic; EF, ejection fraction; IB, inferobasal. (Reproduced with permission from Dor V, Sabatier M, DiDonato M: Efficacy of endoventricular patch plasty in large postinfarction akinetic scar and severe left ventricular dysfunction: comparison with a series of large dyskinctic scars, *J Thorac Cardiovasc Surg.* 1998 Jul;116(1):50-59.)

asymptomatic aneurysms are established. Yet, in low-risk patients during operation for associated coronary disease, investigators report repairing large, minimally symptomatic aneurysms.<sup>108,149</sup> On the other hand, operation is indicated for symptoms of angina, congestive heart failure, or selected ventricular arrhythmias (see Chapter 57) (Table 25-3). For these symptomatic patients, operation offers better outcome than medical therapy.

To be worthy of operation, a dyskinctic or akinetic left ventricular aneurysm should significantly enlarge left ventricular end-systolic volume index ( $>80$  mL/m<sup>2</sup>) and end-diastolic volume ( $>120$  mL/m<sup>2</sup>). These volume criteria are, however, poorly defined and limited by technical difficulty

in measuring left ventricular volume in aneurysmal left ventricles. Because of data suggesting that akinetic versus dyskinctic aneurysms have similar results, Dor and others feel that dyskinesia is not a prerequisite for aneurysm repair.<sup>102,103</sup> Nonetheless, the only randomized trial (the STICH trial) has suggested that little benefit is obtained in terms of survival or symptoms in patients who on average have smaller, akinetic aneurysmal segments (end-systolic volume index 82 mL/m<sup>2</sup> and 50 to 56% of anterior wall involved).<sup>105</sup>

Operation is indicated in viable patients with contained cardiac rupture, with or without development of a false aneurysm. Because left ventricular pseudoaneurysms may have a tendency to rupture when acute or of larger size (either with or without symptoms), operation is indicated.<sup>89-91</sup> Similarly, congenital aneurysms have a presumed risk of rupture and should undergo repair independently of symptoms. Rarely, embolism is an indication for operation in medically treated patients at high risk for repeated thromboembolism. The role of operation in asymptomatic patients with very large aneurysms or documented expansion of aneurysms is uncertain.

Relative contraindications to operation for left ventricular aneurysm include excessive anesthetic risk, impaired function of residual myocardium outside the aneurysm, resting cardiac index less than 2.0 L/min/m<sup>2</sup>, significant mitral regurgitation, evidence of nontransmural infarction (hibernating myocardium), and lack of a discrete, thin-walled aneurysm with distinct margins. Global ejection fraction may be less useful than ejection fraction of the basal, contractile portion of the heart in determining operability.<sup>150</sup>

Angioplasty has an uncertain role in the treatment of left ventricular aneurysms but may be indicated in patients with suitable coronary anatomy, one- or two-vessel disease, a contraindication for operation, or asymptomatic status with inducible ischemia.

## Preparation for Operation

All patients being considered for operation should undergo right- and left-sided heart catheterization with coronary arteriography and left ventriculography. Patients with at least 2+ mitral regurgitation at cardiac catheterization should have echocardiography to assess the mitral valve and to look for intrinsic mitral valve disease not amenable to annuloplasty. Magnetic resonance imaging can be helpful to assess left ventricular volumes and aid in planning the size and extent of left ventricular reconstruction.<sup>151</sup> Patients with significant thrombus in the left ventricular cavity should ideally be treated with 4-6 weeks of anticoagulation prior to operation to avoid the risk of embolism.

Preoperative electrophysiologic study is clearly indicated in any patient with preoperative ventricular tachycardia or ventricular fibrillation. The decision to perform an electrophysiologic study in patients without preoperative ventricular arrhythmias is controversial, because the incidence of postoperative ventricular arrhythmias is low and not changed by endocardial resection at the time of operation.<sup>108</sup> Electrophysiologic study is frequently not helpful in patients

**FIGURE 25-22** Magnetic resonance images of an apical left ventricular aneurysm during diastole (*left panel*) and systole (*right panel*).

with polymorphic ventricular tachycardia occurring within 6 weeks of myocardial infarction.<sup>108</sup>

## Operative Techniques

### GENERAL OPERATION

Operation for left ventricular aneurysm (aneurysmectomy, aneurysmorrhaphy, ventricular restoration) requires cardiopulmonary bypass and a balanced anesthetic technique, as generally used for coronary bypass grafting. After induction of anesthesia and endotracheal intubation, an electrocardiogram monitor, a Foley catheter, a radial arterial line, and a Swan-Ganz catheter are placed. A median sternotomy is performed, and the patient is given heparin. Saphenous vein or arterial conduits are prepared.

Cardiopulmonary bypass is begun after cannulating the ascending aorta. A single, two-stage cannula is generally adequate to cannulate the right atrium, but dual venous cannulation should be considered if the right ventricle is to be opened. Epicardial mapping is performed if necessary. The

left ventricle is inspected to identify an appropriate area of thinned ventricular wall. A linear vertical ventriculotomy, generally on the anterior wall 3 to 4 cm from the left anterior descending coronary artery, is made (Fig. 25-23). The left ventricle is opened (Fig. 25-24), all mural thrombus is carefully removed, and endocardial mapping is performed if necessary. A left ventricular vent is now placed through the right superior pulmonary vein-left atrial junction after mural thrombus is removed. Coronary arteries to be grafted are identified. Endocardial scar, if present, is resected, and afterwards, endocardial mapping is repeated. Body temperature is maintained at 37°C until intraoperative mapping is completed; thereafter, temperature is decreased to 28 to 32°C.

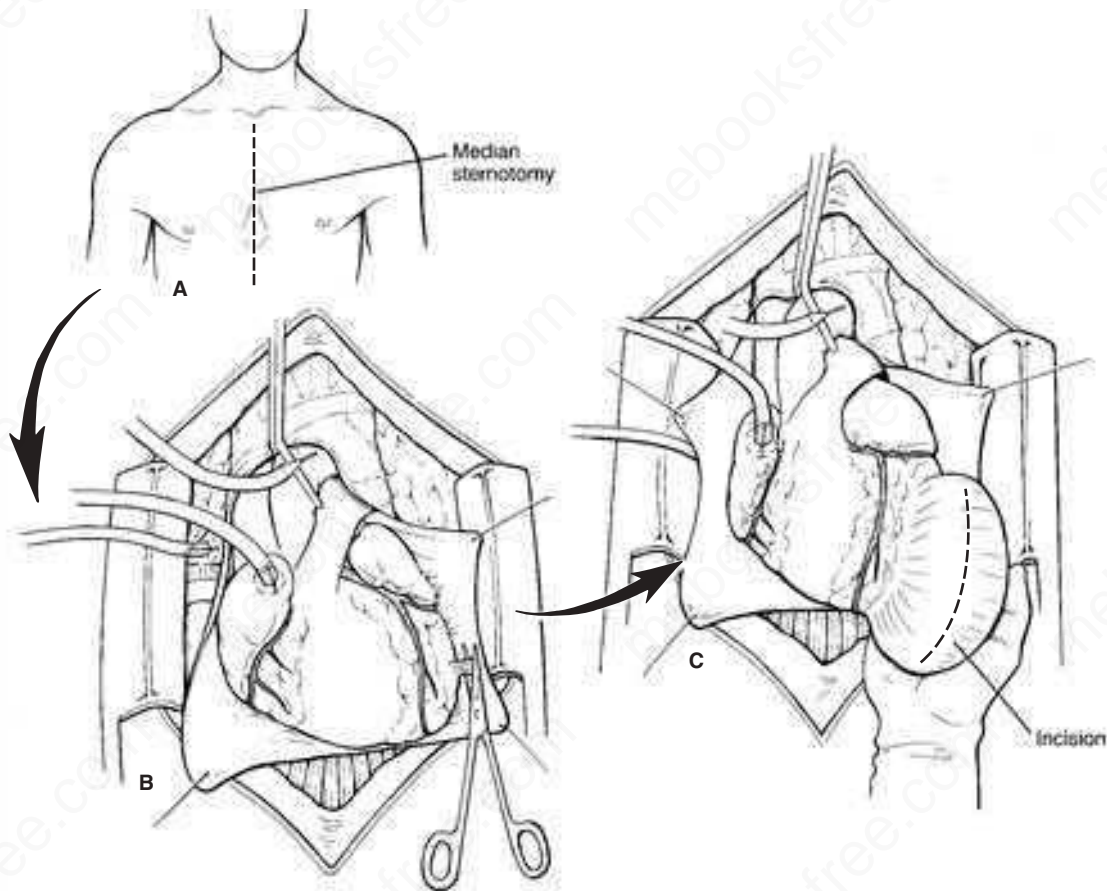

The ascending aorta is clamped, and the heart is arrested with cold antegrade and/or retrograde cardioplegic solution. Alternatively, the aorta is not clamped and the entire procedure is done during hypothermic fibrillation. The left ventricular aneurysm is repaired using one of the techniques described below. The distal coronary anastomoses are performed, followed by releasing the aortic clamp.<sup>151</sup> Air is removed by venting the ascending aorta and left ventricle while filling the heart and ventilating the lungs with the patient in the Trendelenburg position. The patient is rewarmed, and proximal coronary anastomoses are performed. Once normothermia is achieved, an electrophysiologic study may be repeated, if indicated. Temporary pacing wires are placed on the right atrium and right ventricle, cardiopulmonary bypass is discontinued, and heparin is reversed. The heart is decannulated, and the median sternotomy is closed with mediastinal drains after hemostasis is achieved.

Weaning from cardiopulmonary bypass frequently requires some degree of inotropic support. Typically 5 µg/kg/min of dopamine, nitroglycerin to prevent coronary spasm, and nitroprusside for afterload reduction are used. An intra-aortic balloon pump may be needed in patients with borderline ventricular function. Transesophageal echocardiography is

**FIGURE 25-23** Technique of exposure for left ventricular aneurysm repair through a median sternotomy. The ascending aorta and right atrium are cannulated. A left ventricular vent is placed through the right superior pulmonary vein. Pericardial adhesions are divided, and the aneurysm is opened.

**FIGURE 25-24** With the aneurysm wall opened, thrombus is removed, without injury to the papillary muscles.

useful for assessing left ventricular function and to detect residual intracardiac air.

Additional inotropic support may not increase cardiac output significantly because of abnormal ventricular compliance and may produce arrhythmias and poorly tolerated tachycardia. Hypokalemia and hypomagnesemia are corrected immediately to minimize arrhythmias. Intraoperative and postoperative ventricular ectopy is treated aggressively with intravenous lidocaine. Intravascular volume shifts are poorly tolerated in these patients because of poor ventricular compliance; therefore, rapid transfusions are avoided by meticulous hemostasis before closing. Because the left ventricle is poorly distensible, stroke volume is relatively fixed, and a resting heart rate between 90 and 115 beats per minute is not unusual to maintain a cardiac index of approximately 2.0 L/min/m<sup>2</sup>.

Growing experience suggests that the ultimate size of the left ventricular cavity at the end of the procedure is critical to patient outcome.

#### PLICATION

Plication without opening the aneurysm is reserved for only the smallest aneurysms that do not contain mural thrombus.

**FIGURE 25-25** Linear repair. The fibrous aneurysm wall is excised, leaving a 3-cm rim of fibrous aneurysm wall attached to healthy muscle.

A two-layer suture line of 0 monofilament is placed across the aneurysm using a strip of Teflon felt on either side. The suture line is oriented to reconstruct a relatively normal left ventricular contour and does not exclude all aneurysmal tissue.

#### LINEAR CLOSURE

After removing all mural thrombus, the aneurysmal wall is trimmed, leaving a 3-cm rim of scar to allow reconstruction of the normal left ventricular contour (Fig. 25-25). Care is taken not to resect too much aneurysmal wall and overly reduce ventricular cavity size. A monofilament 2-0 suture may be used to reduce the neck of the aneurysm to the proper size before closure of the ventricular wall.<sup>114</sup> Anterior aneurysm defects are closed vertically between two external 1.5-cm strips of Teflon felt, two layers of 0 monofilament horizontal mattress sutures, and finally, two layers of running 2-0 monofilament vertical sutures with large-diameter needles (Fig. 25-26). Similar techniques can be used in less frequent posterior aneurysm resections.<sup>152</sup>

#### CIRCULAR PATCH

Inferior or posterior aneurysms generally require circular patch closure, which also can be applied to anterior aneurysms. After opening the aneurysm (Fig. 25-27) and after debridement of thrombus and aneurysm wall (Fig. 25-28), a Dacron patch is cut to be 2 cm greater in diameter than the ventricular opening. Interrupted, pledgeted 0 monofilament horizontal mattress sutures are placed through the

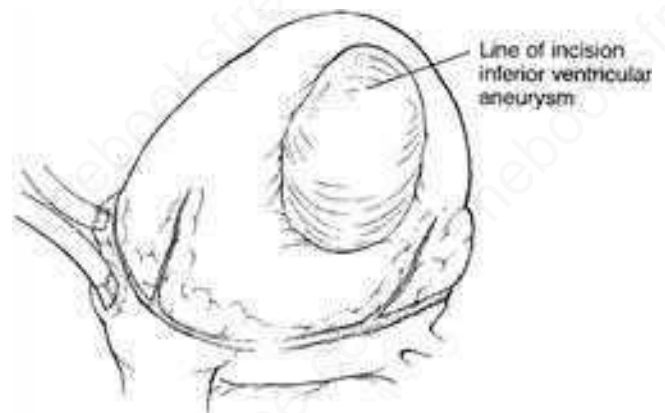

**FIGURE 25-26** Linear repair. The aneurysm walls are closed in a vertical line between two layers of Teflon felt. Two layers of 0 monofilament interrupted horizontal mattress sutures are reinforced with two layers of running 2-0 monofilament sutures.

ventriculotomy rim and then through the patch, leaving the pledgets outside the ventricular cavity (Fig. 25-29). Sutures are tied, and additional interrupted sutures or a second layer of running 2-0 monofilament is placed for hemostasis.

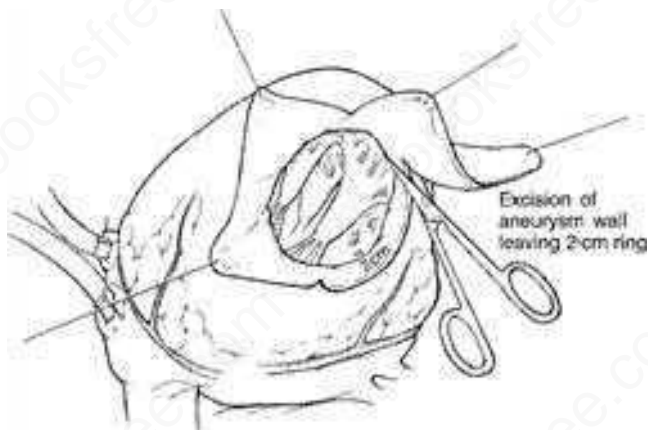

#### ENDOVENTRICULAR PATCH

The endoventricular patch technique is suitable for anterior aneurysms but is less suited for inferior or posterior aneurysms,

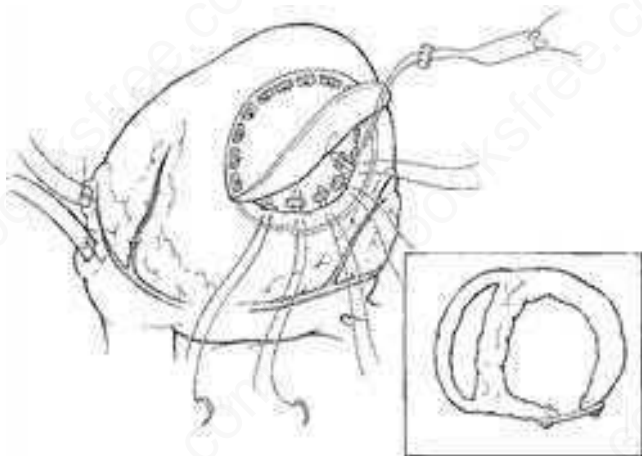

**FIGURE 25-27** Circular patch repair. The aneurysm wall is incised. An inferior aneurysm is shown.

**FIGURE 25-28** Circular patch repair. The aneurysmal wall is excised, leaving a 2-cm rim of fibrous aneurysmal wall attached to healthy muscle.

for which the standard (circular) patch technique is used. After debridement of thrombus, a running 2-0 polypropylene suture may be placed at the aneurysm rim to optimize left ventricular size.<sup>4,17,50,55</sup> Optimizing patch size and residual left ventricular cavity size can be facilitated with plastic or balloon forms (Chase Medical, Richardson, Texas) chosen to leave a left ventricular end-diastolic volume index of 50 to 60 mL/m.<sup>100,147,153</sup> If the remaining ventricular defect is small (<3 cm), then the ventricular wall may be closed linearly.<sup>114</sup> More commonly, a patch (bovine pericardium, Dacron cloth, or polytetrafluoroethylene) is cut to size sufficient to restore normal ventricular size and geometry when secured to the aneurysmal rim (Fig. 25-30). The patch is sutured to normal muscle at the aneurysmal circumference using a running 3-0 polypropylene suture that is secured with single sutures at three or four places around the patch circumference. The patch may extend onto the interventricular septum,<sup>92,102,150</sup> or aneurysmal septum may be plicated.<sup>114</sup> Interrupted 3-0

**FIGURE 25-29** Circular patch repair. The aneurysmal defect is closed with a Dacron patch using interrupted 2-0 monofilament horizontal mattress sutures with reinforcing pledgets.

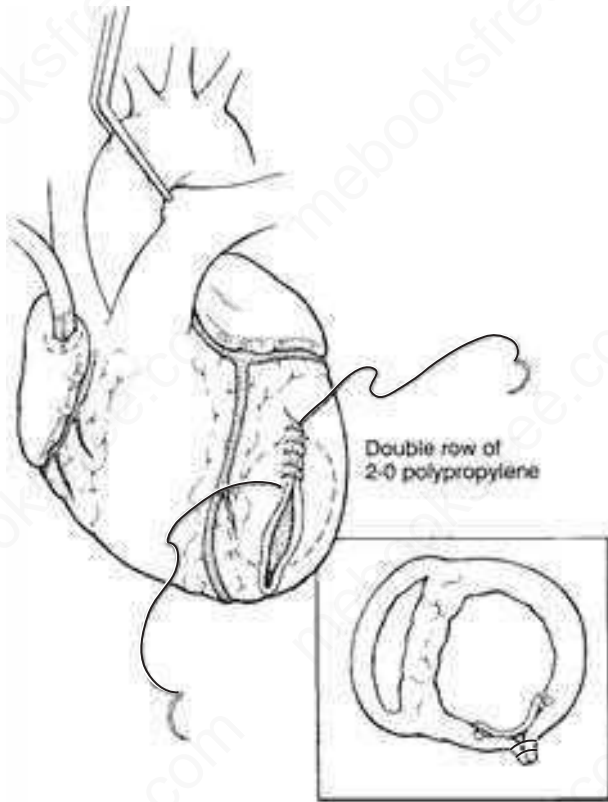

**FIGURE 25-30** Endocardial patch. Without excising the aneurysm wall, the ventricular defect is closed with a Teflon felt patch using 3-0 polypropylene suture secured at three or four points along the suture line. Additional 3-0 pledgeted horizontal mattress sutures may be used to achieve hemostasis.

sutures are placed as needed to ensure good fit. Care is taken not to distort the papillary muscles. The aneurysmal rim is trimmed to allow primary closure of the native aneurysmal wall over the patch using two layers of running 2-0 monofilament suture without pledgets (Fig. 25-31).

Compared with linear and circular patch techniques, the endoventricular patch technique has technical advantages. An endoventricular patch preserves the left anterior descending artery for possible grafting and leaves no external prosthetic material to produce heavy pericardial adhesions. The technique facilitates patching the interventricular septum, and is suitable for acute infarctions when tissues are friable.<sup>108,116,153,156</sup>

#### OTHER VENTRICULAR REMODELING TECHNIQUES

In addition to the techniques listed above where left ventricular infarct tissue is excised and/or replaced with patch material, an alternative would be to alter the biological properties of the infarct scar. Remaining infarct scar (whether aneurysmal or not) can then be seeded with myoblasts or stem cells which offer the potential to restore cardiac muscle mass and contraction. This technique has been termed *cellular cardiomyoplasty*

**FIGURE 25-31** Endocardial patch. The aneurysm wall is closed over a Teflon patch after resecting excess aneurysm tissue. A double row of running vertical 2-0 polypropylene suture is used.

and has been done only on a limited basis in humans.<sup>157</sup> In animals, cellular cardiomyoplasty has successfully improved global left ventricular performance and geometry using either myoblasts, stem cells that differentiate into myocytes, fibrocytes, or cells seeded onto a graft matrix.<sup>158-160</sup> Cellular cardiomyoplasty could be done by direct injection of cells at the time of coronary revascularization, or even by transcatheter or intramyocardial injection in the cardiac catheterization laboratory. Percutaneous insertion of parachute-like device into the left ventricular apex has had some early success in humans with improvement in left ventricular end-diastolic volumes and heart failure symptoms.<sup>161,162</sup>

### CORONARY REVASCULARIZATION

Concurrent coronary revascularization is performed as in standard coronary bypass procedures. Because the endoventricular patch technique does not encroach on the left anterior descending coronary, the left internal mammary artery may be used to graft the left anterior descending coronary artery.

### MITRAL REGURGITATION

The severity of mitral regurgitation should be evaluated before cardiopulmonary bypass by intraoperative transesophageal echocardiography. The need for concurrent mitral

**FIGURE 25-32** Prevalence of performing concomitant mitral valve procedures as a function of preoperative ejection fraction. (Reproduced with permission from Athanasuleas CL, Stanley AWH Jr, Buckberg GD, et al: Surgical anterior ventricular endocardial restoration [SAVER] in the dilated remodeled ventricle after anterior myocardial infarction, *J Am Coll Cardiol.* 2001 Apr;37(5):1199-1209.)

valve operation increases as the preoperative ejection fraction decreases (Fig. 25-32).<sup>163</sup> The mitral valve is also inspected from below after opening the aneurysm and beginning repair of the aneurysm. Transventricular mitral valve repair may be done by placing pledgeted polypropylene sutures at both mitral commissures to reduce the circumference of the annulus.<sup>152</sup> This technique produces satisfactory short-term results, but long-term results are not known. Usually the mitral valve is repaired via left atriotomy after completion of the distal coronary anastomoses and before releasing the aortic cross-clamp. If mitral regurgitation results from annular dilatation and systolic restriction of leaflet motion (Carpentier type IIIB), an undersized, complete, rigid mitral annuloplasty is generally done.<sup>164</sup>

### CARDIAC TRANSPLANTATION

In symptomatic patients with sufficient depression of global left ventricular function to preclude aneurysm repair, transplantation is a reasonable alternative and may have survival and symptomatic benefit similar to ventricular aneurysm repair at a higher dollar cost.<sup>165</sup>

### VENTRICULAR FALSE ANEURYSM

Ventricular free wall false aneurysms are repaired with the same techniques used for true ventricular aneurysms based according to the location and size of the aneurysm.<sup>72,73,80</sup> The circular patch technique is particularly useful in that inferior false aneurysms are common and typically have narrow necks. Usually the wall of the false aneurysm is inadequate to close over the defect. False aneurysms resulting from atrioventricular separation after mitral valve replacement generally require removal of the mitral prosthesis, repair of the neck of the aneurysm at the mitral annulus, and re-replacement of the mitral valve.<sup>70</sup> False aneurysms of the left ventricular

apex after transapical aortic valve replacement may be directly repaired small but may require patching if large.<sup>166</sup>

## Early Results

### HOSPITAL MORTALITY

In a compilation of 3439 operations for left ventricular aneurysm between 1972 and 1987<sup>118</sup> and in a series of 731 ventricular restoration patients from 2002 to 2004,<sup>167</sup> hospital mortality was 9.9 and 9.3%, respectively, and ranged from 2 to 19%. More recent reports suggest that hospital mortality can be as low as 3 to 7% using either patch<sup>108,116,163,168,169</sup> or linear closures.<sup>119,149,169</sup> The most common cause of hospital mortality is left ventricular failure, which occurs in 64% of deaths.<sup>149</sup>

Risk factors for hospital mortality include increased age,<sup>118,149,163,167,169</sup> incomplete revascularization,<sup>149</sup> increased heart failure class,<sup>118,167,169-171</sup> female gender,<sup>118,167</sup> emergent operation,<sup>118</sup> ejection fraction less than 20 to 30%,<sup>163,169,170</sup> concurrent mitral valve replacement,<sup>108,118,163,167</sup> preoperative cardiac index < 2.1 L/min/m<sup>100,103,167</sup> mean pulmonary artery pressure > 33 mm Hg,<sup>103</sup> serum creatinine > 1.8 mg/dl,<sup>103</sup> and failure to use the internal mammary artery.<sup>171</sup>

### IN-HOSPITAL COMPLICATIONS

The most common in-hospital complications are shown in Table 25-4 and include low cardiac output, ventricular arrhythmias, and respiratory failure.<sup>118,119,167-169,172</sup> Low cardiac output may be more common in patients undergoing intraoperative mapping because of perioperative cardiac injury.<sup>173</sup>

### LEFT VENTRICULAR FUNCTION

The preponderance of data from the last two decades have shown that left ventricular function improves in most patients undergoing operation for left ventricular aneurysm. Operation improves ejection fraction whether linear repair<sup>104,104,174-176</sup> or patch repair<sup>116,163,177-181</sup> is used (Fig. 25-33).<sup>176</sup> In a propensity matched series, little difference in outcome was seen between linear versus patch repair.<sup>182</sup> Both techniques decrease end-diastolic and end-systolic volumes<sup>163,175,178,180</sup> and improve exercise response<sup>116,176</sup> (Fig. 25-34).<sup>176</sup> Aneurysmal repair in general may improve diastolic filling, left ventricular diastolic compliance, left ventricular contractility, effective arterial

**FIGURE 25-33** Effects of linear aneurysmectomy on left ventricular end-diastolic volume (LVEDV), ejection fraction (EF), and wall tension. (Reproduced with permission from Kawachi K, Kitamura S, Kawata T, et al: Hemodynamic assessment during exercise after left ventricular aneurysmectomy, *J Thorac Cardiovasc Surg.* 1994 Jan;107(1):178-183.)

elastance (Ea), and left ventricular efficiency.<sup>134,179,180,183,184</sup> However, recent studies have suggested little improvement or even worsening of left ventricular diastolic compliance, particularly in patients with large resections or small ventricular size or without large dyskinetic aneurysms preoperatively.<sup>185</sup>

Controversy remains strong regarding whether patch techniques provide results superior to those achieved with linear closures. Stoney et al<sup>112,186</sup> noted lower left ventricular end-diastolic pressure when more geometric reconstructions were performed. Hutchins and Brawley<sup>187</sup> first

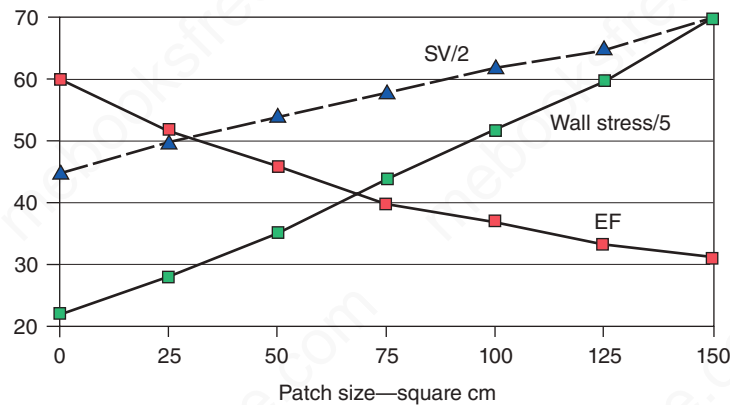

**FIGURE 25-34** Relationship between stroke work index and left ventricular end-diastolic pressure. Data are shown at rest and during exercise before (preop) and after (postop) linear aneurysmectomy. Stroke work index increased only with exercise postoperatively. (Reproduced with permission from Kawachi K, Kitamura S, Kawata T, et al: Hemodynamic assessment during exercise after left ventricular aneurysmectomy, *J Thorac Cardiovasc Surg.* 1994 Jan;107(1):178-183.)

**TABLE 25-4: In-Hospital Complications of Ventricular Aneurysm Repair**

Low cardiac output	22-39%
Ventricular arrhythmias	9-19%
Respiratory failure	4-21%
Bleeding	4-7%
Dialysis-dependent renal failure	4%
Stroke	3-4%

**FIGURE 25-35** Computer prediction of the effects of patch size on stroke volume (SV), ejection fraction (EF), and wall stress (afterload) at a chamber pressure of 100 mm Hg. Predictions are based on data from an animal model of simulated aneurysm repair, neglecting the effects of afterload on stroke volume. Because increasing afterload in reality decreases muscle shortening, patch reconstruction can increase stroke volume only if contractile reserve is sufficient to overcome the afterload from increased ventricular size. (Data from Nicolosi AC, Weng ZC, Detwiler PW, et al: Simulated left ventricular aneurysm and aneurysm repair in swine, *J Thorac Cardiovasc Surg.* 1990 Nov;100(5):745-755.)

noted at autopsy that some patients had severe reduction and distortion of ventricular volume after linear repair. The authors proposed that a more geometric repair might avert these problems. Although no prospective studies compare results from the two procedures, several very experienced groups attribute improved symptoms, less low cardiac output, and greater improvement in ejection fraction to a switch to patch techniques.<sup>108,116,188</sup> In other retrospective comparisons, no differences were seen in postoperative symptoms, ejection fraction, echocardiographic ventricular dimensions, or late survival between linear and patch repairs.<sup>175,188-191</sup> In an animal model of simulated aneurysm repair, Nicolosi et al<sup>185</sup> found no difference in left ventricular systolic or diastolic function between linear and patch techniques. Two groups reported that switch to patch techniques was associated with increased operative mortality, perhaps because of excessive volume reduction,<sup>192,193</sup> whereas other groups found improved survival when switching from linear to patch techniques.<sup>194</sup> One meta-analysis has suggested that the better results with patch techniques are the result of more experience in more recent series.<sup>188</sup>

The durability of functional benefit from aneurysm repair remains poorly documented. In animals and humans, there is a tendency for the initial improvement in ejection fraction, ventricular volume, and filling pressures to diminish over the next 6 weeks to 12 months,<sup>195,196</sup> especially in patients with residual mitral regurgitation.

Although technical differences exist between patch and linear repairs, good functional results are possible with either technique. Suboptimal outcomes result from either technique when left ventricular cavity volume is overly reduced with resultant decreased stroke volume and impaired diastolic filling.<sup>187</sup> Excessively small patches reduce stroke volume and impair diastolic filling, but excessively large patches reduce ejection fraction and increase wall stress (Fig. 25-35).<sup>185</sup>

## Late Results

### SURVIVAL

Survival after operation for left ventricular aneurysm is variable, largely because of differences between patient populations. Five-year survival in recent series varies between 58 and 80%,<sup>104,170</sup> 10-year overall survival is 34%,<sup>170</sup> and 10-year cardiac survival is 57%<sup>149</sup> (Fig. 25-36).<sup>105,170</sup> Cardiac causes are responsible for 57% of late deaths,<sup>173</sup> and most cardiac deaths result from new myocardial infarctions. In aneurysm patients randomized to medical or surgical therapy in the CASS study (most of the patients had minimal symptoms), survival was not different between medical or surgical therapy, except for patients with three-vessel disease.<sup>144</sup> These patients had better survival with surgery (Fig. 25-37).<sup>144</sup>

Preoperative risk factors for late death include age, heart failure score, ejection fraction less than 35%, cardiomegaly on chest radiograph, left ventricular end-diastolic pressure greater than 20 mm Hg, and mitral regurgitation<sup>144,149,163,173</sup> (Figs. 25-38, and 25-39).

The prospective, randomized STICH trial of 1000 patients with ejection fraction of 35% or less and anatomy amenable to ventricular restoration showed that, on average, left ventricular restoration techniques did not affect survival relative to coronary bypass grafting alone (Fig. 25-40).<sup>105</sup> However, post hoc analysis of STICH data showed that, in patients achieving postoperative left ventricular end-systolic volume index (LVESVI) of less than 70 mL/m<sup>2</sup>, the addition of SVR to coronary bypass improved survival, while the opposite was true for patients achieving LVESVI > 70 mL/m<sup>2</sup>.<sup>196</sup> The results of the STICH trial probably resulted from inclusion of relatively few patients with large, classical, dyskinetic aneurysms (mean reduction of end-systolic volume index of 16 mL/m<sup>2</sup> versus 48 mL/m<sup>2</sup> seen in classical aneurysms).<sup>105,106</sup> Although unproven, the net sum of evidence suggests that patients with large, classical, dyskinetic aneurysms who achieve a postoperative LVESVI

**FIGURE 25-39** Nomogram of 18-month survival after ventricular restoration as a function of patient age and postoperative ejection fraction. (Reproduced with permission from Athanasuleas CL, Stanley AWH Jr, Buckberg GD, et al: Surgical anterior ventricular endocardial restoration [SAVER] in the dilated remodeled ventricle after anterior myocardial infarction, *J Am Coll Cardiol*. 2001 Apr;37(5):1199-1209.)

**FIGURE 25-40** Preoperative (PRE) and latest follow-up (POST) symptoms of congestive heart failure (NYHA class) in patients undergoing coronary bypass alone (CABG) or CABG plus ventricular restoration (CABG/SVR) in the randomized STICH trial ( $p = 0.7$  CABG versus CABG/SVR) (Data from Jones RH, Velazquez EJ, Michler RE, et al: Coronary bypass surgery with or without surgical ventricular restoration, *N Engl J Med*. 2009 Apr 23;360(17):1705-1717.)

< 70 mL/m<sup>2</sup> probably obtain more benefit from aneurysm repair than do patients with diffuse ventricular dysfunction or small akinetic segments.<sup>106,197,198</sup>

### SYMPTOMATIC IMPROVEMENT

Studies consistently demonstrate improvement in symptoms after operation relative to preoperative symptoms<sup>104,105,174</sup> (Fig. 25-40). In the study of Elefteriades et al,<sup>174</sup> using a linear repair, mean angina class improved from 3.5 to 1.2 and mean CHF class improved from 3.0 to 1.7. In the randomized CASS study, the subset of patients with left ventricular aneurysm achieved a better heart failure class with surgical therapy than with medicine, and rehospitalization for heart failure was less common for the surgical therapy group than for the medicine group.<sup>144</sup> At 18 months, 85% of patients are free of rehospitalization for congestive heart failure, with rehospitalization peaking at 2 to 4 months.<sup>163</sup> Prucz found in a small, nonrandomized case-control study that ventricular restoration reduced hospitalization rate relative to coronary bypass alone.<sup>199</sup> However, the STICH trial found no benefit on average in symptoms or quality of life relative to coronary bypass alone.<sup>105,200</sup> (Fig 25-24) The STICH trial found that ventricular restoration significantly increased hospital cost by \$14,500 or 26%.<sup>200</sup>

# Pathophysiology of Aortic Valve Disease

Anna Brzezinski • Marijan Koprivanac • A. Marc Gillinov  
• Tomislav Mihaljevic

The aortic valve (AV) is a semilunar valve positioned at the end of the left ventricular outflow tract (LVOT) between the left ventricle and aorta. Proper functioning of this valve is critical in maintaining efficient cardiac function. This chapter explores the anatomical and physiologic properties of the AV.

## EMBRYOLOGIC DEVELOPMENT

Embryologic development of the AV is closely associated with development of the LVOT. In the primary heart tube, blood travels from the primitive ventricle into the bulbous cordis and out from the aortic roots. The midportion of the bulbous cordis, the conus cordis, develops into the outflow tracts of the ventricles. The distal portion of the bulbous cordis, the truncus arteriosus (TA), develops into the proximal portion of the aorta and pulmonary arteries. During the fifth week of development, pairs of opposing swellings appear in the conus cordis and TA (Fig. 26-1). These conotruncal, or bulbar, ridges grow toward each other and fuse to form the aorticopulmonary (AP) septum. The AP septum divides the conus cordis into the left and right ventricular outflow tracts and the TA into the ascending aorta and pulmonary trunk.

When partitioning of the TA is nearly completed, the AV begins to develop from three swellings of subendocardial tissue (see Fig. 26-1). Two swellings arising from the fused truncal ridges develop into the right and left AV leaflets. A third dorsal swelling develops into the posterior leaflet. These swellings are reshaped and hollowed out to form the three thin-walled cusps of the fully developed AV. The pulmonary valve develops in a similar manner.

## ANATOMY

The AV separates the terminal portion of the LVOT from the aorta. The normal AV consists of three semilunar leaflets or cusps projecting outward and upward into the lumen of the ascending aorta (Fig. 26-2). The space between the free edge of each leaflet and the points of attachment to the aorta

comprise the sinuses of Valsalva. Because the coronary arteries arise from two of the three sinuses, the sinuses and the respective leaflets are named the right coronary, left coronary, and posterior (noncoronary) sinuses and leaflets. The ostia of coronary arteries arise from the upper part of the sinuses, with the ostium of the left coronary artery positioned slightly higher than the ostium of the right. The leaflets are separated from one another at the aorta by the right-left, right-posterior, and left-posterior commissures (Fig. 26-3). The area adjacent to the left-posterior commissure is the fibrous continuity, which interconnects the aorta and the mitral valve annulus. The area beneath this commissure is the aortomitral curtain, which is an important anatomical landmark for root enlargement procedures. The posterior leaflet attaches above the posterior diverticulum of the LVOT and opposes the right atrial wall. The right-posterior commissure is positioned directly above the penetrating atrioventricular bundle and membranous septum. The right-left commissure opposes the posterior commissure of the pulmonary valve and the two associated aortic cusps oppose the right ventricular infundibulum. The lateral part of the left coronary sinus is the only part of the AV that is not closely related to another cardiac chamber and is in direct relationship with the free pericardial space.

The AV leaflets meet centrally along a line of coaptation, at the center of which are the thickened nodules of Arantius. Because of the semilunar shape of the leaflets, the AV does not have a true annulus in the traditional sense of a ring-like attachment. Instead, the leaflets have semilunar attachments along a hollow cylinder or cuff of tissue interconnecting the left ventricular (LV) chamber and the proximal aorta (Fig. 26-4).<sup>1</sup> The distal border of the cuff is the sinotubular junction, which is defined by imaginary lines connecting the commissures. The proximal border is the ventriculoarterial (VA) junction, which has both hemodynamic and anatomic parts. The hemodynamic VA junction is marked by the semilunar attachments of the leaflets, whereas the anatomic VA junction is marked by the circular attachment of the proximal aorta and the muscular and membranous ventricular septums.

**FIGURE 26-1** Schematic representation of development of the left and right ventricular outflow tracts and aortic and pulmonary valves. (*Top left*) Cross-section through the cordis showing the conotruncal ridges beginning to develop. (*Top right*) Aorticopulmonary septum forming from fusion of the conotruncal ridges and subendocardial swellings beginning to develop into the aortic and pulmonary valve leaflets. (*Bottom left*) Left and right ventricular outflow tracts separated by the aorticopulmonary septum and further development of the subendocardial swellings. (*Bottom right*) Aortic and pulmonary valves in the adult. (Reproduced with permission from Cleveland Clinic, Cleveland, OH.)

The valve leaflets consist of three layers of endothelially invested connective tissue of distinctly different density and composition. There is no demarcation between the outer layers of the aortic and ventricular sides of the leaflets and outer

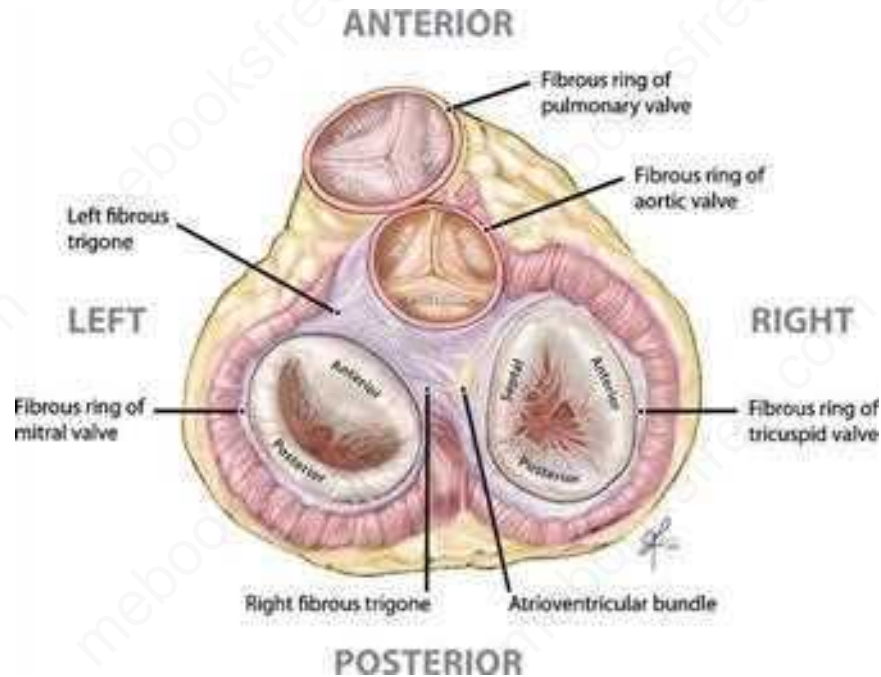

layers of the corresponding aortic and ventricular walls; that is, leaflet endothelial cells form a continuum with aortic and ventricular endothelial cells (Fig. 26-5).<sup>2,3</sup> Beneath the endothelium, there are extensions of the aortic intima and ventricular endocardium, termed the *arterialis* and *ventricularis*, respectively. The next layer is the lamina fibrosa, which is composed of dense collagen mostly in a circumferential pattern. Because of the thickness and density of this layer, it is the strongest layer and important for bearing the stress of diastolic pressure. The middle layer, referred to as the *spongiosa*, forms the core of the leaflets at their bases. It is made of loose connective tissue consisting of water and glycosaminoglycans with sparse fibers and cellularity. The semifluid nature of this layer gives the leaflet considerable plasticity.

**FIGURE 26-2** Anatomical relationship between the aortic valve leaflets and surrounding structures. (Reproduced with permission from Cleveland Clinic, Cleveland, OH.)

## MECHANICS OF MOVEMENT

The AV passively opens and closes in response to pressure differences between the left ventricle and aorta during the cardiac cycle. Pressure generated from ventricular contraction leads to valve opening, and the subsequent relatively higher pressure of the aorta leads to valve closure. The mechanical properties of the AV allow it to open with minimal transvalvular gradient and close completely with minimal flow reversal.

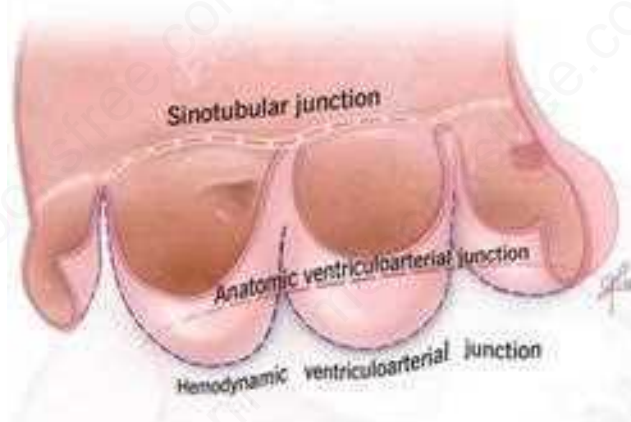

**FIGURE 26-3** Anatomical relationship between the aortic valve and surrounding structures. (Reproduced with permission from Cleveland Clinic, Cleveland, OH.)

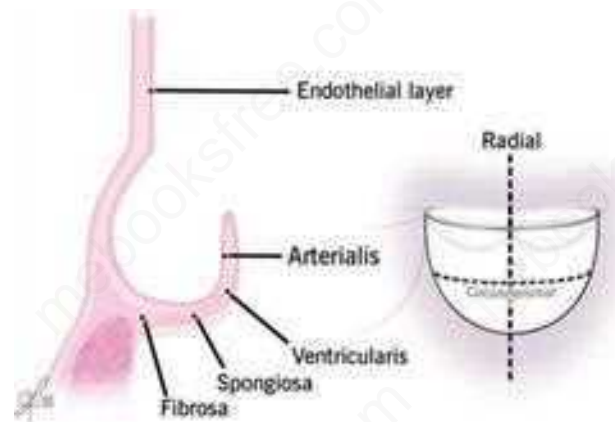

## Opening

Pressure differences between the aorta and the ventricle coupled with compliance of the aortic root cause aortic root dilation and constriction during the cardiac cycle. This dynamic motion of the root plays an important role in opening and closing of the AV. During late diastole, as blood fills the ventricle, a 12% expansion of the aortic root occurs 20 to 40 ms before AV opening.<sup>4</sup> The leaflets begin to open as a result of root dilation even before any generation of positive pressure from ventricular contraction. Root dilation alone opens the

leaflets about 20%.<sup>5</sup> As pressure rises in the LVOT, tension across the leaflets produced from root dilation lessens. As pressure continues to rise, the pressure difference across the leaflets is minimal, and no tension is present within the leaflet.<sup>6</sup> This loss of tension allows the aortic root to further dilate and allows the valve to open rapidly at the beginning of ejection. Under normal circumstances, the AV presents little or no obstruction to flow because the specific gravity of the leaflets is equal to that of blood.<sup>7</sup> These mechanisms permit rapid opening of the valve and minimal resistance to ejection.<sup>8</sup>

**FIGURE 26-4** Schematic representation of the aortic valve cuff. The sinotubular junction marks the distal border. The ventriculoarterial junction, which has both hemodynamic and anatomic parts, marks the proximal border. (Reproduced with permission from Cleveland Clinic, Cleveland, OH.)

**FIGURE 26-5** Schematic representation of a cross-section through the aortic valve leaflet showing the continuity of endocardial and endothelial components with the aortic valve. Inset illustrates the radial and circumferential axes of the valve leaflet. (Reproduced with permission from Cleveland Clinic, Cleveland, OH.)

## Closure

Closure of the AV is an elegant mechanism, which has interested investigators since the time of Leonardo da Vinci.<sup>9</sup> A principal theory involved in closure is vortex theory, which recognizes the importance of the sinuses of Valsalva in valve closure.<sup>10</sup> As ejection occurs, blood creates small eddy currents or vortices along the aortic wall. At the end of ejection and before valve closure, these vortices fill the sinuses and balloon the leaflets away from the aortic wall toward the aortic axis. After the pressure difference across the open AV equalizes, a small flow reversal forces the leaflets completely closed. Apposition of the valve leaflets occurs briskly and the ensuing second heart sound occurs after complete closure of the AV. Upon closing, the elastic leaflets stretch and recoil to generate compression and expansion of blood. The subsequent pressure changes produce the second heart sound; the sound is not produced by physical apposition of the valve leaflets.<sup>11</sup>

## AORTIC STENOSIS

Aortic stenosis (AS) is incomplete opening of the AV, which restricts blood flow out of the left ventricle during systole.

### Prevalence and Etiology

In developed countries, AS is the most prevalent valvular heart disease in adults.<sup>12</sup> Observational echocardiography studies demonstrate that 2% of people 65 years of age or older have isolated calcific AS, whereas 29% exhibit age-related AV sclerosis without stenosis.<sup>13</sup> AS is more common in men and its prevalence increases with age.<sup>14</sup> In patients aged 65 to 75 years, 75 to 85 years, and greater than 85 years, the prevalence of AS is 1.3, 2.4, and 4%, respectively.<sup>15</sup> The most common causes of AS are acquired degenerative disease, bicuspid AV, and rheumatic heart disease.

### Acquired Aortic Stenosis

The most common cause of AS is degenerative calcification of the AV, which typically occurs in septuagenarians and octogenarians. Progressive calcification, initially along the flexion lines at the leaflet bases, leads to immobilization of the cusps. The characteristic pathologic findings are discrete, focal lesions on the aortic side of the leaflets that can extend deep into the aortic annulus. The deposits may involve the sinuses of Valsalva and the ascending aorta. Although long considered to be the result of years of mechanical stress on an otherwise normal valve, it is now understood that the mechanical stress leads to proliferative and inflammatory changes, with lipid accumulation, upregulation of angiotensin-converting enzyme (ACE) activity, and infiltration of macrophages and T lymphocytes in a process similar to atherosclerosis.<sup>16-20</sup> The risk factors for the development of calcific AS are similar to those for atherosclerosis and include elevated serum levels of low-density lipoprotein (LDL) cholesterol, diabetes,

smoking, and hypertension.<sup>15</sup> Therefore, coronary artery disease is commonly present in patients with AS. Age-related AV sclerosis is associated with an increased risk of cardiovascular death and myocardial infarction (MI).

Calcific AS is also observed in a number of other conditions, including Paget's disease of bone and end-stage renal disease.<sup>21</sup> Ochronosis with alkaptonuria is another rare cause of AS, which also can cause a rare greenish discoloration of the AV.<sup>22</sup>

### Bicuspid Aortic Stenosis

A calcified bicuspid AV represents the most common form of congenital AS. Bicuspid AVs are present in approximately 2% of the general population. Gradual calcification of the bicuspid AV results in significant stenosis most often in the fifth and sixth decades of life, earlier in unicommissural than bicuspid valves and earlier in men than women.<sup>23,24</sup> The abnormal architecture of the unicommissural or bicuspid AV induces turbulent flow, which injures the leaflets and leads to fibrosis, increased rigidity, leaflet calcification, and narrowing of the AV orifice.<sup>25</sup> Several genes have been associated with bicuspid AV. Mutations in the signaling and transcriptional regulator *NOTCH1* result in abnormal valve development and subsequent calcium deposition, providing a link between genetic mutations, valve morphology, and subsequent calcification associated with bicuspid AS.<sup>26-29</sup> Structural abnormalities in microfibrils within the AV and aortic root lead to decreased structural integrity, resulting in dilation, aneurysms, and dissection.<sup>25,26,30</sup>

### Rheumatic Aortic Stenosis

In Western countries, rheumatic AS represents the least common form of AS in adults.<sup>31,32</sup> Rheumatic AS is rarely an isolated disease and usually occurs in conjunction with mitral valve stenosis.<sup>33,34</sup> Rheumatic AS is characterized by diffuse fibrous leaflet thickening with fusion, to a variable extent, of one or more commissures. The progression of rheumatic AS is slower than that of degenerative calcific disease.<sup>24,35</sup> The early stage of rheumatic AS is characterized by edema, lymphocytic infiltration, and revascularization of the leaflets, whereas the later stages are characterized by thickening, commissural fusion, and scarred leaflet edges.

### Pathophysiology

In adults with calcific disease, the AV slowly thickens over time. Early, it causes little hemodynamic disturbance as the valve area is reduced from the normal 3 to 4 cm<sup>2</sup> to 1.5 to 2 cm<sup>2</sup>.<sup>24,35</sup> Past this point, hemodynamically significant obstruction of LV outflow develops with a concomitant increase in LV pressure and lengthening of LV ejection time. The elevated LV pressure increases wall stress, which is normalized by increased wall thickness and LV hypertrophy (LVH). As it hypertrophies, the left ventricle becomes less

compliant and LV end-diastolic pressure (LVEDP) increases without chamber dilatation. This reflects diastolic dysfunction and the ventricle becomes increasingly dependent on atrial systole for filling.<sup>36</sup> Hence, if a patient develops an atrial arrhythmia, he or she can rapidly decompensate.

Although adaptive, the concentric hypertrophy that develops has adverse consequences. LVH, increased systolic pressure, and prolonged ejection time all contribute to an increase in myocardial oxygen consumption. Increased diastolic pressure increases endocardial compression of the coronary arteries, reducing coronary flow reserve (or maximal coronary flow).<sup>37</sup> Prolonged ejection also results in decreased time in diastole and therefore reduced myocardial perfusion time. The increased demand of the hypertrophied ventricle and decreased delivery capacity can yield subendocardial ischemia with activity. This can result in angina and LV dysfunction. LVH also makes the heart more susceptible to ischemic injury. Severe LVH is only partly reversed by AV replacement (AVR) and is associated with decreased long-term survival even after initially successful surgery.<sup>38</sup>

In late stages of severe AS, the left ventricle decompensates with resulting dilated cardiomyopathy and heart failure. Cardiac output (CO) declines and the pulmonary artery pressure rises, leading to pulmonary hypertension.

Myocardial hypertrophy in patients with AS is characterized by increased gene expression for collagen I and II, and fibronectin that is associated with activation of the renin-angiotensin system.<sup>39</sup> Reduction in renin-angiotensin parallels regression of hypertrophy after AVR.<sup>40</sup> Experimental studies have indicated a role of apoptotic mechanisms in the progression to LVH and heart failure in patients with AS.<sup>41,42</sup> Patients who present with symptoms of congestive heart failure (CHF) have a 1-year survival of approximately 60%.<sup>43,44</sup>

## Hemodynamics

The severity of AS can be assessed by measuring the AV orifice area (AVA), mean pressure gradient, and peak jet velocity. Effective AVA is calculated using the cross-sectional area of the LVOT ( $CSA_{LVOT}$ ), flow velocity through the LVOT ( $VTI_{LVOT}$ ), and AS jet velocity ( $VTI_{AV}$ ) using the continuity equation, which is based on the concept that stroke volume through the LVOT and AV are equal.<sup>45-49</sup> The continuity equation is

$$AVA = \frac{CSA_{LVOT} \times VTI_{LVOT}}{VTI_{AV}}$$

$CSA_{LVOT}$  is calculated using LVOT diameter ( $D_{LVOT}$ ) as

$$CSA_{LVOT} = \pi \left( \frac{D_{LVOT}}{2} \right)^2$$

Valve areas of less than 1.0 cm<sup>2</sup> represent severe AS. Although the effective AVA is smaller than the anatomic AVA, it is a reliable predictor of clinical outcomes and is generally used in clinical decision making.<sup>47,50</sup>

The Gorlin formula, which describes the fundamental relationships linking the area of an orifice to the flow and pressure drop across the orifice, is used to calculate anatomic AVA using a Fick or thermodilution CO measurement taken during catheterization.<sup>49,51</sup> The Gorlin formula uses the time from AV opening to closure (SEP) as

$$AVA = \frac{CO \left( \frac{mL}{min} \right)}{44.3 \times HR \left( \frac{beats}{min} \right) \times SEP(sec) \times \sqrt{\text{mean pressure gradient (mm Hg)}}$$

The Gorlin formula can also be used to calculate AVA from Doppler but is less favorable than the continuity equation as it underestimates the AVA in low-output states.<sup>52,53</sup>

In patients with AS, the transvalvular pressure gradient can be measured by simultaneous catheter pressure measurements in the left ventricle and proximal aorta. The peak-to-peak gradient, measured as the difference between peak LV pressure and peak aortic pressure, is used commonly to quantify the valve gradient.

Invasive measurements of AS severity have been largely replaced by echocardiographic measurements, which are currently the clinical standard.<sup>47,49</sup> The gradient can be calculated from the Doppler acquired  $VTI_{AV}$  using the Bernoulli equation as

$$\text{Gradient} = \pi VTI_{AV}^2$$

Transesophageal echocardiography (TEE) is an alternative method for assessment of AVA that uses planimetry of the systolic short-axis view of the AV (Fig. 26-6).<sup>54</sup> Planimetry of the valve area is challenging because the valve orifice is a complex, three-dimensional shape, and area measurements assume the valve orifice lies entirely within the image plane.

**FIGURE 26-6** Transesophageal echocardiographic image of aortic stenosis resulting from severe degenerative calcification. Transverse section of the aortic root at the level of the aortic valve orifice showing the aortic ring (arrow), the sinuses of Valsalva (asterisks), and a significantly reduced aortic valve orifice area of 0.44 cm<sup>2</sup> (dotted line).

Thus, it is only recommended when Doppler estimation of flow velocities is unreliable.<sup>47</sup>

## Clinical Presentation

### SYMPTOMS

The cardinal symptoms of AS are angina pectoris, syncope, and symptoms of CHF (dyspnea, orthopnea, and paroxysmal nocturnal dyspnea).<sup>55</sup> Although the mechanisms of angina and heart failure are well understood, the mechanism of syncope is less clear. A common theory is that the augmented stroke volume that usually accompanies exercise is limited by the narrowed outflow orifice. With exercise-induced reduction in peripheral arterial resistance, blood pressure drops, leading to cerebral hypoperfusion and syncope.<sup>56</sup> Syncope also may be the result of dysfunction of baroreceptor mechanisms and a vasodepressor response to the increased LV systolic pressure during exercise. Besides these cardinal symptoms, patients also commonly present with more subtle symptoms, such as fatigue, decreased exercise tolerance, and dyspnea on exertion.<sup>57</sup>

A rare presentation of AS is gastrointestinal bleeding secondary to angiodysplasia occurring predominantly in the right colon, as well as in the small bowel or stomach. This complication arises from shear-stress-induced platelet aggregation with reduction in high-molecular-weight multimers of von Willebrand factor and increases in proteolytic subunit fragments. These abnormalities correlate with the severity of AS and are correctable by AVR.<sup>58</sup> Other late manifestations of severe AS include atrial fibrillation and pulmonary hypertension. Infective endocarditis can occur in younger patients with AS; it is less common in elderly patients with a severely calcified valve.

Patients who develop severe AS have a long period of asymptomatic progression in which morbidity and mortality is relatively low (Fig. 26-7).<sup>55</sup> Sudden death from AS before the onset of symptoms is estimated to be approximately 1% per year.<sup>59</sup> With the onset of symptoms, the mortality rate is 25% per year without surgical intervention.<sup>12</sup> Of the 35% of

patients who present with angina, 50% survive for 5 years. Of the 15% who present with syncope, 50% survive for 3 years, and mean survival for those who present with CHF is 2 years.<sup>55</sup>

### SIGNS

AS is frequently first diagnosed before symptom onset by auscultation of a murmur on physical examination. Classically, AS causes a systolic crescendo-decrescendo murmur, heard loudest at the right upper sternal border. Another sign of AS is a delayed second heart sound ( $S_2$ ) because of prolongation of the systolic ejection time.  $S_2$  also may be single when the aortic component is absent, and if the aortic component is audible, this may give rise to a paradoxical splitting of  $S_2$ .

The classic pulsus parvus (small pulse) is a sign of severe AS or decompensated AS and occurs when stroke volume and systolic and pulse pressures fall. A wide pulse pressure is also characteristic of AS. Prolongation of the ejection phase with slow rise in the arterial pressure also gives rise to the pulsus tardus (late pulse). Pulsus parvus et tardus is diagnosed by palpation.

LVH is evident as a sustained apical thrust or heave. This sign is present only when failure occurs because before failure occurs, the hypertrophy is not accompanied by dilatation, and the apical impulse is not displaced. Conversely, absence of an apical thrust (except in muscular patients, or those with emphysema or adiposity) suggests mild or moderate AS. Other physical findings of significant AS include a prominent atrial kick and prominence of the jugular venous *a* wave secondary to decreased right ventricular compliance caused by right ventricular hypertrophy.<sup>60</sup>

### ELECTROCARDIOGRAM

Most patients with severe AS present with QRS complex or ST-T interval abnormalities reflecting LVH. Patients with a higher gradient are more likely to show a “strain” or “systolic overload” pattern. The conduction abnormalities may result from septal trauma secondary to high intramyocardial tension from hypoxic damage to the conducting fibers or from extension of valvular calcifications into the fibrous septum.

### ROENTGENOGRAM

The roentgenographic characteristics of compensated AS include concentric hypertrophy of the left ventricle without cardiomegaly, poststenotic dilatation of the aorta, and calcification of the valve cusps. With decompensation, there is cardiomegaly in the posteroanterior projection and pulmonary venous congestion. It is important to recognize that a routine chest x-ray may be within normal limits in patients with hemodynamically compensated AS. The rounding of the lower-left heart border may be subtle, the poststenotic aortic dilatation may be equivocal, and the valvular calcification may be invisible on the posteroanterior view. Of equal importance, the presence of cardiomegaly in a normotensive patient with isolated AS indicates decompensated AS.

**FIGURE 26-7** Natural history of aortic stenosis. (Reproduced with permission from Ross J, Braunwald E. Aortic stenosis, *Circulation*. 1968 Jul;38(1 Suppl):61-67.)

## ECHOCARDIOGRAPHY

Echocardiography is the diagnostic tool of choice for confirming the diagnosis of AS and quantification of disease severity. Echocardiography is used to define: (1) the severity and etiology of AS; (2) coexisting valvular abnormalities; and (3) cardiac chamber size and function.

The development of diastolic dysfunction in patients with AS can lead to symptom development, and may increase late mortality after AVR.<sup>38,61</sup> Hence, the quantification of diastolic dysfunction is important in the assessment of AS. LV filling pressures can be assessed by calculating the ratio of transmitral flow velocity and annular velocity obtained at the level of the mitral annulus with tissue Doppler.<sup>62-64</sup> In patients with normal LV function (LVF), stress echocardiography is used to determine if symptom development during exercise is due to diastolic dysfunction.<sup>65</sup> Diastolic dysfunction in patients with normal LVF may cause exercise intolerance for several reasons: (1) elevated LV diastolic and pulmonary venous pressures increase the work of breathing and cause dyspnea; (2) patients with LVH exhibit a limited ability to use the Frank-Starling mechanism during exercise, resulting in a decrease in CO during exercise; and (3) elevated LV diastolic and pulmonary venous pressures result in abnormalities in the diastolic properties of the ventricle.

When AS is suspected, an initial Doppler echocardiogram can confirm the diagnosis and assess the severity. Re-examination should be performed upon change in signs or symptoms, or periodically, every 3 to 5 years for mild AS, every 1 to 2 years for moderate AS, and every 6 months to 1 year for severe AS, to identify worsening stenosis, LV dysfunction, LVH, and mitral regurgitation. Although AS is best understood as a disease continuum, severity can be graded by echocardiographic evaluation of hemodynamics. The current guidelines use definitions based on the AVA, mean pressure gradient, and peak jet velocity (Table 26-1).<sup>49</sup>

**TABLE 26-1: Classification of Aortic Stenosis Severity**

Indicator	Mild	Moderate	Severe
Aortic valve area (cm <sup>2</sup> )	>1.5	1.0-1.5	<1.0
Aortic valve area index (cm <sup>2</sup> per m <sup>2</sup> )			<0.6
Mean pressure gradient (mm Hg)	<25	25-40	>40
Peak jet velocity (m/sec)	<3.0	3.0-4.0	>4.0

Data compiled from Bonow RO, Carabello BA, Chatterjee K, de Leon AC Jr, Faxon DP, et al: 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to revise the 1998 guidelines for the management of patients with valvular heart disease). ## EXERCISE TESTING

Exercise testing should be avoided in symptomatic patients with AS. Traditionally, severe AS has been regarded as a relative contraindication to exercise testing. Recent studies have indicated that quantitative exercise Doppler echocardiography can be performed safely in asymptomatic patients, including those with severe AS, and may be useful for identifying patients who at higher risk of becoming symptomatic and/or requiring AVR. Asymptomatic patients with severe AS who become symptomatic on exercise stress testing have a higher rate of cardiac death or progression to AVR.<sup>49,66,67</sup> Thus, patients with provoked symptoms should be considered symptomatic. Dobutamine stress echocardiography is occasionally used in severe AS, specifically to assess contractile reserve in patients with moderate to severe AS with a low AV gradient and depressed LVF.<sup>68,69</sup>

## CARDIAC CATHETERIZATION

Although Doppler echocardiography can provide adequate anatomic and hemodynamic information for most patients, cardiac catheterization is recommended when noninvasive tests are inconclusive or there is a discrepancy between noninvasive tests and clinical findings to determine the severity of AS.<sup>49,70</sup> Cardiac catheterization remains the gold standard for measuring the transvalvular gradient. Left-sided heart catheterization is also used to calculate the AVA based on the Gorlin equation, as described earlier, and can provide an assessment of ejection fraction (EF) through ventriculography and information about the presence or absence of other valve lesions. Coronary artery disease is common in patients with AS and should be evaluated prior to intervention. Cardiac catheterization is indicated in patients with angina, evidence of ischemia, history of CAD, or coronary risk factors to assess coronary anatomy and evaluate the need for combined AVR and myocardial revascularization. Cardiac catheterization should also be performed in patients with epicardial CAD detected by computed tomography (CT) coronary angiography to evaluate the extent of obstruction.<sup>49</sup>

## COMPUTED TOMOGRAPHY

CT is the only noninvasive modality that provides direct assessment of the amount of AV calcification. While CT provides the highest-resolution anatomic data of the AV, it does not provide hemodynamic data, and therefore is not recommended for the diagnosis of AS.<sup>71</sup> Electrocardiographically gated multidetector row CT has shown high accuracy and reproducibility in quantifying AV calcification and its progression<sup>71,72</sup> and estimating AVA by planimetry.<sup>73,74</sup> The quantification of calcification may develop into clinical applications with respect to the prognostic relevance of AV sclerosis, as well as the problem of calcification of bioprostheses after surgery. Prior to valve intervention, patients with low to intermediate probability of CAD should undergo CT coronary angiography to exclude the presence of severe obstructive CAD.<sup>49</sup> CT is useful preoperatively for patients

undergoing transcatheter aortic valve replacement (TAVR) for measurement of the native valve annulus, leaflet length, and annular to coronary ostial distance to guide the selection of appropriate TAVR size and evaluate the prosthesis after deployment.<sup>71,75</sup>

## MAGNETIC RESONANCE IMAGING

Cardiac magnetic resonance imaging (MRI) has emerged as an alternative noninvasive imaging modality for AS.<sup>76</sup> Similar to echocardiography, cardiac MRI records images throughout the cardiac cycle. Cardiac MRI uses a range of pulse sequences to assess structural heart disease. The steady-state free precession (SSFP) cine pulse sequence is commonly used in cardiac MRI and provides detailed images of AV leaflet number, leaflet thickening, valve calcification, and commissural fusion. This sequence is also useful for assessing the effects of AS, including LVH and LVEF.<sup>77</sup> MRI is useful when acoustic windows in the echocardiogram are poor or there are discordant imaging and catheterization results.<sup>78,79</sup> MRI has also been used to demonstrate improvement in LVEF, myocardial metabolism, and diastolic function, as well as reduced hypertrophy after AVR for AS.<sup>80</sup>

## Management

### SYMPTOMATIC PATIENTS

There is no effective medical therapy for AS. Given the biologic similarity of the calcific lesions of AS to atherosclerosis, there has been substantial effort to investigate the role of lipid-lowering agents in slowing the progression of AS, but to date prospective randomized trials have not found any benefits.<sup>81-84</sup> Acquired AS is considered a moderate risk condition for acquiring infective endocarditis after dental or surgical procedures, and antibiotic prophylaxis is recommended.<sup>49,85</sup> Management of CHF from AS has traditionally consisted of diuretics and inotropes. Beta-blockers are avoided as reduced contractility may lead to decreased CO in an overloaded ventricle. Vasodilators are avoided in AS because their administration can lead to hypotension, syncope, and reduced coronary perfusion. However, in patients with severe AS with decompensated heart failure and severe LV systolic dysfunction, vasodilators may improve cardiac function and may be used as a bridge to AVR.<sup>49,86</sup>

The definitive treatment for severe AS is AVR, and onset of symptoms is the primary indication for surgery. Choice of size of valve prosthesis is of substantial importance for long-term outcome. Prosthesis-patient mismatch will occur after implantation of small prosthesis, thereby increasing the residual transvalvular gradient and subsequently negatively affecting regression of LVH and coronary flow reserve, resulting in worse survival.<sup>38,87-89</sup>

TAVR is a viable option for treatment of severe AS in patients who are at high risk for surgical AVR. TAVR has shown superior survival to standard medical therapy and similar survival to surgical AVR but with lower periprocedural risks in the high-risk population.<sup>90-92</sup> It is also indicated in

cases that meet an indication for AVR but have prohibitive risk for surgical approach and predicted post-TAVR survival greater than 12 months.<sup>49,93</sup>

Percutaneous aortic balloon dilatation is ineffective long-term since most valves tend to restenose. Currently, it is indicated as a bridge to AVR or TAVR in severely symptomatic patients with severe AS.<sup>49,94-96</sup>

### ASYMPTOMATIC PATIENTS

As AVR has become a safer procedure and technology for assessing disease severity has improved, an identifiable high-risk subset of asymptomatic patients with severe AS has shown to benefit from AVR. While the risk of asymptomatic severe AS is low, surgery is indicated if associated with a combination of the following factors: worsening of hemodynamic parameters (LVEF < 50%, maximum aortic velocity  $\geq 4$  m/s, mean pressure gradient  $\geq 40$  mm Hg), decreased systolic opening of calcified valve, cardiac surgery for other causes, low surgical risk, and decreased exercise tolerance on exercise stress test.<sup>49</sup> Asymptomatic patients with an aortic jet velocity greater than 4 m/s,<sup>57</sup> high rates of aortic jet velocity progression and valve calcification,<sup>97</sup> or small AVAs and LVH<sup>59</sup> progress to symptom development quickly and soon require AVR. Exercise stress testing, as described earlier, is also useful to stratify high-risk patients and identify truly asymptomatic patients.

Asymptomatic patients with severe AS has significantly improved survival compared to medically managed patients.<sup>98,99</sup> In patients undergoing AVR for severe AS, LVH is only partly reversed and is associated with decreased long-term survival even after initially successful surgery. This suggests that intervening before development of LVH may improve outcomes.<sup>38,100-104</sup> Efforts have been made to better characterize asymptomatic AS patients and identify patients that would benefit from earlier AVR.<sup>105,106</sup> In summary, there is increasing evidence that AVR can be beneficial to a wider subset of asymptomatic patients with severe AS, but these conclusions may only apply to centers with a high volume of valve surgeries and cannot be generalized.<sup>107,108</sup>

## AORTIC REGURGITATION

Aortic regurgitation (AR) is the diastolic reflux of blood from the aorta into the left ventricle due to failure of coaptation of the valve leaflets at the onset of diastole.

### Prevalence and Etiology

AR has numerous causes, which can be grouped according to the structural components of the valve apparatus affected. AR may be caused by primary disease of the aortic leaflets and/or disease of the aortic root.

Aortic leaflet calcific degeneration, myxomatous degeneration, infective endocarditis, rheumatic disease, a bicuspid AV, and anorectic medications, such as fenfluramine and phentermine, all lead to distortion of the valve leaflets and prevent

proper coaptation.<sup>25,109-111</sup> Aortic root dilatation caused by aortic dissection; trauma; chronic systemic hypertension; aortitis from syphilis, viral syndromes, or other systemic artritides (eg, giant cell and Takayasu); and connective tissue disorders, such as Marfan's syndrome, Reiter's disease, Ehlers-Danlos syndrome, osteogenesis imperfecta, and rheumatoid arthritis, leads to improper leaflet coaptation and consequent AR.<sup>112-117</sup> AR is seen most commonly in combination with AS due to calcific or rheumatic disease in which some degree (usually mild) of AR is present. In patients with pure AR undergoing AVR, AR secondary to aortic dilation is now more common than primary valve disease.<sup>118</sup>

## Pathophysiology

The pathophysiology of AR varies according to the onset and duration of the disease process.

### ACUTE AORTIC REGURGITATION

AR that presents in the acute setting is typically caused by aortic dissection, endocarditis, or trauma. By definition, acute AR is a significant aortic incompetence of sudden onset across a previously competent AV. The blood returned to the left ventricle in diastole causes a sudden increase in LV end-diastolic volume (LVEDV) and reduces the effective or forward stroke volume. LVEDV only increases mildly (20-30%) because the ability of the left ventricle to dilate acutely is limited. This leads to a rapid increase in LVEDP. This increase is greatest in the less compliant, concentrically thickened, hypertrophic myocardium seen in those with AS or chronic systemic hypertension. Increased LVEDP results in increased mean LA and pulmonary venous pressures and produces varying degrees of pulmonary edema.<sup>119</sup> The rapid rise in LVEDP also blunts or abolishes the normally widened pulse pressure seen in chronic AR.<sup>120</sup> In the acute setting, two compensatory mechanisms attempt to maintain an effective CO: an increase in contractility attributable to the Frank-Starling mechanism and an increase in heart rate (HR). The maintenance of an appropriate effective CO depends on the adequacy of these mechanisms, especially systolic pump function.

### CHRONIC AORTIC REGURGITATION

In contrast, chronic AR is a slow, insidious process, which sets in motion numerous compensatory mechanisms. The diastolic regurgitant flow in AR increases LVEDV, LVEDP, and wall stress. Adaptive signals lead to an increase in myocyte length and addition of sarcomeres in series in a pattern of remodeling known as *eccentric hypertrophy*. Typically there is a modest increase in LV wall thickness such that the ratio of wall thickness to radius is close to normal. Chamber enlargement in the setting of normal systolic function increases total stroke volume and maintains forward stroke volume (total stroke volume minus regurgitant volume).<sup>121</sup> The increased total stroke volume coupled with a normal to slightly elevated LVEDP is responsible for the wide pulse pressure seen

in chronic AR. Forward stroke volume in AR is increased by any physiologic change that decreases afterload or increases HR. Increasing HR increases forward stroke volume by itself, but it also decreases diastolic filling time and hence regurgitant flow time and volume. The peripheral vasodilatation and increased HR that accompany exercise increase forward stroke volume in this manner.<sup>122</sup> This also illustrates the physiologic basis for vasodilator therapy in the treatment of AR, and explains why bradycardia and use of negative chronotropic agents should be avoided.

As AR progresses, the hypertrophic response becomes inadequate,<sup>123</sup> and/or the preload reserve is eventually exhausted.<sup>124</sup> Thereafter, any further increase in afterload creates afterload mismatch and results in a reduction in EF. Although the hypertrophied myocardium may provide adequate compensation for many years, eventually maladaptive signals, which lead to decreased myocyte survival and fibrosis, predominate. The myocardium becomes incapable of sustaining the increased work load imposed upon it and heart failure ensues.

Myocardial ischemia in AR, which can result from both decreased coronary artery perfusion and increased myocardial oxygen demand, may lead to further impairment of LVEF. The decrease in diastolic coronary perfusion that occurs with a severe reduction in aortic diastolic pressure is only partially compensated by increased coronary arterial flow during systole. In severe AR, there may even be reversal of coronary arterial flow. Superimposed CAD only exacerbates the effect of decreased diastolic coronary perfusion pressure. On the other hand, increased LV muscle mass, wall tension, and systolic ventricular pressure all contribute to increased myocardial oxygen demand. The subsequent ischemia caused by decreased perfusion and increased oxygen demand can lead to cell death and fibrosis, and chronically, can contribute to systolic dysfunction.

## Clinical Presentation

### SYMPTOMS

The presentation varies depending on the acuity of onset, severity of regurgitation, compliance of the ventricle and aorta, and hemodynamic conditions present at the time. Acute AR can be debilitating and life threatening if not treated emergently, whereas chronic AR is usually well tolerated for years. Severe acute AR commonly presents catastrophically with sudden cardiovascular collapse. Patients also often present with ischemic chest pain caused by decreased coronary blood flow coupled with rapidly increased myocardial oxygen consumption.

Patients with chronic, compensated AR remain asymptomatic for prolonged periods of time while the left ventricle gradually enlarges. Symptoms of heart failure, such as exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, usually develop gradually only after considerable ventricular hypertrophy and decompensation. Patients with severe AR may experience palpitations during emotional stress or exertion, an uncomfortable awareness of each heartbeat, especially at the ventricular apex, angina pectoris, nocturnal

angina, or atypical chest pain syndromes, such as thoracic pain owing to pounding of the heart against the chest wall.<sup>125</sup>

## SIGNS

Physical examination findings of AR vary with the chronicity of the disease process. Many of the classic findings of chronic AR are a result of the widened pulse pressure. They include a “water-hammer pulse” (Corrigan pulse), head bobbing with each heartbeat (De Musset sign), capillary pulsations in the lips and fingers (Quincke pulses), pulsus bisferiens, “pistol shot sounds” on auscultation of the femoral artery (Traube sign), pulsations of the uvula (Müller sign). Although interesting, these signs are not necessarily clinically useful. The classic auscultatory finding of AR is an immediate to early diastolic, blowing, decrescendo murmur. It is best heard with the diaphragm at the left sternal border while the patient is sitting, leaning forward, and holding respiration in deep exhalation. The murmur is often better heard along the right sternal border when AR is caused primarily by root disease.<sup>126</sup> When it is soft, isometric exercise, such as handgrip, can increase its intensity by increasing aortic diastolic pressure. In severe AR, the murmur may be holodiastolic.  $S_1$  is usually soft because the mitral leaflets are close to each other at the onset of systole.  $S_2$  is usually single because the AV does not close properly, or because LV ejection time is prolonged and  $P_2$  is obscured by the early diastolic murmur. Other findings, if present, are associated with CHF, for example, rales and  $S_3$ .<sup>125</sup> As discussed, the pulse pressure in acute AR is not widened; hence many of the classic signs of chronic AR are not seen in the acute setting. Instead, signs of CHF predominate.

## ELECTROCARDIOGRAM

The increased LV mass in chronic AR leads to left axis deviation and increased QRS complex amplitude. A strain pattern and reduction in the total QRS complex amplitude in patients with chronic severe AR is highly predictive of severe depression of EF resulting from inadequate hypertrophy.<sup>127</sup> Q waves in leads I, V1, and V3 through V6 are indicative of diastolic volume overload.<sup>128</sup> LV conduction defects occur late in the course and are usually associated with LV dysfunction. Overall, ECG is an inaccurate predictor of AR severity.

## ROENTGENOGRAM

The chest radiograph typically shows a “normal”-sized heart with pulmonary edema, although there may be some enlargement of all cardiac chambers and the main pulmonary artery. The aorta may be dilated if aortic root disease is the cause of AR. There may be signs of pulmonary emboli in AR caused by endocarditis when there is concomitant tricuspid valve endocarditis.

## ECHOCARDIOGRAPHY

Echocardiography is the most useful diagnostic modality in both the initial diagnosis and continued monitoring of patients with AR. Transthoracic echocardiography (TTE) is

the most commonly used imaging tool. TTE provides noninvasive assessment of the AV and aortic anatomy; the presence, severity, and etiology of regurgitation; and the size and function of the left ventricle. TEE is used when the patient's body habitus does not allow for adequate assessment with TTE and to evaluate the AV and ascending aorta in patients with suspected aortic dissection (Fig. 26-8).

Two-dimensional (2D) echocardiography with Doppler color-flow mapping has been used routinely to assess the severity of AR.<sup>49,129-131</sup> The color-flow jets are typically composed of three components: (1) a proximal flow convergence zone (area of acceleration into the orifice); (2) the vena contracta (the narrowest and highest-velocity region of the jet); and (3) the distal jet itself in the LV cavity. Assessment of the severity of AR is determined qualitatively by jet width and vena contracta width, and quantitatively by regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 26-2). The regurgitant orifice area is calculated by dividing the regurgitant volume by the velocity time integral of the AR jet calculated by continuous wave Doppler.<sup>132</sup> Measurement of LV dimensions, such as end-systolic

**FIGURE 26-8** Transesophageal echocardiographic images of aortic regurgitation due to acute aortic dissection. (Top) Showing dilated annulus, prolapse of aortic valve leaflet (dotted arrow), and intimal flap (solid arrow). (Bottom) Color Doppler showing regurgitant flow.

**TABLE 26-2: Classification of Aortic Regurgitation Severity**

Indicator	Mild	Moderate	Severe
Angiographic grade	1+	2+	3-4+
Jet width	<25%	25-65%	>65%
	LVOT	LVOT	LVOT
Vena contracta width (cm)	<0.3	0.3-0.6	>0.6
Regurgitant volume (mL per beat)	<30	30-59	≥60
Regurgitant fraction (%)	<30	30-49	≥50
Regurgitant orifice area (cm <sup>2</sup> )	<0.10	0.10-0.29	≥0.30

and end-diastolic volumes and wall thickness, are useful for determining LV changes and function. Additional echocardiographic findings in AR include premature closure of the mitral valve, diastolic fluttering of the anterior mitral leaflet from regurgitant flow, and less commonly, diastolic fluttering of the posterior mitral leaflet.<sup>133</sup>

### EXERCISE STRESS TESTING

Exercise stress testing can provide valuable information in patients with AR, especially in those whose symptoms are equivocal or difficult to assess. In the management of AR, the presence of symptoms with exercise testing is equivalent to symptoms at rest, as both circumstances warrant AVR.

### CARDIAC CATHETERIZATION

Cardiac catheterization is less frequently used to assess the severity of AR. It is most commonly used during preoperative assessment of coronary anatomy in patients requiring AV repair or replacement. The amount of regurgitant flow can be determined by calculating the angiographic stroke volume minus a measured fixed stroke volume. The difference between these two measured volumes divided by the angiographic stroke volume determines the regurgitant fraction. LVEDP is measured directly and EF is estimated roughly.

### COMPUTED TOMOGRAPHY

CT can be used to assess the severity of AR by measurement of the regurgitant orifice area, but currently the results are inferior to echocardiography.<sup>134</sup> Several studies have demonstrated the utility of CT to detect moderate and severe AR, but inaccuracies are seen with lesser degrees of AR.<sup>135-137</sup>

### MAGNETIC RESONANCE IMAGING

With the recent advancements in MRI technology, MRI cineangiography is able to provide some of the same information provided by TTE and TEE. MRI in some aspects provides superior resolution of the valves and better quantification of regurgitant flow and LVEF. The regurgitant volume

can be calculated by quantitative assessment, wherein aortic flow is subtracted from the ventricular stroke volume measured by the volumetric technique. It also can be assessed using flow mapping downstream from the AV by measuring the retrograde volume flow after valve closure. This method is more reproducible and is used more frequently for follow-up studies. However, MRI is costly, and expertise is not available in most centers. Future improvements in technology may reduce costs and increase its availability, thereby making it a standard imaging modality along with or in substitution for echocardiography.<sup>77,138,139</sup>

## Management

Surgical options for AR are AV repair and AV replacement. AV repair is preferred due to longer durability, equal short-term- and better long-term survival, and no added risk of prosthetic valve complications. When feasible, AV repair should be attempted prior to performing AV replacement.<sup>140,141</sup> Patients with AR associated with ascending aortic aneurism can undergo valve-sparing aortic root replacement, also called David's procedure. Effort is made to preserve the natural AV to avoid the need for long-term anticoagulation and reduce risk of stroke.<sup>142,143</sup>

Medical management of patients with chronic AR and hypertension consists of calcium channel blockers or ACE inhibitors/angiotensin receptor blockers (ARBs). Beta blockers are only indicated for patients with severe AR who are not candidates for surgical intervention with symptoms or LV dysfunction.<sup>49</sup>

Acute AR is treated by early AV repair or replacement, depending on the etiology. With inadequate time for the left ventricle to compensate by eccentric hypertrophy, progressive CHF, tachycardia, and diminished CO occur rapidly. Vasodilators and inotropic agents, which augment forward flow and reduce LVEDP, may be helpful to manage the patient temporarily before surgery.

Compensated chronic AR is well tolerated by most patients.<sup>144-146</sup> Current recommendations for the management of chronic AR depend on the presence of symptoms, LVEF, and LV dimensions. Patients with symptoms or EFs less than or equal to 50% should undergo AV repair or replacement.<sup>49</sup> Surgery is currently not recommended for patients who are asymptomatic and have normal LVEF and LV dimensions, even with severe chronic AR. In asymptomatic patients with normal LVEF, it is reasonable to perform surgery with an LV end-systolic dimension (LVESD) approaching 50 mm or LV end-diastolic dimension (LVEDD) approaching 65 mm if surgical risk is low.<sup>49</sup>

After surgery, LVEDV and LVEDP decrease significantly and with the decrease in preload, EF also decreases.<sup>147</sup> LV size and function eventually return to normal if the operation is timed correctly.<sup>148-159</sup> The best postoperative predictor of recovery in systolic function is reduction in LVEDD because the magnitude of reduction correlates well with the magnitude of increase in EF.<sup>148</sup> Importantly, 80% of the total reduction in LVEDD after AVR occurs within 10 to 14 days after

surgery.<sup>148,153,160</sup> Additional changes postoperatively include regression of myocardial hypertrophy, normalization of mass-to-volume ratio, increase in diastolic coronary perfusion, and decrease in peak systolic wall stress.<sup>148,160,161</sup>

Despite surgery, LV dilation and/or impaired LVF may continue in some patients. The best predictors of persistent LV dilation are greater preoperative LVESD and end-diastolic radius to wall thickness ratio.<sup>162,163</sup> In addition to these measures, greater preoperative LVEDD and duration of LV dysfunction, and reduced EF and fractional shortening predict persistent LV dysfunction.<sup>148,152,164-167</sup>

Predictors for the development of future symptoms, LV dysfunction, or death include age, LVESV, LVEDV, and EF during exercise.<sup>144,168-172</sup> Currently, there is insufficient evidence to determine if EF during exercise is a reliable predictor because exercise EF is dependent on too many factors, such as myocardial contractility,<sup>173</sup> severity of volume overload,<sup>144,173-175</sup> and exercise-induced changes in preload and PVR.<sup>175</sup>

# Aortic Valve Replacement with a Mechanical Cardiac Valve Prosthesis

Robert W. Emery • Rochus K. Voeller • Robert J. Emery

In 1931, Paul Dudley White stated “There is no treatment for aortic stenosis.” Even today the medical therapy of aortic stenosis has not significantly advanced.<sup>1</sup> Conversely, patients may tolerate aortic insufficiency for many years, but as the ventricle starts to dilate, a progressive downhill course begins and early operation is warranted.<sup>2</sup> Definitive therapy for aortic valve disease was unavailable until the advent of cardiopulmonary bypass. Innovative cardiovascular surgeons then began to develop cardiac valve prostheses. Over the subsequent 60 years,<sup>3</sup> the variety of prostheses that have become available for use have expanded greatly. Available aortic valve substitutes include mechanical valve prostheses, stented biologic valve prostheses, stentless biologic valve prostheses, human homograft tissue (both as isolated valve replacement and aortic root replacement), and a combination of a biologic valve utilizing a pulmonary autograft and pulmonary outflow tract replacement with heterograft prostheses (Ross procedure). Most recently, innovative transarterial/apical aortic valve replacement (TAVR) has gained approval in Europe and North America with acceptable intermediate term results.<sup>4</sup> Reports of the use of novel sutureless bioprosthetic valves are appearing.<sup>5</sup> This chapter focuses on the use of mechanical valve replacement in the aortic position.

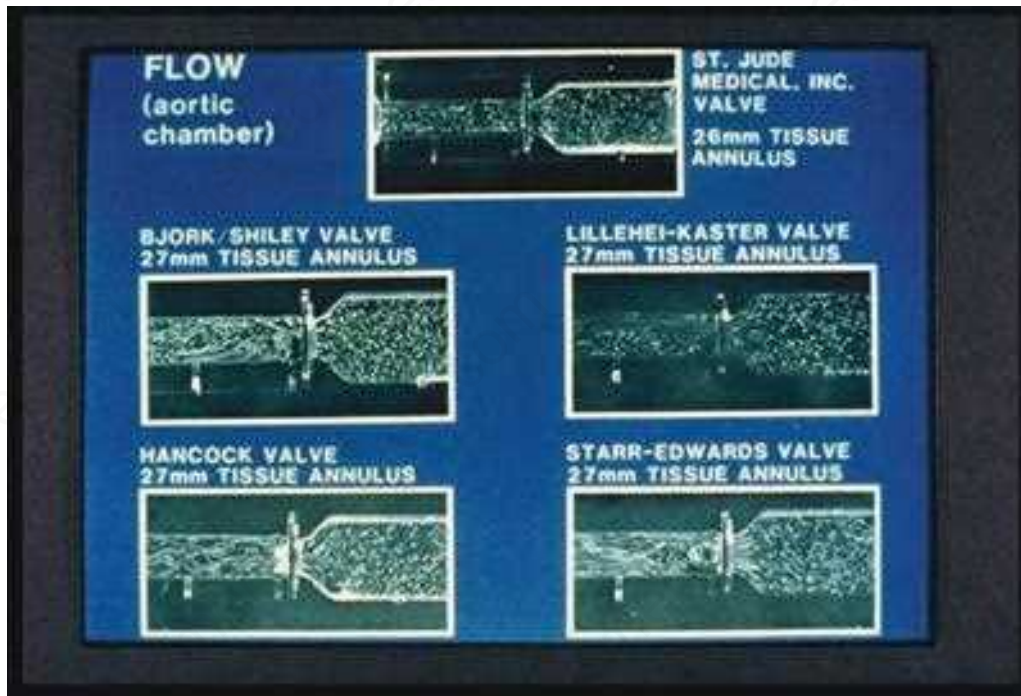

## HISTORY

In 1952, Hufnagel used an aortic valve ball and cage prosthesis heterotopically in the descending thoracic aorta to treat aortic insufficiency.<sup>6</sup> After the advent of cardiopulmonary bypass, initial attempts at aortic valve replacement (AVR) consisted of replacement of the individual aortic cusps with Ivalon gussets or fascialata sewn to the annulus or repair of aortic valve by bicuspidization.<sup>7</sup> When successful, these prostheses often calcified and results were short-lived. Shortly thereafter, surgical pioneers Starr, Braunwald, and Harkin began replacement of the aortic valve in the orthotopic position. First-generation aortic valve prostheses, the ball and cage, became the standard for AVR for over a decade (Fig. 27-1).

Many of these prostheses have remained durable for up to 40 years.<sup>8,9</sup> Multiple modifications ensued including changing the material of the ball from Silastic to Stellite, changes in the shape of the cage, depression of the ball occluder, the addition of cloth coating to the sewing ring and the cage, and changes in the sewing ring itself. These valves, however, required intense anticoagulation.<sup>10</sup> Hemodynamic performance was compromised, as there were three areas of potential outflow obstruction: the annular size of the sewing ring (the effective orifice area of the valve), the distance between the cage and the walls of the ascending aorta (particularly in the small aortic root), and obstruction to outflow by the ball itself distal to the aortic annulus. Flow patterns were also abnormal (Fig. 27-2). These problems led to the development of the next generation of aortic valve prostheses: the tilting disc valve. Innovators such as Bjork, Hall, Kastor, and Lillehei developed three models of tilting disc prostheses that became the second generation of commonly implanted aortic valve replacement devices between 1968 and 1980. The low-profile

**FIGURE 27-1** Prototype model of a ball and cage valve, an early Starr-Edwards model.

**FIGURE 27-2** Prosthetic valve flow patterns utilizing the Weiting CBA-77-03 pulse duplicator with high-speed photography and resin particles. Note the laminar flow with the bileaflet aortic valve as opposed to other clinically available prostheses and the flow similarity between the bileaflet valve and the tissue valve in the lower left corner. Tilting disk valves show directional flow, stasis at the minor flow orifice, and eddy current formation distally. The ball valve demonstrates stasis beyond the ball and eddy current formation around the ball itself. Note that the ball is obstructive to outflow, as is the proximity of the ball cage to the walls of the outflow chamber. (Reproduced with permission from Emery RW, Nicoloff DM: The St. Jude Medical cardiac valve prosthesis: In vitro studies. *J Thorac Cardiovasc Surg.* 1979 Aug;78(2):269-276.)

configuration simplified surgical implantation (Fig. 27-3). Problems with the tilting disc valve included stasis and eddy current formation at the minor flow orifice (see Fig. 27-2), and sticking or embolization of the leaflet, the latter leading to discontinuation of the Bjork prosthesis in spite of otherwise good long-term results.<sup>11</sup> The Lillehei-Kastor prosthesis evolved into the Omniscience valve, now discontinued. The Medtronic Hall valve, the third tilting disc prosthesis, is also now discontinued (Fig. 27-4A).

Kalke and Lillehei developed the first rigid bileaflet valve, but it had very limited clinical use. In 1977, the St. Jude Medical (SJM) prosthesis was developed and implanted by Nicoloff and associates (Fig. 27-4C).<sup>3,12,13</sup> Over the following decades, the dramatic step of a bileaflet prosthesis nearly obviated the use of all other kinds of mechanical prosthetic valves in the United States and to a large extent elsewhere. The SJM valve demonstrated low aortic gradients, minimal aortic insufficiency, and low rates of thromboembolism (TE).<sup>12,14</sup> Anticoagulation continued to be necessary but to a lesser extent than with previous design models.<sup>15</sup> Because of the low-profile design and lesser need for orientation, surgical implant was further simplified. Following the introduction of the SJM valve, several other third-generation models of bileaflet prostheses were introduced, including the Sulzer CarboMedics valve (Fig. 27-4B), the ATS Medical prosthesis (Fig. 27-4D), and the On-X prosthesis (Fig. 27-4E). Since the introduction

of the bileaflet valve, over 2 million implants on a global basis have been accomplished and extensive literature has developed. Surgeons have become more confident in earlier aortic valve replacement and guidelines for anticoagulation necessary for all mechanical valves have been developed for each generation of prosthesis at progressively decreasing target levels.<sup>15,16</sup>

**FIGURE 27-3** Low-profile prostheses simplify the surgical implant. The lowest profile is that of the bileaflet valve, and orientation of the leaflets is most commonly not necessary, as compared to tilting disc prostheses, for which the major flow orifice should be directed along the greater curvature of the aorta.

**FIGURE 27-4A** The Medtronic Hall valve.

**FIGURE 27-4E** On-X valve. Note the flange of the inflow portion of the valve housing which seats in the left ventricular outflow tract.

**FIGURE 27-4F** St. Jude Medical Regent valve.

Over the past 25 years, design and configurational changes have been made in bileaflet prostheses. The ATS Medical valve changed the “rabbit ears” pivot style of other bileaflet prostheses, incorporating a convex or open-pivot design allowing more complete washing of the moving parts of the valve and possibly a quieter valve closing.<sup>17,18</sup> The sewing ring of the SJM valve has changed (SJM HP) to allow a larger valve size implantation for any given tissue annulus, as has ATS Medical with its AP design. The sewing ring of the Sulzer CarboMedics valve has been modified such that this valve is implanted in a supra-annular position (top hat model). The On-X valve incorporates advanced pyrolytic carbon technology using a purer, more flexible coating to allow flanging of the inflow portion of the valve housing, better mimicking the normal flow pattern.

The most recent development in bileaflet valve design was the introduction of the SJM Regent valve (Fig. 27-4F). This valve model not only modified the sewing ring, but also redefined the external profile in a nonintrinsic structural portion of the valve, increasing the effective flow orifice area. Thus, a larger prosthesis could be implanted for any given tissue annulus diameter. This was the first mechanical prosthesis to demonstrate left ventricular mass regression across all valve sizes.<sup>19,20</sup> The Regent valve is seated supra-annular with only the pivot guards protruding into the aortic annulus.<sup>21</sup>

In spite of advances in the design and performance of AVR with a mechanical valve prosthesis, the use of mechanical aortic valves has decreased over the last decade. This is due to improvements in the longevity of bioprosthetic aortic valves, the introduction of TAVR, and the theoretical potential of valve-in-valve TAVR for failed bioprosthetic valves. More importantly, however, is the fear of chronic anticoagulation with warfarin by both patient and physician essential over the long term in patients having mechanical aortic valve prostheses.

## PATIENT SELECTION

As with any medical therapy, AVR with a mechanical prosthesis is not indicated for all patients. Several prospective randomized studies have shown no difference in survival in patients having biologic or mechanical valve prostheses or among mechanical prostheses per se.<sup>22-27</sup> However, follow-up was limited to less than 15 years. Conversely, in other nonrandomized studies of patients followed over longer time frames, freedom from all valve-related events and from reoperation were improved in patients with mechanical valve prostheses as compared to patients with biologic prostheses.<sup>11,28</sup>

Most recently several publications have shown improved survival in patients having bileaflet mechanical valve prosthesis, most likely related to improved anticoagulation regimens and longer patient follow-up.<sup>29,30</sup> Importantly quality of life was similar to that of a biologic prosthesis, even in the elderly.<sup>30</sup>

While the advantages of large effective flow orifice and durability with a mechanical valve are paramount, the confounding effects resulting from the necessity for anticoagulation

continue. Patients that are transient, noncompliant, or incapable of managing medications are not good candidates for long-term chronic anticoagulation, nor are those with dangerous lifestyles or hobbies.<sup>31</sup> Patients with higher levels of education, and those from geographic areas with a sophisticated medical infrastructure and a static population have better compliance with necessary medication, anticoagulant monitoring, and those with fewer risk factors for TE are good candidate for AVR with a mechanical valve prosthesis.<sup>32</sup>

Home monitoring of anticoagulation has become an important adjunct in managing international normalized ratios (INRs) in Europe, but is unfortunately lesser used in North America.

A mechanical valve prosthesis is recommended to patients having second valve reoperations regardless of the nature of the first procedure, as re-reoperative risks increase substantially.<sup>33,34</sup> Some studies report low mortality for reoperation of patients with failed biologic valves, but failures can occur abruptly, creating more risk.<sup>35</sup> Reoperative risk is also higher in those patients having combined procedures<sup>33,36</sup> or after prior coronary bypass.

Many surgeons have opted for an age of >70 years as the indication for bioprosthetic AVR, based on data by Akins.<sup>33</sup> In patients younger than 60 years of age, most would opt for a mechanical prosthesis based on prosthesis durability.<sup>37</sup> In the decade between 60 and 70 years of age, other factors have to be taken into account.<sup>38,39</sup>

## SURGICAL TECHNIQUES

Implantation of mechanical valve prostheses has been previously described and is straightforward.<sup>14</sup> Historically, high-profile aortic valve prostheses could be difficult to implant, particularly in small aortic roots. In such cases, a hockey-stick aortotomy is used to “unroll” the aorta and expose the annulus. While the implantation of low-profile bileaflet prostheses is simpler, problems can still arise in the small aortic root. If a tilting disc prosthesis is utilized, orienting the major flow orifice toward the greater curve of the aorta is necessary. Because bileaflet prostheses are the most commonly utilized, the surgical technique for implantation of these devices is described: A midline incision and sternotomy is made and a pericardial well created. Alternatively, a right anterior thoracotomy approach with femoral cannulation may be used. A partial sternotomy is also an alternative in thin patients, creating a sternal “T” at the fourth inter-space.<sup>40</sup>

These alternative techniques are particularly amenable to the implantation of low-profile aortic valve prostheses. The patient is cannulated via the aorta and a single atrial venous cannula. Most commonly, retrograde cardioplegic solution is utilized and a left ventricular vent is placed via the right superior pulmonary vein to maintain a dry operative field. After cross-clamping of the aorta, a transverse aortotomy is made approximately 1 cm above the take off of the right coronary artery, slightly above the level of the sinotubular ridge (Fig. 27-5). The incision is extended three-quarters of the way around the aorta, leaving the posterior one-quarter of

**FIGURE 27-5** A transverse aortotomy has been made above the level of the sinotubular ridge. The diseased valve can readily be visualized and excised in toto.

the aorta intact allowing excellent visualization of the native aortic valve and annulus. The leaflets of the aortic valve are excised to the level of the annulus and the annulus is thoroughly débrided of any calcium. Extensive de-calcification will minimize the risk of paravalvular leak, particularly in newer-generation prostheses with thinner sewing rings, and allows for better seating of the valve prosthesis. Braided 2-0 sutures with pledgets are utilized. Beginning at the noncoronary commissure, the annulus is encircled with interrupted mattress sutures (Fig. 27-6) extending from the aortic to the ventricular surface (everting). Recently, a technique of placing sutures from the ventricle to the aorta has been used to place the prosthesis in a supra-annular position. Alternatively, multiple single interrupted sutures may be placed. After placement, the suture bundles are divided into two equal portions and two individual sutures placed into the sewing ring at the level of the pivot guards, orienting the pivot guard toward the ostia of the left and right coronary artery (Fig. 27-7). Next, each half of the suture bundles are inserted through the sewing ring and the prosthesis seated (Fig. 27-8).

The pivot guard sutures are tied first followed by the sutures beginning at the left coronary cusp extending to the mid-portion of the right coronary cusp. Lastly, the sutures of the noncoronary cusp are secured, seating the valve appropriately. In a small aortic root, should a valve not be able to be seated, paravalvular leak can be prevented if the unseated area of the valve is in the noncoronary cusp. External aortic sutures can be placed from outside the aorta to the valve sewing ring, securing the prosthesis and preventing paravalvular regurgitation. Because of the low-profile nature of the leaflets, opening and closing can still occur unimpeded. Leaflet motion should always be checked and the surgeon must be assured that the coronary arteries are not obstructed. The aortotomy is closed with a double layer of polypropylene suture consisting of

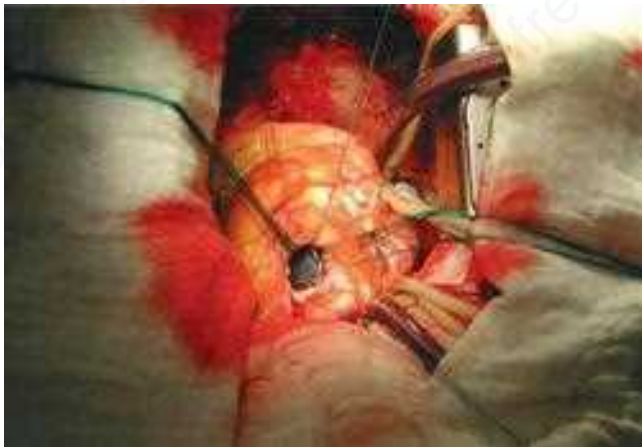

**FIGURE 27-6** The annulus has been encircled with multiple interrupted pledgeted mattress sutures of 2-0 braided suture. The annulus can be readily visualized and all calcification has been extensively débrided.

an underlying mattress suture and a more superficial over-and-over suture. The patient is placed in the Trendelenburg position and the heart filled with blood and cardioplegic solution, vented, and the cross-clamp removed. After resuscitation and de-airing of the heart, the procedure is completed and the patient transferred to the intensive care unit. On the first postoperative day the chest tubes are removed if output is less than 125 mL in the previous 8 hours. Following the removal of the chest tube, the patient is begun on subcutaneous heparin (5000 U every 8 hours) or low-molecular-weight heparin (1 mg per kg twice a day), and warfarin therapy started. Valve implantation can usually be accomplished in under 40 minutes of aortic cross-clamping and with cardiopulmonary bypass times of approximately 1 hour, allowing limited coagulopathic and homeopathic alterations.

**FIGURE 27-7** The pivot guard sutures have been placed aligning the pivot guards with the right and the left coronary artery.

**FIGURE 27-8** All sutures have been passed through the sewing ring and the valve is lowered to the aortic annulus and seated appropriately by placing gentle leverage on the valve sewing ring and traction on the suture bundles.

When coronary bypass grafting is indicated, the order of the operation changes. The diseased valve is excised, distal vein or free arterial grafts constructed, the valve is replaced, and the aortotomy closed. Proximal anastomoses are then completed, with one left untied for de-airing. The distal anastomoses of pedicled grafts (internal maxillary artery, IMA) are then completed. De-airing is accomplished through the untied proximal anastomosis.

## ANTICOAGULATION

The durability and function of mechanical valve prostheses, particularly those of the modern generation, is unquestioned.<sup>28,37,40-44</sup> It is the process of anticoagulation that is key and drives long-term success. INR is the standard to which anticoagulation levels should be targeted.<sup>31,45</sup> Anticoagulation is begun slowly following removal of the chest tubes, as the danger of overshooting target INR to dangerous levels is common.<sup>46</sup> Current data on anticoagulant regimens indicate that a one-size-fits-all recipe is inadequate to obtain excellent long-term results.<sup>15,32,47</sup> Horstkotte noted that complications occur during fluctuations in the INR, and less often during steady-state levels, be they high or low.<sup>48</sup> When levels of INR increase, bleeding episodes become more common, and when levels of INR decrease, thromboembolic episodes become more common, both on the slope of the change. These events are opposite ends of the continuum of anticoagulation-related complications. The presence of a mechanical valve prosthesis is also not the only risk factor for TE.<sup>32,46</sup>

Traditional risk factors for TE listed in Table 27-1 predispose patients to thromboembolic episodes, and as such higher therapeutic INRs are warranted. Similarly, as shown in Table 27-2, nontraditional risk factors for TE will also predispose patients to embolic events.<sup>32,46-49</sup> Butchart has noted that the more of these risk factors patients have, the greater the

**TABLE 27-1: Traditional Risk Factors for Thromboembolism**

- Atrial fibrillation
- Increased left ventricular cavity size
- Regional wall motion abnormality
- Depressed ejection fraction
- Hypercoagulability
- Increased age

incidence of events and the greater the need for a higher target INR (Fig. 27-9).<sup>19,32</sup> Thus, it is imperative in the modern era that patient risk factors be taken into account and the INR individualized for a given patient.<sup>15,16,47</sup> Recommendations for INR target levels in our practice are shown in Table 27-3. These levels are more liberal than those offered by the American College of Cardiology/American Heart Association and the American College of Chest Physicians (ACCP) guidelines, but more conservative than those recommended by the European self-anticoagulation trials.<sup>50-52</sup> These later reports are especially relevant, because they demonstrate that a lower INR is consistent with a lower incidence of TE if patients are maintained in the therapeutic target range.<sup>50,53</sup> Patients with home testing were maintained in the therapeutic range a substantially greater percentage of the time than those whose status was monitored at anticoagulation clinics.<sup>50,53</sup> Starting self-management early after mechanical valve replacement further reduced valve-related events.<sup>46</sup> Puskas et al in a prospective FDA approved randomized trial substantiated these data and showed that in patients using home INR monitoring between target INR of 1.5 and 2.0 with the addition of low-dose aspirin in these without contraindication.<sup>16</sup> This report documented a significantly lower risk of bleeding without a significant increase in thromboembolic events. In the United States, home testing has not become commonplace or popular. However, home testing can certainly be expected to lower the incidence of valve-related thromboembolic and bleeding events. It has been approved for reimbursement for weekly testing in patients with a mechanical valve prosthesis

**FIGURE 27-9** The correlation of number of risk factors to thromboembolic events. (Data from Butchart EG, Ionescu A, Payne N, et al: A new scoring system to determine thromboembolic risk after heart valve replacement, *Circulation*. 2003; 108(Suppl II):II-68.)

or atrial fibrillation, but only after a 3-month waiting period. Obtaining appropriate funding for access in the immediate postoperative period would be an important initiative that could acutely reduce the incidence of valve-related events.

In a report of patients followed over 25 years noted that approximately 40% of the bleeding episodes occurred in the first year following surgery. It is thus important during this initial postoperative time frame when the patient's anticoagulant levels are more likely to fluctuate, that INR be measured more frequently.<sup>37</sup> In the early postoperative period, INR can occasionally jump to supratherapeutic levels and result in significant bleeding events. This is an independent risk factor for mortality at 60 days.<sup>54</sup> Furthermore, the most important independent predictor of reduced survival is anticoagulant variability.<sup>31</sup> We and others therefore recommend in the early postoperative period that one proceed slowly to bring the INR to target levels while the patient is under the protection of subcutaneous enoxaparin (100 IU/kg twice a day) or heparin (5000 U every 8 hours) until the INR is therapeutic.<sup>15,16,37,55,56</sup> Recent data based from emerging genotype technology indicate an improved therapeutic ratio can be obtained using a pharmacogenetic algorithm for initial warfarin dosage required in transition to stable dosage.<sup>47</sup>

The addition of aspirin to a warfarin regimen can be expected to result in a lower incidence of TE at any given therapeutic INR with a low probability for bleeding events and so is recommended in those without contraindication.<sup>16,57,58</sup>

**TABLE 27-3: Target INR Recommendations**

1. Normal ejection fraction and cavity size, NSR: INR 1.6-2.0, ASA
2. Any single factor: INR 2.0-2.5, ASA
3. Multiple factors or atrial fibrillation: INR 2.5-3.5
4. ? Antiplatelet only

ASA, aspirin; INR, international normalized ratio; NSR, normal sinus rhythm.

An educational program to teach patients how to manage their anticoagulation is an important part of the overall operative process. Patients should be instructed on the influence of alcohol and diet on anticoagulant levels, the need for regular dosing, and the potential impact of travel and gastrointestinal illnesses on fluctuations in anticoagulant levels. Warfarin, the world's most commonly used anticoagulant, is well known to be high risk, as is insulin, yet both drugs can be managed with proper compliance and education so that the impact on lifestyle and quality of life is minimal.<sup>10,30,59</sup> Patient age does not appear to be a risk factor for anticoagulation<sup>56,60-62</sup> as long as there are no specific contraindications to anticoagulation due to the importance of regular testing cannot be overstated. The presence of a mechanical valve per se is not a risk factor for long-term neurocognitive dysfunction.<sup>63</sup>

Newer antithrombin agents may obviate several of the issues discussed above. These agents are showing promise in the treatment of atrial fibrillation, with a lower incidence of embolism and bleeding complications. The drugs are expensive, require multiple administrations per day, and may cause hepatic dysfunction, yet they do not require blood testing or physician visits to maintain the therapeutic effect<sup>64</sup>. Their application to mechanical valve prostheses is as yet unknown. One trial was stopped early due to a high incidence of cerebrovascular events, but trial design has been criticized. More data are necessary.

Notably, platelet activation may be more important in the long-term therapy of an aortic prosthesis than mitral where areas of stasis predominate.<sup>13</sup> This is likely the reason there is no difference in the freedom from embolic events in mechanical versus biologic prosthesis over the long term.<sup>16,28</sup> Thus aortic valve prostheses could in theory be managed with newer strong anti-platelet therapy. Garcia-Rinaldi has tested this theory in 178 patients followed out to 7.8 years treated only with clopidogrel. Results were excellent with few bleeding episodes and minimal thromboembolic events.<sup>65</sup> Importantly, the authors note the majority of patients having thromboembolic events when tested for platelet inhibition were resistant to the drug or had been removed from the drug by themselves or by a physician. They stressed the importance of measurement of platelet responsiveness if only anti-platelet therapy is utilized.<sup>60,65</sup> A prospective randomized trial is warranted to confirm those results.

## RESULTS

Outcomes from aortic valve replacement with mechanical valve prostheses vary among reports depending on the patient population. Patients with higher risk factors for TE and those with risk factors for anticoagulation will have a higher incidence of valve-related events, making meta-analyses less meaningful.<sup>66</sup> Older patients are at higher risk for valve-related events, particularly thromboembolic episodes, because of the greater number of risk factors that accumulate with aging.<sup>32</sup> The incidence of valve-related events is also determined by the intensity with which the

investigators follow their patients. A higher incidence of early hemorrhagic events may also be diluted over the longer periods of follow-up.<sup>67</sup> Compliance is key to good long-term outcomes. Traditional and nontraditional risk factors for embolism and risk factors for anticoagulation and valve-related events must be considered.<sup>32,46</sup> Several trials have indicated no significant differences in events among various mechanical prostheses, but follow-up was limited.<sup>23,25,27,68</sup> There are, however, certain standards within which one should expect a mechanical valve to perform, and within which the medical decisions for anticoagulation must be made. The majority of valve-related morbidity is related to TE and anticoagulation-related hemorrhage (ARH).<sup>26,29,39</sup> The sections below deal with specific valve-related complications and acceptable current incidence.

Improvements in mechanical valve prostheses and in anticoagulation regimens, along with maintaining and lowering target INR has led to updating of objective performance criteria (OPC) for heart valves.<sup>69</sup> Current criteria for events for both mechanical and biologic valves have been lowered (Table 27-4). Events including TE and perivalvular leak are similar between mechanical and bioprosthetic valves, but the OPC for hemorrhage and thrombosis is higher in mechanical valves, in spite of being quite low but prosthesis longevity favors mechanical prostheses.<sup>69</sup>

## Valve Type

Freedom from all valve-related events over the long term is shown in Fig. 27-10. In the early follow-up period, ARH is the most common untoward event for mechanical valve prostheses. Thus, over the first 10 years of follow-up there

**FIGURE 27-10** Freedom from all valve-related complications over 20 years. Note that in the first 10-year period of follow-up, complications related to mechanical valves exceeded those of tissue valves. The lines cross at approximately 10 years, and over the following period, complications from tissue valves were more frequent than those from mechanical valves. (Reproduced with permission from Khan SS, Trento A, DeRobertis M, et al: Twenty-year comparison of tissue and mechanical valve replacement. *J Thorac Cardiovasc Surg.* 2001 Aug;122(2):257-269.)

is a higher incidence of valve-related events in patients with mechanical prostheses as opposed to those with biologic valves.<sup>28</sup>

However, over the subsequent period of 10 to 20 years, the incidence of biologic valve failure changes this ratio such that the valve-related complications of biologic prostheses become more common than those with mechanical valve prostheses. In a series of aortic reoperations, Potter has noted that the time to biologic valve failure was only 7.6 years.<sup>35</sup> This failure rate will increase over time.<sup>28,70</sup> Overall, freedom from valve-related events is more strongly influenced by preexisting comorbidities than the presence of a mechanical prosthesis per se.<sup>28,32,37,41</sup>

## Anticoagulant-related Hemorrhage

ARH is the most common valve-related event. The more intense the anticoagulation regimen, the higher the incidence of valve-related hemorrhage. Most commonly ARH will occur during fluctuations in INR values especially related to changes in warfarin dosing or medical or drug interactions.<sup>48</sup> The most common site for ARH is the gastrointestinal tract, the second being the central nervous system.<sup>32</sup> ARH also accounts for the highest incidence of patient mortality for valve-related events. Acceptable ARH rates range from 1.0 to 2.5% per patient-year in long-term reports.<sup>11,28,37,41-44</sup> Recent data indicate the OPC for major hemorrhage to be 1.6%.<sup>69</sup> The long-term reports dilute the short-term impact, as ARH risks are higher early after valve replacement.<sup>37,44,67</sup> With individualized and home monitored anticoagulant regimens, both related events, TE and ARH, are diminished.<sup>50</sup> Freedom from anticoagulation at 10 and 20 years is 75 to 80% and 65 to 70%, respectively. Importantly, one long-term

**FIGURE 27-11** Kaplan-Meier curve of freedom from anticoagulation-related hemorrhage for patients having aortic valve replacement. (Reproduced with permission from Emery RW, Krogh CC, Arom DV, et al: The St. Jude Medical cardiac valve prosthesis: A 25-year experience with single valve replacement, *Ann Thorac Surg.* 2005 Mar;79(3):776-782.)

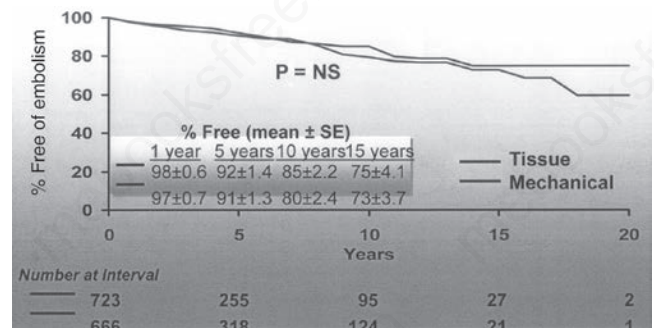

study noted that nearly 40% of all ARH that occurred over a 25-year follow-up period occurred during the first year of anticoagulation (Fig. 27-11), indicating that a slow increase to therapeutic levels, coupled with close follow-up during this early period is warranted.<sup>15,37,54,55</sup> Results of the European self-anticoagulation study indicate that a lower INR target is appropriate if home testing is initiated, as a greater time is spent in the therapeutic range.<sup>50</sup> This was recently verified by Puskas et al indicating the value of lowered target INR and the importance of home monitoring of INR.<sup>16</sup> Mortality more commonly occurs in relation to bleeding events than in relation to thromboembolic events.<sup>15,37</sup>

### Thromboembolism

Thromboembolic episodes (TE) are the second most common valve-related event and are the major reason that chronic anticoagulation is warranted. Khan and associates reported in a large series of patients that the incidence of thromboembolic events between bioprostheses and mechanical prostheses are the same (Fig. 27-12), but the mechanical valve patients are on warfarin.<sup>28</sup> Wu et al in a meta-analysis confirms that TE rates are similar between aortic mechanical and bioprosthesis as does Puskas.<sup>16,69</sup> Acceptable thromboembolic rates range between 0.8 and 2.3% per patient-year.<sup>11,28,37,41-44,70-71</sup> Approximately one-half of these events are neurologic events, 40% are transient, and 10% peripheral.<sup>37</sup> Freedom from thromboembolic events at 10 and 20 years is approximately 80 to 85% and 65 to 70%, respectively.

TE is a continuous risk factor that is present throughout the life of the mechanical valve prosthesis. As patients age, risk factors for TE increase, so one must be on guard to maintain therapeutic anticoagulant levels. Changes in the target INR may be necessary as individual risks increase.

Interestingly, not all neurologic events classified historically as embolic are indeed embolic. Piper et al reported a study of patients prospectively admitted to a single institution with a neurologic event postmechanical valve replacement and intensively worked up. More than 75% were found

**FIGURE 27-12** Freedom from thromboembolism in patients followed for 20 years. Note that there is no difference in the incidence of thromboembolic events between mechanical and tissue valves. (Reproduced with permission from Khan SS, Trento A, DeRobertis M, et al: Twenty-year comparison of tissue and mechanical valve replacement. *J Thorac Cardiovasc Surg.* 2001 Aug;122(2):257-269.)

to have intracerebral hemorrhage as the etiology of the event as opposed to embolism. These data would indicate target anticoagulant levels may be artificially high, that not all neurologic events that appear to be embolic in fact are not<sup>72</sup> and support efforts for lower target INR.<sup>15,16</sup>

## Valve Thrombosis

Valve thrombosis in the aortic position is an unusual event that most commonly occurs late after valve replacement and is due to inadequate anticoagulation or noncompliance.<sup>73,74</sup> In bileaflet valves, thrombus formation impinging valve function occurs at the pivot guards and in the crevices of the valve. Only one bileaflet design does not have convexities into which the leaflets fit.<sup>75</sup>

In tilting disc valves, thrombus is most common at the minor flow orifice. The incidence of thrombosis is approximately <.3% per patient-year and freedom from valve thrombosis at 20 years is >97%.<sup>11,28,37,41-44</sup> Thromboses is rare in biologic valves but does occur.<sup>69</sup>

## Prosthetic Valve Endocarditis

Prosthetic valve endocarditis is also a rare event in the modern era with prophylactic antibiotics. Approximately 60% of events occur early and are associated with staphylococci. The mortality for this event is high. The remainder appear late (>60 days). Prosthetic valve endocarditis is also a continuous variable, and patients must be cautioned to take prophylactic antibiotics for any invasive procedure. Freedom from endocarditis with mechanical valve prostheses is 97 to 98% at 20 to 25 years.<sup>37,44</sup>

The expected incidence is similar between mechanical and biologic valves.<sup>69</sup> The major reason for re-replacement of mechanical valves is endocarditis as opposed to degeneration of the prosthesis in biologic valves.<sup>35</sup>

## Paravalvular Leak

Paravalvular leak is an operative complication and is most commonly related to implant technique but occasionally to endocarditis. With annular decalcification and closely placed sutures, these events can be minimized. The Silzone experience showed an increased incidence of paravalvular leak wherein the silver impregnated in the sewing ring not only impeded bacterial growth, but also healing of the annular ring, doubling the accepted rate of this complication.<sup>76</sup> The Silzone-coated sewing ring was removed from the market. There may be an anatomic predisposition to paravalvular leak in the area of the annulus extending from the right and noncoronary commissure, one-third the distance along the right coronary cusp, and two-thirds the distance to the noncoronary cusp, due to intrinsic weakness in this area of the annulus.<sup>77</sup> The acceptable range of paravalvular leak is approximately less than 0.1% per patient-year, with early postoperative occurrence predominating.<sup>34,37,69</sup>

## Structural Failure

Structural failure of bileaflet aortic prostheses due to wear has not been observed or reported in long-term studies totaling more than 50,000 patient-years of follow-up. This indicates the high structural integrity of these modern aortic devices.<sup>28,37,44</sup> In a single study totaling 21,742 patient-years with 94% complete follow-up, there was no structural failure.<sup>55</sup>

## Freedom from Reoperation

The long-term durability of modern mechanical valve prostheses is excellent, and a valve replacement rate of less than 2% over 25 years (Fig. 27-13) can be expected, and re-reoperation after AVR replacement is even more rare.<sup>34</sup> Subvalvular pannus formation is also rare with aortic bileaflet valves.<sup>37,44</sup> The most common reasons for prosthetic valve reimplantation are pre- and postoperative endocarditis, paravalvular leak, and valve thrombosis.

## SPECIAL CIRCUMSTANCES

### Technical Considerations

While the technique of implanting a mechanical valve prosthesis is very straightforward, special circumstances arise. Because of the large size of the valve housing of the St. Jude Medical Regent valve compared to the tissue annulus, entry into the aorta annulus can sometimes be difficult. Occasionally, patients have the smallest diameter of their aortic root at the sinotubular ridge. While the sizer will pass readily through the aortic annulus, seating the Regent valve itself into the annulus can sometimes be difficult and frustrating. It is important to gently rock the valve back and forth through the sinotubular ridge, tilting the valve circumferentially through the narrowest part. Once the valve is below the level of the sinotubular ridge, it will seat readily in the annulus if sizing has been correct. When tying the valve into the annulus, sutures in the pivot guards and the left and right coronary cusps should be first completed. The last sutures ligated are those of the noncoronary cusp for two reasons. It may seem like the Regent valve will not seat because of the large-sized valve housing; however, with gentle persistence seating can be completed as long as sizing has been correct. The Regent valve sits supra-annular and only the pivot guards lie inside the annulus (Fig. 27-14).

Therefore, one should leave the last sutures to be tied in the mid-part of the noncoronary cusp with the valve oriented so the leaflets are parallel to the ventricular septum.<sup>78</sup> With proper annular decalcification and flexibility of the annulus, we have not seen a Regent valve that has not been able to be seated properly.

Similarly, when using the On-X valve one has to be sure that the flare of the valve inflow is seated properly in the left ventricular outflow tract. Gentle manipulation and patience may be necessary. Walther and colleagues note that exact sizing requires some experience.<sup>24</sup>

**FIGURE 27-13** Freedom from reoperations in patients having mechanical valve replacement followed over 25 years. Note that the rate of reoperation in patients with aortic valve replacement is less than 2% in over 21,000 patient-years of follow-up. (Reproduced with permission from Emery RW, Krogh CC, Arom DV, et al: The St. Jude Medical cardiac valve prosthesis: A 25-year experience with single valve replacement, *Ann Thorac Surg.* 2005 Mar;79(3):776-782.)

**FIGURE 27-14** The St. Jude Medical Regent valve on the right as compared to the St. Jude Medical HP valve on the left. With the Regent valve only the pivot guards insert into the annulus, allowing a larger valve housing for any given tissue annulus diameter. (Reproduced with permission from Emery RW, Krogh CC, Arom DV, et al: The St. Jude Medical cardiac valve prosthesis: A 25-year experience with single valve replacement, *Ann Thorac Surg.* 2005 Mar;79(3):776-782.)

If an oversized bileaflet valve has been implanted purposefully in a small aortic root, a bileaflet valve can be tilted and will still function without coronary obstruction as long as the highest portion of the valve is in the noncoronary cusp. Pledged sutures placed from outside the aorta through the sewing ring of the valve can prevent paravalvular leak, and opening and closing can still occur due to the low-profile nature of the prosthetic valve. In our review of nearly 3000 bileaflet aortic valve replacements, no annular enlarging procedures were completed.<sup>55</sup>

### Patient-prosthesis Mismatch

Patient-prosthesis mismatch (PPM) is a concept first described by Rahimtoola and popularized by Pibarot and Dumesnil.<sup>79,80</sup> Unfortunately, views are varied on the importance of PPM.<sup>81-84</sup> This is due to the fact that virtually all contributions to the literature study mixtures of mechanical and biologic prostheses and varying types of each. In a

25-year follow-up of patients with a single-model mechanical valve prosthesis, no difference was found in overall valve-related mortality for patients who had severe PPM, moderate PPM, or insignificant PPM according to the criteria described by Blais and associates.<sup>83</sup> This similarity in long-term survival was sustained whether the effective area was measured by in vitro (internal geometric valve area) or in vivo criteria (echo-calculated valve area) as shown in Figs. 27-15 and 27-16. This study also found no difference in valve-related events, including operative mortality, long-term cumulative mortality, ARH, TE, valve thrombosis, paravalvular leak, or diagnosis of congestive heart failure. Follow-up in this study was 94% complete and extended over 13,000 patient-years.<sup>85</sup> Therefore, with bileaflet mechanical valve prostheses, PPM does not appear to be an issue. This retrospective study was limited in that it did not address patient age (ie, younger vs older), patient activity, or ventricular function. Thus, it is likely that PPM is important in patients with small biologic prostheses, because as the valve leaflets stiffen, clinically significant aortic stenosis becomes prominent early in the postoperative follow-up period, affecting symptoms and survival in younger and more active patients and in those with depressed ventricular function. If one is, however, concerned about PPM, the indexed effective orifice area can be calculated for any given prosthetic valve and a determination made whether an annular enlarging procedure or a different model prosthesis with

a larger effective orifice area is warranted.<sup>86</sup> PPM has been minimized by the new-generation Regent valve and is very rare with this prosthesis.<sup>20,55</sup>

## Stopping Anticoagulation

Anticoagulation is recommended in all patients with mechanical valve prostheses. Limited trials have been undertaken with low-risk patients, but only after a several-month course of systemic anticoagulation. An increased incidence of valve thrombosis but with little increase in the incidence of TE has been reported in patients not taking chronic anticoagulation if antiplatelet agents are utilized.<sup>73,87,88</sup> One study found no significant differences in valve-related events in patients on warfarin as compared to antiplatelet therapy alone, but follow-up was limited.<sup>89</sup> One prospective study is currently ongoing consisting of a randomized trial of antiplatelet therapy versus warfarin after 3 months of formal anticoagulation, but the results are not yet available.<sup>90</sup> Certainly one can expect that highly selected patients with bileaflet mechanical valve prostheses will do well off warfarin on antiplatelet agents, but this is unproven.<sup>21,91</sup>

In a prospective nonrandomized trial of clopidogrel along after bileaflet aortic valve replacement, Garcia-Rinaldi et al as noted above, found thromboembolic events limited to those patients that had clopidogrel discontinued or were

**FIGURE 27-15** Kaplan-Meier determination of valve-related late mortality in patients having insignificant, moderate, or severe patient-prosthesis mismatch according to the criteria of Pibarot and colleagues. After implant of a bileaflet prosthesis, in vitro determination is calculated from the geometric flow orifice by the manufacturer. Note there is no difference in these three curves. Numbers at the bottom of the figure represent patients available for follow-up.

**FIGURE 27-16** Kaplan-Meier determination of valve-related late mortality in patients having insignificant, moderate, or severe patient-prosthesis mismatch by the in vivo criteria according to Blais and associates determined echocardiographically. There is no difference in the survival curves after implant of a bileaflet prosthesis. The numbers at the bottom of the graph represent patients available for follow-up.

nonresponders.<sup>65,90</sup> While such an approach is rational based on deductive reasoning from available data, a prospective randomized trend is required before this approach can be recommended.

When anticoagulation requires reversal electively, as for scheduled surgery, the INR is allowed to slowly drift toward normal over 5 days and the patient is admitted for intravenous heparin therapy 24 hours prior to the procedure.

Anticoagulation is restarted after the procedure with antiplatelet therapy, and subcutaneous heparin with warfarin restarted on postoperative day one. Abrupt reversal of INR in patients who have bleeding episodes may be warranted, but carries increased risk of TE. Fresh frozen plasma will gently reverse INR when necessary, but it is best to avoid the use of vitamin K. Frequent INR checks are warranted.

Following ARH episodes, when feasible, because of the high incidence of recurrent bleeding, anticoagulant therapy is withheld up to 2 weeks, using antiplatelet agents only<sup>88</sup> or until the source of the bleeding has been identified and definitively treated. For those patients in whom anticoagulant therapy cannot be restarted, antiplatelet therapy is warranted, but the patient should be informed of an increased incidence of TE to approximately 4% per patient-year and that of valve thrombosis to 2% per patient-year with bileaflet valves.<sup>73,87,88,92</sup>

## Mechanical Valve Replacement in the Younger Patient

A major deterrent to mechanical valve replacement in the younger patient is the impact of long-term anticoagulation. Mechanical valves are, however, more ideal for younger patients due to their excellent durability characteristics. Most importantly, younger patients (ie, patients under the age of 50 years) are a low-risk subset for valve-related events. These individuals have very few risk factors for TE, and thus anticoagulation can be run at the lower end of the therapeutic target range, decreasing the incidence of ARH without altering the incidence of TE. In fact, many infants and children have been managed with only aspirin with quite good long-term results.<sup>93</sup> While this is not recommended in patients older than infancy, it is a feasible alternative. A recent study in patients under 50 years of age followed 254 patients for up to 20 years and found an exceedingly low rate of valve-related events (Table 27-5), an exceptional long-term overall survival of nearly 88%, and event-free survival probability of 92% at 19 years.<sup>94</sup>

Chiang et al published a propensity-based analysis of patients having AVR with a mechanical versus biologic prosthesis ages 50-69 years from the New York State database.<sup>27</sup> They found there was no difference in stroke or survival at up to 15 years. The patients having biologic prosthesis had

**TABLE 27-5: Valve-Related Events with the St. Jude Medical Prosthetic Valve in Young Patients**

Event	No. of events	Percent per patient-year	No. of deaths
Endocarditis	3	0.15	0
Paravalvular leak	6	0.30	2
Embolism	6	0.30	0
Valve thrombosis	2	0.10	0
Bleeding	6	0.10	2
Structural failure	0	0	0

Data from Emery RW, Krogh CC, Jones DJ, et al: Five-year follow up of the ATS mechanical heart valve. *J He+H220art Valve Dis.* 2004 Mar;13(2):231-238; Emery RW, Krogh CC, Arom DV, et al: The St. Jude Medical cardiac valve prosthesis: A 25-year experience with single valve replacement, *Ann Thorac Surg.* 2005 Mar;79(3):776-782.

a higher rate of reoperation with a 9% operative mortality. No mention is made of morbidity such as postoperative stroke or renal failure. The mortality rate is high compared to available literature.<sup>35</sup> Economic impact during the operative and postoperative period are also not addressed. The incidence and timing of reoperation may also be underestimated as estimates of up to one third of patients with failed bioprostheses have substantive contraindications to reoperative surgery and thus are not included in statistics for replacement of a degenerated valve. The reoperative mortality is thus be artificially low. Patients with mechanical prostheses had a significantly higher rate of ARH, but higher target INR was used compared to current recommendations.<sup>15,16</sup> Home anticoagulant monitoring was not utilized. Both of these factors would lower ARH incidence. The data are thus not definitive for recommending bioprosthesis for patients in this younger age group. Individual preferences and thorough discussion are thus warranted.

A further reason for implanting bioprostheses in younger patients is the feasibility and recent successes with TAVR valve-in-valve.<sup>95,96</sup> The experience is limited, however, and this reasoning may offer false hope as valve-in valve procedures are not effective in smaller bioprosthetic valves.<sup>97,98</sup>

The longest surviving patient in a series of bileaflet valve replacement patients is currently over 30 years from his procedure, which was completed in his early forties and has been without complication. The low incidence of valve-related complications in younger patients should drive a discussion of the alternative prostheses available for such individuals, especially with new aggressive and reversible antiplatelet drugs. Operative mortality increases with each succeeding procedure; therefore discussion of durability with patients becomes mandatory.<sup>33-35</sup> As anticoagulant regimens become further refined the incidence of ARH will be lowered, making the use of mechanical aortic valves safer.

**TABLE 27-6: Considerations for Mechanical Valve Replacement**

- High probability for anticoagulant use
- Need for chronic anticoagulation (any age)
- Preferences of patient
- Surgical risk for reoperation
- Age < 60 years
- Age 60-70 years with patient discussion
- Reoperations
- Good medical infrastructure

## Follow-up

With the use of any valve prosthesis, long-term follow-up is a key factor. Ten years is certainly not long enough to ascertain the true durability of a biologic prosthesis. Grunkemeier reviewed several types of biologic prostheses and found that the 10-year durability was excellent, but between 12 and 18 years durability fell off and prosthetic replacement was necessary.<sup>70</sup> These data were echoed by Khan and colleagues and Chiang et al.<sup>27,28</sup> Valve-related failure of all biologic alternatives including stented prosthetic replacements, stentless prostheses, and homograft and autograft replacements have all shown long-term durability to be less than that of modern mechanical valve prostheses.

Even with some mechanical valve prostheses, durability after 10 years has not been adequate. In recommending mechanical valve replacement, one should be assured to have clinically available data on the prostheses that extend beyond 15 years, which is now available.

In conclusion, with proper selection of patients for mechanical valve replacement, one can expect excellent long-term results, long-term survival, and a low incidence of valve-related complications. Possible indications for recommending aortic valve replacement with mechanical prostheses are shown in Table 27-6.

# Stented Bioprosthetic Aortic Valve Replacement

Bobby Yanagawa • Subodh Verma • George T. Christakis

This chapter provides an overview of aortic valve replacement (AVR) with stented bioprostheses. The *indications for aortic valve surgery* are reviewed with an emphasis on evidence-based guidelines and contemporary clinical and physiologic outcomes of aortic valve surgery with currently available stented bioprostheses.

## NATURAL HISTORY AND INDICATIONS FOR OPERATION

### Aortic Stenosis

#### NATURAL HISTORY

Aortic stenosis (AS) is primarily caused by degenerative calcification in patients over 70 years of age and bicuspid aortic valve in patients under 70 years of age in the developed world. Rheumatic valve disease is the third most common cause of AS affecting patients across the age spectrum. AS is also associated with systemic diseases such as Paget's disease of bone and end-stage renal disease. The pathogenetic mechanisms of aortic valve calcification include valvular interstitial cell transformation, inflammation and lipid accumulation, reminiscent of the pathogenesis of atherosclerotic plaques.<sup>1</sup> The overall incidence of calcific AS is rising with the aging population in developed countries. A population-based study of Olmstead County reported the increase in prevalence of degenerative AS and other valvulopathy in patients with age from 55 to 64 (0.6%), 65 to 74 (1.4%) and  $\geq 75$  years (4.6%;  $p < .0001$ , Fig. 28-1).<sup>2</sup>

Valvular degenerative calcification is characterized as a progressive reduction of orifice cross-sectional area caused by calcification of the cusps. The normal human aortic valve area (AVA) is between 3.0 and 4.0 cm<sup>2</sup> with minimal to no gradient. AS is defined as mild, moderate, severe and very severe with the corresponding AVA, mean gradients and peak jet velocities as shown (Table 28-1). In the presence of normal cardiac output, transvalvular gradient is usually greater than 50 mm Hg when the AVA is less than 1.0 cm<sup>2</sup>.<sup>3</sup> A rapid increase in transvalvular gradient is seen with AVAs between 0.7 and 1.0 cm<sup>2</sup>. However, discordant echocardiographic parameters are not uncommon. Minners et al<sup>4</sup> examined 3483 echocardiographic studies with severe AVA, 25% had

less-than-severe mean gradient and 30% has less-than-severe peak velocities leaving only 40% of patients with all echocardiographic criteria consistent with severe AS. Thus, echocardiographic data require careful assessment of images and correlation with hemodynamic parameters such as preload and afterload conditions.

Hemodynamic obstruction to flow created by the reduced orifice area of the aortic valve elevates intracavitary pressures. The resultant wall stress and ischemia-induced myocardial fibrosis leads to compensatory concentric left ventricular hypertrophy (LVH) to normalize wall tension and to maintain cardiac output.<sup>5</sup> With progressive LVH, ventricular compliance decreases and end-diastolic pressure rises.<sup>6</sup> The contribution of atrial contraction to preload becomes more significant and loss of sinus rhythm to atrial fibrillation may lead to rapid progression of symptoms.

#### SYMPTOMATIC PATIENTS

As AS progresses to become hemodynamically significant, progressive LVH leads to the cardinal symptoms of AS, those being (1) angina, (2) syncope, and (3) dyspnea or congestive heart failure (CHF). The average AVA is 0.6 to 0.8 cm<sup>2</sup> at the onset of symptoms.<sup>5</sup> Classic natural history studies have demonstrated that average life expectancy in patients with hemodynamically significant AS is 4 years with angina, 3 years with syncope, and 2 years with CHF.<sup>7</sup> Symptom development in the context of AS is an absolute indication for surgical intervention.<sup>8</sup> Excessive delay of AVR in symptomatic patients is associated with rate of sudden death of  $>10\%$  per year. Once a patient is symptomatic, average survival is less than 3 years typically from ventricular arrhythmia or CHF.<sup>9</sup>

#### ASYMPTOMATIC PATIENTS

The management of asymptomatic patients with hemodynamically significant AS remains a challenge. First, such patients should be exercised to confirm whether they are in fact asymptomatic. Symptoms on exertion will be unveiled in approximately one-third of patients during exercise testing. For truly asymptomatic patients, when considering AVR, the risk of sudden death and progressive ventricular remodeling

**FIGURE 28-1** Prevalence of valvular heart disease by age (A) Frequency in population-based studies (N = 11,911) and (B) in the Olmsted County community (N = 16,501). (Reproduced with permission from Nkomo VT, Gardin JM, Skelton TN, et al: Burden of valvular heart diseases: a population-based study, *Lancet* 2006 Sep 16;368(9540):1005-1011.)

should be weighed against the institutional surgical outcomes or the Society of Thoracic Surgeons Adult Cardiac Surgery Database (STS ACSD) surgical mortality of 3.9%, if appropriate.<sup>10</sup> For uncorrected AS, the average decrease in AVA is 0.12 cm<sup>2</sup> per year, while the average increase in transvalvular pressure is often 10 to 15 mm Hg per year.<sup>11</sup> Overall, up to 7% of patients with asymptomatic AS experience death or

surgery 1 year after diagnosis which rises to 38% at 5 years.<sup>12</sup> Furthermore, freedom from death or AVR was 67% at 1 year, 56% at 2 years, and 33% at 4 years. However, the high-risk patient subset with very severe AS (jet velocity  $\geq$  5m/s) progressed much more rapidly with event-free survival of 64% at 1 year, 36% at 2 years, 12% at 4 years and 3% at 6 years.<sup>13</sup>

Early surgery in asymptomatic severe AS may limit and even reverse concentric myocardial injury and fibrosis. In high-volume centers, the operative mortality for isolated AVR is significantly lower than that reported mortality in the STS ACSD.<sup>10</sup> Furthermore, loss to follow up and delay from the time of symptoms to surgical referral are also of concern. For these reasons, early surgery may be a reasonable strategy, particularly for young patients who are unlikely to escape the need for surgical valve replacement.

On the other hand, there is considerable variation in the rate of disease progression, there can exist a prolonged and stochastic latent period before symptoms emerge and many patients do not experience any change in gradient for several

**TABLE 28-1: Classification of AS**

	Mild	Moderate	Severe
AVA (cm <sup>2</sup> )	>1.5	1.5-1.0	<1.0*
Indexed AVA (cm <sup>2</sup> /m <sup>2</sup> )			<0.6
Mean Gradient (mm Hg)	<25	25-40	>40
Peak Jet Velocity (m/s)	<3.0	3.0-4.0	>4.0

\*AVA < 0.6 cm<sup>2</sup> is considered very severe.

years. Sudden death is rather uncommon in the asymptomatic patient with AS and even with severe AS, the rate is less than 1% per year.<sup>12</sup> Furthermore, the vast majority of patients who experience sudden death will become symptomatic in the months immediately prior. In addition, early and late outcomes were similar among patients with severe AS who underwent surgery with symptoms or without.<sup>14</sup> Thus, watchful waiting with close clinical and echocardiographic follow up may also be considered for those with asymptomatic AS.

It is difficult to predict who will eventually need surgical intervention and to identify asymptomatic patient subsets that will benefit from an early surgical approach. As mentioned, asymptomatic patients with increases in high peak velocity jet are substantially more likely to need an operation.<sup>13</sup> Patients with very severe AS (AVA  $\leq 0.75$  cm<sup>2</sup> and jet velocity  $\geq 4.5$  m/s or mean gradient  $\geq 50$  mm Hg) have lower-mid-term all-cause mortality ( $2 \pm 1\%$  vs  $32 \pm 6\%$ ,  $p < .001$ ) with early surgery versus conventional treatment.<sup>15</sup> Severe LVH (left ventricular mass [LVM] index  $\geq 180$  g/m<sup>2</sup>) and enlarged left atrium ( $\geq 5.0$ -cm diameter) are markers of longstanding AS and are associated with reduced survival post-AVR.<sup>16</sup> B-type natriuretic peptide (BNP) is released in response to increased myocardial wall stress and is a well-established marker of heart failure. Several groups have shown BNP to be a marker of symptomatic AS and an independent and objective predictor of outcome in patients with AS.<sup>17-19</sup> Further clinical studies will be needed to determine the clinical value of such echocardiographic measurements and biomarkers as triggers to guide the timing of surgical intervention.

### LOW-GRADIENT AORTIC STENOSIS

Patients with very poor ventricular function (ejection fraction  $< 50\%$ ) who have severely stenotic valves but nonsevere ( $< 40$  mm Hg) transvalvular gradients or jet velocity ( $< 4$  m/s) are termed low-gradient AS (LGAS). Compromised left ventricular function in these patients may be caused by afterload mismatch created by the stenotic valve or by intrinsic cardiomyopathy, or both, particularly in the setting of chronic ischemia from diffuse coronary disease. In these patients, measurement of transvalvular gradient and valve area at rest and with positive inotropy (eg, dobutamine stress echocardiography) may distinguish cardiomyopathy versus true valvular stenosis as the most responsible diagnosis. Those patients with contractile reserve that experience an increase in valve gradient ( $\geq 40$  mm Hg) or jet velocity ( $\geq 4$  m/s) with dobutamine inotropy are considered to have **true LGAS**. An increase in augmented flow resulting in only a mild increase in transvalvular gradient but an increase in valve area by  $\geq 0.2$  cm<sup>2</sup> suggests **pseudosevere LGAS**. The lack of increase in gradient nor AVA with dobutamine suggests pseudosevere LGAS lacking contractile reserve. Severe diastolic dysfunction with EF  $\geq 50\%$  and indexed AVA  $\leq 0.6$  cm<sup>2</sup> but mean gradient  $< 40$  mm Hg, jet velocity  $< 4$  m/s and indexed stroke volume  $< 30$  cc/m<sup>2</sup> is termed **paradoxical LGAS**. The latter is associated with pronounced left ventricular concentric remodeling,

**FIGURE 28-2** Kaplan-Meier survival estimates for patients with low gradient aortic stenosis with (Group 1) and without (Group 2) contractile reserve by dobutamine stress echocardiography. (Reproduced with permission from Monin JL, Quéré JP, Monchi M, et al: Low-gradient aortic stenosis: operative risk stratification and predictors for long-term outcome: a multicenter study using dobutamine stress hemodynamics. *Circulation*. 2003 Jul 22;108(3):319-324.)

moderate-to-severe diastolic dysfunction, decreased longitudinal strain and reduced stroke volume.

Patients with LGAS are a high-risk patient population with lower 5-year survival compared with those with high gradient severe AS. A retrospective study of 1154 patients with severe AS confirmed higher operative mortalities with LGAS (6.3%) and paradoxical LGAS (6.3%) compared with normal flow severe AS (1.8%).<sup>20</sup> However, such patients experience a significant survival benefit from valve replacement compared with medical management alone (Fig. 28-2).<sup>21</sup> Tribouilloy et al<sup>22</sup> report a high operative mortality (22%) but in survivors, an improved propensity-matched 5-year survival with AVR ( $65 \pm 11\%$  vs  $11 \pm 7\%$ ,  $p = .019$ ). Thus, patients with LGAS should be carefully selected but can benefit from surgical AVR.

### MEDICAL THERAPY

Medical therapy for afterload reduction may be beneficial in AS but there is no known medical therapy that has been shown to alter its natural history. Hypertension is associated with greater cardiovascular events and improved survival, and thus medical treatment for hypertension is reasonable.<sup>23</sup> Afterload reduction may be considered for patient with AS in heart failure but should be initiated and titrated cautiously as a sudden decrease in systemic vascular resistance can result in an acute reduction in cardiac output.<sup>24</sup> With regard to targeted therapy, three randomized controlled trials (RCTs) did not show a benefit of statins in did not halting or lowering the rate of disease progression in AS.<sup>25-27</sup> The importance of osteogenic processes as key mechanisms in AS has suggested potential targets for therapy but these studies are still very much in the experimental stages.<sup>28</sup>

### INDICATIONS FOR SURGERY

In 2014, a joint task force of the American College of Cardiology (ACC) and the American Heart Association (AHA) developed evidence-based consensus guidelines for management

of patients with valvular heart disease.<sup>29</sup> These guidelines encompass several important overarching changes since the 2006AHA/ACC guidelines and the 2008 updates.<sup>30,31</sup>

1. Regarding AS and aortic regurgitation (AR), the revised guidelines include a new classification of heart valve diseases based on valve anatomy, valve hemodynamics, hemodynamic consequences, and symptoms. There are four stages with treatment recommendations for each stage: (A) at risk; (B) progressive asymptomatic; (C) severe asymptomatic (C1, with ventricular compensation; C2, with ventricular decompensation); and (D) severe symptomatic.
2. Symptomatic severe AS is subdivided into high gradient ( $V_{\max} \geq 4$  m/s or mean gradient  $\geq 40$  mm Hg), LGAS with reduced left ventricular ejection fraction (LVEF) (severe leaflet calcification with severely reduced motion, effective orifice area [EOA]  $\leq 1.0$  cm<sup>2</sup>, and  $V_{\max} < 4$  m/s or gradient  $< 40$  mm Hg with LVEF  $< 50\%$ , and EOA remaining  $\leq 1.0$  cm<sup>2</sup>, but  $V_{\max} \geq 4$  m/s at any flow rate during dobutamine echocardiography), and paradoxical LGAS with normal LVEF (severe leaflet calcification with severely reduced motion, EOA  $\leq 1.0$  cm<sup>2</sup> and  $V_{\max} < 4$  m/s or gradient  $< 40$  mm Hg with LVEF  $\geq 50\%$ ).
3. A focus on the Heart Team approach for clinical decision-making, particularly given the availability of surgical and transcatheter interventions.
4. An integrative approach to the procedural risk, which incorporates risk scoring, frailty, major organ system dysfunction and procedural impediments.

The specific recommendations for AVR for patients with AS are shown (Table 28-2 and Fig. 28-3).<sup>29</sup> To summarize, AVR should be performed in all symptomatic patients with

severe AS or in patients with severe asymptomatic AS who require concomitant cardiac surgery or with left ventricular dysfunction (LVD; LVEF  $< 50\%$ ). It is reasonable to perform AVR in patients with moderate AS requiring concomitant cardiac surgery. AVR is reasonable in otherwise asymptomatic patients with very severe AS (valve area  $< 0.6$  cm<sup>2</sup> and jet velocities  $\geq 5$  m/s), severe AS and exercise-induced symptoms, and in those with true or paradoxical LGAS. Asymptomatic patients with severe AS with rapid progression may be considered for valve replacement prior to significant ventricular decompensation or sudden death.

## Aortic Regurgitation

### ACUTE AORTIC REGURGITATION

Acute AR is caused by (1) acute dilatation of the aortic annulus or sinotubular junction or both, preventing adequate cusp coaptation or by (2) disruption of the valve cusps themselves. The specific causes of AR include aortic dissection, infective endocarditis, trauma, aortic cusp prolapse secondary to VSD, aortitis or arteritis (eg, syphilitic, giant cell, Takayasu) and iatrogenesis (eg, post-aortic balloon valvotomy).

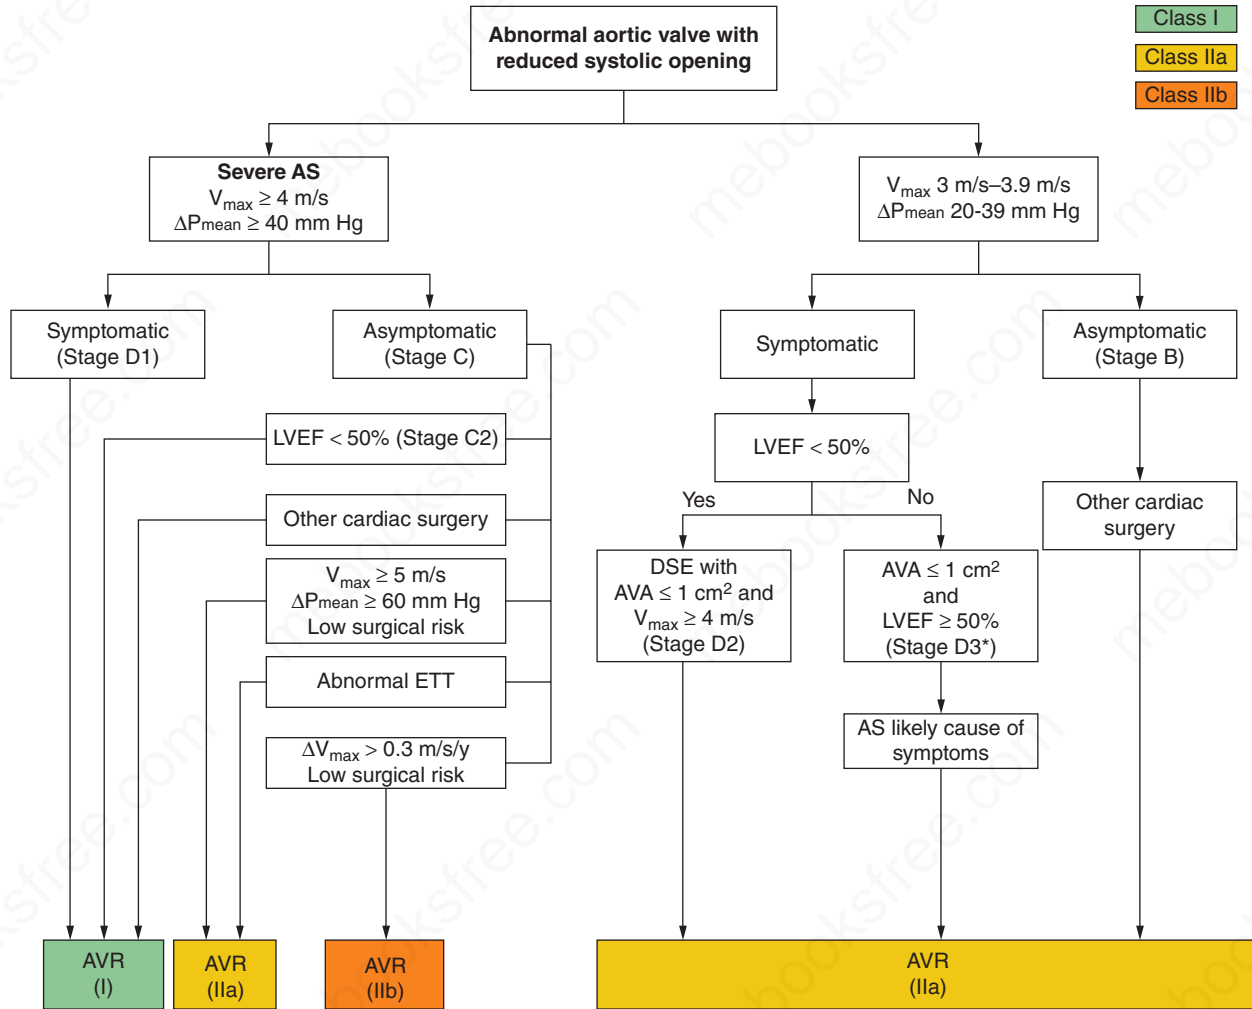

The heart is relatively intolerant to acute AR, as the left ventricle is unable to compensate for the sudden increase in end-diastolic volume caused by a large regurgitant volume load. A dramatic reduction in forward stroke volume ensues. In the context of a hypertrophic and poorly compliant left ventricle, hemodynamic decompensation is significantly more dramatic. Tachycardia is the initial compensatory response to acute decline in forward stroke volume. Progressive volume overload causes the left ventricular end-diastolic pressure to acutely rise above left atrial pressure resulting in early closure

**TABLE 28-2: 2014 ACC/AHA Guidelines for Aortic Valve Replacement in Patients with Aortic Stenosis**

Recommendation	Class	Level
AVR is recommended with severe high-gradient AS who have symptoms by history or on exercise testing (stage D1)	I	B
AVR is recommended for asymptomatic patients with severe AS (stage C2) and LVEF $< 50\%$	I	B
AVR is indicated for patients with severe AS (stage C or D) when undergoing other cardiac surgery	I	B
AVR is reasonable for asymptomatic patients with very severe AS (stage C1, aortic velocity $\geq 5.0$ m/s) and low surgical risk	IIa	B
AVR is reasonable in asymptomatic patients (stage C1) with severe AS and decreased exercise tolerance or an exercise fall in BP	IIa	B
AVR is reasonable in symptomatic patients with low-flow/low-gradient severe AS with reduced LVEF (stage D2) with a low-dose dobutamine stress study that shows an aortic velocity $\geq 4.0$ m/s (or mean pressure gradient $\geq 40$ mm Hg) with a valve area $\leq 1.0$ cm <sup>2</sup> at any dobutamine dose	IIa	B
AVR is reasonable in symptomatic patients who have low-flow/low-gradient severe AS (stage D3) who are normotensive and have an LVEF $\geq 50\%$ if clinical, hemodynamic, and anatomic data support valve obstruction as the most likely cause of symptoms	IIa	C
AVR is reasonable for patients with moderate AS (stage B) (aortic velocity 3.0 to 3.9 m/s) who are undergoing other cardiac surgery	IIa	C
AVR may be considered for asymptomatic patients with severe AS (stage C1) and rapid disease progression and low surgical risk	IIb	C

Adapted with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Thorac Cardiovasc Surg.* 2014 Jul;148(1):e1-e132.

\*AVR should be considered with stage D3 AS only if valve obstruction is the most likely cause of symptoms, stroke volume index is <35 mL/m<sup>2</sup>, indexed AVA is  $\leq 0.6$  cm<sup>2</sup>/m<sup>2</sup>, and data are recorded when the patient is normotensive (systolic BP <140 mm Hg).

**FIGURE 28-3** Indications for AVR in patients with AS. (Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Thorac Cardiovasc Surg.* 2014 Jul;148(1):e1-e132.)

of the mitral valve.<sup>32</sup> Although this protects the pulmonary venous circulation from excessively high end-diastolic pressures, rapid progression of pulmonary edema and cardiogenic shock is unavoidable. Death secondary to progressive cardiogenic shock and malignant ventricular arrhythmias are the commonest endpoints of acute AR regardless of etiology. Thus urgent surgical treatment is warranted for all causes of hemodynamically significant acute AR.

**CHRONIC AORTIC REGURGITATION**

Chronic AR is caused by either slow enlargement of the aortic root or dysfunction of the valve cusps. Common causes of chronic AR include congenital abnormalities (eg, bicuspid, unicuspid, quadricuspid aortic valve), calcific cusp degeneration, rheumatic fever, endocarditis, Marfan syndrome, Ehlers-Danlos syndrome, myxomatous proliferation, osteogenesis imperfect and ankylosing spondylitis. The echocardiographic and catheter-based parameters for AR are shown (Table 28-3).

Chronic AR causes a persistent volume overload of the left ventricle. Initially, the ratio of wall thickness to chamber diameter, ejection fraction, and fractional shortening are maintained.<sup>33</sup> However, this volume burden eventually leads to progressive chamber enlargement without increasing

**TABLE 28-3: Classification of AR**

	Mild	Moderate	Severe
EROA (cm <sup>2</sup> )	>0.1	0.1-0.3	>0.3
Regurgitant fraction (%)	<30	30-50	>50
Regurgitant volume (mL)	<30	30-60	>60
Jet width (% LVOT)	<25	25-65	>65

end-diastolic pressure during the asymptomatic phase of the disease. Chamber enlargement is accompanied by adaptive eccentric hypertrophy, associated at the cellular level with sarcomere replication and elongation of myocytes. The combination of chamber dilatation and hypertrophy leads to a massive increase in left ventricular mass. A vicious cycle of chamber enlargement, continually increasing wall stress and maladaptive ventricular hypertrophy ensues. Development of interstitial fibrosis is an important pathogenic mechanism that limits further ventricular dilation elevating end-diastolic pressure and leading to left ventricular systolic dysfunction, and CHF.<sup>34</sup> Natural history studies of AR show that symptoms, LVD, or both develop in <6% of patients per year.<sup>35</sup> Progression to LVD without symptoms occurs in <4% of patients per year and sudden death occurs in <0.2% per year.<sup>36</sup> Independent predictors of progression to symptoms, LVD, or death in asymptomatic patients include age, left ventricular end-systolic dimension, rate of change in end-systolic dimension, and resting ejection fraction.<sup>37</sup> Once LVD develops, the onset of symptoms occur at a rate exceeding 25% per year.<sup>38</sup>

The decision to operate on patients with AR and LVD is indeed challenging since the outcomes are poor with surgery and with medical therapy. Patients with more severe LVD have decreased perioperative and late survival due to irreversible ventricular remodeling including hypertrophy and interstitial fibrosis.<sup>39,40</sup> Vasodilator therapy may delay progression of ventricular dysfunction by decreasing afterload thus reducing regurgitant flow. This is currently indicated in asymptomatic patients with hypertension; asymptomatic patients with severe AR, ventricular dilatation, and preserved systolic function; and for short-term hemodynamic tailoring prior to operation. This therapy is not recommended in patients with severe AR and LVD, as it does not improve survival but may be considered if such patients are considered inoperable.

## INDICATIONS FOR OPERATION

A summary of the 2014 ACC/AHA Guidelines for AVR for chronic AR is presented in Table 28-4 and Fig. 28-4.<sup>29</sup> Symptomatic patients experience > 10% mortality per year thus

surgery is absolutely indicated.<sup>39</sup> Since symptoms, such as angina and dyspnea, develop only after significant ventricular decompensation has occurred, surgery is advocated prior to the symptomatic phase of the disease. Surgical intervention for asymptomatic patients is based on the identification of subtle but measurable changes in myocardial function before they become irreversible and negatively affect the patient's long-term prognosis.

## CORONARY ANGIOGRAPHY AND AORTIC VALVE REPLACEMENT

Many patients requiring AVR have coexistent coronary artery disease (CAD). In North America, more than one-third of AVR procedures are accompanied with coronary artery bypass graft surgery.<sup>10</sup> Risk assessment for ischemic heart disease is complicated in patients with aortic valve disease since angina may be related to true ischemia from hemodynamically significant coronary lesions, or other causes such as left ventricular wall stress with subendocardial ischemia or chamber enlargement in the setting of reduced coronary flow reserve, or both.

According to the 2014 ACC/AHA Guidelines, during preoperative planning for AVR, coronary catheterization should be performed for the presence of angina, ischemia, LVD, or history of CAD; males > 40 years old; and postmenopausal women (Class I, Level of Evidence C). CT coronary angiography may be performed with low or intermediate pretest probability of CAD (Class IIa, Level of Evidence B).<sup>29</sup>

## Technique of Operation

### MYOCARDIAL PROTECTION AND CARDIOPULMONARY BYPASS

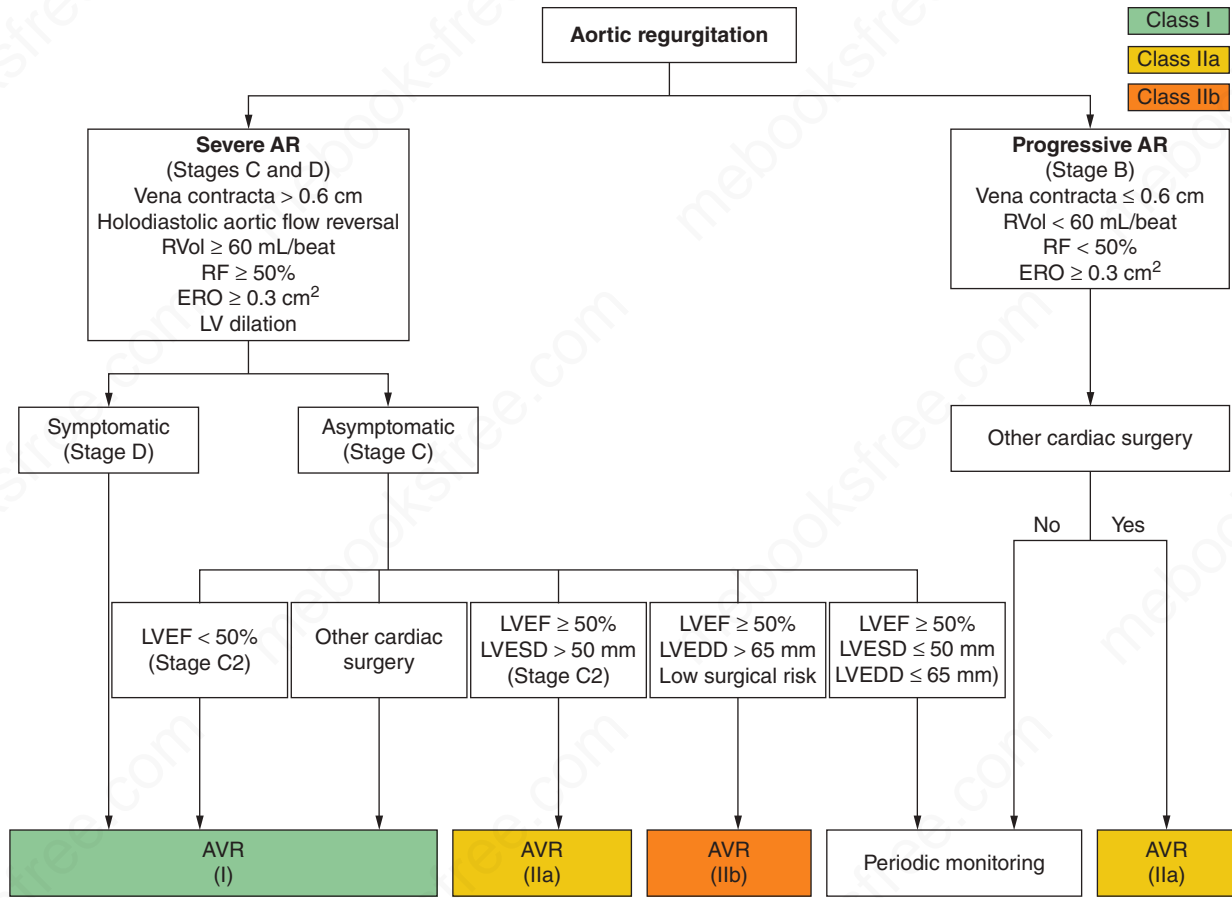

Isolated AVR is performed using a single, two-stage right atrial venous cannula and an arterial cannula into the ascending aorta for systemic perfusion of oxygenated blood. A retrograde cardioplegia cannula may be placed into the coronary sinus via the right atrium. A left ventricular vent cannula may be placed in the right superior pulmonary vein and advanced

**TABLE 28-4: 2014 ACC/AHA Recommendations for Aortic Valve Replacement in Chronic Severe Aortic Regurgitation**

Indication	Class	Level
AVR is indicated for symptomatic patients with severe AR regardless of LV systolic function (stage D)	I	B
AVR is indicated for asymptomatic patients with chronic severe AR and LV systolic dysfunction (LVEF < 50%) (stage C2)	I	B
AVR is indicated for patients with severe AR (stage C or D) while undergoing cardiac surgery for other indications	I	C
AVR is reasonable for asymptomatic patients with severe AR with normal LV systolic function (LVEF ≥ 50%) but with severe LV dilation (LVESD > 50 mm, stage C2)	IIa	B
AVR is reasonable in patients with moderate AR (stage B) who are undergoing other cardiac surgery	IIa	C
AVR may be considered for asymptomatic patients with severe AR and normal LV systolic function (LVEF ≥ 50%, stage C1) but with progressive severe LV dilation (LVESD > 65 mm) if surgical risk is low	IIb	C

**FIGURE 28-4** Indications for AVR in patients with AR. (Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Thorac Cardiovasc Surg.* 2014 Jul;148(1):e1-e132.)

into the left ventricle to ensure a bloodless field and to prevent ventricular distention with aortic insufficiency. Alternatively, a vent may be placed into the pulmonary artery or directly in the left ventricular outflow tract (LVOT) via the aortotomy. Once cardiopulmonary bypass (CPB) is initiated, careful dissection of the pulmonary artery from the aorta ensures that the cross-clamp will be fully occlusive on the aorta and prevents inadvertent opening of the pulmonary artery with the aortotomy incision. Care is needed to prevent pulmonary artery injury, as this tissue is substantially more friable than the aorta.

After the cross-clamp is applied, myocardial protection is initially delivered as a single dose of high potassium blood through the ascending aorta. This will trigger prompt diastolic arrest unless there is moderate-to-severe AR in which arrest can be achieved with direct ostial or retrograde cardioplegia. Myocardial protection is maintained by continuous infusion of cold or tepid oxygenated blood cardioplegia delivered via direct cannulation of both coronary ostia after the aorta has been opened. The angiogram should be examined to rule out a short left main coronary artery, in which case, direct ostial antegrade cannulation may preferentially perfuse either the LAD or circumflex system. In the presence

of severe CAD, antegrade cardioplegia may not perfuse myocardial segments distal to significant coronary obstruction. Furthermore, direct cannulation of left main coronary artery risks endothelial injury and potential dissection or promotion of atherosclerosis development.

An alternative method of cardioprotection in aortic valve cases is retrograde cardioplegia, in either intermittent or continuous forms and utilized in isolation or in combination with antegrade cardioplegia. This is helpful in patients with significant AR or severe concomitant coronary disease. However, there are some questions regarding the quality of right ventricular perfusion using retrograde alone. If a retrograde cannula cannot be guided into the coronary sinus, conversion to bicaval cannulation will allow opening the right atrium and direct placement of the cannula into the coronary sinus. Do not place the retrograde cannula beyond the origin of the right coronary vein ostium in the coronary sinus to ensure adequate right ventricular myocardial protection.

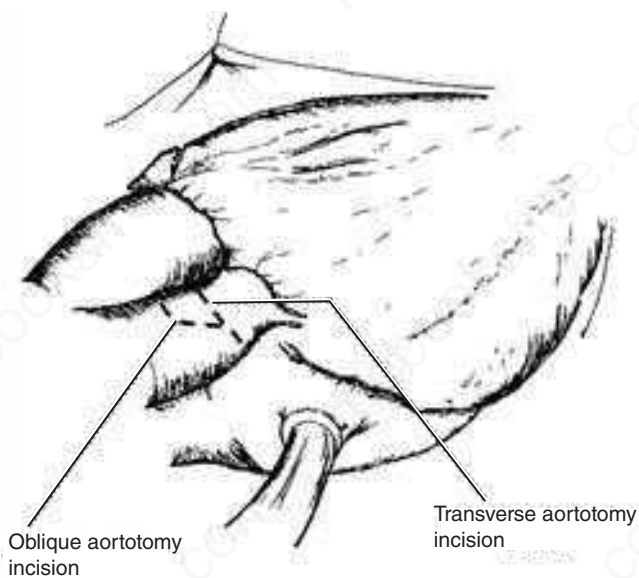

Right ventricular myocardial protection can be a challenge for a small nondominant right coronary artery (RCA) that will not accept a direct ostial cannula. One solution is to drift the patient's temperature to 28°C with cold topical slush and frequent retrograde cardioplegia.

## AORTOTOMY, VALVE EXCISION, AND DEBRIDEMENT

Once the cross-clamp has been applied and cardioplegic arrest has been achieved, the aorta is opened either with a transverse or oblique aortotomy. The low transverse aortotomy is a common approach to the aortic valve when using stented bioprostheses or mechanical valves. The aortotomy is started approximately 10 to 15 mm above the origin of the RCA and extended anteriorly and posteriorly. The initial transverse incision over the RCA may also be extended obliquely in the posterior direction into the noncoronary sinus or the commissure between the left and noncoronary cusps (Fig. 28-5). The oblique incision is often used in patients with small aortic roots, in whom root enlargement procedures may be required.

Morphology of the valve is then inspected (Fig. 28-6). The valve cusps are incised with scissors at the right cusp between the right coronary ostium and the commissure between the right and noncoronary cusps using Mayo scissors or special right-angled valve scissors (Fig. 28-7). One to two millimeters of tissue is left behind to support a sewing surface. Right cusp excision is carried first toward the left coronary cusp and then toward the noncoronary cusp and the cusp is removed as a single piece if possible. A moistened radiopaque sponge may be placed into the outflow area to catch calcific debris, which must be removed before placing the valve sutures. Thorough decalcification is then performed with a scalpel or rongeur. Debridement of all calcium deposits back to soft tissue improves seating of the prosthesis and decreases the incidence of paravalvular leak and dehiscence.

Care must be taken to prevent aortic perforation while calcific deposits are debrided from the aortic wall, particularly at the commissure between the left and noncoronary cusps,

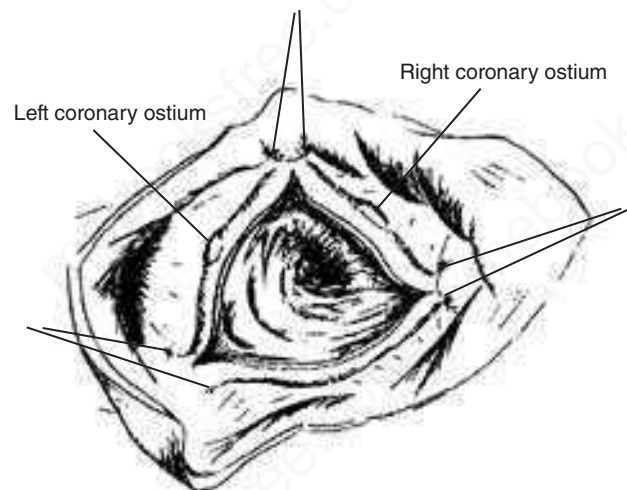

**FIGURE 28-5** Exposure and aortotomy incision. A two-stage venous cannula is in place in the right atrial appendage. The aortotomy (dashed line) may be made in the transverse or oblique direction.

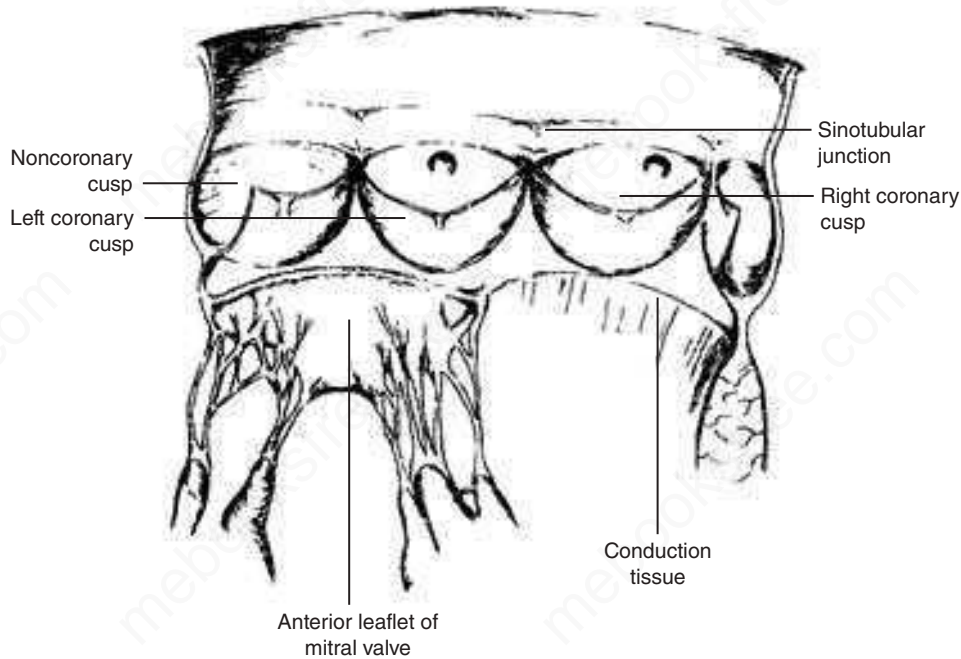

**FIGURE 28-6** The exposed aortic valve.

where perforation is most likely. Several anatomic relationships must be respected during valve excision (Fig. 28-8). The bundle of His (conduction system) is located below the junction of the right and noncoronary cusps in the membranous septum. Deep debridement in this area can result in permanent heart block. The anterior leaflet of the mitral valve is in direct continuity with the left aortic valve cusp. If it is damaged during decalcification, an autologous pericardial patch can be used to repair the defect.

Once debridement is completed, the aortic root is copiously flushed with saline while the left ventricular vent is stopped. To prevent pushing debris into the left ventricle, saline in a bulb syringe is flushed through the left ventricular vent and out the aortic valve in an antegrade manner instead of retrograde through the valve. The irrigation solution is suctioned with the external wall suction and not into the cardiomy suction.

**FIGURE 28-7** The aortic valve after leaflet excision.

**FIGURE 28-8** Anatomic relationships of the aortic valve.

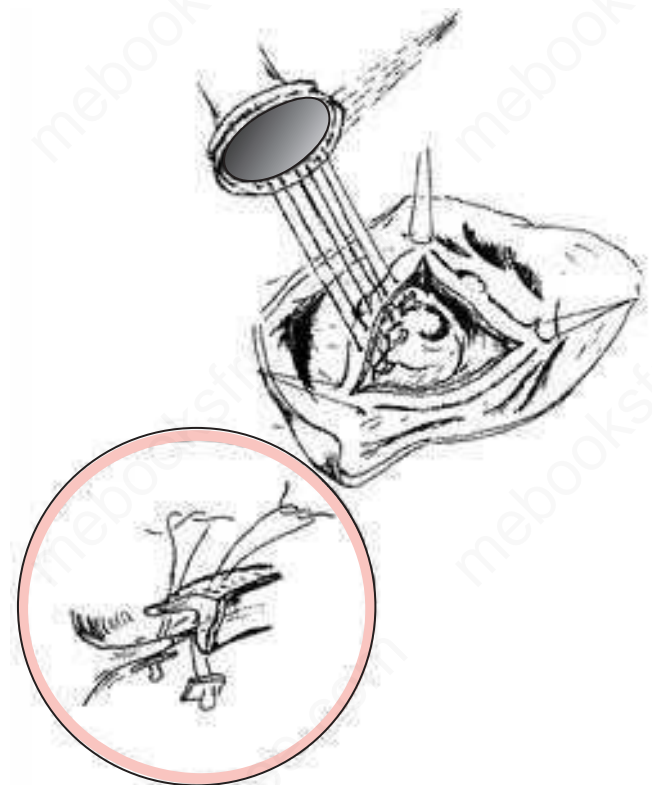

### VALVE IMPLANTATION

The annulus is sized with a valve-sizer designed for the selected prosthetic device. The valve is secured to the annulus using 12 to 16 double-needled interrupted 2-0 synthetic braided pledgeted sutures that are alternating in color. The pledgets can be left on the inflow/ventricular side or the outflow/aortic side of the aortic annulus (Figs. 28-9 and 28-10). Placing the pledgets on the inside of the annulus allows supra-annular placement of the valve and generally will allow implantation of as slightly larger prosthesis. If the coronary ostia are close to the annulus, supra-annular placement may only be possible along the noncoronary cusp. Mattress sutures are first placed in the three commissures and retracted to assist visualization. Some surgeons will place the commissural suture between the right and noncoronary cusps from the outside of the aorta (ie, the pledget is left on the outside of the aorta) to prevent injury to the conduction system. Pledgeted mattress sutures are then placed in a clockwise fashion typically starting in the noncoronary cusp. Sutures may be placed into the sewing ring of the prosthetic valve with each annular suture or after all annular sutures are placed. The sutures for each of the three cusps are held separately with three hemostats and retracted while the prosthesis is slid into the annulus. Sutures are then tied down in a balanced fashion alternating among the three cusps.

### AORTIC CLOSURE AND DE-AIRING

The aorta is closed with a double row of synthetic 4-0 polypropylene sutures. The first suture line is started on the right side at the posterior end of the aortotomy and the double-needled suture is secured slightly beyond the incision to ensure there is no leak in this region. One end of the suture is run

as a horizontal mattress anteriorly to the midpoint of the aortotomy, and then the second end of the suture is run anteriorly, slightly superficial to the horizontal mattress suture, in an over-and-over manner. On the left side, a similar technique is

**FIGURE 28-9** Placement of sutures with pledgets below the annulus.

**FIGURE 28-10** Placement of sutures with pledgets above the annulus.

performed, the aorta is de-aired, and the two sutures are tied to themselves and to each other at the aortotomy midpoint.

During AVR, air is entrained into the left atrium and ventricle, and aorta. This must be removed to prevent catastrophic air embolization. Immediately prior to tying the suture of the aortotomy, the heart is allowed to fill, the vent in the superior pulmonary vein is stopped, the lungs are inflated, and the cross-clamp is briefly partially opened. The influx of blood should expel most air from these cavities out of the partially open aortotomy. Closure of the aortotomy is then completed and the cross-clamp is fully removed. The cardioplegia cannula in the ascending aorta and the left ventricular vent are then placed on suction to remove any residual air as the heart begins electrical activity. A small needle (21-gauge) can be used to aspirate the apex of the left ventricle and the dome of the left atrium. To prevent air entrapment, the left ventricular vent must be removed while the pericardium is filled with saline irrigation. De-airing maneuvers are verified with visualization using transesophageal echocardiography. Vigorous shaking and careful manual compression of the heart while suctioning through the aortic vent (ie, cardioplegia tack) is helpful to remove air trapped within trabeculations. Once de-airing is complete, the aortic vent is removed. The patient is then weaned from CPB and decannulated in the standard fashion. If patients are pacemaker dependent when weaned from CPB in the operating room, it is recommended to insert atrial pacing wires to allow for synchronous atrioventricular pacing.

### CONCOMITANT CORONARY ARTERY BYPASS GRAFTING

Operative technique is modified when there is concomitant CAD to optimize myocardial protection. Distal anastomoses

are performed prior to AVR so that antegrade cardioplegia may be administered through these grafts during the operation. The left internal mammary artery should be used for revascularization of the left anterior descending artery. This anastomosis is performed after the aortotomy is closed to ensure that the coronary circulation is not exposed to systemic circulation during cardioplegic arrest and to prevent trauma to the anastomosis during manipulation of the heart.

The 2014 ACC/AHA Guidelines recommend concomitant surgical revascularization for coronary stenosis  $\geq 70\%$  or left main stenosis  $\geq 50\%$  (Class IIa, Level of Evidence C).<sup>29</sup> The benefit of revascularization should be balanced with the increased operative mortality, which increases from 3.9 to 5.9% for combined CABG/AVR according to the STS ACSD.<sup>10</sup> Concomitant CABG at the time of AVR is common as reported rates were 30% in patients 51 to 60 years of age, 41% in 61 to 70 years of age and 50% in  $>71$  years of age.<sup>41</sup>

### CONCOMITANT ASCENDING AORTIC REPLACEMENT

The threshold for concomitant replacement of the ascending aorta at the time of AVR is an area of debate. Borger et al,<sup>42</sup> reviewed patients with bicuspid aortic valve undergoing AVR and report 15-year freedom from aorta-related complications was 86, 81, and 43% in patients with an aortic diameter of  $<4.0$  cm, 4.0 to 4.4 cm, and 4.5 to 4.9 cm, respectively (Fig. 28-11). Extrapolating from these data and others to all patients with concomitant ascending aortic dilation, the current 2014 ACC/AHA Guidelines recommend aorta replacement when maximal diameter exceeds 4.5 cm for patients undergoing aortic valve surgery (Class IIa, Level of Evidence C).<sup>29</sup> In patients with Marfan or Loeys-Dietz Syndromes, the aortopathy is much more aggressive and a lower trigger point for replacement may be appropriate. Given the lack of data, there are currently no recommendations for concomitant

**FIGURE 28-11** Freedom from ascending aortic complications for patients with a bicuspid aortic valve with an ascending aortic diameter of  $<4$  cm, 4.0 to 4.5 cm, and 4.5 to 4.9 cm at the time of aortic valve replacement. (Reproduced with permission from Borger MA, et al: Should the ascending aorta be replaced more frequently in patients with bicuspid aortic valve disease? *J Thorac Cardiovasc Surg* 2004; Nov;128(5):677-683.)

replacement of ascending aorta when replacing a tricuspid aortic valve. Clearly the threshold should be between 4.5 and 5.5 cm. The decision is left to the surgeon and should be based on the additive risk of the procedure, patient's age, comorbidities, and overall life expectancy.

### AORTIC ROOT ENLARGEMENT PROCEDURES

Detailed descriptions of aortic root enlargement procedures are presented in a later chapter. Briefly, either an anterior or posterior annular enlargement procedure may be performed in a patient with a small aortic root to allow for implantation of a larger valve. The posterior approach is the most commonly used aortic root enlargement procedure in adults and can increase the annular diameter by 2 to 4 mm. Nicks and colleagues in 1970 described a technique of root enlargement in which the aortotomy is extended downward through the noncoronary cusp, through the aortic annulus to the anterior mitral leaflet with patch augmentation.<sup>43</sup> In 1979, Manouguian and Seybold-Epting described a procedure extending the aortotomy incision in a downward direction through the commissure between the left and noncoronary cusps into the interleaflet triangle and into the anterior leaflet of the mitral valve with patch augmentation.<sup>44</sup> The anterior approach is generally used in the pediatric population. Described by Konno and colleagues in 1975, this technique, which is also known as aortoventriculoplasty, is used when more than 4 mm of annular enlargement is required.<sup>45</sup> Instead of a transverse incision, a longitudinal incision is made in the anterior aorta and extended to the right coronary sinus of Valsalva and then through the anterior wall of the right ventricle to open the right ventricular outflow tract. The ventricular septum is incised, allowing significant expansion of the aortic annulus and left ventricular outflow tract.

### REOPERATIVE AORTIC VALVE SURGERY

Reoperative AVR may be performed for prosthetic valve-related complications or commonly for progressive AS post-CABG. Prosthetic valve-related causes include structural valve deterioration, prosthetic endocarditis, prosthesis thrombosis, or paravalvular leak. Chest reentry is the most hazardous portion of any repeat cardiac procedure. The proximity of cardiac structures to the posterior sternum must be assessed prior to redo sternotomy. This can be accomplished by lateral chest x-ray (CXR), computed tomography (CT) scan, or magnetic resonance imaging (MRI). Before making an incision, there should be blood transfusion units in the room, external defibrillator pads on the patient and the CPB pump should be primed. Femoral or axillary vessels may be exposed or CPB may be instituted through the peripheral vessels in the case of high-risk chest reentry. An oscillating saw is used to open the sternum and as little tissue as possible is dissected. Extreme caution must be employed during dissection when there are patent bypass grafts that cross the midline.

Once cardioplegic arrest is established, the old prosthesis is excised with sharp dissection. Care must be taken to count and remove all sutures and pledgets from the annulus.

Annular injuries caused while excising the prosthesis are repaired with pledgeted interrupted sutures or with a patch, typically of treated bovine pericardium. Removal of stentless prostheses may be particularly difficult. In the setting of endocarditis, aggressive debridement of all infected tissue must be performed with annular and aortic root reconstruction with pericardium when root abscesses are present.<sup>46</sup> Any foreign material can be seeded with bacteria, including Dacron aortic grafts, must be excised in the presence of active endocarditis as grafts can be seeded with bacteria.

In the presence of a Dacron prosthesis in the ascending aorta, chest reentry may be extremely hazardous since exsanguination will occur if the graft is inadvertently opened during dissection. To limit the systemic consequences of exsanguination at normothermia, the patient may be placed on femoro-femoral CPB and cooled to 18 to 20°C prior to chest reentry. If the Dacron graft is accidentally opened, local control of the bleeding is established and CPB is stopped. Under circulatory arrest, the graft is repaired or replaced. CPB may then be restarted. In all repeat aortic procedures, rigorous myocardial protection must be applied since these procedures often have very long ischemic times. Antegrade cold blood cardioplegia is usually employed in a continuous fashion throughout the case by selective cannulation of the coronary ostia. Retrograde cardioplegia may have benefit in the setting of patent old saphenous vein grafts.<sup>47</sup> More and more patients with previous cardiac surgery that require high-risk reoperative AVR are increasingly being referred to Heart Teams for consideration of transcatheter aortic valve replacement (TAVR).

### PORCELAIN AORTA

Porcelain aorta is the most severe form of aortic atherosclerosis. The major risk of manipulation of a calcified aorta is atheroemboli with stroke being the most common clinical sequelae.<sup>36</sup> Calcified or porcelain aorta is found in approximately 1 to 2% of cases and can be diagnosed based on preoperative imaging or intraoperative assessment. A history of risk factors such as smoking, hypercholesterolemia, diabetes, hypertension, or stroke as well as imaging demonstrating ostial coronary disease, peripheral vascular disease or carotid disease should trigger a high index of suspicion for aortic atheroma. Preoperative imaging to demonstrate aortic calcification includes CXR, transthoracic echocardiogram, angiogram, CT, or MRI. Intraoperative assessment includes direct palpation, transesophageal echocardiography and epi-aortic ultrasound. Of these, epi-aortic ultrasound is the most sensitive modality to detect aortic calcification, particularly for soft, nonechogenic, and nonpalpable plaque components.<sup>37</sup>

The key strategic decisions are (1) central versus peripheral cannulation, (2) cross-clamp versus circulatory arrest, and (3) isolated AVR versus AVR and RAA. Gillinov et al<sup>48</sup> reported a series of patients with severe aortic calcification and AS treated with endarterectomy, replacement of ascending aorta, cross-clamp during DHCA and balloon occlusion of aorta via aortotomy with Foley catheter. Cannulation sites were aorta (34%), femoral artery (34%), axillary artery (24%), and

innominate artery (8%), and all patients underwent circulatory arrest. More recently, TAVR has changed the landscape, offering an alternative to surgical valve replacement in this high-risk patient subset. In fact, porcelain aorta is the primary indication in approximately 10 to 15% of patients that undergo TAVR.<sup>49</sup>

## POSTOPERATIVE MANAGEMENT

Special consideration must be given to the underlying pathologic changes to the ventricle during the immediate postoperative period. The severely hypertrophied, noncompliant left ventricle resulting from AS is highly dependent on sufficient preload for adequate filling. Filling pressures should be carefully titrated between 15 and 18 mm Hg with intravenous volume infusion. Subvalvular left ventricular outflow obstruction with systolic anterior wall motion of the mitral valve should be avoided. Intravenous beta-adrenergic blockade may relieve this obstruction by decreasing inotropy and chronotropy. In extreme cases reoperation and surgical myectomy may be required.

Maintenance of sinus rhythm is also essential since up to one-third of cardiac output is derived from atrial contraction in a noncompliant ventricle. Up to 10% of patients will experience low cardiac output syndrome in the immediate postoperative period. If pacing is required postoperatively, synchronous atrioventricular pacing is beneficial in preventing low cardiac output syndrome.

Complete heart block occurs in 3 to 5% of AVR patients. This complication may be due to suture placement or injury from debridement near the conduction system at highest risk inferior to the right-non commissure. Transient complete heart block caused by perioperative edema usually resolves in 4 to 6 days. After this time, insertion of a permanent pacemaker is recommended if there is no resolution.

Profound peripheral vasodilation, often seen in patients with aortic insufficiency, is treated with vasoconstrictors including alpha-adrenergic agonists or vasopressin. Adequate filling of the dilated left ventricle may also require volume infusion.

## STENTED BIOPROSTHETIC AORTIC VALVEREPLACEMENT DEVICES

Stented bioprostheses may be constructed with porcine aortic valves or bovine pericardium. Over the past 40 years, advances in tissue fixation methodology and various proprietary chemical treatments have been developed to prevent extracellular matrix and calcium deposition. All heterograft valves are preserved with glutaraldehyde, which acts by cross-linking collagen fibers to reduce tissue antigenicity. Glutaraldehyde also ameliorates *in vivo* enzymatic degradation and causes the loss of cell viability, thereby preventing extracellular matrix turnover.<sup>50</sup> Glutaraldehyde fixation of porcine valves can be performed at high pressure (60 to 80 mm Hg), low pressure (0.1 to 2 mm Hg), or zero pressure (0 mm Hg). Porcine prostheses

**FIGURE 28-12** The Medtronic Hancock II porcine aortic prosthesis. (©Medtronic 2016.)

fixed at zero pressure retain the collagen architecture of the relaxed aortic valve cusp.<sup>51</sup> Pericardial prostheses are fixed in low- or zero-pressure conditions.

When comparing bioprostheses, it is important to be aware of lack of standardization in methodologies for labeling valve sizes by the different manufacturers. In general, label sizes refer to either the internal or the external diameter of the stent, not the external diameter of the sewing cuff or the maximal opening diameter of the valve leaflets. Thus, the same aortic annulus will likely fit different-sized valves from different manufacturers, depending on the convention they use and the size of their sewing cuff.

## Earlier-generation Prostheses

First-generation bioprostheses were preserved with high-pressure fixation and were placed in the annular position. Second-generation prostheses are treated with low- or zero-pressure fixation. Several second-generation prostheses may also be placed in the supra-annular position, which allows placement of a slightly larger prosthesis. The Medtronic Hancock II Ultra is a porcine bioprosthesis (Medtronic, Minneapolis, MN; Fig. 28-12) and the Carpentier-Edwards Perimount (Edwards Life Sciences LLC, Irvine, CA; Fig. 28-13) is a pericardial bioprosthesis. Despite the introduction of newer-generation prostheses, some surgeons prefer implantation of Hancock II Ultra and Perimount valves because of the established long-term clinical follow up and performance of these valves.<sup>52-56</sup>

## Third-generation Prostheses

Newer-generation prostheses incorporate zero- or low-pressure fixation with anti-mineralization processes that are designed to reduce material fatigue and calcification. Stents have become progressively thinner allowing a lower profile. Porcine valves have a lower stent post and base profile to minimize protrusion into the aortic wall and facilitate

**FIGURE 28-13** The Edwards Perimount pericardial aortic prosthesis. (Used with permission from Edwards Lifesciences LLC, Irvine, CA.)

coronary clearance (Medtronic Mosaic Ultra; Fig. 28-14). For this reason, they are particularly favorable for tissue mitral valve replacement as the stents occupy less space in the left ventricle.

The third-generation bovine bioprostheses include the Carpentier-Edwards Magna Ease (Edwards Life Sciences LLC; Fig. 28-15), Mitroflow (Sorin, Fig. 28-16), and Trifecta (St. Jude, St. Paul, MN; Fig. 28-17). The Magna Ease is the evolution of the Perimount pericardial valve, with a narrower sewing cuff and scalloped sign for supra-annular placement. The Mitroflow Pericardial aortic prosthesis and the Trifecta are pericardial valves with the pericardium placed around the exterior of the stent, allowing for a larger opening diameter and optimal flow characteristics.

Head-to-head comparisons have been performed and despite small but significant differences in hemodynamic parameters, no valve has demonstrated improved survival nor left ventricular remodeling over another. Thalji et al<sup>57</sup>

**FIGURE 28-15** The Edwards Magna Ease pericardial aortic prosthesis. (Used with permission from Edwards Lifesciences LLC, Irvine, CA.)

**FIGURE 28-16** The Sorin Mitroflow pericardial aortic prosthesis. (Courtesy of Sorin Group, Saluggia, Italy.)

**FIGURE 28-14** The Medtronic Mosaic Ultra porcine aortic prosthesis. (©Medtronic 2016.)

**FIGURE 28-17** The St. Jude Trifecta pericardial aortic prosthesis. (Trifecta, Quartet and St. Jude Medical are trademarks of St. Jude Medical, Inc. or its related companies. Reproduced with permission of St. Jude Medical, ©2016. All rights reserved.)

performed a RCT in 241 patients with AS to receive the largest possible St. Jude Epic, Edwards Magna and Sorin Mitroflow valve. There was small but significant hemodynamic advantage for the Magna valve with respect to indexed EOA ( $0.93 \pm 0.28$ ,  $1.04 \pm 0.28$ , and  $0.96 \pm 0.26$  cm<sup>2</sup>/m<sup>2</sup>,  $p = .015$  for Epic, Magna, and Mitroflow, respectively) and mean gradient ( $15.2 \pm 5.5$ ,  $12.3 \pm 4.3$ , and  $16.2 \pm 5.7$  mm Hg,  $p < .001$ ), primarily driven by valve sizes 23 mm and greater. However, short-term clinical outcomes and LVM regression was not different. Whether meaningful long-term clinical differences will emerge between these third-generation valves remain an open question. A retrospective comparison of Trifecta, Edwards Magna, and Magna Ease valves also found that valve type was not an independent predictor of valve area nor mean gradient overall.<sup>58</sup> However, for the subset of patients with small aortic roots, a 19-mm Trifecta and Mitroflow offer excellent hemodynamic properties *in vivo* and may be considered.<sup>58,59</sup> Dumesnil et al<sup>60</sup> reviewed hemodynamic properties of a range of stented bioprostheses and find comparable orifice areas with most currently available prostheses (Table 28-5).

## OUTCOMES OF AORTIC VALVE REPLACEMENT

### Operative Mortality

Operative mortality is defined as all-cause mortality within 30 days of operation or during the same hospital admission. In 1999, the STS ACSD reviewed the results of 86,580 valve procedures to find an overall mortality of 4.3% for isolated AVR, and 8.0% for AVR with CABG.<sup>61</sup> Then in 2009, they again reviewed 67,292 cases of AVR between 2002 and 2006, and found an improved mortality of 3.2% for isolated AVR, and 5.6% for AVR with CABG (Table 28-6).<sup>62</sup> Recently, Thourani et al<sup>63</sup> reviewed 141,905 cases of AVR in the STS ACSD between 2002 and 2010 to show lower observed mortality rates than the STS predicted risk of mortality (PROM) in low- (1.4 vs 1.7%), medium- (5.1 vs 5.5%), and high-risk (11.8 vs 13.7%) patients groups ( $p < .0001$ ). They further demonstrate a slight increase in overall operative mortality in the current surgical era (2007 to 2010) compared to previous (2002 to 2006; 2.7 vs 2.5%,  $p = .018$ ) despite a significant increase

in overall STS PROM ( $3.05 \pm 3.73\%$  vs  $2.82 \pm 3.69\%$ ,  $p < .0001$ ). This was attributed to lower mortality in both the moderate (5.4 vs 6.4%,  $p = .002$ ) and high-risk (11.9 vs 14.4%,  $p = .0004$ ) patient cohorts. It is important to note that information in this database is voluntarily submitted and includes both low-volume and high-volume centers.

### Long-term Survival

There have been three major long-term RCTs comparing survival between patients receiving mechanical and bioprosthetic valves.<sup>64-67</sup> The 12-year results from the Edinburgh Heart Trial improved survival free from reoperation and a trend toward improved overall survival with the Bjork-Shiley mechanical prosthesis.<sup>64</sup> The 20-year results found no survival advantage with mechanical valves.<sup>65</sup> In the Veterans Affairs Trial, all-cause mortality after AVR was lower with the mechanical valve versus bioprosthesis (66 vs 79%,  $p = .02$ ) at 15 years.<sup>66</sup> In patients  $\geq 65$  years after AVR, primary valve failure was not different between bioprosthetic and mechanical valves

AVR, aortic valve replacement; Comp, composite adverse event (any); CVA, cerebrovascular accident (stroke); DSWI, deep sternal wound infection; Mort, mortality; PLOS, prolonged length of stay; Reop, reoperation; RF, renal failure; SLOS, short length of stay; Vent, prolonged ventilation.

Data from O'Brien SM, Shahian DM, Filardo G, et al: The Society of Thoracic Surgeons 2008 cardiac surgery risk models: part 2—isolated valve surgery, *Ann Thorac Surg.* 2009 Jul;88(1 Suppl):S23-S42.

(9 ± 6 vs 0%,  $p = .16$ ). However, reoperation was higher for bioprosthetic AVR and bleeding was higher with mechanical valves. These landmark trials form the basis of our guidelines but the Bjork-Shiley single disc is no longer utilized and third generation pericardial bioprostheses are generally favored over porcine valves and the Hancock bioprostheses. Increased bioprosthetic structural deterioration in these early trials was likely influenced by the use of first-generation prostheses that are more prone to structural failure than newer generation prostheses. A more recent study of 310 patients between 55 and 70 years old randomized to either tissue or mechanical AVR showed no difference in mortality but more SVD and higher reoperation with bioprosthetic valves after 10 years (Fig. 28-18).<sup>67</sup> Importantly, higher bleeding events with mechanical prostheses in the VA and Edinburgh studies were not seen in the recent trial, possibly due to a lower target international normalized ratio (2-2.5).

There are several nonrandomized long-term clinical follow-up series of early generation and contemporary bioprostheses. Brennan et al<sup>10</sup> report long-term outcomes on 145,911 patients ≥ 65 years in the STS database undergoing AVR and AVR/CABG from 1991 to 2007 (Fig. 28-19). The

Adapted with permission from Brennan JM, Edwards FH, Zhao Y, et al: Developing Evidence to Inform Decisions About Effectiveness—Aortic Valve Replacement (DEcIDE AVR) Research Team. Long-term survival after aortic valve replacement among high-risk elderly patients in the United States: insights from the Society of Thoracic Surgeons Adult Cardiac Surgery Database, 1991 to 2007. *Circulation* 2012 Sep 25;126(13):1621-1629.

median survival in patients 65 to 69, 70 to 79, and ≥80 years of age undergoing AVR was 13, 9, and 6 years, respectively (Table 28-7). Figure 28-20 shows long-term mortality stratified by STS perioperative risk of mortality. Although only 5% of isolated AVR patients had a high STS perioperative risk of mortality (≥10%), their median survival was 2.5 to 2.7 years. Importantly, severe lung disease and renal failure were each associated with a ≥50% reduction in median survival. LVD and prior cardiac operation were associated with a 25% reduction in median survival.<sup>10</sup> The comorbidities of age, concomitant CAD, LVD, and poor functional status on middle-to-late survival after bioprosthetic AVR are additive. Other risk factors for late mortality include concomitant renal disease, female gender, concomitant cardiac or vascular procedure, and atrial fibrillation.

### Valve-related Mortality

A committee of the American Association for Thoracic Surgery (AATS), STS, and European Association for Cardio-Thoracic Surgery (EACTS) has standardized prosthetic valve surgery outcomes. Valve-related mortality is defined as all deaths caused by structural valve deterioration, nonstructural

valve dysfunction, valve thrombosis, embolism, bleeding event, operated valvular endocarditis, or death related to reoperation of an operated valve.<sup>68</sup> Sudden, unexplained, unexpected deaths of patients with an operated valve are included as valve-related mortality. Deaths caused by progressive heart failure in patients with satisfactorily functioning cardiac valves are not included. In the Hammermeister series, valve-related deaths accounted for 37% of all deaths in patients with mechanical valves and 41% of all deaths in patients with bioprostheses at 15 years.<sup>64</sup> Nonvalvular cardiac deaths accounted for 17 and 21% of deaths at 15 years in patients with mechanical and bioprostheses, respectively.

### NONFATAL VALVE EVENTS

The joint AATS/STS/EACTS committee also defined specific guidelines for reporting outcomes on structural and nonstructural valve deterioration, valve thrombosis, embolic events, bleeding events, and prosthetic endocarditis.<sup>68</sup> *Structural valve deterioration* refers to any change in function of an operated valve resulting from an intrinsic abnormality of the valve that causes stenosis or regurgitation (eg, leaflet tears, suture line disruption). *Nonstructural dysfunction* is any abnormality

**FIGURE 28-20** Long-term survival after aortic valve replacement in elderly patients between 1991 and 2007 in the STS Database stratified by STS PROM Score. (Reproduced with permission from Brennan JM, Edwards FH, Zhao Y, et al: Developing Evidence to Inform Decisions About Effectiveness—Aortic Valve Replacement (DEClIDE AVR) Research Team. Long-term survival after aortic valve replacement among high-risk elderly patients in the United States: insights from the Society of Thoracic Surgeons Adult Cardiac Surgery Database, 1991 to 2007, *Circulation* 2012 Sep 25;126(13):1621-1629.)

of an operated valve resulting in stenosis or regurgitation that is caused by factors not intrinsic to the valve itself (eg, pannus overgrowth, inappropriate sizing, or paravalvular leak). *Valve thrombosis* is any thrombus that interferes with valve function in the absence of infection. *Embolism* is any embolic event that occurs after the immediate postoperative period in the absence of infection. *Cerebral embolic events* are subclassified into *transient ischemic attacks* are short fully reversible neurologic events and *Strokes* are neurologic deficits lasting longer than >72 hours. *Bleeding event* is any episode of major internal or external bleeding that causes death, hospitalization, or permanent injury, or requires transfusion, regardless of the patient's anticoagulation status. This does not include embolic stroke followed by hemorrhagic transformation and intracranial bleed. Finally, *operated valvular endocarditis* is any infection involving an operated valve; any structural or

nonstructural valvular dysfunction, thrombosis, or embolic event associated with operated valvular endocarditis.

## Structural Valve Deterioration

### STENTED BIOPROSTHESES

Several large series describe long-term follow-up of first-, second-, and now third-generation stented bioprostheses (Table 28-8).<sup>55,69-78</sup> These series are not directly comparable since they took place in different patient populations and in different eras; however, there are some overarching results. Long-term follow-up of second-generation stented bioprostheses, including the Medtronic Hancock II porcine and Carpentier-Edwards pericardial valves show approximately 90% freedom from structural valve deterioration at 12-year follow-up. However, beyond 15-year follow-up, freedom from SVD falls rapidly in most series. In a long-term follow up of the Hancock II valve, independent predictors of reoperation due to SVD were age (odds ratio [OR]: 0.72; 95% confidence interval [CI]: 0.58 to 0.90,  $p < .01$ ) and prosthesis-patient mismatch (OR: 1.63; 95% CI: 1.01 to 2.63;  $p = .045$ ).<sup>55</sup> In large series, freedom from reoperation is approximately 95% at 5 years, 90% at 10 years, but 70% at 15 years (Table 28-8).<sup>58-77</sup> Notably, the freedom from SVD may be underestimated in the literature since most series report SVD by the actuarial method instead of the actual or cumulative incidence method.<sup>79</sup> Actuarial statistical analysis overestimates SVD in older patients since it assumes that patients who have died of other causes will continue to be at risk for SVD.

Younger patients are predisposed to premature bioprosthetic SVD.<sup>80,81</sup> In a younger patient cohort (age < 60 years), actuarial freedom from re-AVR was 87.4, 62.6, and 52.2% at 10, 15, and 20 years postoperatively, respectively.<sup>56</sup> Jamieson et al reported long-term clinical outcomes of 230 patients < 60 years old with the Carpentier-Edwards supra-annular aortic valve. Freedom from SVD at 18 years after operation was 51.0% in patients aged 51 to 60 years and 31.9% in patients < 50 years. Forcillo et al<sup>80</sup> report their 20-year experience in 144 patients < 60 years old (mean age  $51 \pm 9$  years) that underwent AVR with the Edwards pericardial valves. Freedom from SVD was  $84 \pm 4\%$  and  $57 \pm 6\%$  at 10 and 15 years, respectively. Patients underwent reoperation for SVD at an average of  $11 \pm 5$  years with no perioperative mortality.

## Optimal Antithrombotic Therapy

Bioprosthetic valves do not require long-term anticoagulation with warfarin unless the patient is at high risk for thromboembolism or has had a thromboembolic event with their prosthesis. Stented bioprostheses have a linearized risk for thromboembolism between 0.5 and 1% per year. This risk appears to be lower in patients with stentless heterograft, allograft, or autograft valves.<sup>83-85</sup> Aspirin significantly decreases the risk of thromboembolism in low-risk patients with bioprostheses versus no antiplatelet therapy.<sup>86,87</sup> This risk is approximately the same risk of thromboembolism as fully

\*Values for cohort > 65 years.

anticoagulated mechanical valves, with fewer bleeding complications. Interestingly, by 15 years in the Edinburgh Heart Trial, the proportion of patients with bioprosthetic AVR on warfarin was 33%, mostly for atrial fibrillation or LVD.<sup>65</sup> If a patient has identified high-risk factors for thrombosis preoperatively, a mechanical prosthesis may be considered unless the risk factor is amenable to correction since formal anticoagulation with warfarin will still be necessary.

There is an immediate increased hazard function for thromboembolism before the exposed surfaces of stented bioprostheses endothelialize. In a study from the Mayo Clinic, a 41 and 3.6% per year risk of thromboembolism was reported in the interval 0-10 days and 10-90 days following bioprosthetic AVR, respectively.<sup>86</sup> A retrospective study of 25,656 elderly patients in the STS database report lower risk of death (relative risk [RR]: 0.80, 95% CI: 0.66 to 0.96) and embolism (RR: 0.52, 95% CI: 0.35 to 0.76) but higher risk of bleeding events (RR: 2.80, 95% CI: 2.18 to 3.60) with aspirin and warfarin versus aspirin alone in the first 3 months following bioprosthetic AVR.<sup>87</sup> This study revealed considerable variation in short-term anticoagulation strategies for patients with bioprosthetic AVR. There are two small prospective RCTs comparing formal anticoagulation vs antiplatelet alone postbioprosthetic AVR. In the TRAC Trial, 193 patients that underwent bioprosthetic aortic or mitral valve replacement received Triflusal (an antiplatelet agent similar to aspirin) or acenocoumarol (a vitamin K antagonist similar to warfarin). There was no difference in thromboembolic complications but greater bleeding events with anticoagulation (10 vs 3.1%,  $p = .048$ ).<sup>88</sup> The WoA Epic Pilot Trial randomized 69 low thrombotic risk patients undergoing bioprosthetic AVR to ASA or warfarin. There was no difference in strokes (2.9 vs

2.9%,  $p = .99$ ), bleeding events (2.9 vs 8.8%,  $p = .36$ ).<sup>89</sup> The current 2014 ACC/AHA Guidelines recommend anticoagulation with warfarin (INR between 2 and 3) for the first 3 months for bioprosthetic valves (Class IIa, Level of Evidence C) then low dose aspirin as well as aspirin alone (Class IIa, Level of Evidence B).<sup>29</sup> The early use of anticoagulation primarily reflects the increased risk of thromboembolic events due to the lack of endothelialization of the various prosthetic materials.

Warfarin remains the only approved oral anticoagulant for patients with prosthetic valve(s). Although nonwarfarin oral anticoagulants (NOACs) have shown improved efficacy over warfarin in large trials of venous thromboembolism and non-valvular atrial fibrillation.<sup>90-92</sup> The RE-ALIGN phase 2 dose-validation study comparing dabigatran versus warfarin for patients with mechanical prosthetic valves report higher stroke (5 vs 0%) and higher major bleeding (4 vs 2%) in the dabigatran group.<sup>93</sup> The use of NOAC for prosthetic valve anticoagulation is thus currently a class III recommendation (will cause harm; Level of Evidence B) and should not be used.<sup>29</sup>

## Prosthesis Thrombosis

Prosthesis thrombosis is a rare but potentially devastating outcome after bioprosthetic AVR. The incidence of prosthesis thrombosis is <0.2% per year and occurs more often with mechanical prostheses.<sup>94</sup> Thrombolytic therapy may be used in some patients but it is often ineffective and cannot be used in the immediate postoperative period due to excessive bleeding risk. Thrombolysis is recommended in patients with left-sided thrombosis who are experiencing mild heart failure (NYHA Class I or II) or who are in severe heart failure but are

considered too high risk for surgery.<sup>29</sup> A risk of thrombolytic therapy is cerebral or peripheral thromboembolism. Surgical treatment is recommended in severe heart failure (NYHA Class III or IV) and includes replacement of the valve or open thrombectomy, and mortality from either procedure is similar at approximately 10 to 15%. Recurrent thrombosis after de-clotting occurs in up to 40% of patients and we recommend valve replacement in virtually all patients who are managed operatively.

## Prosthetic Valve Endocarditis

Prosthetic valve endocarditis (PVE) is separated into two time frames: early (<60 days postimplantation) and late (>60 days postimplantation). Early PVE is usually a sequela of perioperative bacterial seeding of the valve, either during implantation or postoperatively from wound or intravascular catheter infections. *Staphylococcus aureus*, *S. epidermidis*, Gram-negative bacteria, and fungal infections are common during this period.<sup>95-98</sup> Although most cases of late PVE are caused by septicemia from noncardiac sources, a small proportion of late cases in the first year are attributable to less virulent organisms introduced in the perioperative period, particularly *S. epidermidis*. Organisms responsible for late PVE include *Streptococcus* and *Staphylococcus* species and other organisms commonly found in native valve infectious endocarditis. All unexplained fevers should be meticulously investigated for PVE with serial blood cultures and transthoracic or transesophageal echocardiography. Transesophageal echocardiography provides more detailed anatomic information such as the presence of vegetations, abscesses, and fistulas. Transthoracic views may provide better views of the anterior portion of the valve. The annual risk of PVE in the aortic position is 0.6 to 0.9% per patient year.<sup>95,96</sup> The 5-year freedom from PVE is >95%.<sup>97</sup> Mechanical valves may have a slightly higher early hazard for PVE than stented bioprostheses.<sup>98</sup> However, no difference exists in risk between patients with mechanical and stented bioprosthetic prostheses after the early phase.

Outcome for patients with PVE is very poor. Invasive paravalvular infection occurs in up to 40% of cases of PVE.<sup>96</sup> Early PVE is associated with 30 to 80% mortality, while late PVE is associated with 20 to 40% mortality.<sup>97</sup> According to the 2014 ACC/AHA Guidelines, early surgeries indicated for PVE with valve dysfunction and heart failure (Class I, Level of Evidence B); paravalvular leak or partial dehiscence; presence of a new conduction defect, abscess or penetrating lesion (Class I, Level of Evidence B); persistent bacteremia and fever despite 5-7 days of appropriate antibiotic therapy (Class I, Level of Evidence B); vegetations (>10 mm); and surgery for relapsing infection (Class I, Level of Evidence C) and multiple systemic emboli with persistent vegetations (Class IIa, Level of Evidence B).<sup>29</sup> Notably, all fungal, and most virulent strains of *Staphylococcus aureus*, *Serratia marcescens*, and *Pseudomonas aeruginosa* require operation, as these organisms are highly invasive and antibiotic therapy alone is generally ineffective (Class I, Level of Evidence B).

## Paravalvular Leak and Hemolysis

Paravalvular leak is uncommon when pledgeted sutures are routinely used, outside of the setting of infective endocarditis. Technical errors may result in inappropriately large gaps between sutures, leaving a small portion of the prosthesis unattached to the annulus. If paravalvular leak is sufficient to cause significant hemolysis or heart failure from acute aortic insufficiency, surgical correction should be performed (Class I, Level of Evidence B).<sup>29</sup> Repair can be accomplished with a few interrupted pledgeted sutures or a large defect may require valve explant, patch repair and valve reimplant. Pannus overgrowth and prosthetic structural degeneration interfering with normal valve opening and closure may also cause hemolysis severe enough to warrant reoperation. Milder cases of hemolysis may be managed conservatively by dietary supplementation with iron and folic acid, and routine measurement of hemoglobin, serum haptoglobin, and lactate dehydrogenase.

## HEMODYNAMIC PERFORMANCE AND VENTRICULAR REMODELING

### Left Ventricular Mass Regression

Pressure and volume overload caused by aortic valve disease leads to increased intracavitary left ventricular pressures and compensatory LVH. In severe AS, concentric ventricular hypertrophy occurs without increasing end-diastolic dimension until late in the disease process, thus maintaining the ventricular wall thickness:cavity radius ratio. On the other hand, severe AR causes volume overload with an increase in left ventricular end-diastolic volume and eccentric hypertrophy, but may not change the ratio of ventricular wall thickness to cavity radius. Both pathologies result in an increase in LVM which has a strong negative prognostic effect.<sup>99,100</sup> The overall goal of AVR is to alleviate the pressure and volume overload on the left ventricle, allowing myocardial remodeling and regression of LVM.

The clinical impact of LVM regression is not as well understood, despite its widespread acceptance as a measure of outcome after aortic valve surgery. In patients after AVR for isolated AS, LVM generally regresses significantly over the first 18 months and returns to normal limits.<sup>101-102</sup> Ventricular mass regression may continue for up to 5 years after valve replacement.<sup>103</sup> However, some patients never experience adequate LVM regression which can be associated with poor clinical outcome. In particular, patient-prosthesis mismatch (PPM), in which poor hemodynamic performance of a prosthesis results in poor regression of LVH, is associated with poor patient outcome.

## Prosthesis-Patient Mismatch

### DEFINITIONS

The term PPM has been applied to several different clinical situations. It has been used to describe absolute small valve size (ie, <21 mm), small valve size in a patient with a large

body surface area, excessive transvalvular gradient postimplantation, increased transvalvular gradient with exercise, indexed EOA, and various combinations of these variables. Rahimtoola<sup>104</sup> originally defined PPM as a condition that occurs when the valve area of a prosthetic valve is less than the area of that patient's normal valve. Ultimately, the valve performance cannot meet the cardiac output requirements of the patient, resulting in either no relief or worsening of symptoms due to the obstructive nature of the prosthesis, which creates a residual stenosis resulting in an elevated transvalvular gradient. To varying degrees, all valve prostheses are inherently stenotic. The presence of rigid sewing rings, and in the case of stented bioprostheses, struts to hold the valve commissures, cause obstruction to outflow and will therefore cause a residual gradient despite normal prosthesis function. Patient-prosthesis mismatch is further exacerbated by annular fibrosis, annular calcification, and LVH, as seen in AS, that cause contraction of the native annulus, leading to the implantation of a smaller prosthesis. Two distinct terms are commonly used to describe the size of prosthetic valves: EOA and geometric orifice area (GOA).

### EFFECTIVE ORIFICE AREA

The most commonly cited definition of PPM is a low-indexed effective orifice area (iEOA). The iEOA is calculated by dividing the echocardiographically determined EOA by the body surface area. EOA is calculated by a reconfiguration of the continuity equation:

$$EOA = (CSA_{LVOT} \times TVI_{LVOT}) / TVI_{AO}$$

EOA is effective orifice area (cm<sup>2</sup>).

CSA<sub>LVOT</sub> is cross-sectional area of the LVOT (cm<sup>2</sup>).

TVI<sub>LVOT</sub> is velocity time integral of forward blood flow (cm) as derived from pulse-wave Doppler in the LVOT.

TVI<sub>AO</sub> is velocity time integral of forward blood flow (cm) as derived from software integration of transvalvular continuous wave Doppler.

The EOA and mean systolic gradient of several commonly available bioprostheses are shown in Table 28-9.<sup>105</sup>

The EOA is a functional estimate of the minimal cross-sectional area of the transvalvular flow jet downstream of a valve and dependent on the (1) geometric area of the prosthesis, (2) shape and size of the LVOT and ascending aorta, (3) blood pressure, and (4) cardiac output. Doppler-derived EOA correlates best with catheter-derived EOA (as determined by the Gorlin formula) when the ascending aortic diameter is 4 cm, but tends to underestimate EOA in patients with smaller aortic diameters.<sup>106</sup> The EOA varies widely for valves from different producers. The measured EOA cannot be known for a specific valve in a specific patient until the valve has actually been implanted. Studies examining the effect of low iEOA on clinical outcomes have typically used projected iEOA using published tables of EOA derived from historical controls instead of actually measuring true in vivo postoperative EOA. Moreover, these tables have been derived from relatively small

numbers of valves in each size for each manufacturer with wide variability between studies. Nevertheless, such reference values can be helpful to predict the presence and severity of PPM for any given patient and valve. EOA correlates with postoperative valve gradients, which are not surprising considering that they are mathematically related. Echocardiographic mean and peak gradients are calculated according to the Bernoulli equation:

$$\text{Peak gradient (mm Hg)} = 4 \times (V_{AVmax}^2 - V_{LVOTmax}^2)$$

$$\text{Mean gradient (mm Hg)} = 4 \times (V_{AVmean}^2 - V_{LVOTmean}^2)$$

Several authors suggest PPM occurs at an iEOA of  $\leq 0.85$  cm<sup>2</sup>/m<sup>2</sup> with moderate and severe PPM at an iEOA of 0.85 to 0.65 and  $\leq 0.65$  cm<sup>2</sup>/m<sup>2</sup>, respectively.<sup>107,108</sup> These thresholds are used in the 2009 American Society of Echocardiography/European Association of Echocardiography Guidelines.<sup>109</sup> Pibarot and Dumesnil<sup>109</sup> have redefined PPM as a condition "when the EOA of the prosthesis is too small in relation to the patient's body size, resulting in abnormally high postoperative gradients." This definition is based on the assumption that transvalvular gradients begin to rise substantially at iEOAs below this value, and that these elevated gradients result in increased left ventricular work preventing regression of LVH.

### GEOMETRIC ORIFICE AREA

The GOA (also known as the internal geometric area) of the valve is the ex vivo measured maximal cross-sectional area of the valve opening that does not vary significantly between same-sized valves from the same manufacturer. It is a static measure that is known preoperatively for any given prosthesis based on manufacturer specifications or by measurement with calipers. The GOA is larger than the EOA for any given prosthesis (Figure 28-21).

### CLINICAL SIGNIFICANCE

The incidence of PPM is steadily decreasing. Pibarot and Dumesnil<sup>110</sup> studied PPM in 1266 patients undergoing AVR and found moderate (iEOA < 0.85 cm<sup>2</sup>/m<sup>2</sup>) or severe (iEOA < 0.65 cm<sup>2</sup>/m<sup>2</sup>) PPM to be present in 38% of patients. A more recent study found moderate and severe PPM in only 15 and 6% of patients, respectively.<sup>111</sup> In another study, the rate of severe PPM after implantation of the Trifecta, Mitroflow, and Perimount Magna valves was 1.3% (2/150), 5.8% (44/758), and 3.2% (3/95).<sup>105</sup> The low contemporary incidence of PPM is likely a result of improved hemodynamic performance of newer generation bioprostheses and the increased awareness of poor outcomes with severe PPM and thus greater use of preventive strategies.<sup>60</sup>

There are several studies demonstrating the adverse impact of severe PPM on survival but the significance of moderate PPM still controversial.<sup>112-118</sup> Ruel and colleagues showed that overall survival and LVM regression was poorer in patients with PPM and LVD than those who had LVD without PPM.<sup>115</sup> A retrospective study of 3343 patients

AV, Aortic valve; EOA, effective orifice area; EOAI, effective orifice area index; LVOT, left ventricular outflow tract.

Data from Ugur M, Suri RM, Daly RC, et al: Comparison of early hemodynamic performance of 3 aortic valve bioprostheses, *J Thorac Cardiovasc Surg*. 2014 Nov;148(5):1940-1946.<sup>105</sup>

**FIGURE 28-21** Diagrammatic representation of effective orifice area and geometric orifice area in relation to the left ventricular outflow tract and aortic root.

with mechanical and bioprosthetic AVR found that for the subgroup with LVD (EF < 50%), severe PPM was associated with greater 15-year mortality ( $p = .049$ ).<sup>117</sup> Two meta-analyses both showed that severe PPM impact mortality and should be avoided. A meta-analysis of 34 studies including 27,186 patients found that 34.2 and 9.8% of patients undergoing AVR had moderate and severe PPM, respectively.<sup>118</sup> Any PPM was associated with an increase in all-cause mortality (hazard ratio [HR] = 1.34, 95% confidence interval [CI]: 1.18 to 1.51). Furthermore, moderate and severe PPM increased all-cause mortality (HR = 1.19, 95% CI: 1.07 to 1.33 and HR = 1.84, 95% CI: 1.38 to 2.45) and cardiac-related mortality (HR = 1.32, 95% CI: 1.02 to 1.71 and HR = 6.46, 95% CI: 2.79 to 14.97) (Fig. 28-22). Takagi et al<sup>119</sup> reviewed 24 studies revealed a 31% increase in all-cause mortality with any PPM (HR = 1.31; 95% CI: 1.16 to 1.48;  $p < .00001$ ). Furthermore, severe PPM was associated with a 27% increase in mortality (HR = 1.27; 95% CI: 1.11 to

**FIGURE 28-22** Pooled estimate for cardiac-related mortality: ratios demonstrate the additional hazard with prosthesis-patient mismatch in relation to a no prosthesis-patient mismatch reference group. (Reproduced with permission from Head SJ, Mokhles MM, Osnaubrugge RL, et al: The impact of prosthesis-patient mismatch on long-term survival after aortic valve replacement: a systematic review and meta-analysis of 34 observational studies comprising 27 186 patients with 133 141 patient-years, *Eur Heart J* 2012 Jun;33(12):1518-29.)

1.46;  $p = .0008$ ) but moderate PPM was not (HR 0.99; 95% CI: 0.92 to 1.07;  $p = .78$ ). As described by Pibarot et al<sup>120</sup> this is explained by the fact that moderate AS is well tolerated with normal LV but not with depressed LV. Furthermore, increased hemodynamic stress from moderate PPM may beget rapid structural valve deterioration progressing to severe PPM.<sup>121</sup>

### SMALL AORTIC ROOT

Many surgeons express concern regarding postoperative outcomes in patients with small aortic roots in whom only a very small (19 mm) valve can be implanted. However, several studies have shown no difference in LVM regression, NYHA functional class, CHF or survival with small diameter AVRs.<sup>122-124</sup> De Paulis et al<sup>122</sup> show no difference in LVM regression between patients receiving 19 and 21 mm mechanical valves versus those with 23 or 25 mm valves. Kratz et al<sup>123</sup> also report that small valve size was not predictive of CHF or late death. Khan et al<sup>124</sup> studied 19 to 23 mm Carpentier-Edwards pericardial valves and found that significant LVM regression occurred with each valve size, including 19 mm valves.

### DATA SYNTHESIS

The literature is clear in that severe PPM should be avoided, particularly in those patients with poor ventricular function, but the clinical significance of less-than-severe PPM remains divided. The options to avoid PPM are implantation of a less-obstructive mechanical or stentless bioprosthesis or to perform root replacement or aortic root enlargement. Stentless prostheses in the subcoronary position may be a lower profile alternative but requires additional technical skill and cross-clamp time. Aortic root replacements or enlargement procedures require greater experience operating on the aortic root and may carry excessive mortality and wide variability in surgical outcomes even among highly experienced centers. When faced with potential PPM in the operating room, the decision to perform a more complex, higher-risk procedure must be balanced carefully with the potential benefits of implanting a larger prosthesis. Some reports have shown that transvalvular gradients in patients with lower iEOA often rise substantially with exercise.<sup>125</sup> Although the majority of patients undergoing AVR are elderly and unlikely to experience functional limitations from this situation, in younger,

highly active patients or those with LV dysfunction, either root enlargement or stentless prostheses may provide better functional outcome with lower transvalvular gradients. In the rare circumstance of anticipated extreme mismatch (ie, iEOA < 0.6 cm<sup>2</sup>/m<sup>2</sup>) root enlargement is an acceptable approach in the hands of an experienced surgeon. Except in these circumstances, given the paucity of long-term data to support more complex procedures and well-documented increased risk, routine AVR with modern standard prostheses is acceptable and preferable.

## PROSTHESIS SELECTION

An ideal aortic prosthesis would be simple to implant, widely available, possess long-term durability, would have no intrinsic thrombogenicity, would not have a predilection for endocarditis, and would have no residual transvalvular pressure gradient. Such a valve does not currently exist. Currently available options include mechanical valves, stented biologic heterograft valves, stentless biologic heterograft valves, allograft valves, and pulmonary autograft valves. Among these options pulmonary autograft and allograft valves are the most physiologic prostheses. They are less prone to thrombosis or endocarditis and have excellent hemodynamic characteristics.<sup>126,127</sup> They are most beneficial in children and younger adults. Allograft valves may also improve the results of AVR in active endocarditis.<sup>128</sup> Despite their potential benefits, these prostheses can be very technically demanding to implant. A further discussion of these valves is presented in subsequent chapters. The remainder of this discussion will focus on issues regarding selection of mechanical or bioprosthetic valves.

## Mechanical versus Biologic Valves

When selecting between mechanical and biologic heart valves, the surgeon and patient together must balance the risks of SVD with bioprosthetic valves versus need for anticoagulation with mechanical valves. The 2014 AHA/ACC Guidelines emphasizes the importance of patient preference regarding the choice of valve prosthesis.<sup>29</sup>

## AGE CONSIDERATIONS

Generally, patients over 70 years of age at the time of surgery should receive a biologic valve and patients under the age of 60 years should have a mechanical prosthesis to minimize the risk of structural failure requiring repeat AVR as an octogenarian. Patients between 60 and 70 represent the group in whom there is still debate regarding prosthesis selection. Those patients who have comorbidities such as severe CAD may be less likely to outlive their prosthesis and should receive a biologic valve. Having said that, there is a steady shift to greater use of bioprostheses for patients in all age cohorts, especially given the burden of anticoagulation and the potential for subsequent transcatheter valve-in-valve implantation. The STS ACSD reported a 20% absolute increase in the proportion of patients selecting bioprostheses over mechanical valves

for all patient age cohorts.<sup>129</sup> There was also an increase in the proportion of patients undergoing bioprosthetic AVR from 72.6% between 2002 and 2006 to 83.8% between 2007 and 2010 ( $p < .0001$ ).<sup>63</sup> Chiang et al<sup>130</sup> studied 2002 propensity-matched young patient (50 to 69 years) with bioprosthetic versus mechanical AVR in New York State (1997 to 2004). As expected, they report greater 15-year reoperation rate (12.1 vs 6.9%) and lower bleeding events (6.6 vs 13.0%) bioprostheses valves but there were no difference in 15-year actuarial survival (60.6 vs 62.1%) nor stroke events (7.7 vs 8.6%). This suggests that bioprosthetic valves offer noninferior survival without the burden of anticoagulation even for patients younger than 60 years old. As mentioned earlier, two randomized comparisons of mechanical and bioprosthetic aortic valves performed in the 1970s and one in the recent era demonstrated equivalent survival between valve types at 10 to 20 years of follow-up.<sup>54-56</sup> However, long-term event-free survival beyond 15 years was superior in the mechanical valve groups as the risks of reoperation and structural failures of bioprostheses became more common. A detailed and comprehensive discussion of these risks and benefits of prosthesis selection should occur with all patients and their families prior to entering the operating room.

## SPECIAL PATIENT GROUPS

Patients with an absolute requirement for long-term anticoagulation such as permanent atrial fibrillation, previous thromboembolic events, hypercoagulable state, severe LVD, another mechanical heart valve in place, or intracardiac thrombus, should receive a mechanical valve regardless of age. Further considerations which may impact future patient decisions include testing for genetic variants of the *CYP2C9* and *VKORC1* genes which influence warfarin response and the use of devices to facilitate home INR monitoring.

Patients with a relative or absolute contraindication to anticoagulation, such as women of child-bearing age wishing to become pregnant, patients with bleeding disorders, those who refuse or those unreliable to take oral anticoagulation should receive a bioprosthesis. However, young patients do have a higher incidence of early SVD and need to be thoroughly counselled as such.<sup>131</sup> Furthermore, higher incidence of accelerated SVD (47 vs 14%,  $p < .05$ ) and lower freedom from reoperation (20 vs 64%,  $p < .05$ ) were reported in young women during pregnancy when compared to their nonpregnant counterparts.<sup>132</sup> Alternatively, implantation of mechanical prostheses in such women combined with anticoagulation using subcutaneous low-molecular weight heparin injections during the pregnancy is a possibility. The current 2014 ACC/AHA Guidelines suggest that for patients taking  $\leq 5$  mg warfarin/day to continue until delivery (Class IIa, Level of Evidence B) then switch to unfractionated heparin (UFH; Class I, Level of Evidence C). Those patients taking  $> 5$  mg warfarin/day are advised to switch to UFH or low molecular weight heparin during the first trimester (Class IIa, Level of Evidence B) and just prior to delivery (Class I, Level of Evidence C).<sup>29</sup>

Aortic valve prosthesis selection for patients with end-stage renal failure requiring dialysis is complicated by rapid SVD in bioprosthetic valves and dialysis-related bleeding due to anticoagulation necessary for mechanical prostheses. A systematic review of the literature report an acceptable operative mortality, no difference in survival between bioprosthetic versus mechanical valves (HR = 1.3; 95% CI: 1.0 to 1.9,  $p = .09$ ) but lower valve-related complications (OR: 0.4; 95% CI: 0.2 to 0.7,  $p = .002$ ), including bleeding and thromboembolism.<sup>133</sup> The 2014 ACC/AHA Guidelines do not offer recommendations for valve selection in this patient subset and ultimately, the decision should be individualized balancing the risks of valve-related complications as well as the anticipated survival of the patient.

### Stented versus Stentless Biologic Valves

Stentless porcine valves gained popularity in cardiac surgery due to pioneering work by Dr. Tirone David at the Toronto General Hospital in 1988.<sup>134</sup> Stentless valves lack obstructive stents and strut posts, thus have residual gradients that are similar to those of freehand allografts. However, their use involves a more complex operation as they are more difficult to implant and require a longer cross-clamp time. Walther and colleagues<sup>135</sup> performed a randomized trial comparing the ability of stented porcine and stentless porcine valves to cause regression of LVH. They showed that patients in the stentless valve group received larger valves for a given annular size and had a slightly higher degree of LVM regression. Borger et al<sup>136</sup> showed modestly lower mean gradients in stentless prostheses versus stented prostheses (9 vs 15 mm Hg) and LVMI (100 vs 107 g/m<sup>2</sup>) but no difference in survival. Cheng et al<sup>137</sup> performed a meta-analysis of 17 randomized trials and 14 nonrandomized studies comparing stented to stentless aortic valves. They showed no difference in 2–10 year mortality (OR: 0.82, 95% CI: 0.50 to 1.33), PPM (OR: 0.30, 95% CI: 0.05 to 1.66), but stentless valves were associated with greater EOA index and lower mean gradients.

Little evidence exists regarding any incremental benefit of hemodynamic improvements afforded by stentless valves in LVM regression or clinical outcomes. Thus, the routine use of stentless bioprostheses cannot be recommended for most patients with small aortic roots based on currently available data. At this time, stentless porcine valves are most useful in younger active patients with small aortic roots who are likely to be limited by the elevated residual gradient a small stented bioprosthesis may create.

## PERCUTANEOUS VALVULAR INTERVENTIONS

### Percutaneous Aortic Balloon Valvotomy

As an alternative to surgical management for AS, percutaneous aortic valvotomy may be performed.<sup>138</sup> Inflation of the balloon within the valve orifice can stretch the annular tissue and fracture calcified areas or open fused commissures. There is no

role for valvotomy in the patient with significant AR, as this will become significantly worse after the procedure.<sup>139,140</sup> Balloon valvotomy is rarely successful if significant calcification is present and carries a prohibitive risk of stroke from calcific emboli.<sup>141</sup> The long-term outcomes of this procedure in adult patients are dismal, with restenosis usually occurring within 1 year. Prior to the TAVI era, patients with severe symptomatic AS who were too hemodynamically unstable to tolerate an operation or have comorbid illnesses, such as advanced malignancy, which contraindicate an operation, may have benefited from palliative balloon valvotomy.<sup>142,143</sup> Currently, this procedure may be considered to temporize a critically ill patient with AS until definitive surgery or TAVR can be performed (AHA/ACC Guidelines, Class IIb, Level of Evidence C).<sup>29</sup>

### Transcatheter Aortic Valve Replacement (TAVR)

Surgical AVR is the gold standard treatment for aortic valve stenosis but up to one-third of patients are not candidates due to advanced age, heart failure, or other specific anatomic factors.<sup>144</sup> Since the first clinical description in 2002, TAVR offers an alternative to surgical AVR in select patients.<sup>145</sup> Currently, two commonly used valve systems are the SAPIEN 3 (Edwards Life Sciences) and the CoreValve Evolut R (Medtronic), although various other valves exist in different stages of development and evaluation (Fig. 28-23). Each valve system includes (1) the valve prosthesis, (2) the stent or frame, (3) the loading system and (4) the delivery system. The Edwards Lifesciences SAPIEN 3 (Edwards Lifesciences) is based on the perimount design with a bovine pericardial valve on a balloon-expandable stent. Whereas the CoreValve Evolut R (Medtronic) and Portico (St. Jude Medical) are porcine pericardial valves on self-expanding nitinol frames.

The approach is accomplished via a retrograde transarterial or transapical manner. The retrograde femoral approach involves femoral artery access, retrograde cannulation of the aortic valve, balloon dilatation, and device delivery. Alternatively transapical transcatheter valve delivery involves creating a small thoracotomy, direct cannulation of the left ventricular apex, and passing of a wire and stent-mounted valve under fluoroscopic and echocardiographic guidance. Both techniques require rapid ventricular pacing to ensure there is no cardiac output during device deployment. Other reported access routes include direct aortic via hemisternotomy or sternotomy, as well as retrograde via axillary, subclavian, or carotid arteries.

The PARTNER Trials have demonstrated symptom relief and survival benefit with TAVR for high-risk and prohibitive risk, nonoperative patients.<sup>146-149</sup> In PARTNER B, TAVI was associated with lower death or mortality at 1 year (43 vs 72%) and lower death at 2 years (43 vs 68%) compared with medical management in 358 nonoperative patients with severe symptomatic AS.<sup>146-147</sup> In PARTNER A, 699 patients with high-risk (operative mortality > 15% and STS PROM >10%) severe symptomatic AS were randomized to TAVR or surgical AVR. Both 1-year (24 vs 27%, NS) and 2-year mortality (34 vs 35%, NS) were not different between TAVR

**FIGURE 28-23** SCorValve Evolut R (©Medtronic 2016) and SAPIEN 3 (Used with permission from Edwards Lifesciences LLC, Irvine, CA. Edwards, Edwards Lifesciences, Edwards SAPIEN, SAPIEN, SAPIEN XT and SAPIEN 3 are trademarks of Edwards Lifesciences Corporation).

and surgery.<sup>148-149</sup> In both studies TAVR was associated with higher stroke and vascular complications. Decision making between TAVR and surgery has emphasized the importance of a multidisciplinary Heart Team in the evaluation of higher risk patients (ACC/AHA Guidelines, Class I, Level of Evidence C). The composition of the Heart Team will vary between centers but should include specialists from cardiac imaging, interventional cardiology, cardiac anesthesia, and cardiac surgery. Based on the results of PARTNER Cohort B, TAVR should be considered for inoperable patients with AS and a life expectancy of >1 year (ACC/AHA Guidelines, Class I, Level of Evidence B). Based on the results of PARTNER Cohort A, TAVR is reasonable for high-risk operable patients with AS (ACC/AHA Guidelines, Class IIa, Level of Evidence B).<sup>148,149</sup> High-risk patients are defined as those with STS PROM > 8%,  $\geq 2$  frailty indices, compromise in 2 organ systems or possible presence of a procedure-specific impediment. Importantly, TAVR should not be offered to patients with severe comorbidities limiting life despite relief of AS (Class III, Level of Evidence B). This is a result of the lack of benefit from TAVR in the PARTNER Cohort B study subset with STS score > 15%.<sup>147</sup>

A nonrandomized trial of CoreValve Evolut R (Medtronic) showed comparable safety (8.4% 30-day all-cause mortality) and efficacy (99.4% implantation) with SAPIEN (Edwards Life Sciences).<sup>150</sup> Then the CHOICE Study randomized high-risk patients to either SAPIEN XT (Edwards Life Sciences) versus CoreValve (Medtronic) and report no difference in 30-day cardiovascular mortality (RR: 0.97; 95% CI: 0.29 to 3.25;  $p = .99$ ) and lower residual aortic insufficiency (4.1 vs 18.3%; RR: 0.23; 95% CI: 0.09 to 0.58;  $p < .001$ ) but higher heart block requiring permanent pacemaker with

the CoreValve (Medtronic, 37.6 vs 17.3%,  $p = .001$ ).<sup>151</sup> The incidences of TAVR mortality and complications are consistent with that published by the large European registries France 2 and German Transcatheter Aortic Valve Interventions-Registry.<sup>152,153</sup>

Given the success of the PARTNER trials in high and prohibitive surgical risk patients and retrospective studies of TAVR in low and moderate risk patients, the PARTNER II (<http://clinicaltrials.gov/ct2/show/NCT01314313>) and SURTAVI (<http://clinicaltrials.gov/show/NCT01586910>) RCTs are testing the outcome of broadening the application of TAVR into intermediate risk patients with severe AS.<sup>154</sup>

# Stentless Aortic Valve and Root Replacement

Paul Stelzer • Robin Varghese

Replacement of the aortic valve or the full aortic root can be performed using a variety of stentless valve devices. The three main options are a porcine aortic root-valve conduit (Medtronic Freestyle, Medtronic Inc., Minneapolis, MN), and the “human” valve options of the aortic homograft and the pulmonary autograft (Ross Procedure). Having reviewed the subject almost 30 years ago,<sup>1</sup> it is interesting to note how some things have changed but much has remained the same. Table 29-1 summarizes advantages and disadvantages of current replacement options.

## HISTORICAL PERSPECTIVE

The first choice for aortic valve replacement (AVR) was the homograft aortic valve. Gordon Murray created an animal model to implant an aortic homograft valve in the descending aorta<sup>2</sup> and was the first to apply the concept in the human demonstrating function for up to 4 years.<sup>3</sup>

Duran and Gunning at Oxford described a method for orthotopic (subcoronary) implantation of an aortic homograft valve in 1962<sup>4</sup> and in 1962 both Donald Ross in London,<sup>5</sup> and Sir Brian Barratt-Boyes in Auckland,<sup>6</sup> did this successfully in humans.

Initially, homograft aortic valves were implanted shortly after collection.<sup>7</sup> This impractical method was rapidly supplanted by techniques to sterilize and preserve the valve for later use. Early methods employed beta-propiolactone<sup>6,8</sup> or 0.02% chlorhexidine,<sup>9</sup> followed by ethylene oxide or radiation exposure.<sup>10</sup> Some were preserved by freeze-drying.<sup>6,10</sup> Recognizing that the incidence of valve rupture was high in chemically treated valves, Barratt-Boyes introduced antibiotic sterilization of homografts in 1968.<sup>11</sup> Cryopreservation of allografts was introduced in 1975 by O'Brien and continues to be the predominant method.<sup>12,13</sup> Experimental use of autologous valve transplantation began in 1961 when Lower and colleagues at Stanford transposed the autologous pulmonic valve to the mitral position in dogs<sup>14</sup> and shortly thereafter to the aortic position.<sup>13</sup> Donald Ross applied this

to humans, reporting in 1967 clinical experience replacing either the aortic or the mitral valve with a pulmonary autograft.<sup>14</sup> Nearly 20 years later the autograft was finally done in America by Elkins and Stelzer.<sup>15</sup> The operation came to be known as the Ross procedure. After an initial surge of interest in the 1990s (over 240 surgeons worldwide reported their experience to the Ross Procedure International Registry<sup>16</sup>), its use diminished in the next decade.

The porcine aortic root (Medtronic Freestyle aortic root bioprosthesis (Medtronic Inc., Minneapolis, MN)) is readily available preserved in glutaraldehyde (Fig. 29-1). Its “off the shelf” availability in a wide range of sizes make it a more flexible option compared to the homograft which is limited in both number and size by the tissue donor pool and what is available in the tissue bank. The Freestyle porcine root employed third-generation tissue technology with zero-pressure fixation and treatment with alpha amino oleic acid (AOA) which aims to decrease both leaflet and aortic wall calcification. This device first began with clinical investigation in 1992. It employed zero-pressure glutaraldehyde fixation and AOA treatment to enhance durability as a third-generation tissue valve. It was approved for clinical use in 1998. The conduit is a complete porcine aortic root with a 3-mm rim of polyester fabric along the proximal end providing additional strength for suturing.

## HOMOGRAFTS

### Cellular and Immunologic Aspects of Homografts

The normal living valve contains multiple viable cell types including endothelial cells, fibroblasts, and smooth muscle cells incorporated in a complex extracellular matrix. The cells and matrix elements are in a constant state of remodeling under the influence of regulatory systems that optimize the structure and function of the valve mechanism. It is understandable, therefore, that efforts to preserve homograft

**TABLE 29-1: Comparison of Mechanical and Tissue Alternatives for Aortic Valve Replacement**

	Mechanical	Stented bioprosthesis	Stentless bioprosthesis	Allograft	Autograft
Advantages	Long durability Easy implantation Good EOAI	Easy implantation No anticoagulation	Larger EOAI compared with stented valve. Root replacement is available option	Excellent EOAI All biologic material good for use in endocarditis	Excellent EOAI Living valve Long durability possible
Disadvantages	Anticoagulation Emboli/bleeding Noise	Durability limited Poor EOAI in small valve sizes	Durability limited More complex operative technique Harder reoperation	Complex technique Availability limited Durability limited	Complex operation Double valve or Root replacement with potential late failure of either

structure and function were translated into efforts to maintain homograft cellular viability. Radiation and chemical treatment led to very early failure and were quickly abandoned.<sup>6,8,10,11,17</sup> Antibiotic sterilization of homografts and storage at 4°C does not maintain cellular viability beyond a few days.<sup>18,19</sup> Cryopreservation became the gold standard when donor fibroblast viability was shown long after implantation.<sup>12</sup> Although antigenicity of the fibroblast is low and other cell types do not survive the freezing process, panel reactive antibody and donor-specific HLA I and II antibody testing is positive in 60 to 80% of homograft recipients.<sup>20-22</sup> The potential advantages of viability may be defeated by the detrimental effects of this immune system response. Animal studies have confirmed an immune mechanism by demonstrating that deterioration in homograft valve function is prevented by immunosuppression<sup>23</sup> and does not occur in T-cell-deficient rats.<sup>24</sup> Clinical use of immunosuppression, however, could not be justified for homograft patients.

Tissue engineering concepts led to decellularization which lyses cells and “rinses” out antigenic proteins leaving an inert

matrix and intact structural framework. Preserved mechanical properties and structural integrity were demonstrated in a sheep model of such a scaffold. In addition, the empty matrix seemed to attract circulating recipient stem cells which repopulated the framework and differentiated into appropriate cell lines capable of maintaining the matrix.<sup>25</sup> Initial use of the decellularized aortic homograft in humans demonstrated that structural integrity could be maintained with low, stable gradients and minimal regurgitation similar to standard cryopreserved homografts.<sup>26</sup> The same concept has been applied to the pulmonary homograft used in the Ross operation.<sup>27,28</sup> The decellularized aortic homograft has been largely abandoned because of early failure rates but the decellularized pulmonary homograft has been at least as good or better than the standard pulmonary homograft when used on the right side of the heart.<sup>29</sup> Long-term studies are needed to determine if native cell in growth occurs reliably. A decellularized xenograft valved conduit has also been used successfully for the right ventricular outflow tract (RVOT) reconstruction with the Ross but results were poor.<sup>30</sup>

In summary, despite intensive investigation over decades, the relative contribution of the immune response, preservation techniques, and warm ischemia time to ultimate valve degeneration is not clear. More importantly, after consideration of the structural benefits and the immune-reaction risks, the net advantage of maintaining cellular (particularly fibroblast) viability in the homograft is not well defined.<sup>31</sup>

### Indications for the Porcine Xenograft (Freestyle) and Aortic Homograft

AVR with a stentless valved conduit such as the porcine root or aortic homograft has a number of advantages including excellent hemodynamic profile with low transvalvular gradients and possibly enhanced regression of left ventricular mass,<sup>32</sup> low risk of thromboembolism without the need for systemic anticoagulation, and low risk of prosthetic valve infection. However, these conduits are subject to structural

**FIGURE 29-1** The Medtronic Freestyle Aortic Root Bioprosthesis. The porcine coronary arteries lie approximately 90° apart. This is in contrast to the human orientation of 140 to 160° apart.

deterioration that is inversely proportional to recipient age. Older homograft donor age may also increase rates of degeneration. Furthermore, the availability of homografts is still limited especially in the larger sizes. The strongest indication for a homograft is for treatment of active aortic valve endocarditis particularly in patients with root abscess, fistula formation, or prosthetic valve infection.<sup>33</sup> This is the only Class I indication for a homograft in the most recent guidelines.<sup>34</sup>

The porcine root is also an option in aortic valve endocarditis with root destruction requiring a root replacement with the advantage that it possesses minimal prosthetic material compared with a polyester valved-conduit graft. The pliable handling characteristics and ease of coronary reimplantation make both the homograft and porcine root a great option in root infections. The homograft is further well suited to this challenging task as it comes with the added benefits of having the attached donor mitral anterior leaflet, and the ability to reconstruct the debrided root with all biological material to minimize risk of persistent infection. The homograft's very low early hazard rate for endocarditis sets it apart from other valve alternatives.<sup>35</sup>

The stentless porcine root and aortic homograft are also a reasonable option in the older patient (>60 years of age) with a small aortic root. The hemodynamic advantages of the homograft translate into better relief of outflow obstruction and improved exercise tolerance. The root replacement option also eliminates the risk of coronary obstruction from

an oversized aortic prosthesis. Given its resistance to thromboembolic complications the aortic homograft can also be considered for younger patients requiring composite aortic valve or root replacement who cannot be anticoagulated. However, recent data from a prospective randomized trial would argue that most of the advantages of the homograft can be duplicated by the stentless porcine root replacement which has a significantly lower reported rate of calcification and valve dysfunction.<sup>36</sup>

## Preoperative Evaluation

Preoperative transthoracic echocardiography (TTE) is an invaluable diagnostic tool for evaluation of the AV and associated anatomic structures. Echo measurement of the left ventricular outflow tract can accurately predict aortic annulus diameter and thus the size of the porcine root/homograft required.<sup>37-39</sup>

Computed tomographic angiography (CTA) or cardiac magnetic resonance (CMR) imaging can also be very useful in the evaluation of potential homograft patients particularly those with aortic root abscess (see Fig. 29-2). Coronary angiography should be employed with the standard indications but may be hazardous in patients with mobile vegetations on the aortic leaflets. Standard chest computed tomography with and without contrast should be considered in any reoperative setting to assess location of bypass grafts, proximity of vital structures to the sternum, and extent of ascending aortic or

**FIGURE 29-2** CTA of root abscess in setting of prosthetic aortic valve endocarditis. The abscess projects from under the valve sewing ring near the left main coronary extending over the left atrial roof under the right pulmonary artery. (A) 3D reconstruction. (B) Standard CT showing prosthetic valve outline.

arch calcification or aneurysm. Heavy calcification around the coronary ostia may preclude safe reimplantation of coronary “buttons” or even a distal subcoronary suture line.

Transesophageal echocardiography (TEE) is often necessary to establish the presence of a root abscess, but its major role is for intraoperative confirmation of the anatomy and assessment of both valve and ventricular function.

## OPERATIVE TECHNIQUE

### General Preparation

Routine cardiac surgical monitoring including TEE is considered standard of care. An antifibrinolytic agent such as epsilon-aminocaproic acid is helpful. A standard midline sternotomy incision provides full exposure of the heart, ease in cannulation, and access for optimal myocardial protection. Routine distal aortic cannulation and a dual stage venous cannula can usually be employed.

Unless circulatory arrest is needed, minimal systemic cooling (32°C) is adequate if the heart is maintained at 10 to 15°C using a standard insulating pad and directly monitoring the myocardial septal temperature. A combination of antegrade and retrograde cold blood cardioplegia can be used with the bulk of the protection coming from the retrograde. The open aortic root reveals coronary return from both ostia to confirm effective retrograde.

A transverse aortotomy high (1.5–2 cm) above the commissures is usually best. The diseased aortic valve is excised and the annulus is measured with cylindrical sizers. The sinotubular junction should also be evaluated for the subcoronary technique. If using the porcine root, its size can then be confirmed and the prosthesis opened and rinsed.

If using the homograft, sufficient time (20 minutes) is required to thaw the prosthesis and so a decision to use the homograft with a specific size is required prior to exposing the root and sizing it directly. Hence the measurement of the aortic annulus on TEE is essential after induction of anesthesia allowing the time to ensure that the appropriate sized conduit is available onsite.

The homograft is trimmed appropriately. In general, 3 to 4 mm of tissue proximal to the nadir of each cusp is advised for security in suture placement leaving even more for full root replacements.

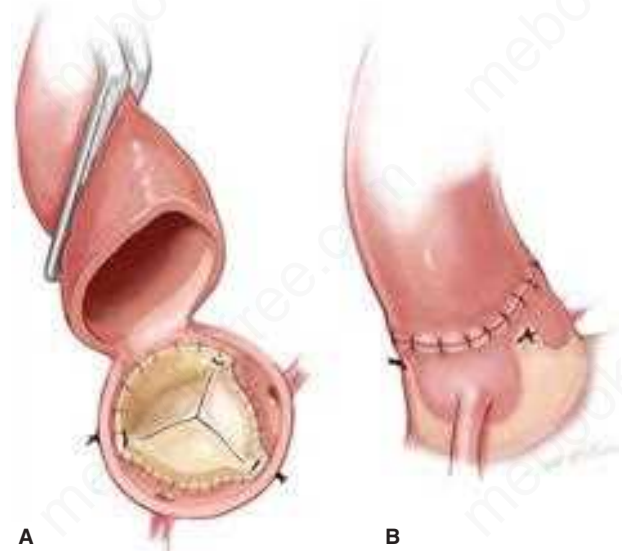

### Techniques of Porcine Root/Homograft Placement

#### SUBCORONARY IMPLANT TECHNIQUE

The subcoronary method involves two suture lines within the native root. The prosthesis is usually oriented anatomically to properly align the commissures and the coronaries. The proximal end of the prosthesis is sewn to the native annulus in a circular plane at the level of the nadir of each sinus curving upward slightly in the membranous septum to avoid injury to the conduction system. This anastomosis can be done with either interrupted or continuous sutures (see Figs. 29-3 and 29-4).

**FIGURE 29-3** Subcoronary Freestyle implantation. The Freestyle is oriented anatomically and the proximal end attached in a circular plane at the level of the nadir of the recipient sinuses using either interrupted or continuous sutures. The same technique can be employed for the subcoronary homograft valve implantation.

**FIGURE 29-4** Distal Freestyle/homograft suture line. (A) The subcoronary implant is completed by tacking the aortic wall of the Freestyle/homograft to the recipient aortic wall with continuous fine polypropylene suture after trimming out the tissue in the coronary sinuses to allow blood flow to the native coronaries. The noncoronary sinus is usually left intact. (B) The aortotomy is closed in standard fashion incorporating the top of the Freestyle/homograft in the process.

The top of each commissure is tacked to the aortic wall. The right and left sinus walls are then scalloped out to a point 3 to 5 mm from the leaflets. The noncoronary sinus can also be removed but is usually left intact. A 4-0 or 5-0 polypropylene suture is started at the lowest point under each coronary ostium and a continuous suture line constructed from there up to the top of the commissure on either side. On the top of the noncoronary sinus, excess prosthetic tissue is trimmed down and tacked to the top of the aortotomy. The aortotomy is then closed with continuous 4-0 polypropylene suture incorporating the top of the prosthesis noncoronary sinus with the native aortic wall. The ascending aorta is vented as the aortic clamp is removed. TEE can quickly assess any regurgitation at this point. Distension of the ventricle should be avoided by prompt defibrillation (if necessary) and pacing if required.

Because even slight malalignment of the commissures can result in regurgitation, the subcoronary implant technique is considered more demanding than the other techniques and may have poorer long-term results.<sup>40-44</sup> The subcoronary technique is good for patients with small, symmetric aortic roots and sinotubular junctions, while it is a poor choice for those with dilated, asymmetric, or severely diseased roots.

### Porcine Root/Homograft Cylinder: Inclusion Root Technique

The cylinder modification of the subcoronary technique was developed in an attempt to preserve the native geometry of the prosthesis inside the recipient aortic root. The proximal suture line is identical to the subcoronary method but the sinuses are not scalloped out. Instead, a buttonhole is made in the right and left sinuses in such a way as to allow the porcine root/homograft wall to be sewn to the native sinus wall around the coronary ostia. After the coronaries are secure, the distal end of the prosthesis is attached at the commissures and then incorporated circumferentially into the aortotomy closure.

Sievers and colleagues<sup>45</sup> and Skillington<sup>46</sup> have carefully described technical aspects of these operations that have proven very effective in their hands and should be reviewed by surgeons interested in using this method.

### Porcine Root/Homograft Root Replacement

The root replacement technique can be used in any root and is particularly useful in small roots or in roots destroyed by endocarditis. The root replacement allows size flexibility that allows thawing an appropriate homograft without wasting clamp time. Very large roots may require commissural plication as described by Northrup.<sup>47</sup>

The aorta is opened transversely well above the commissures of the valve. The diseased valve is excised and annulus debrided. The aorta is transected and the coronary ostial

buttons are mobilized in standard fashion. If antegrade cardioplegia is used after this point it must be done very carefully to avoid injury to the mobilized ostia.

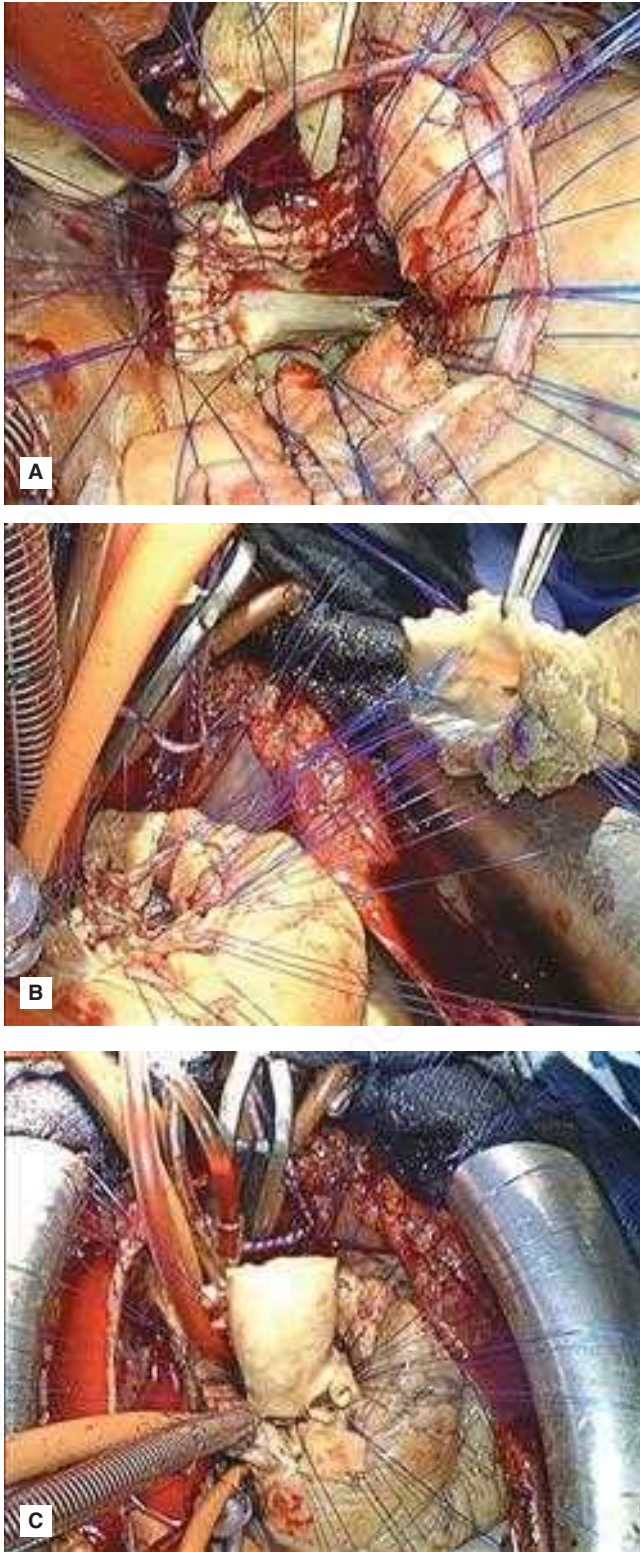

The homograft root is usually oriented anatomically while the porcine root is commonly oriented with the left coronary os matching that of the patient's right coronary—making matching the two roots easiest. (Porcine coronaries are closer together than human.) The proximal suture line can be constructed with either continuous or interrupted technique. Interrupted is best in difficult reoperations especially for prosthetic valve endocarditis (PVE) because it allows for very accurate, deep placement of individual stitches while distributing tension across multiple sutures. A strip of autologous (or bovine) pericardium is used to reinforce this crucial anastomosis. Polypropylene sutures of 3-0 or 4-0 are used and organization scrupulously maintained on suture guides. The homograft parachutes down as the sutures are carefully tightened (Fig. 29-5).

The Freestyle root is most often sutured with a continuous suture technique with 4-0 polypropylene begun at the right-left commissure and sewing towards oneself through the left sinus, then the noncoronary and finally the right sinus to end at the noncoronary-right commissure. The fibrous trigones and commissures of the native and homograft/Freestyle roots serve as anatomical landmarks and should match up as one proceeds around. It is recommended that the valve be sewn with the sutures kept loose during the left and noncoronary sinus suturing and the conduit parachuted down progressively. Keeping the suture line loose is essential to completing the right sinus suture line. Once all the sutures have been placed, the initially loose suture line is tightened carefully with nerve hooks and tied securely into position. Gentle tissue handling with bites 1.5 to 2 mm apart incorporating a strip of pericardium or Teflon felt is helpful in securing hemostasis at this crucial level that is virtually invisible at the end.

The coronary buttons are attached with continuous 5-0 or 6-0 polypropylene. The coronary stumps of the homograft often times are well aligned to mark locations for the new coronary ostia. For the porcine root usually the left ostium of the porcine root will line up with the left button and then one has to determine if the right ostium lines up appropriately or whether it needs to be suture ligated and another hole made for the right button. Rotating the device 120° clockwise puts the porcine left in the patient's right if that looks better. Once the buttons are completed attention can be turned to the distal anastomosis. The distal end of the conduit and the native aorta are trimmed and sewn together with continuous 4-0 polypropylene usually incorporating another strip of pericardium or felt for support. The native aorta is vented anteriorly and systemic flow rate lowered as the cross clamp is removed.

Care is taken to avoid systemic hypertension or vigorous traction on the reconstructed root to avoid bleeding. Topical hemostatic agents and biological glues may be used, but they should not be routinely necessary. Blood and blood products are not routinely required unless the

**FIGURE 29-5** Homograft root replacement. (A) Interrupted 3-0 or 4-0 polypropylene sutures are placed deep in solid tissue, then passed through a pericardial strip and organization is scrupulously maintained on suture guides. (B) Sutures are then passed through the homograft from inside out. (C) The homograft parachutes down as the sutures are carefully tightened maintaining organization until each suture is tied precisely.

patient is coagulopathic or small in size with a low total blood volume.

### Post Replacement Assessment

Ventricular function, regional wall motion abnormalities, and valve function may all be accurately determined with TEE. With appropriate loading conditions, moderate-to-severe aortic regurgitation (AR) warrants inspection and revision of the valve conduit. Mild AR is usually tolerated well and does not warrant reexploration.

### Postoperative Management

Even mild hypertension should be avoided to prevent disruption of crucial aortic suture lines. Coagulopathic bleeding is best addressed with products targeted to specific abnormalities defined by laboratory studies.

Adequate volume replacement is required to keep the stiff ventricle of aortic stenosis (AS) filled and alpha adrenergic support is often required for the patient who is vasodilated. Atrial rhythm disturbances should be treated aggressively. Elderly patients, particularly females, with AS and diastolic dysfunction are at increased risk of morbidity and even mortality from postoperative atrial fibrillation. The increased volume loading needed to overcome the loss of atrial transport often leads to pulmonary congestion sometimes requiring reintubation and prolonged support. Forward cardiac output is impaired and renal function may deteriorate in tenuous patients. Cardioversion should be considered early in these patients and loading with intravenous amiodarone is usually indicated. Preoperative loading with amiodarone may minimize the incidence and consequences of this arrhythmia.<sup>48</sup>

Temporary pacing, preferably atrial as well as ventricular, should be enabled. Permanent pacing is indicated if epicardial wires become unreliable, heart block was present preoperatively, or the underlying rhythm fails to return within a week after surgery.

Stroke risk can be minimized by careful intraoperative epicardial ultrasound to guide or avoid cannulation and clamping of atheromatous aortic disease. TEE-guided evacuation of air is essential and flooding the field with carbon dioxide may be helpful.

Myocardial dysfunction is best prevented by careful temperature-monitored myocardial protection but long operations may still require temporary inotropic support. Caution must be used in the hyperdynamic ventricle with diastolic dysfunction. The combination of a hyperdynamic left ventricle and a dysfunctional right heart is very challenging. These patients may benefit from atrial pacing (if pacing is required), phosphodiesterase inhibitors, adequate volume replacement, and alpha agonists.

Renal insufficiency is a risk minimized by maintenance of adequate flows and pressure during bypass and generous volume administration in the early postoperative period. A thirsty patient with dry mucous membranes is a good clue that intravascular volume is still depleted. Later, diuretics are

needed to encourage mobilization and excretion of this extra fluid. Hypotension should be avoided but vasopressors can have direct negative effects on renal blood flow.

Low-dose aspirin is often recommended for homograft patients, but is not necessary and formal anticoagulation with warfarin is not required at all unless dictated by other conditions. A routine predischarge echo should be done to confirm valve function, ventricular function and freedom from pericardial effusion.

## Homograft Root Results

### PERIOPERATIVE COMPLICATIONS

In patients without active endocarditis at the time of surgery, operative mortality in the current era is 1 to 5%.<sup>42,49,50</sup> The risk in experienced hands is comparable to using a stented bioprosthetic or mechanical valve. Ischemic time for a root replacement with either stentless porcine or aortic homograft is approximately 90 minutes.<sup>51</sup> A contemporary series of 100 consecutive aortic homografts (virtually all root replacements including 13 reoperations) demonstrated no hospital mortality with 100% survival at 1 year and 98% at 5 years.<sup>52</sup>

In contrast, patients with active endocarditis exhibit a higher early mortality ranging from 8 to 16%.<sup>42,53-56</sup> PVE (17.9-18.8%) is worse than native (2.6-10%).<sup>53,57</sup>

Hemorrhage, heart block, stroke, myocardial infarction, and wound complications occur with similar frequency to those of other AVRs, but early risk of endocarditis is lower with homografts than any other replacement valve.<sup>35</sup>

## Hemodynamics and Exercise Capacity

Hemodynamic characteristics of homografts are excellent at short- and medium-term follow-up, both at rest and during exercise.<sup>58,59</sup> A study of 31 patients demonstrated increases in peak and mean gradients of 6.6 and 3.0 mm Hg, respectively, without a significant change in effective orifice area (EOA).<sup>58</sup> Importantly, the EOA of even the 17 to 19 mm homografts was 1.7 cm<sup>2</sup> and larger valves approximated the normal aortic valve areas as high as 2.7 cm<sup>2</sup> for 24 to 27 mm homografts.

The typical subcoronary homograft implant demonstrates a 1 to 2 mm Hg drop in mean transvalvular gradient over the first 6 months but with full root replacement, the hemodynamic benefit is fully realized immediately. In the randomized trial of homograft versus stentless porcine root replacement the mean gradients were only 6 ± 1 mm Hg in the stentless and 5 ± 2 mm Hg in the homografts. Only one patient in each group had mild regurgitation after 5 years.<sup>51</sup> These authors concluded that stentless and homograft root replacements are hemodynamically equivalent in the mid-term.

## Long-term Outcomes

Long-term outcome has been shown to be technique dependent in a meta analysis of over 3000 patients (37% full root, 63% subcoronary) from 18 studies with a mean

follow up of 12.5 years. Reoperation was significantly lower in the root replacement group.<sup>60</sup> There may have been some bias against reoperation in failing roots, where failing subcoronary implants were more readily subjected to reoperation.

The pioneering work of Mark O'Brien in Brisbane, Australia produced a huge series of homograft patients over nearly three decades with 99.3% follow-up.<sup>50</sup> This series demonstrated that rates of reoperation were lower in the full root patients (n = 3, 0.85%) than the subcoronary (n = 18, 3.3%). Of note, operative mortality was only 1.13% in 352 root patients.

Long-term durability was compromised by young age of recipient to the point that those under 20 years of age had a 47% rate of reoperation for structural valve degeneration at 10 years. Conversely, those over 60 had a 94% freedom from reoperation at 15 years and those between 21 and 60 had 81 to 85% freedom at 15 years. This series confirmed the very low incidence of thromboembolic phenomena (without anticoagulation) and a low but not insignificant rate of endocarditis.

Lund reported crude survival at 10 and 20 years to be 67 and 35%, respectively,<sup>44</sup> while Langley and O'Brien reported actuarial survival at 10, 20, and 25 years to be 81, 58, and 19%.<sup>49,50</sup>

Structural valve failure of homografts increases with time, and approximates 19 to 38% at 10 years and 69 to 82% at 20 years.<sup>44,49</sup> Freedom from repeat AVR, for any reason, parallels structural valve failure and is 86.5 and 38.8% at 10 and 20 years, respectively.<sup>49</sup> As heterograft tissue technology has progressed, the difference between homograft and heterograft durability has narrowed to the point of near equivalency with both showing a dramatic age-dependent relationship with youngest patients failing most rapidly.<sup>61</sup>

Freedom from endocarditis at 10 years is 93 to 98%,<sup>49,50</sup> and at 20 years 89 to 95%.<sup>44,49,50</sup> Freedom from thromboembolism at 15 and 20 years is 92 and 83%, respectively.<sup>50</sup> Thrombosis of a homograft has been reported, but in the setting of lupus anticardiolipin antibody syndrome.<sup>62</sup>

In patients with active endocarditis requiring AVR, results may be poorer with survival ranging from 58% at 5 years<sup>53</sup> to 91% at 10 years,<sup>56</sup> and is significantly lower in patients with PVE.<sup>54</sup> Of note, however, the risk of recurrent endocarditis is <4% up to 4 years postoperatively.<sup>43,53,54,56</sup> These results still compare favorably with alternatives so aortic homograft is considered by many to be the valve of choice for aortic valve or root replacement in patients with active endocarditis.

## Stentless Porcine Root Results

Very few randomized trials exist comparing stentless and stented valves. Most data available are single-center case series outcomes or case cohort analyses comparing stentless valves to previously published stented valve outcomes. We present the current literature looking at perioperative outcomes, hemodynamics, and durability.

## Perioperative Outcomes

Operative mortality defined as death during the index hospitalization or within 30 days ranges between 1.8 and 9.6%<sup>61,62</sup> with most experienced centers reporting operative mortalities around 3 to 5%. Many of the series that reported their mortality outcomes included patients who received concomitant coronary bypass or other valve surgery at the time of Freestyle root implantation making it difficult to compare these outcomes to isolated AVR or isolated bio-Bentall results. The predictors of operative mortality in these series included concomitant valve surgery, congestive heart failure, age, and coronary disease.<sup>63</sup> In a recent systematic review of the literature Sherrah and colleagues found the weighted mean for mortality to be 5.2% and 5.5% for adverse neurological events.<sup>64</sup>

## Hemodynamics and Durability

The Freestyle stentless valve is often selected for its superior hemodynamic performance that has been demonstrated in multiple series.<sup>65,66</sup> A meta-analysis of 919 patients by Kunadian and colleagues demonstrated that compared with stented valves, the Freestyle exhibited a larger effective orifice area index (EOAI) and lower transvalvular gradients.<sup>67</sup> The weighted mean difference in aortic gradients was 3.57 mm Hg which some may argue is small; however, there was a more rapid rate of left ventricular mass regression in Freestyle valve patients although this difference disappeared at 12 months. Of note the majority of valves in this meta-analysis were implanted using the subcoronary technique as opposed to the full root replacement. Although the full root replacement technique is a longer and slightly more complicated procedure, it has been shown to yield even lower transvalvular gradients.<sup>68</sup>

The hemodynamic benefits of stentless valves are further exaggerated during exercise. In a study of 106 patients, Khoo and colleagues compared the hemodynamic performance of five different stentless and stented valves under rest and stress using dobutamine stress echocardiography.<sup>69</sup> They found the stentless bioprostheses exhibited a resting gradient of 9 mm Hg that increased to 16 mm Hg under peak stress. Conversely the stented porcine and bovine valves exhibited rest gradients of 15 and 20 mm Hg, respectively, that under peak stress increased to 29 and 30 mm Hg, respectively. Of note, the mean valve size implanted was 23 mm for the Freestyle, 23 mm for the stented porcine valve, and 21 mm for the stented bovine valve. There have been some early data to suggest that newer-generation stented valves have improved transvalvular gradients.<sup>70</sup>

A number of large case series have reported excellent long-term durability of the stentless porcine prosthesis. More recently Amabile and colleagues examined a cohort of 500 patients undergoing Freestyle valve implantation.<sup>71</sup> In this series 96% of cases were done using the modified subcoronary technique with the remaining 4% being a full root replacement. Mean age of patients was 74.5 years and 10-year

actuarial survival for all-cause mortality was 44% and survival from valve-related mortality was 70%. Moreover, freedom from structural valve deterioration was 94% at 10 years yielding a cumulative incidence of structural valve deterioration of 3.7% at 10 years. When the authors examined outcomes in patients, less than 65 years at time of implantation the 10-year actuarial survival from valve-related mortality was 87%. Bach and Kon examined 15-year outcomes of the Freestyle valve in their patients with a mean age of 72 years and found a freedom from valve-related death to be 92.7%.<sup>72</sup> This study found the specific causes of valve-related death to include thromboembolism, endocarditis, anticoagulation-related hemorrhage, and structural valve deterioration. The results of the Freestyle valve show it has similar durability to standard stented prostheses.

## Stentless Valve Reoperations

Because of extensive calcification after many years the risk at reoperation after homograft or Freestyle valve replacement can be as high as 20%.<sup>73</sup> The subcoronary implants may be easier in this regard because the native aortic root is preserved. The full root replacement is more of a problem. Up to about 10 years, the calcification is limited and it is theoretically possible to place a new valve inside the stentless valve annulus after removing the leaflets.<sup>74</sup> Ultimately, however, the conduit becomes so rigid as to preclude such an alternative and complete re-replacement of the root is required (see Fig. 29-5). The most hazardous part of this operation is related to the coronary ostial buttons which must be protected and available for use again.

Reoperation can be made easier by anticipating the need for this at the original operation. Keeping the coronary buttons large at the initial operation is one way to avoid problems with dissecting them again. The stentless valve-root should be kept as short as possible to minimize the extent of ultimately calcified wall and maximize the amount of normal aorta available for subsequent cannulation and clamping. Closing the pericardium or using a pericardial substitute can make sternal reentry safer. Careful assessment of the aorta and mediastinum on CT preoperatively can alert one to the need for early peripheral cannulation and even sternotomy under circulatory arrest.

Clamping the aorta distal to the main pulmonary artery is very useful in these cases and avoids the hazards of entering a great vessel while dissecting between them before the clamp is on. Complete excision of the calcified wall is often the best policy but leaving a little margin around each coronary ostium may make reconstruction easier. Another stentless valve is often an excellent solution because it is easier to reimplant the coronary ostia especially with the homograft, but even a Ross operation can be done in this setting as was done for the 40-year-old man (shown in Fig. 29-6).

An increasingly attractive option in the future for older patients is transcatheter valve replacement which should be well suited to the calcified stentless root as reported from Milan.<sup>75</sup> (see Fig. 29-7).

**FIGURE 29-6** Calcified aortic homograft. (A) Lateral view of calcified homograft at catheterization 23 years after implantation. (B) Microscopic appearance of this homograft showing fibrosis with essentially acellular mass of collagen fibers.

## PULMONARY AUTOGRAFT: ROSS PROCEDURE

### Theoretical Considerations

The pulmonary autograft shares the hemodynamic advantages and antithrombotic features of the homograft but is the only valve which has the benefit of being fully viable

**FIGURE 29-7** Percutaneous valve placement in calcified homograft root. (A) CTA appearance of heavily calcified homograft root. (B) Percutaneous valve being deployed in this root. (Adapted from Dainese L, Fusari M, Trabattani P, Biglioli P: Redo in aortic homograft replacement: Transcatheter aortic valve as a valid alternative to surgical replacement. *J Thorac Cardiovasc Surg.* 2010 Jun;139(6):1656-1657.)

autologous tissue. Pulmonary leaflets have been found to have equivalent breaking strain to aortic leaflets and even higher tensile strength.<sup>76</sup> The living pulmonary valve demonstrates the adaptability of human biology to change in response to changing physiologic conditions. The histologic features of this adaptation have been elegantly described and illustrated.<sup>77</sup> The initial response is to lay down a collagen-rich support on the ventricular aspect of the leaflets. This thins out later but remains slightly thicker than normal aortic leaflets. All three layers of the leaflets, fibrosa, spongiosa, and ventricularis contain viable cells which maintain a rich extracellular matrix to support the leaflet function. Endothelial cells are transformed to become capable of smooth muscle actin production becoming more like the aortic than the pulmonary phenotype. The autograft (pulmonary artery) walls are a different story. There is rapid loss of elastin with fragmentation and loss of cellularity and increasing collagen deposition. This may reflect the need to sacrifice elasticity for strength to withstand systemic pressure.

## Patient Selection

The cardinal principal in selecting patients for the Ross Procedure is that they must have a life expectancy of at least 20 to 25 years. Other simpler alternatives can be expected to give 10 to 15 years even in young patients although durability of tissue valves in patients under 35 years of age can be very limited. Active lifestyle, potential for child-bearing, and contra-indications to anticoagulation favor the Ross. Many young people seek out this option specifically to avoid the issues of anticoagulation and to allow even extreme athletic activity such as mountain biking and triathlons. Practically speaking, the ideal patient is under 50 years of age but special circumstances can extend this to 65 or even slightly higher. The improvements in tissue valves and hope for “valve-in-valve” catheter-based rescue in the future has pushed the age downward for tissue valves to relegate the Ross to the youngest ages.

The generally accepted contraindications are significant pulmonary valve disease, congenitally abnormal pulmonary valves (eg, bicuspid or quadricuspid), Marfan syndrome, other connective tissue disorders, complex coronary anomalies, and probably severe coexisting autoimmune disease, particularly if it is the cause of the aortic valve disease. Active rheumatic disease is a relative contra-indication as the autograft can be attacked early by the acute rheumatic process and lead to early failure.<sup>78</sup> Bacterial endocarditis is not a contra-indication for the Ross procedure, though it is best used when only leaflet destruction is present or when root involvement can be reconstructed without distortion.<sup>79</sup>

Comorbid conditions should also be considered prior to offering this operation to any given patient. These conditions often limit life expectancy and also influence the ability of the patient to withstand this longer procedure. Poor left ventricular function, multivessel coronary disease and need for complex mitral repair are examples. Ascending aortic dilatation and aneurysm have been considered contra-indications by some, but these can be easily addressed and

should be. Previous AVR or other open cardiac operations are not a contra-indication to the Ross, but all the standard considerations of reoperative surgery apply including appropriate imaging to allow safe sternal reentry.

Bicuspid aortic valves (BAVs) are the most common etiology of severe AS or regurgitation in patients under 65 years of age. Some have felt this group should not undergo the Ross procedure because of potential complications of intrinsic aortopathy which is common in BAV patients.<sup>80</sup> Since this is the largest group of patients potentially to benefit from the operation, it has been the quest of Ross surgeons to find ways to make the operation safe and durable in this situation. Controversy still exists as to whether primary AR is less favorable than primary AS.<sup>81,82</sup> The patient with AS is more likely to have a smaller annulus which is resistant to dilatation as opposed to the AR patient whose annulus is often dilated and continues to dilate if not supported. Tirone David suggests that 27 to 28 mm is the largest annulus to allow a Ross or 15 mm/m<sup>2</sup>.<sup>83</sup>

There is also more of a tendency to distal aortic dilatation in the setting of AR as opposed to AS. These issues are addressable by technical modifications which will be discussed later in detail.

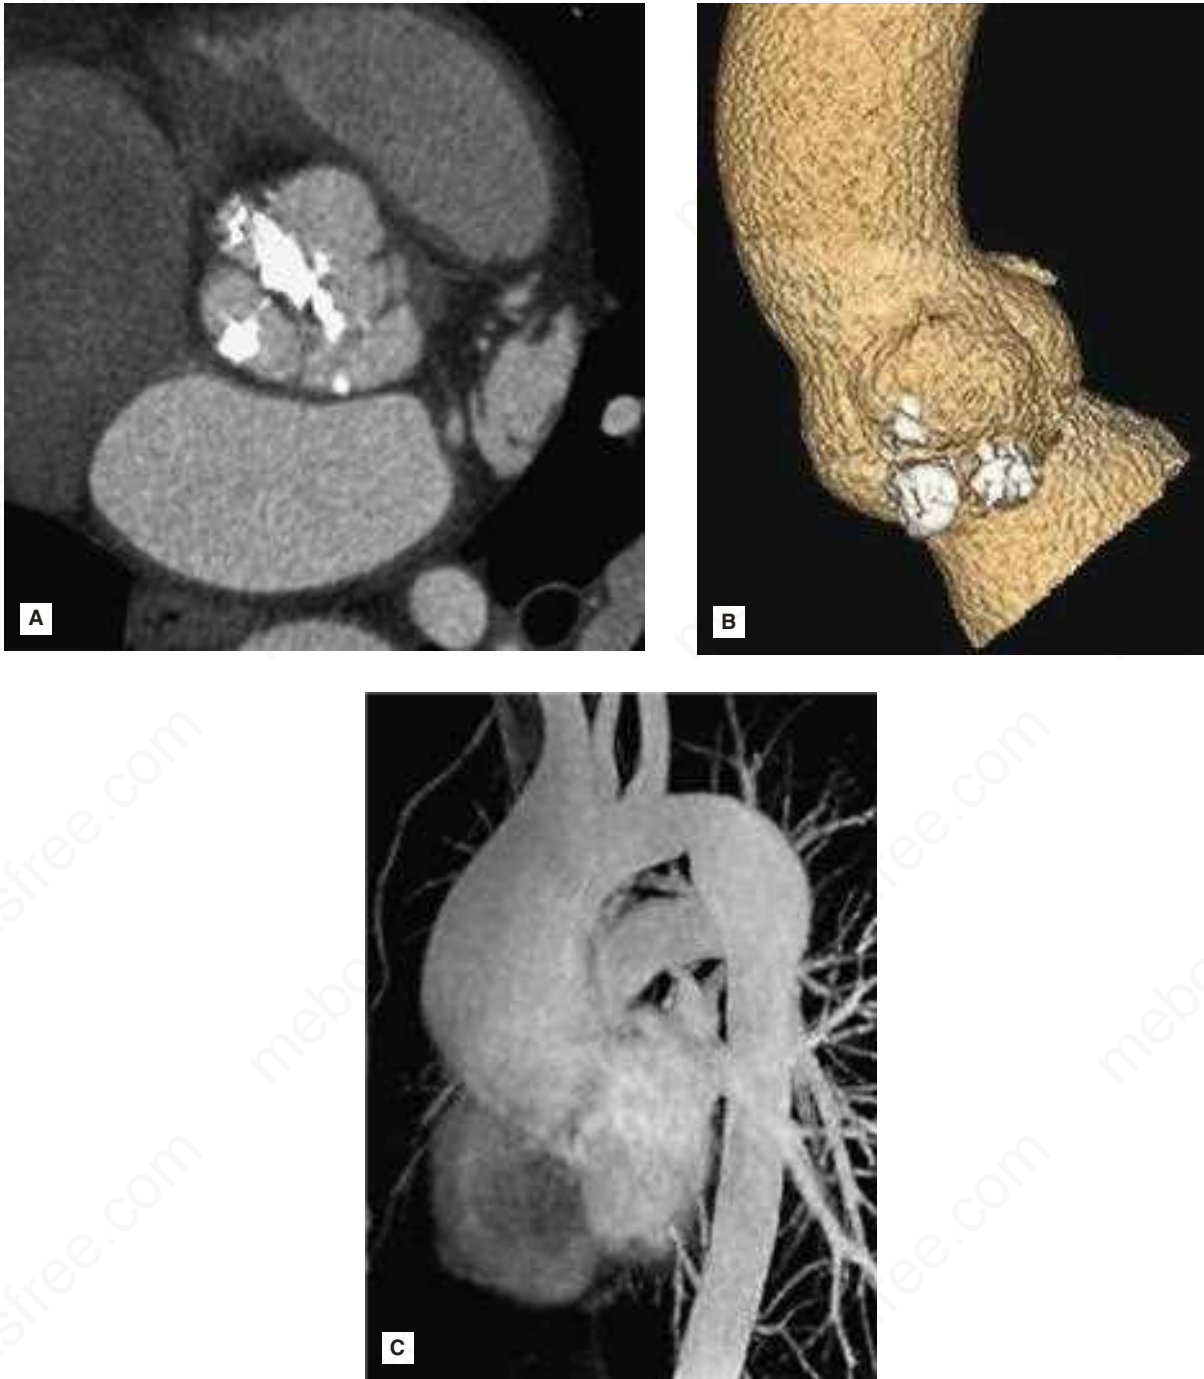

## Preoperative Evaluation

Because most candidates for the Ross are under 50 years of age, it is not usually necessary to subject them to cardiac catheterization. CTA is an excellent tool to evaluate the entire ascending aorta and arch as well as the proximal coronary arteries. CMR can be used as well but does not give as much resolution as CTA for the coronaries. Both give excellent imaging of the entire aorta (see Fig. 29-8). TTE gives excellent assessment of the aortic valve, ventricular function, and aortic root. Approximately 1% of patients will be found to have a bicuspid pulmonary valve at surgery. Unfortunately, echo, CTA, and CMR have all been limited in their ability to define the morphology of the pulmonary valve. With proper gating, timing of contrast and attention to the pulmonary trunk, however, this can be determined fairly reliably (see Fig. 29-9).

## Technique

The original description by Donald Ross involved a fully scalloped subcoronary implant of the pulmonary autograft using essentially the same technique he had used for a subcoronary homograft implant. Modifications were adopted to decrease the immediate incidence of regurgitation by maintaining the cylindrical geometry of the autograft either within the aortic root or as a complete replacement thereof. The root replacement has become the most commonly employed technique.

Full median sternotomy is usually the best incision. Aortic cannulation should be kept high and bicaval cannulation is preferable because the open RVOT is a constant source of air. Initial antegrade and then generous retrograde cold blood cardioplegia is employed insulating the heart from surrounding structures and monitoring the effectiveness of myocardial

**FIGURE 29-8** Preoperative imaging of the aorta. (A, B) Computed tomographic angiography. (C) Cardiac magnetic resonance.

cooling with a septal temperature probe. Traditional venting via the right superior pulmonary vein is not necessary as the open pulmonary artery serves that purpose.

Extensive dissection between the great vessels allows retraction of the aorta with an umbilical tape and keeps the cross clamp off the right pulmonary artery. After clamping the aorta, the space between the aortic and pulmonary roots is dissected until the roots are completely separated. Final

separation is often safest after the aorta is opened and coronary locations can be readily identified. The last few millimeters must be done very gently as the facing pulmonary sinus is virtually fused to the aortic root at the right-left commissure.

A rather high transverse aortotomy incision keeps all technique options open but if a subcoronary implant is planned, splitting the root down vertically into the noncoronary sinus can be employed to increase exposure. The aortic valve

**FIGURE 29-9** Evaluation of pulmonic valve by CMR. (A) Longitudinal view. (B) Cross-sectional view showing three distinct leaflets and sinuses.

pathology is inspected as well as coronary ostial positions. A stenotic valve can be excised at this point and the annulus debrided and measured. A dilated annulus can be plicated down at the posterior commissure. A subcommissural annuloplasty can be done to support a subcoronary or inclusion root procedure at this point.

Common to any of the techniques is the need to harvest the pulmonary autograft from the RVOT. The close proximity of the left coronary system and general constraints of this maneuver are obvious from the elegant anatomical casts

published by Muresian.<sup>84</sup> The main pulmonary artery is incised transversely just distal to the valve and the opening extended to either side taking care to avoid the left coronary. A flexible sucker can be placed in the distal PA as a vent. The pulmonic valve is inspected to make sure it is a healthy, three leaflet valve with minimal fenestrations. The remainder of the PA is divided. The adipose tissue between the back of the PA and the left main is gently dissected down to the muscle in the back of the RVOT with the cautery. The left anterior descending coronary artery can be very close to the back and the left side of the RVOT and must be protected.

The RVOT is opened with a #15 blade well below the anterior commissure as determined by palpation or by passing a suture or clamp through the muscle about 5 to 6 mm below the valve from inside out (see Fig. 29-10). The initial incision is cautiously extended until the leaflet can be clearly seen. The dissection then continues around each side leaving 3 to 4 mm of muscle cuff. Posteriorly, a natural plane can be appreciated between the right and left ventricular septal components. The septal perforators are always in the left side and can be avoided by taking only the right ventricular part of the septum. Most often they are not seen. Small branches of the coronary sinus posteriorly can be the source of annoying venous bleeding at the end so gentle administration of retrograde can identify these and allow control at this point.

**FIGURE 29-10** Pulmonary autograft harvest. A right-angle clamp can be passed through the right ventricular outflow tract muscle below the anterior commissure to assure safe beginning of the harvest incision.

The autograft is trimmed by following the curvilinear course of the leaflets on the inflow end leaving a smooth 3 to 4 mm cuff of muscle. The inflow end is measured by gently inserting cylindrical sizers. The RVOT opening can also be measured at this time. An appropriate pulmonary homograft can then be thawed.

### Subcoronary Technique

If the subcoronary or inclusion cylinder technique is chosen, the operation proceeds similarly to subcoronary homograft replacement. Proximal and distal suture lines are constructed as described. Of note, the aortic root must match the autograft at both the annulus and the sinotubular junction. Accordingly, tailoring of the root with annuloplasty and/or downsizing the sinotubular junction may be required.<sup>85</sup> The tops of the autograft commissures must be placed at least a centimeter above the top of the natives to maintain adequate height of the new valve. The potential advantage of this technique is to preserve the native root support around the autograft which may prevent autograft dilatation and insufficiency. However, if the native aorta dilates, the autograft will do so as well.

### Root Replacement Technique

In preparation for full root replacement, the aortic transection is completed and the coronary ostial buttons are dissected out and mobilized appropriately. The native noncoronary sinus and the “pillar” of tissue between the right and the left buttons are preserved for later “reinclusion” around the autograft root (Fig. 29-11). The best orientation for the autograft is determined

**FIGURE 29-11** Proximal autograft suture line. The continuous suture technique is facilitated by leaving the sutures loose enough to easily see the leaflets to optimize depth and spacing and minimize tearing of this delicate muscle cuff. A measured strip of felt is incorporated in this suture line. Note that the noncoronary sinus tissue and the “pillar” of tissue between the coronary buttons has been preserved for later inclusion around the autograft root.

by placing it in the aortic root. Usually the bare area from the back of the PA is positioned in the left coronary sinus.

A strip of Teflon felt about 5 to 7 mm wide is cut to length around a sizer 2 mm larger than the inflow size of the autograft. The proximal autograft suture line is constructed incorporating the felt strip. This can be done with interrupted 3-0 or 4-0 simple sutures best organized on suture guides. Continuous 4-0 polypropylene can also be used beginning under the right-left commissure and working down the left sinus. The noncoronary and right sinuses follow. The sutures are left loose and slightly remote to facilitate visibility. When completed, the suture line is carefully tightened with nerve hooks and tied securely.

The coronary buttons are then reimplemented with continuous 6-0 Prolene. The position of the right coronary is always higher than anticipated, usually just at the sinotubular junction of the autograft. Occasionally, it is so high that it must be implanted in native aorta above the distal autograft suture line.

Excess pulmonary artery wall is trimmed from the autograft down to just above the commissures and very close to the tops of the coronary buttons. The native aortic wall elements that were preserved earlier are now brought up beside the autograft and shortened if necessary. If the native root was dilated or frankly aneurismal, artificial support can be employed using felt patches or vascular graft material.

The distal autograft is attached to the ascending aorta with continuous 4-0 polypropylene incorporating the natural and/or fabric support elements along with another strip of felt placing the sutures right at the tops of the commissures to establish a new sinotubular junction (see Fig. 29-12). With the aorta closed, antegrade cardioplegia can be administered to give a test of valve competence and integrity of the coronary and distal suture lines.

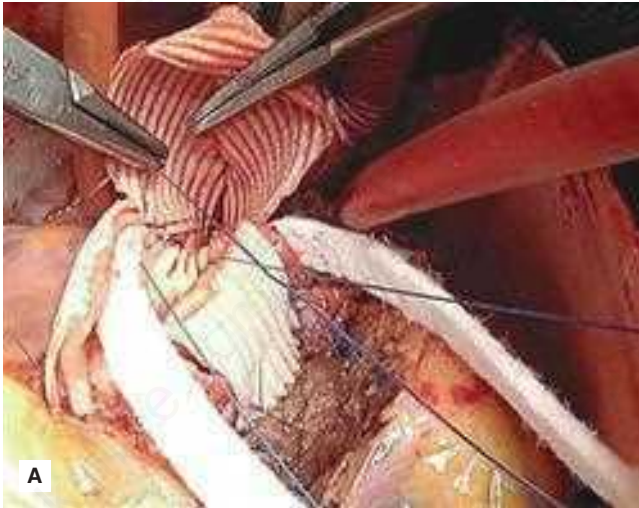

The pulmonary homograft is now attached to the RVOT with continuous 4-0 polypropylene. Care is taken to take long and superficial bites posteriorly over the area of the septal perforator. The distal suture line is completed with continuous 4-0 or 5-0 polypropylene. Warm blood can be administered retrograde during the last half of this suture line.

The ascending aorta is vented and the cross-clamp removed. Generous reperfusion time is recommended. Bleeding is certainly a risk with so many needle holes in delicate tissue submitted to aortic pressure. For this reason, care must be taken to avoid vigorous retraction which can cause more harm than good. Amicar is recommended as is autologous blood removal at the beginning of the operation for return at the end. Biological glues can be helpful but their use is not a substitute for accurate suture line construction.

### Concomitant Aortic Surgery

Because of the recognition that patients with BAVs are at risk for late dilatation and aneurysm of the ascending aorta, one should resect any aorta >5 cm in diameter. Below 3.5 cm it is hard to justify any treatment. Between 3.5 and 4.5 cm it is reasonable to employ plication or lateral aortorrhaphy concepts to bring the aorta down to 3.5 or less.<sup>86,87</sup> Between

**FIGURE 29-12** Fabric support of autograft wall. (A) The arterial wall of the autograft is supported by segments of vascular graft material especially when native aortic wall is intrinsically poor. The entire autograft is enclosed with a combination of native aortic wall and vascular graft material and attached to the ascending aortic graft incorporating another strip of felt. (B) Completed Ross with external fabric support and ascending aortic replacement as well.

4.5 and 5 cm special judgment is required to individualize treatment. Because the vast majority of dissection in the BAV patient begins in the ascending aorta,<sup>88</sup> complete resection of aneurysms up to the arch (hemiarch replacement) should be considered. This actually adds very little time to the operation if planned appropriately. The proximal end of the aortic graft is attached to the (usually reinforced) autograft root to restore aortic continuity.

## Results

No discussion of the Ross Operation could be complete without a careful look back at the pioneer series of patients treated

by Donald Ross.<sup>89</sup> The 1997 paper from this seminal source analyzed 131 hospital survivors followed for 9 to 26 years with a mean of 20 years. The technical problems that led to early reoperation with the subcoronary technique were recognized in that series and the cylinder modification adopted. Even the full root replacement method was employed as an alternative by Ross in 20 patients beginning as early as 1974.<sup>90</sup> Survival at 10 and 20 years was a remarkable 85 and 61%, respectively. Freedom from autograft replacement was 88 and 75%, where freedom from homograft replacement was 89 and 80% each at 10 and 20 years. Of 53 late deaths, 46 were cardiac. Importantly, of the 30 autografts that were explanted, only three had evidence of degenerative changes which was patchy and did not involve all leaflets. The remainder had completely viable structure as long as 24 years after implantation. Clearly, the transplanted pulmonary autograft is and remains a fully living valve. Homograft stenosis accounted for all but 1 of 20 late reoperations on the right side. Thromboembolic phenomena were documented in 20 patients but only one did not have another systemic risk factor for a source.

## Exercise Hemodynamics of the Ross Operation

Multiple studies demonstrate the excellent hemodynamic profile offered by the autograft in the Ross operation. A comparison with normal age- and gender-matched controls showed peak gradients going from only 2 to 4 mm Hg in both groups with exercise.<sup>91</sup> EOAs of 3.5 cm<sup>2</sup> (EOAI 1.9 cm<sup>2</sup>/m<sup>2</sup>) did not change with exercise in either group. Full root Ross patients had better hemodynamics than subcoronary Ross patients but the difference (1.98 ± 0.57 vs 1.64 ± 0.43 cm<sup>2</sup>/m<sup>2</sup>) was more important statistically than it was clinically.<sup>92</sup> This study also documented the superiority of the Ross hemodynamics over stented and stentless valves and even over aortic homografts.

It is important to remember that the Ross operation includes RVOT reconstruction and the hemodynamics of that structure can adversely affect exercise capacity. One study documented an average resting gradient of 14 ± 10 mm Hg rising to 25 ± 22 mm Hg for the pulmonary homografts of Ross patients compared to only 3 ± 1 mm Hg at rest and 5 ± 4 mm Hg with exercise in the normal native RVOT of aortic homograft recipients.<sup>93</sup> The higher gradients in the RVOT may contribute to slightly lower maximal oxygen consumption compared to normal controls even though Ross patients easily exceeded 100% of predicted consumption.

## Contemporary Results

There was a lot of enthusiasm for doing the Ross procedure in the 1990s which faded soon after 2000 after results were less than optimal. Those suboptimal results are at the heart of a study by Reece et al.<sup>94</sup> reviewing data from the STS database from 1994 through 2010 which reported a nearly threefold higher operative mortality for Ross as opposed to standard AVR after propensity matching (2.7 vs 0.9%; *p* = .001).

Importantly, the data available in the STS database for that time period included many of the very low volume operators (132 of 220 centers reported less than 6 total cases in this time period) and did not include any of the patients done by the highest volume surgeon in North America. They excluded 66 surgeons who only did one case in these 14 years. In addition, they noted more reexplorations for bleeding (9.4 vs 5.8%) and more renal failure (2.6 vs 0.8%) for the Ross operations. The conclusion was that the Ross could not be considered a reasonable alternative to simpler forms of AVR because of this higher rate of morbidity and mortality. These data in low volume centers are in stark contrast to results from high volume centers. Zebele and colleagues in the United Kingdom, performed a recent review of aortic valve procedures between 2000 and 2011 in children and young adults (16-30 years old) and showed a steadily decreasing trend in the use of the Ross despite an increasingly low mortality rate which reached 0% for the last 4 years of the study. The 1-year survival rate after Ross was 98.8% compared to 96.6% after AVR.<sup>95</sup> They concluded that the Ross operation could be done very safely in all young age groups with a lower mortality than alternatives. They observed decreased utilization of the technique but could not explain it on the basis of technical complexity or operative mortality alone. The author's own experience demonstrated a "learning curve" with three deaths in the first 30, three more in the next 178 and no deaths or reoperations for bleeding in the next 300.<sup>96</sup> Clearly the complexities of reoperative status, need for circulatory arrest replacement of ascending aneurysm, and concomitant mitral repair should encourage referral to an experienced surgeon if a Ross procedure is to be considered. Individualized discussion with each patient should examine the options and consider the potential risks and benefits of each. Hence it seems more appropriate using the Society for Thoracic Surgeons Database results to conclude that Ross operations should not be performed in very low-volume centers but should be referred to regional reference centers with strong experience in aortic root surgery including the Ross.

When done in experienced hands, there are solid data from four continents to support the fact that this operation can be done with only 1% mortality risk and no increase in morbidity despite the longer ischemic and perfusion times for this more complex procedure that often includes replacement or repair of the ascending aorta.<sup>46,96-98</sup> There is definitely a learning curve but much of that learning can be minimized by training under experienced operators.

With operative mortality now approaching that of alternative valve replacements, the long-term results are the key point in considering the Ross operation for any given patient. The comparative incidence of reoperation for structural valve deterioration with present-generation tissue valves and the continuing risks of thromboembolism and anticoagulant-related hemorrhage with modern mechanical devices must be fairly presented to patients along with the data for the Ross.

A thorough review of available series confirms that survival is extremely good after the Ross operation and approximates that of the normal age-matched population.<sup>83,99</sup> Combined

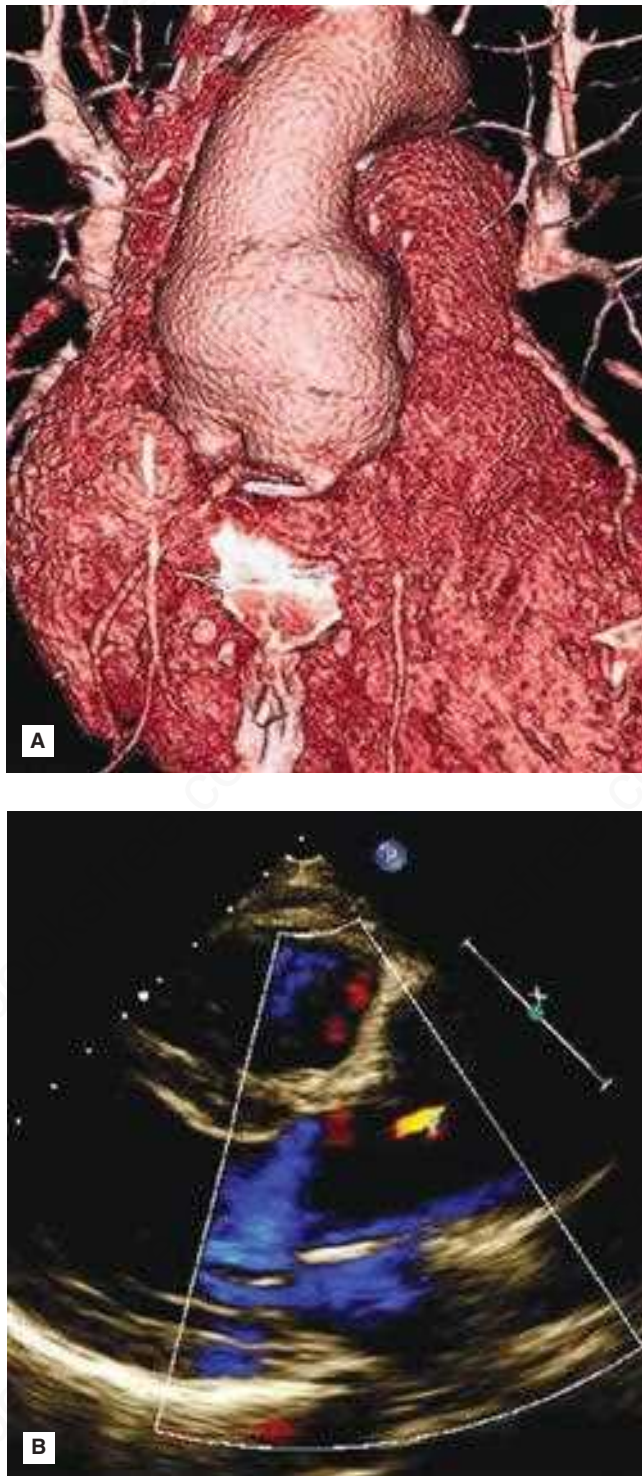

with its low incidence of thromboembolic complications and endocarditis as well as avoidance of anticoagulation with its risks of bleeding, the Ross is a very attractive option for young people. Some of these patients will undoubtedly require further surgery, but the outcomes of subsequent surgery have also been extremely good which contributes to the long-term survival.<sup>99,100</sup>

Elkins reported results in 487 patients operated between 1986 and 2002.<sup>101</sup> Hospital mortality occurred in 19 patients (3.9%). Of 15 late deaths, none were due to reoperation but only seven were not cardiac related. Actuarial freedom from all cause mortality was  $92 \pm 2\%$  at 10 years and  $82 \pm 6\%$  at 16 years. There was only one documented thromboembolic event. Actuarial freedom from endocarditis was  $95 \pm 6\%$  at 16 years. Of 38 patients who needed further surgery, autograft reoperation was more common than homograft reoperation. Importantly, the vast majority of these patients had bicuspid or even unicuspid morphology but their risk of reoperation was actually lower than the 9/78 three leaflet valve patients. Patients with primary AR fared significantly worse until 1996 when the institution of routine annular reduction and fixation was initiated. Subsequent results in AR were then only slightly inferior to those in AS in whom the 15-year freedom from autograft valve failure was  $82 \pm 6\%$ . Technique seemed important as only 21/389 full roots required reoperation where 17/79 intra-aortic implants did. Autograft support was subsequently shown to be beneficial in the German-Dutch Ross Registry data.<sup>102</sup>

## Incidence of Reoperation Post Ross Overall, Autograft, Homograft

### PULMONARY AUTOGRAFT DYSFUNCTION

Pulmonary autograft stenosis has never been reported but the incidence of regurgitation increases with time and seems to be due to autograft or native aortic dilatation or both (Fig. 29-13). The recognition of early AR due to technical problems with intra-aortic implants led to wide-spread acceptance of the root replacement method when we reported this in 1989.<sup>103</sup> Unfortunately, the totally unsupported autograft as a freestanding aortic root replacement proved to have potential for dilatation with root aneurysm and AR as a result. Annular dilatation was appreciated early and addressed with annuloplasty and external fixation with fixed pericardium or prosthetic material. Dilatation at the sinus and sinotubular junction levels was not appreciated and addressed until about a decade later. Much light has been shed on this problem over the last few years. Brown found that preoperative ascending aortic dilatation, male gender, and postoperative systemic hypertension were significant in a Cox proportional hazard analysis for the development of moderate neo-AR.<sup>104</sup> Hypertension, particularly early postoperatively, can cause acute dilatation and damage to the delicate autograft leaflets before they have time to adapt to the systemic pressure environment. The unsupported root technique having failed in 22 of 142 patients in Rotterdam over a 17-year period, the adult Ross procedure was abandoned at Erasmus.<sup>105</sup> David

**FIGURE 29-13** Dilated Ross procedure at 10 years. (A) CTA appearance. (B) Echocardiogram showing minimal central AR.

expressed concern about the potential for dilatation at multiple levels particularly in bicuspid valve patients because of a higher incidence of aortic wall pathology.<sup>106</sup> The data from the German-Dutch Ross Registry include 1642 adult patients

with mean follow up over 7 years.<sup>102</sup> There were 120 autograft reinterventions in 113 patients. The use of an unreinforced root replacement technique and preoperative pure AR were significant predictors of shorter time to reoperation. BAV had no influence on reoperation rate. A lower reoperation rate was observed in reinforced roots although this was not statistically significant from subcoronary operations.

### ROOT REINFORCEMENT TECHNIQUES

In the quest to further address autograft support and prevention of late dilatation, a number of surgeons have developed techniques (in addition to those described earlier) to support the autograft. One of the more disseminated techniques is a full fabric jacket around the autograft made from vascular graft material.<sup>107,108</sup> The jacket is sized approximately 4 mm larger than the autograft and the autograft is sewn to the jacket at the proximal and distal ends with generous openings created for the coronary buttons. The autograft and vascular graft jacket are then sewn to the aortic annulus and distal aorta. When sewing the coronary buttons, some advocate including the jacket in this anastomosis while others have just sewn the buttons directly to the autograft wall.<sup>109,110</sup> Al Rashidi and colleagues reported 4.5-year results using this jacket support method in 13 patients and showed no failures and less autograft dilatation compared to patients who did not have jacket support.<sup>111</sup>

Other techniques similar to the ones described in this author's technique focus on supporting the annulus and STJ using felt support to fix these regions and prevent dilatation at these points (Fig. 29-12). This has been shown to decrease autograft failure in the German-Dutch Ross Registry.<sup>102</sup> In order to prevent proximal autograft dilatation, a number of surgeons have suggested plicating the aortic annulus and or distal aorta if they are dilated.<sup>112</sup>

### PULMONARY HOMOGRRAFT DYSFUNCTION

As part of the Ross operation, the single aortic valve operation becomes a double-valve operation also leaving the RVOT substitute at risk for future problems. The pioneer series clearly demonstrated the homograft to be superior to other alternatives of that day, but controversy remains particularly over the advantages and disadvantages of homograft viability over the advantages and disadvantages of homograft viability on the right side. Although the initial hemodynamics of the cryopreserved pulmonary homografts are excellent, consistent increase in transvalvular gradients occurs within 6 to 12 months. This early increase in gradient usually stabilizes by 2 years but can be progressive in 1 to 2% of patients. An immune system response has been implicated but the mechanisms are poorly understood.<sup>113</sup>

Late imaging of pulmonary homografts reveals extensive calcification of the inflow end indicative of an intense scar response to the homograft muscle cuff (Fig. 29-14). Schmidtke and associates tried to minimize this with a unique trimming of the muscle and replacing it with a cuff of pericardium.<sup>114</sup> This proved effective over the first 2 years but failed to make a long-term difference. An intense adventitial inflammatory

**FIGURE 29.14** Calcified pulmonary homograft. The inflow anastomosis of this pulmonary homograft is markedly narrowed and calcified 16 years after a Ross procedure. Gradient was only 28 at rest but 75 mm Hg with exercise. (A) Appearance on CT scan. (B) Gross specimen at explant. (C) Microscopic showing acellular scar.

reaction with diffuse thickening along the entire homograft was described with elegant magnetic resonance imaging flow studies by Carr-White.<sup>115</sup> This caused extrinsic compression of the conduit portion of the homograft.

The incidence of homograft stenosis is probably 5 to 10% at 10 years. Risk factors proposed include younger donor age, shorter time of cryopreservation, and homograft size.<sup>116</sup> Because small size is the most consistent risk factor, oversizing helps reduce the effect of shrinkage. In a series of 338 patients in France, only three patients required isolated homograft intervention and all were treated successfully with a catheter-based valve. The low incidence was felt due to policy of oversizing and use of anti-inflammatory drugs early after surgery.<sup>100</sup>

Review of the homograft outcomes in the German-Dutch Ross Registry show a mean gradient of 4.7 at one month increasing to 10 by 14 years with peak gradients going from 8.4 to 18.5 mm Hg. Most of the increase comes in the first 2 years and then levels off to very slow increase. They found that smaller conduit size (mean was  $26 \pm 2.15$  mm) was the most important risk factor with lesser impact from younger patient and donor age.<sup>97</sup>

Most patients tolerate peak gradients up to 50 mm Hg without symptoms so the clinical significance is less than the incidence of stenosis. In the Oklahoma series, homograft failure (reoperation or percutaneous intervention) occurred in 33 of 487 patients giving actuarial freedom from failure of  $90 \pm 2\%$  at 10 years and  $82 \pm 4\%$  at 16 years.<sup>101</sup> The advent of catheter-based valve replacement has made it possible to treat some of these patients percutaneously.<sup>117</sup>

Moderate or even severe homograft regurgitation may also be detected by echocardiography in as much as 10% of patients by 10 years but this lesion is well tolerated by the right ventricle in the absence of pulmonary hypertension. It is probable that most pulmonary homografts will ultimately suffer this mode of failure but the majority will last 20 to 25 years before they reach this point.

After four decades of use and research, the cryopreserved pulmonary homograft is the best RVOT substitute documented for use in the Ross procedure. Rarely, a stentless porcine bioprosthesis has been used. Tissue engineering concepts seem ideally suited to this low pressure area where a decellularized homograft or even heterograft matrix can perform nicely while providing an environment suitable for maturation of new cellular elements derived from circulating stem cells, adjacent ingrowth, or preoperative seeding. Initial clinical studies with both show promise.<sup>30,118,119</sup> and mid-term outcomes from the German-Dutch Ross Registry observed that decellularized homografts exhibited lower gradients than cryopreserved grafts at 6 years.<sup>97</sup>

Use of alternatives to the homograft has been disappointing. Stentless tissue valves have been shown to be an acceptable alternative when homografts are not available but calcification of the xenografts is worse than the homografts.<sup>120</sup> A large series included 73 stentless porcine devices in the pulmonary position had a 10-fold incidence of gradients over 40 mm Hg compared to homografts.<sup>121</sup> Tissue-engineered

porcine pulmonary devices have been troubled by poor outcomes in the short term.<sup>122</sup>

## POST ROSS REOPERATION

The prospect of reoperation after a Ross procedure has been regarded as a complex and hazardous undertaking.<sup>105</sup>

It is important to realize that reoperative aortic root surgery is not simple and should be done only in centers with considerable experience and volume. Redo Ross surgery is certainly in this category, perhaps more so because of the homograft in the RVOT to make things more complicated. Stulak et al. reported the Mayo Clinic experience with 56 patients requiring reoperation after a Ross most of which (43) had been done at other institutions.<sup>123</sup> Only one patient died (1.8%), but six patients had respiratory failure and three required ECMO support. There were four more deaths within 8 months. This experience brought them to the conclusion that patients need to be warned about potential for risky reoperative surgery in the future when they choose to have a Ross procedure in the first place.

On the other hand, the largest experience reported for reoperative surgery after Ross is from the German-Dutch Ross Registry and paints a far less ominous picture. One hundred and sixty reoperations were done on either the autograft 82, homograft 61, or both 17.<sup>124</sup> All patients survived short and long term. The updated series in 2012 revealed that six patients had died at 224 reoperations (2.6%) in the Registry.<sup>125</sup> Five of the six had endocarditis and all needed urgent or emergent surgery. There was still no mortality with elective reoperation. Emergency surgery for endocarditis is a challenging problem but this is true for any infected prosthetic root. Planned reoperation in experienced hands has lower mortality rate than many series of elective root surgery.

The availability of the bovine jugular vein with its intrinsic valve in a stent frame has become a valuable tool to treat pulmonary homograft stenosis. Initial dilatation with a balloon while demonstrating angiographic patency of the left main system is essential to avoid coronary compromise with this technique.<sup>126</sup>

Alsoufi and colleagues in Saudi Arabia had a predominantly young rheumatic population in which 50 of 510 patients had redo AVR at a median of 3.8 years after Ross root replacement (without support in all but 7). There was minimal root dilatation so the autograft leaflets were simply removed and a stented bioprosthesis (12) or mechanical (38) valve was placed in a standard fashion at the annulus. Follow up after the redo operations averaged 8.4 years. Only one patient required a redo root replacement in that time which made them conclude that just replacing the valve was a valid option in Ross roots less than 4 cm in diameter at the time of reoperation.<sup>127</sup>

The Stuttgart team did 645 Ross operations almost all freestanding roots with support. Forty-nine autograft reoperations were required in 46 patients. A David procedure was done in 18 of 35 with primarily autograft dilatation at a mean of 11 years after the original surgery. Only one of these

required further surgery within 3 years. An interesting finding that has been observed by others is that the native pulmonary valve leaflets are found to have remodeled over time to look like typical aortic valve leaflets including the development of nodules of Aranti.<sup>128</sup>

In Brussels where valve-sparing aortic root surgery is common, this technique was employed to save the autograft in 26 of 28 patients. Twenty of these had originally had root replacement Ross while the other six patients had an inclusion technique. Neo-aortic root dilatation was the primary reason for reoperation. Primary cusp prolapse was also treated but had unsatisfactory outcomes after repair.<sup>129</sup>

Concern about dissection and rupture is largely unsupported. Rupture of the autograft has never been reported. Localized dissection of the autograft does occur but does not extend across circumferential suture lines that protect the distal aorta and the coronary ostia. The wall of the autograft, though thinner than native aorta, is encased in scar tissue from the original surgery making leakage into a free pericardial space extremely unlikely.

If moderate autograft regurgitation has developed with root dilatation, a policy of waiting for symptoms or ventricular dysfunction/dilatation typically indicative for surgical intervention should be considered appropriate, not just treating a sinus dimension. If distal native aorta dilates to 5.0 cm or greater, it may be reasonable to intervene before it gets to 5.5 cm in the setting of original BAV disease. If other valve disease or coronary disease dictates operative intervention, the dilated autograft should not be ignored. If the patient had no support at the original operation and root dilatation is the primary problem, then a valve-sparing technique can be considered or a Bentall option employed. The living autograft tissue makes mobilization of the coronary buttons easier because there is no calcification but they are still more delicate than native aorta and adhesions to the adjacent pulmonary homograft can make dissection in that area difficult. A Yacoub technique<sup>130</sup> is suitable if the annulus was supported with a felt strip at the original operation, but a David technique is needed if the annulus is dilated and/or unsupported. Alternatively, the Yacoub can be combined with annuloplasty or independent annular support to avoid extensive dissection between the autograft and homograft.<sup>131</sup> Need for major leaflet revision is a marker for less durability just as it is in primary valve-sparing surgery.

Complete redo root replacement should be considered if both the leaflets and the sinuses are problematic. The living, pliable autograft makes this much easier than a redo after a homograft or stentless porcine root and perhaps even after a standard Bentall.

Safe reoperation begins with appropriate planning at the original operation where closure of the pericardium or coverage of the heart with pericardial substitute will allow safe sternal reentry. Central cannulation is almost always possible, but peripheral cannulation should be considered in multiple reoperative settings or when preoperative imaging suggests perilous reentry. Crucial to safe conduct of these operations is avoidance of the plane between the pulmonary homograft and the aorta. There is usually plenty of room distal to the

pulmonary artery to clamp the aorta before this plane needs to be addressed. Coronary buttons are often very close to the distal autograft anastomosis so aortotomy at reoperation should never be proximal to this suture line. The complete spectrum of replacement options is open at reoperation including simple mechanical or stented tissue valves, subcoronary or full root stentless, aortic homograft, or Bentall operation with biologic or mechanical valved conduit. The RVOT homograft should be left alone unless grossly abnormal by preoperative evaluation. If reoperation is required for RVOT obstruction, this can be accomplished on the beating heart. The old conduit is opened longitudinally from normal right ventricular muscle to normal PA. The thick proximal scar is resected carefully and as much of the old conduit is removed as necessary to allow placement of a new homograft. The posterior wall and that facing the aorta can be left intact to avoid injury to the autograft and coronary tree.

## FINAL THOUGHTS

Stentless aortic valve options provide unique advantages over stented valves. They are known for superb hemodynamics particularly in the small aortic annulus. For patients requiring replacement of the aortic root and valve, the stentless valves provide a conduit by which both issues can be addressed with one graft. Furthermore, in the setting of aortic root replacement the tissue of the stentless valve is friendlier when working with coronary button anastomoses and this is predominantly true in cases of reoperative aortic root surgery. The durability of both the homograft and Freestyle has been shown to be similar to that of the best of the stented valve options.

The stentless valve option can lead to a more complicated reoperation in either the subcoronary or full root technique and patients should be referred to expert centers where these surgeries can be done safely with low mortality and morbidity.

The Ross operation should be offered as an option for any patient under the age of 50 years with aortic valve disease and a life expectancy in excess of 20 to 25 years. Under ideal circumstances, it can be considered in the 50- to 65-year-old population where the Ross has the possibility of lasting to the end of a normal life span. Of all the substitutes for the diseased aortic valve, only the pulmonary autograft has all the biologic advantages of a truly living structure. It is delicate and demands precise implantation technique for immediate and long-term success. Appropriate aortic tailoring or support is needed in the majority of patients to prevent late autograft dilatation and dysfunction. Approximately 20% of patients will probably require additional surgery for either the neo-aortic or the neo-pulmonary aspects of this operation by 20 years but they will not require anticoagulation and will not be limited in activity or lifestyle during that time. In appropriate hands, this operation can be done very safely and is a durable and excellent choice for young active people with aortic valve disease. Compared to the virtually 100% reoperation rate at 20 years for animal tissue valves, unavoidable and ongoing risks of thromboembolic and hemorrhagic complications with mechanical valves and proven advantage

of the Ross over aortic homograft in randomized prospective trial,<sup>132,133</sup> the Ross is a very viable option. Long-term survival may actually be superior to any other aortic valve operation. Failure to offer this option misses an opportunity for this survival benefit.<sup>55</sup>

# Aortic Valve Repair and Aortic Valve-Sparing Operations

Tirone E. David

## FUNCTIONAL ANATOMY OF THE AORTIC VALVE

The aortic valve is a complex structure that is best described as a functional and anatomic unit, the aortic root. The aortic root has four components: aortoventricular junction or aortic annulus, aortic cusps, aortic sinuses, and sinotubular junction. In addition, the triangles beneath the commissures of the aortic valve, although part of the left ventricular outflow tract, are also important for valve function.

The aortic annulus unites the aortic cusps and aortic sinuses to the left ventricle. It is attached to ventricular myocardium (interventricular septum) in approximately 45% of its circumference and to fibrous structures (anterior leaflet of the mitral valve and membranous septum) in the remaining 55% (Fig. 30-1). The aortic annulus has a scalloped shape. Histologic examination of the aortic annulus reveals that it is a fibrous structure with strands attaching itself to the muscular interventricular septum and has a fibrous continuity with the mitral valve and membranous septum. The fibrous structure that separates the aortic annulus from the anterior leaflet of the mitral valve is the intervalvular fibrous body. An important structure immediately below the membranous septum is the bundle of His. The atrioventricular node lies in the floor of the right atrium between the annulus of the septal leaflet of the tricuspid valve and the coronary sinus. This node gives origin to the bundle of His, which travels through the right fibrous trigone along the posterior edge of the membranous septum to the muscular interventricular septum. At this point, the bundle of His divides into left and right bundle branches that extend subendocardially along both sides of the muscular interventricular septum.

The aortic cusps are attached to the aortic annulus in a scalloped fashion (see Fig. 30-1). The aortic cusps have a semilunar shape whereby the length of the base is approximately 1.5 times longer than the length of the free margin, as illustrated in Fig. 30-2. There are three cusps and three aortic sinuses: left, right, and noncoronary. The aortic sinuses are also referred to

as sinuses of Valsalva. The left coronary artery arises from the left aortic sinus and the right coronary artery arises from the right aortic sinus. The left coronary artery orifice is closer to the aortic annulus than is the right coronary artery orifice. The highest point where two cusps meet is called the commissure, and it is located immediately below the sinotubular junction. The scalloped shape of the aortic annulus creates three triangular spaces underneath the commissures. The two triangles beneath the commissures of the noncoronary cusp are fibrous structures, whereas the triangular space beneath the commissure between the left and right cusps is mostly muscular. These three triangles are seen in Fig. 30-1. The aortic annulus evolves along three horizontal planes within a cylindrical structure. Thus, the annulus of each cusp inserts itself in the aortic root along a single horizontal plane. The sinotubular junction represents the end of the aortic root. It is an important component of the aortic root because the commissures of the aortic valve are immediately below it and changes in the diameter of the sinotubular junction affect the function of the aortic cusps.

The geometry of the aortic root and its anatomic components varies among individuals, but the geometry of these components is somewhat interrelated. For instance, the larger the aortic cusps, the larger are the diameters of the aortic annulus and sinotubular junction. The aortic cusps are semilunar (crescent shape) and their bases are attached to the annulus; the free margins extend from commissure to commissure, and the cusps coapt centrally during diastole. The size of the aortic cusps varies among individuals and within the same person, but as a rule the noncoronary cusp is slightly larger than the right and left. The left is usually the smallest of the three. Because of the crescent shape of the aortic cusps and the fact that their free margins extend from commissure to commissure, the diameter of the aortic valve orifice must be smaller than the length of the free margins. Indeed, anatomic studies of fresh human aortic roots demonstrated that the average length of the free margins of the aortic cusps was one-third longer than the diameter of the aortic orifice.

**FIGURE 30-1** A photograph of a human left ventricular outflow tract and aortic root.

The diameter of the aortic annulus is 15 to 20% larger than the diameter of the sinotubular junction in children, but this relationship changes with age and the diameter of the aortic annulus is often smaller than the diameter of aortic annulus in older persons (see Fig. 30-2).

The aortic annulus, the aortic cusps, and the sinotubular junction play an important role in maintaining valve competence. On the other hand, the aortic sinuses play no role in valve competence, but they are believed to be important in minimizing mechanical stress on the aortic cusps during the cardiac cycle by creating eddies currents between the cusps and the aortic sinuses.

All components of the aortic root are very elastic and compliant in children but compliance decreases with aging as elastic fibers are replaced by fibrous tissue. Expansion and contraction of the aortic annulus during the cardiac cycle are heterogeneous probably because of its attachments to contractile myocardium as well as to fibrous structures such as the membranous septum and intervalvular fibrous body. On the other hand, the expansion and contraction of the sinotubular junction are more uniform. The aortic root also displays

**FIGURE 30-2** Geometric relationships of various components of the aortic root. The base of the aortic cusp is 1.5 times longer than its free margin. The diameter of the aortic annulus is 10 to 15% larger than the diameter of the sinotubular junction in children and young adults but it tends to become equal with aging. Three semilunar cusps seal the aortic orifice. The height of the cusps must be longer than the radius of the aortic annulus.

some degree of torsion during isovolumic contraction and ejection of the left ventricle. The movements of the aortic annulus, cusps, sinuses, and sinotubular junction also change with aging as elastic fibers are replaced by fibrous tissue.

## AORTIC VALVE PATHOLOGY

Anatomically normal aortic cusps may become calcified late in life and cause aortic stenosis. This type of lesion is called dystrophic calcification, senile calcification, or degenerative calcification. The range of histopathologic lesions includes calcification, chondroid and osseous metaplasia, neovascularization, inflammation, and lipid deposition.

Bicuspid aortic valve is estimated to occur in 0.5% to 1.5% of the population.<sup>1</sup> Males are affected more than females at a ratio of 4:1. There is a relatively high incidence of familial clustering, which suggests an autosomal dominant inheritance with reduced penetrance.<sup>2</sup> Extensive research in the genetics of bicuspid aortic valve is being presently conducted and this disorder is likely heritable.<sup>2</sup> Most patients with bicuspid aortic valve have three aortic sinuses and two cusps of different sizes. The larger cusp often contains a raphe instead of a commissure. The raphe extends from the mid portion of the cusp to the aortic annulus, and its insertion in the aortic root is at a lower level than the other two commissures. Bicuspid aortic valves with two aortic sinuses and no raphe are least common and called “type 0”; the most common is with one raphe and is called “type 1”; and finally with two raphes is “type 2.”<sup>3</sup> Types 1 and 2 can be subclassified according to the fused cusps: L-R is the most common form (a raphe in between the left and right cusps). Most patients with bicuspid aortic valves have a dominant circumflex artery and a small right coronary artery. Bicuspid aortic valve may function satisfactorily until late in life when it may become calcified and stenotic.<sup>4</sup> It may also become incompetent, particularly in younger patients and is often associated with dilated aortic annulus and prolapsed cusp.

Other congenital anomalies of the aortic valve are the unicuspid and quadricuspid valves. Subaortic membranous ventricular septal defect can cause aortic insufficiency because of distortion of the aortic annulus and prolapse of the right cusp.

Numerous connective tissue disorders (ankylosing spondylitis, osteogenesis imperfecta, rheumatoid arthritis, Reiter’s syndrome, lupus, etc.) can cause aortic insufficiency. The anorexigenic drugs phentermine and fenfluramine can also cause aortic insufficiency. Rheumatic aortic valve disease is still prevalent in developing countries and can cause aortic stenosis and/or insufficiency by causing fusion, fibrosis, and contraction of the cusps.

## AORTIC ROOT AND ASCENDING AORTA PATHOLOGY

Degenerative diseases of the media with aneurysm formation are the most common disorders of the aortic root and ascending aorta. A broad spectrum of pathologic and clinical entities

is grouped under degenerative disorders, and it ranges from severe degeneration of the media, which can become clinically important early in life in cases such as Loeys-Dietz syndrome, to cases of the not so important mild dilation of the ascending aorta in elderly patients. Bicuspid and unicuspid aortic valve disease often display premature degeneration of the media with dilation of the aorta. Atherosclerosis, infectious and noninfectious aortitis are other pathologic entities.

Aneurysms of the ascending aorta are often caused by cystic medial degeneration (cystic medial necrosis). Histologically, necrosis and disappearance of muscle cells in the elastic lamina, and cystic spaces filled with mucoid material are often observed. Although these changes occur more often in the ascending aorta, they may affect any portion or the entire aorta. These changes weaken the arterial wall, which dilates and forms a fusiform aneurysm. The aortic root may be involved in this pathologic process, and in patients with Marfan syndrome, the aneurysm usually begins in the aortic sinuses. A large proportion of patients with aortic root aneurysms do not fulfill the criteria of diagnosis of Marfan syndrome, but the gross appearance of the aneurysm and the histology of the arterial wall may be indistinguishable from that of Marfan syndrome. These cases are referred to as *forma frusta* of Marfan syndrome.

Patients with aortic root aneurysms are usually in their second or third decade of life when the diagnosis is made. These patients develop aortic insufficiency because of dilation of the sinotubular junction and/or aortic annulus (Fig. 30-3). Annuloaortic ectasia is a term used to describe dilation of the aortic annulus.

Other patients have relatively normal aortic roots but develop ascending aortic aneurysms. These patients are usually in their fifth or sixth decade of life. Finally, certain

patients have extensive degenerative disease of the entire aorta and develop the so-called mega-aorta syndrome with dilation of the entire thoracic and abdominal aorta. Ascending aortic aneurysm may cause dilation of the sinotubular junction with consequent aortic insufficiency (Fig. 30-3).

## Marfan Syndrome

Marfan syndrome is an autosomal dominant variably penetrant inherited disorder of the connective tissue in which cardiovascular, skeletal, ocular, and other abnormalities may be present to a variable degree. The prevalence is estimated to be around 1 in 5000 individuals. It is caused by mutations in the gene that encodes fibrillin-1 (FBN1) on chromosome 15. This is a large gene (approximately 10,000 nucleotides in the mRNA), and identification of the mutation is a complex task. More than 1000 mutations in FBN1 have been identified. The phenotype presents a highly variable degree because of varying genotype expression.

The clinical features of Marfan syndrome were thought to be a result of weaker connective tissues caused by defects in fibrillin-1, a glycoprotein, and principal component of the extracellular matrix microfibril. This concept was inadequate to explain the overgrowth of long bones, osteopenia, reduced muscular mass, and adiposity and craniofacial abnormalities often seen in Marfan syndrome.<sup>5</sup> Dietz and colleagues<sup>5,6</sup> showed in an experimental mouse with Marfan syndrome that many findings are the result of abnormal levels of activation of transforming growth factor beta (TGF- $\beta$ ), a potent stimulator of inflammation, fibrosis, and activation of certain matrix metalloproteinases, especially matrix metalloproteinases 2 and 9. Excess TGF- $\beta$  activation in tissues correlates with failure of lung septation, development of a myxomatous mitral valve, and aortic root dilation in mice. This combination of structural microfibril matrix abnormality, dysregulation of matrix homeostasis mediated by excess TGF- $\beta$ , and abnormal cell-matrix interactions is responsible for the phenotype features of the Marfan syndrome. Ongoing destruction of the elastic and collagen lamellae and medial degeneration result in progressive dilation of the aortic root, as well as a predisposition to aortic dissection from the loss of appropriate medial layer support. Loss of elasticity in the media causes increased aortic stiffness and decreased distensibility.

The diagnosis of Marfan syndrome is made on clinical grounds, and it is not always simple because of the variability in clinical expression. A multidisciplinary approach is needed to diagnose and manage patients afflicted with this syndrome. The revised Ghent criteria to diagnose Marfan syndrome is summarized in Table 30-1.<sup>7</sup> The most common cardiovascular features are aortic root aneurysm and mitral valve prolapse. These anatomical abnormalities may cause aortic rupture, aortic dissection, aortic insufficiency, and mitral insufficiency.

**FIGURE 30-3** Dilation of the sinotubular junction causes aortic insufficiency because it displaces the commissures outward and prevents the cusps to coapt centrally.

## Loeys-Dietz Syndrome

Mutations in the genes encoding TGF- $\beta$  receptors 1 and 2 have been found in association with a continuum of clinical

**TABLE 30-1: Revised Ghent Criteria for Diagnosis of Marfan Syndrome**

*In the absence of family history the diagnosis of Marfan is confirmed with:*

1. Aortic root dilatation ( $Z \geq 2$ ) or dissection + ectopialentis
2. Aortic root dilatation ( $Z \geq 2$ ) or dissection + FBN1 mutation
3. Aortic root dilatation ( $Z \geq 2$ ) or dissection + systemic manifestations ( $\geq 7$  points)
4. Ectopialentis + FBN1 mutation associated with aortic dissection but without aortic root dilatation or dissection

*In the presence of family history of Marfan syndrome:*

5. Ectopialentis + family history
6. Systemic manifestations ( $\geq 7$  points) + family history
7. Aortic root dilatation ( $Z \geq 2$  above 20 years old or  $\geq 3$  below 20 years old) + family history

*Point system for Marfan syndrome:*

- Wrist and thumb sign—3 (wrist or thumb separately 1 point)
- Pectus carinatum deformity—2 (pectus excavatum or chest asymmetry separately—1)
- Hindfoot deformity—2 (plain pes planus—1)
- Pneumothorax—2
- Dural ectasia—2
- Protrusioacetabuli—2
- Reduced upper segment/lower segment ratio and increased arm/height no severe scoliosis—1
- Scoliosis or thoracolumbar kyphosis—1
- Reduced elbow extension—1
- Facial features (3/5) —1 (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia)
- Skin striae—1
- Myopia  $> 3$  diopters—1
- Mitral valve prolapse (all types)—1

(Maximum total: 20 points; score  $\geq 7$  indicates systemic involvement)

features. On the mild end, the mutation have been found in association with presentation similar to that of the Marfan syndrome or with familial thoracic aneurysm and dissection, and on the severe end, they are associated with a complex phenotype in which aortic dissection or rupture commonly occurs in childhood.<sup>8</sup> This complex phenotype is characterized by the triad of hypertelorism, bifid uvula or cleft palate, and generalized arterial tortuosity with widespread vascular aneurysm and dissection. This phenotype has been classified as Loeys-Dietz syndrome. Affected patients have a high risk of aortic dissection or rupture at an early age and at relatively small diameters. CT angiograms should be obtained from head to pelvis.

## Ehlers-Danlos Syndrome

Vascular Ehlers-Danlos syndrome is a rare autosomal dominant inherited disorder of the connective tissue resulting from mutation of the COL3A1 gene encoding type III collagen. Spontaneous rupture without dissection of large- and

medium-caliber arteries such as the abdominal aorta and its branches, the branches of the aortic arch, and the large arteries of the limbs accounts for most deaths. Aortic root dilation was present in 28% in a series of 71 patients with Ehlers-Danlos syndrome.<sup>9</sup> Aortic dissection is uncommon. Diagnosis is confirmed either by biochemical assays showing qualitative or quantitative abnormalities in type III collagen secretion or by molecular biology studies demonstrating mutation of the COL3A1 gene. Varied molecular mechanisms have been observed with different mutations in each family. No correlation has been established between genotype and phenotype. Diagnosis should be suspected in any young person presenting with arterial or visceral rupture or colonic perforation.

## Other Aortic Root Aneurysm Associated with Genetic Syndromes

Aneurysm-osteoarthritis syndrome is associated with pathogenic SMAD-3 gene and is clinically characterized by aortic root aneurysm, aortic dissection, arterial aneurysms and dissection, arterial tortuosity, mitral valve prolapse, congenital cardiac defects, and osteoarthritis, soft skin, flat feet, scoliosis and recurrent hernias.<sup>10</sup> Aortic root aneurysms can also be associated with mutations of TGF $\beta$ -2 and with mutations of fibrillin-4 gene (FBLN4; cutis laxa syndrome).<sup>11,12</sup>

## Other Pathologies

Familial thoracic aneurysms can be associated with mutations of various genes (TGF $\beta$ 1-2, ACTA2, MLCK, SMAD3, TGF2) without systemic syndrome such as those described above. Atherosclerotic aneurysms of the ascending aorta are uncommon. They are more common in the abdominal aorta and to a lesser degree in the descending thoracic aorta. Atherosclerosis often causes irregular and saccular aneurysms of the ascending aorta rather than a more fusiform shape as seen with degenerative diseases.

Infectious aneurysms of the ascending aorta are rare. Syphilis was a common cause of aneurysm of the ascending aorta but it is seldom seen. The spirochetal infection destroys the muscular and elastic fibers of the media, which are replaced by fibrous and other inflammatory tissues. The ascending aorta is the most common site of involvement and the aneurysm is usually saccular. The wall of the ascending aorta is frequently calcified. Syphilitic aortitis also causes coronary ostial stenosis and aortic valve insufficiency. Other bacteria can also cause aneurysm of the ascending aorta.

Various types of aortitis may involve the ascending aorta. Giant cell arteritis is among the more common and it involves medium-sized arteries, but the aorta and its branches are involved in approximately 15% of the cases. The etiology is unknown. The characteristic lesion is a granulomatous inflammation of the media of large- and medium-caliber arteries such as the temporal artery. Occasionally the inflammatory process weakens the aorta leading to aneurysm formation, aortoannular ectasia, and aortic insufficiency.

Ankylosing spondylitis, Reiter's syndrome, psoriatic arthritis, and polyarteritis nodosa can cause aortic insufficiency because of annuloaortic ectasia. Behçet's disease can cause aneurysm of the ascending aorta.

## NATURAL HISTORY OF AORTIC VALVE DISEASE

### Aortic Stenosis

Asymptomatic patients with aortic stenosis have a good prognosis.<sup>13</sup> Sudden death in asymptomatic patients is uncommon. However, when symptoms develop, the prognosis becomes poor and the average survival is 2 to 3 years for patients with symptoms of angina and syncope, and 1 to 2 years for those with congestive heart failure.<sup>14</sup>

### Aortic Insufficiency

The prognosis of symptomatic patients with aortic insufficiency is poor with death occurring within 4 years after development of angina and within 2 years after the onset of congestive heart failure.<sup>15</sup>

### Bicuspid Aortic Valve Disease

A prospective follow-up on 642 adult patients (mean age  $35 \pm 9$  years) with bicuspid aortic valve during a mean  $9 \pm 5$  years in our institution revealed a late survival similar to that of the general population in spite the fact that 161 patients had an adverse event (cardiac death, aortic valve/ascending aorta surgery, dissection, or congestive heart failure).<sup>16</sup> Age greater than 30 years, and moderate or severe aortic stenosis or insufficiency were independent predictors of adverse event.<sup>16</sup> In a study from the Mayo Clinic on 212 patients (mean age  $32 \pm 20$  years) with normal or minimally dysfunctional bicuspid aortic valve who lived in Olmsted County and followed for a mean of  $15 \pm 6$  years revealed a 20-year survival similar to that of the general population, but the incidence of surgery on the aortic valve and/or ascending aorta was  $27 \pm 4\%$  and the total adverse cardiovascular events was  $42 \pm 5\%$ .<sup>4</sup>

### Aortic Root and Ascending Aortic Aneurysms

Aortic root/ascending aortic aneurysm can cause aortic insufficiency, aortic dissection, or rupture. The transverse diameter of the aneurysm is a determinant of rupture or dissection. In a study by Coady and associates<sup>17</sup> on 370 patients with thoracic aneurysms (201 ascending aortic aneurysms), during a mean follow-up of 29.4 months the incidence of acute dissection or rupture was 8.8% for aneurysms less than 4 cm, 9.5% for aneurysms of 4 to 4.9 cm, 17.8% for 5 to 5.9 cm, and 27.9% for those greater than 6 cm. The median size of the ascending aortic aneurysm at the time of rupture or dissection was 5.9 cm.

In Coady's study, the growth rate ranged from 0.08 cm/year for small (<4 cm) aneurysms to 0.16 cm/year for large (8 cm) aneurysms.<sup>17</sup> The growth rates for chronic nondissecting aneurysms were much higher than for chronic nondissecting aneurysms.

The growth rates for aortic root aneurysms may be higher than in ascending aortic aneurysms, particularly in patients with Marfan syndrome. Aortic dissection is rare in aortic root aneurysm of less than 50 mm, unless the patients have family history of aortic dissection. Without surgery, most patients with Marfan syndrome die in the third decade of their lives from complications of aortic root aneurysm such as rupture, aortic dissection, or aortic insufficiency.<sup>18</sup> Pregnancy in women with Marfan syndrome has two potential problems: the risk of having a child who will inherit the disorder and the risk of acute aortic dissection during the third trimester, parturition, or the first month postpartum. The offspring has a 50% risk of inheriting the syndrome.

Patients affected with Loeys-Dietz syndrome have a high risk of aortic dissection or rupture at an early age and at relatively small aortic root diameters. Surgery is recommended in adults when the aortic root exceeds 4 cm.

Patients with bicuspid aortic valve had larger aortas than patients with tricuspid aortic valve and the rate of dilation of the ascending aorta was higher (0.19 vs 0.13 cm per year, respectively) in a study by Davies et al.<sup>19</sup> Among patients with bicuspid aortic valve, those with aortic stenosis had a higher risk of rupture, dissection, or death.

## DIAGNOSIS OF AORTIC VALVE/ROOT DISEASE

Patients with aortic stenosis remain asymptomatic for many years. Symptoms usually appear late in the course of the disease. The symptoms are: angina pectoris, syncope, and congestive heart failure. The clinical presentation of patients with aortic insufficiency is dependent on the rapidity with which aortic insufficiency develops. Patients with chronic aortic insufficiency remain asymptomatic for many years while the heart slowly enlarges. Palpitations and head pounding may occur during exertion. Angina pectoris may occur, but it is not as common as with aortic stenosis. Syncope is rare. The symptoms of congestive heart failure are usually an indication of left ventricular dysfunction. Acute aortic insufficiency is frequently associated with cardiovascular collapse, with extreme fatigue, dyspnea, and hypotension resulting from reduced stroke volume and elevated left atrial pressure. Echocardiography confirms the diagnosis of aortic valve dysfunction and provides information regarding its mechanism. Radionuclide imaging is useful in assessing the left ventricular function at rest and during exercise, valuable information in asymptomatic patients.

Most patients with aortic root aneurysm are asymptomatic and have no physical signs if the aortic valve is competent. Some patients may complain of vague chest pain. Severe chest pain is suggestive of rapid expansion or intimal tear with dissection. Echocardiography establishes the diagnosis and provides information regarding the aortic cusps. A computed

tomography scan and magnetic resonance imaging of the chest are also diagnostic and it is useful to provide information regarding the thoracic aorta.

## INDICATIONS FOR SURGERY

Surgeons must be familiar with the guidelines for heart valve surgery prepared by a joint committee of the ACC and AHA<sup>20</sup> and for surgery for aortic root and ascending aortic aneurysm set by the STS.<sup>21</sup>

## SELECTION OF PATIENTS FOR AORTIC VALVE REPAIR

Most candidates for aortic valve repair have aortic insufficiency or normally functioning aortic valve with aortic root or ascending aortic aneurysm. Transesophageal echocardiography is the best diagnostic tool to study the aortic valve and the mechanism of aortic insufficiency. Each component of the aortic root must be carefully interrogated, and in particular the aortic cusps. The number of cusps, their thickness, the appearance of their free margins, and the excursion of each cusp during the cardiac cycle must be examined in multiple views. The lines of coaptation of the aortic cusps should be interrogated by color Doppler imaging and the direction and size of the regurgitant jets recorded in multiple views. Information regarding the morphologic features of the aortic annulus, aortic sinuses, sinotubular junction, and ascending aorta should be obtained.

The aortic cusps are the most important determinant of aortic valve repair. If the cusps are thin, mobile with smooth free margins, the feasibility of aortic valve repair is very high, including bicuspid aortic valve. Calcified or scarred and fibrotic aortic cusps preclude aortic valve repair unless autologous or xenograft glutaraldehyde fixed pericardium is used for partial excision and patch repair of the cusps.

Patients with aortic root and ascending aortic aneurysms often have normal or minimally stretched aortic cusps and reconstruction of the aortic root with preservation of the native aortic cusps is feasible. Grossly dilated aortic annulus and/or sinotubular junction are likely to have overstretched, thinned out aortic cusps with stress fenestrations along the commissural areas and may not be suitable for repair.

## TECHNIQUES OF AORTIC VALVE REPAIR

### Cusp Perforation

Occasionally a cusp perforation is the sole reason for aortic insufficiency. The perforation may be iatrogenic, a sequelae of healed endocarditis, or the result of resection of a papillary fibroelastoma. A simple patch of fresh or glutaraldehyde fixed autologous pericardium is adequate to correct the problem. Fresh autologous pericardium can also be used to repair small holes (<5 mm) but the patch should be larger than the defect

because it retracts during healing. We use a continuous fine polypropylene to suture the patch around the defect on the aortic side of the cusp.

### Cusp Extension

Cusp augmentation has been used to repair incompetent aortic valves due to rheumatic and congenital disease. Glutaraldehyde fixed bovine or autologous pericardium has been used for this purpose.

### Cusp Prolapse

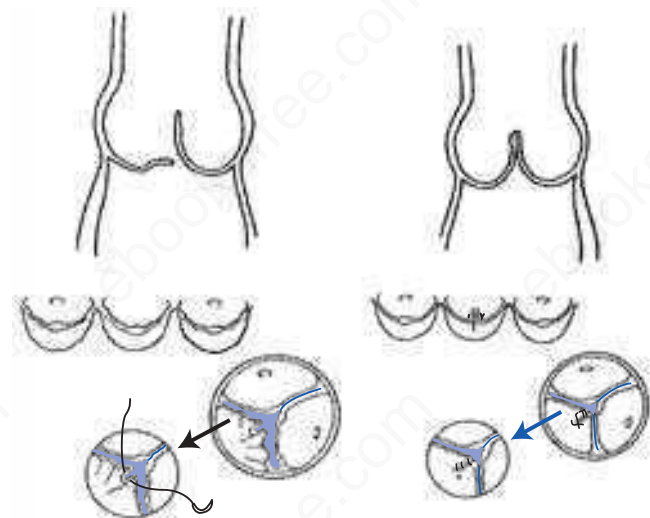

Cusp prolapse is caused by elongation of the free margin. This is corrected by plication along the nodule of Arantius as illustrated in Fig. 30-4. The degree of shortening is determined by examining the other cusps and their level of coaptation.

### Cusp with Stress Fenestration

Dilation of the sinotubular junction increases the mechanical stress along the free margin of the cusp near the commissures and may cause a stress fenestration with thinning and sometimes even detachment from the commissure. This type of lesion has been successfully corrected by weaving a double layer of 6-0 expanded polytetrafluoroethylene suture along the free margin of the cusp as illustrated in Fig. 30-5.

### Bicuspid Aortic Valve

The most commonly performed aortic valve repair in adults is for bicuspid aortic valve with prolapse of one cusp. Although the anatomic arrangement of the bicuspid aortic valve varies, most patients have an anterior cusp attached to the interventricular septum and a posterior cusp attached to the fibrous components of the left ventricular outflow tract. The anterior

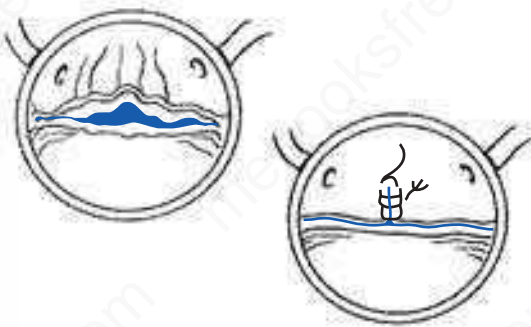

**FIGURE 30-4** Repair of cusp prolapse. The free margin is shortened by plicating the area of the nodule of Arantius.

**FIGURE 30-5** Reinforcement of the free margin with a double layer of 6-0 expanded polytetrafluoroethylene suture. This is often done in patients with stress fenestration.

cusps often contains a raphe at approximately where the commissure between the right and left cusps would be (Type 1, L-R). This cusp is usually the one that is elongated and prolapsed. As long as the posterior cusp is normal, repair is feasible and relatively simple. The raphe is excised and the free margin of the anterior cusp is shortened with plicating sutures as illustrated in Fig. 30-6. The lengths of the free margins of both cusps should be similar and should coapt at the same level. Suspending the arterial walls immediately above the commissures and observing the level of coaptation

**FIGURE 30-6** Repair of incompetent bicuspid aortic valve. The elongated cusp is shortened and the subcommissural triangles narrowed with sutures.

of each cusp gives an estimate of the level of coaptation of the cusps.

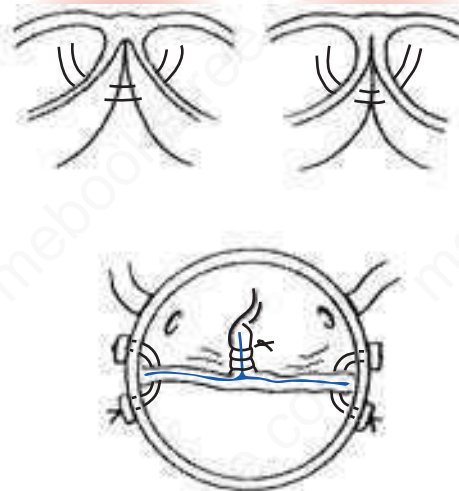

Because most patients with incompetent bicuspid aortic valves have dilated aortic annulus, aortic valve-sparing operation may be more appropriate procedure than simple cusp repair. However, if the aortic sinuses are not aneurismal and the annulus is only mildly dilated, a reduction annuloplasty to increase the coaptation area of the cusps can be done. This is accomplished by plicating the subcommissural triangles using horizontal mattress sutures of 4-0 polypropylene with Teflon felt pledgets on the outside of the aortic root (Fig. 30-7). The suture is first passed from the outside to the inside of the aorta through the aortic annulus of both cusps 2 mm below their commissure. The same suture is passed again through the annulus and subcommissural triangle 4 or 5 mm below the first one and the ends are tied together over Teflon felt pledgets on the outside of the aorta.

## AORTIC VALVE-SPARING OPERATIONS

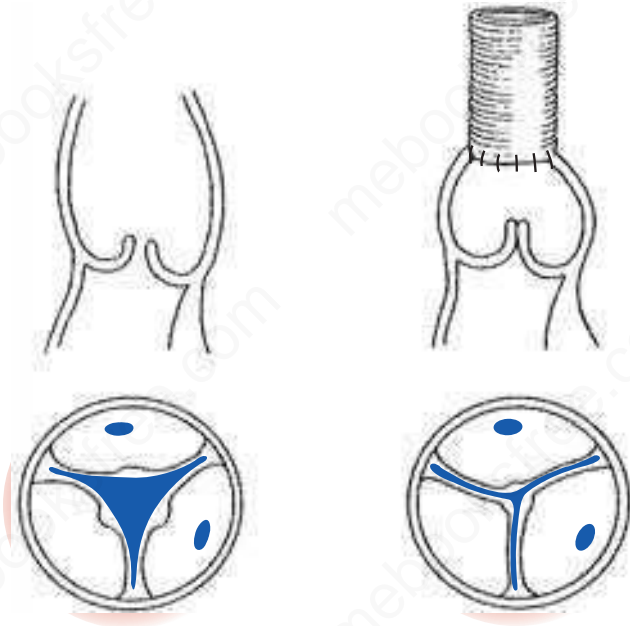

Aortic valve-sparing operations include various procedures used to preserve the aortic cusps in patients with aortic root aneurysm or ascending aortic aneurysm with aortic insufficiency.

### Ascending Aortic Aneurysm with Aortic Insufficiency

Dilation of the sinotubular junction displaces the commissures of the aortic valve outward and prevents the cusps from coapting during diastole (see Fig. 30-3). These patients are often on the sixth, seventh, or eighth decade of their lives and have ascending aortic aneurysm. The dilation of the sinotubular junction is often asymmetrical, and the commissures of

**FIGURE 30-7** Dilation of the sinotubular junction causes aortic insufficiency. Correction of the dilation with a tubular Dacron graft of appropriate diameter corrects aortic insufficiency.

noncoronary aortic cusp are more affected than the other two. If the other components of the aortic root are normal, simple adjustment of the sinotubular junction restores valve competence. This is accomplished by transecting the ascending aorta 5 mm above the sinotubular junction and pulling the three commissures upward and close to each other until the cusps coapt. The three commissures form an imaginary triangle. The diameter of a circle that contains this imaginary triangle is the diameter of the graft that should be used to reconstruct the sinotubular junction. Because the aortic cusps and sinuses have different sizes, this triangle is not always equilateral and the commissures must be spaced according to the length of the free margin of each cusp. The diameter of the graft and the space between commissures are facilitated by sizing the diameter of the circle that contains all three commissures with a transparent valve sizer, such as the one used to size the aortic annulus for a stentless porcine aortic valve. Those valve sizers have three equidistant marks, and one can determine the space between the commissures by comparing to the distance between marks. The tubular Dacron graft is sutured right at the level of the sinotubular junction with a continuous 4-0 polypropylene suture (see Fig. 30-7). If after adjusting the sinotubular junction, the cusps do not coapt at the same level, one or more cusps may be elongated and the free margin has to be shortened as illustrated in Fig. 30-4. Aortic valve competence can be tested at this time by injecting cardioplegia into the graft under pressure and observing the left ventricle for distension.

If the noncoronary aortic sinus is dilated or altered by aortic dissection, a neo-aortic sinus can be created by tailoring the graft with a tongue of tissue that is sutured directly to the aortic annulus as illustrated in Fig. 30-8. The height of the

neo-aortic sinus of Dacron should be 3 or 4 mm more than the diameter of the graft, and the width should be 3 or 4 mm more than the estimated intercommissural distance to allow the graft to bulge and create a neo-aortic sinus.

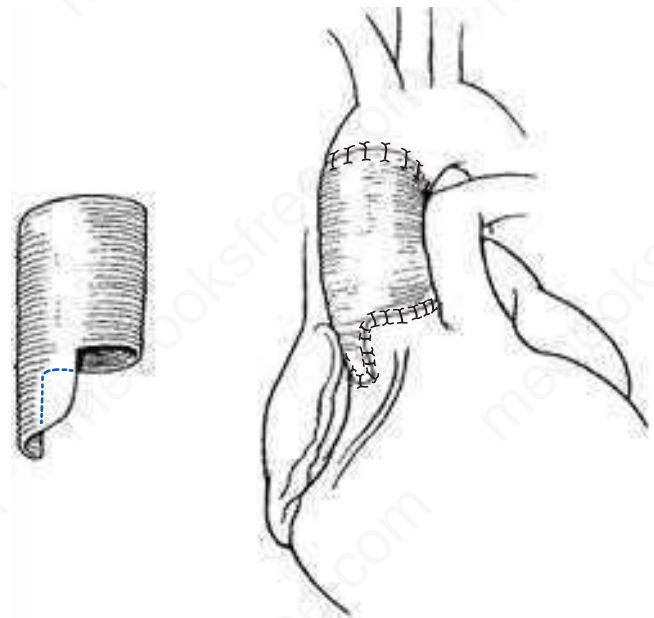

Small diameter grafts (<24 mm) should be avoided in large adult patients because they may increase left ventricular afterload, particularly if long segments of aorta are replaced such as with concomitant transverse arch replacement using the elephant trunk technique. If the estimated diameter of the sinotubular junction is less than 24 mm, a larger graft should be used and the end that is anastomosed to the aortic root to recreate the sinotubular junction should be reduced by plicating the graft in the area of the anastomosis.

## Aortic Root Aneurysm

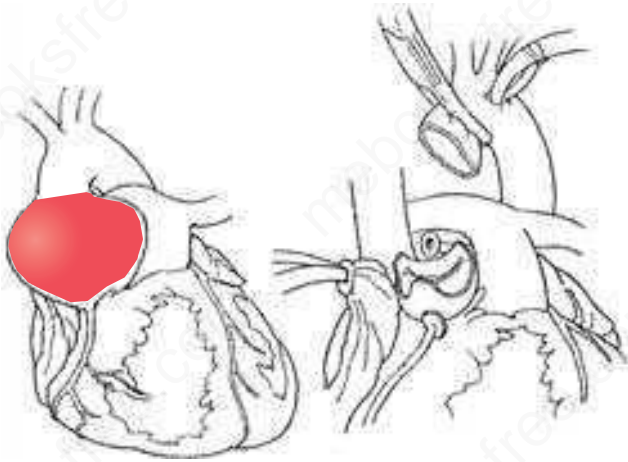

A large proportion of patients with aortic root aneurysm has normal or minimally stretched aortic cusps and an aortic valve-sparing operation is feasible. There are basically two types of aortic valve-sparing operations for patients with aortic root aneurysm: remodeling of the aortic root and reimplantation of the aortic valve.<sup>22,23</sup>

## Remodeling of the Aortic Root

The ascending aorta is transected and the aortic root is dissected circumferentially down to the level of the aortic annulus. All three aortic sinuses are excised, leaving approximately 4 to 6 mm of arterial wall attached to the aortic annulus and around the coronary artery orifices as illustrated in Fig. 30-9. The three commissures are gently pulled vertically

**FIGURE 30-8** Correction of the sinotubular junction and replacement of the noncoronary aortic sinus.

**FIGURE 30-9** Remodeling of the aortic root. The aortic sinuses are excised leaving 4 to 6 mm of arterial wall attached to the aortic annulus and around the coronary arteries.

and approximated until the cusps coapt. The three commissures form a triangle and the diameter of the circle that contains that triangle is the diameter of the graft to be used for remodeling. In our experience, most grafts are 24, 26, or 28 mm in diameter. Here again, the stentless valve sizers are very useful to determine the diameter of the graft and also the distance between commissures because they may not be equidistant. The spaces in between the commissures are marked in one of the ends of the graft, and the graft is tailored to create three neo-aortic sinuses (Fig. 30-10). The heights of these neo-aortic sinuses should be approximately equal to the diameter of the graft. The three commissures are suspended in the graft (Fig. 30-11), which is then sutured to the remnants of the aortic wall as close as possible to aortic annulus with continuous 4-0 polypropylene sutures. The coronary arteries are reimplanted into their respective neo-aortic sinuses. The aortic cusps are inspected to make sure that all three coapt at the same level and well above the nadir of the aortic annulus. If one or more cusp is prolapsing, the free margin is shortened as described previously. If one or two cusps have stress fenestrations, the free margin should be reinforced with a double layer of a fine expanded polytetrafluoroethylene suture from commissure to commissure. Aortic valve competence can be assessed by injecting cardioplegia under pressure into the reconstructed aortic root and observing the left ventricle for distension. The graft is then anastomosed to the distal ascending aorta or transverse aortic arch graft depending on the extent of the aneurysm (Fig. 30-11).

Remodeling of the aortic root may be inappropriate for patients with aortic root aneurysms associated with genetic syndromes because it has been documented that the aortic annulus may dilate postoperatively. An aortic annuloplasty along the fibrous component of the left ventricular outflow tract<sup>18</sup> did not prevent late dilation of the aortic annulus in patients with Marfan syndrome in our experience. Thus, reimplantation of the aortic valve may be a better operative procedure for patients with annuloaortic ectasia (Fig. 30-12)

**FIGURE 30-10** A graft of diameter equal to the diameter of the sinotubular junction is tailored to recreate three aortic sinuses. The three commissures are suspended into the tailored graft and the neo-aortic sinuses are sutured to the aortic annulus and remnants of arterial wall.

**FIGURE 30-11** Remodeling of the aortic root. The coronary arteries are reimplanted into their respective neo-aortic sinuses and the graft anastomosed to the distal aorta.

**FIGURE 30-12** Annuloaortic ectasia. The subcommissural triangles of the noncoronary aortic cusps are flattened by dilation of the fibrous tissue.

because this operative procedure corrects and prevents annular dilation, whereas remodeling of the aortic root may be more suitable for patients with normal aortic annulus.

### Reimplantation of the Aortic Valve

This procedure can be performed in all patients with aortic root aneurysms, but it is particularly valuable in patients with dilated aortic annulus and in acute type A aortic dissection. It is technically more demanding than remodeling of the aortic root because it requires greater knowledge of the functional anatomy of the aortic root. This is because the geometry of the aortic annulus, the aortic sinuses, the sinotubular junction, and even the aortic cusps are potentially altered during the procedure. In the original description of this procedure, the aortic valve was reimplanted into a tubular Dacron graft and

no neo-aortic sinuses were created. Some investigators have suggested that the presence of the aortic sinuses is important for normal cusp motion, and potentially, cusp durability. Several modifications to the reimplantation procedure were introduced to create neo-aortic sinuses. There is now a commercially available graft with sinuses of Valsalva (Vascutek Ltd. Renfrewshire, Scotland); however we have not used it because it distorts the aortic annulus because its sinuses are spherical, whereas the normal aortic annulus develops along a crescent shape on a single horizontal plane within a cylinder. However, this graft is used by many surgeons but the long-term results remain unknown.<sup>24</sup>

Following is a description of this procedure as we have been performing for more than two decades with excellent long-term results. The three aortic sinuses are excised as described for the remodeling procedure (see Fig. 30-9). Multiple horizontal mattress sutures of 2-0 or 3-0 polyester are passed from the inside to the outside of the left ventricular outflow tract, immediately below the nadir of the aortic annulus, through a single horizontal plane from the nadir of the left and noncoronary cusps and slightly scalloped between the subcommissural triangle of the left and right cusps and less so along the membranous septum to avoid the bundle of His as illustrated in Figure 30-13. These sutures frequently pass through right atrial wall in the area of the membranous septum and left atrial wall in the area of the sub-commissural triangle between the left and noncoronary cusps. If the fibrous portion is thin, sutures with Teflon felt pledgets should be used. A tubular Dacron graft of diameter equal to double the average height of the cusps minus 2 or 3 mm is selected and three equidistant marks placed in one

**FIGURE 30-13** Reimplantation of the aortic valve. Sutures are passed below the aortic annulus in a single horizontal plane along the fibrous portion of the left ventricular outflow tract and following the scalloped shape of the aortic annulus along the muscular interventricular septum. These sutures are also passed from the inside to the outside of a tubular Dacron graft.

of its ends. A small triangular segment is cut off along the mark that corresponds to the subcommissural triangle of the left and right cusps. The sutures previously placed in the left ventricular outflow tract are now passed through the graft. The sutures should be spaced symmetrically in the graft if the aortic annulus is not dilated. If there is obvious dilation of the aortic annulus, the sutures should be spaced symmetrically along the muscular interventricular septum and around the nadirs of the aortic annulus but closer together beneath the subcommissural triangles of the noncoronary aortic cusp because that is where dilation occurs in patients with connective disorders. The sutures are then tied on the outside of the graft. Care must be exercised not to purse-string this suture line. The graft is then cut in a length of approximately 5 cm and pulled gently, and the three commissures are also pulled vertically and temporarily secured to the graft with transfixing 4-0 polypropylene sutures buttressed on small Teflon felt pledgets, but these sutures are not tied. Once all three commissures are suspended inside the graft, the commissures and the cusps are inspected to make sure they are all correctly aligned. The subcommissural triangles should also be inspected to make sure they are as narrow as the diameter of the graft allows, that is, the triangles should have a narrower base than before surgery. Next, the sutures are tied on the outside of the graft and used to secure the aortic annulus into the graft. This is accomplished by passing the suture sequentially from the inside to the outside right at the level of the annulus and from the outside to the inside at the level of the remnants of the arterial wall. We start at the level of the commissure and stop at the nadir of the aortic annulus where the sutures are tied together. The coronary arteries are reimplanted into their respective sinuses (Fig. 30-14). The coaptation of the aortic cusps is inspected and prolapse is corrected if necessary. It is important that the coaptation level is well above the aortic annulus. Creation of neo-aortic sinuses are by plicating the graft at the level of the sinotubular junction and in between two commissures allows the aortic cusp to move a bit more centrally and increased its mobility as illustrated in Fig. 30-15. Valve competence can be assessed by occluding the distal graft and injecting cardioplegia under pressure. If the ventricle does not distend, no more than trace aortic insufficiency is present. The distal anastomosis is performed either to the distal ascending aorta or transverse aortic arch depending on the pathology. The graft sizes in our patients ranged from 26 to 34 mm, mean of 31 mm.

## RESULTS OF AORTIC VALVE REPAIR

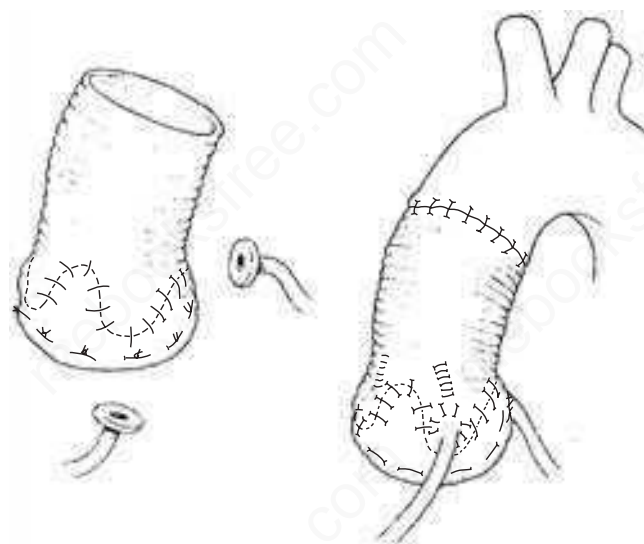

One of the earliest series of aortic valve repair for aortic insufficiency caused by prolapse of bicuspid aortic valve came from the Cleveland Clinic.<sup>25</sup> In a series of 94 patients with a mean age of 38 years, the freedom from reoperation was 84% at 7 years.<sup>21</sup> The only factor predictive of reoperation was residual aortic insufficiency at the time of repair.<sup>25</sup>

The appropriateness of aortic valve repair in patients with incompetent bicuspid aortic valve remains unclear. Competent bicuspid aortic valves appear to be durable because a large

**FIGURE 30-14** Reimplantation of the aortic valve. The commissures and the aortic annulus are sutured inside the graft and the coronary arteries reimplanted.

proportion of patients who require aortic valve replacement for aortic stenosis in their fifth, sixth, or seventh decades of life are found to have bicuspid aortic valves. Thus, aortic valve repair for incompetent bicuspid aortic valves is a reasonable surgical approach in young adults but the best type of repair remains to be determined. Incompetent bicuspid aortic valves

**FIGURE 30-15** Reimplantation of the aortic valve. Neo-aortic sinuses can be created by plicating the graft in the spaces in between the commissures at the level of the sinotubular.

are often associated with dilated aortic annulus and subcommissural plication may be inadequate to prevent future dilation and recurrent aortic insufficiency. Reimplantation of the aortic valve may provide better long-term results than simple valve repair in patients with incompetent bicuspid aortic valve and dilated aortic annulus.<sup>26</sup>

### Ascending Aortic Aneurysm with Aortic Insufficiency

We reported our experience with aortic valve repair in patients with ascending aortic aneurysm, normal or minimally dilated aortic sinuses, and moderate or severe aortic insufficiency.<sup>27</sup> There were 103 patients whose mean age was  $65 \pm 12$  years and 53% were men. The aneurysm extended into the transverse aortic arch in 60% of the patients and 20% had mega-aorta syndrome. The aortic valve repair consisted in adjusting the diameter of the sinotubular junction in all patients. In addition, repair of cusp prolapse was needed in 36 patients, and replacement of the noncoronary aortic sinus in 8. Associated procedures were: replacement of the transverse aortic arch in 62 patients, coronary artery bypass in 28, and mitral valve repair or replacement in 7. The follow-up was complete at  $5.8 \pm 2.3$  years. There were 2 operative and 30 late deaths. The survival at 10 years was  $54 \pm 7\%$ . Independent predictors of late death were transverse arch aneurysm, the use of elephant trunk technique to replace the arch and mega-aorta syndrome. Only two patients required aortic valve replacement: one for endocarditis and one for severe aortic insufficiency. The freedom from aortic valve replacement at 10 years was 98%. Only one patient developed severe and six developed moderate aortic insufficiency during the follow-up. The freedom from severe or moderate aortic insufficiency at 10 years was  $80 \pm 7\%$ . These findings suggest that aortic valve repair in these patients is an excellent alternative to valve replacement and the repair remains stable in most patients during the follow-up. Late survival was suboptimal because of the extensiveness of the vascular disease.

### Aortic Root Aneurysm

We reported our current experience with aortic valve-sparing operations for aortic root aneurysm in 371 patients.<sup>28</sup> Their mean age was  $47 \pm 15$  years, 78% were men, 35.5% had the Marfan syndrome, 12% had type A aortic dissection, and 9% had bicuspid aortic valves. Approximately one-half of the patients had moderate or severe aortic insufficiency before surgery. The technique of remodeling of the aortic root was used in 75 patients and the reimplantation of the aortic valve in 226. The follow-up was complete at  $8.9 \pm 5.2$  years. All patients had echocardiographic studies during the follow-up. There were 4 operative and 35 late deaths. Patients' survival at 18 years was 76.8% and approximately 10% lower than that of the general population of Ontario matched for age and gender. Age greater by 5-year increments, aortic dissection, preoperative aortic insufficiency, and left ventricular ejection fraction less than 40% were independent predictors of death.

Eighteen patients developed moderate or severe aortic insufficiency (12 reimplantation and 6 remodeling). Overall freedom from moderate or severe aortic insufficiency at 18 years was 78% and similar for both types of aortic valve-sparing operations. Ten patients required reoperation on the aortic valve (5 reimplantation and 5 remodeling) for aortic insufficiency in 8 and infective endocarditis in 2. One valve was re-repaired and 9 replaced; all patients survived reoperation. The freedom from reoperation on the aortic valve at 18 years was 94.8%. These findings suggested that aortic valve-sparing operations provide excellent long-term outcomes but there is evidence of gradual deterioration in aortic valve function during the first two decades of follow-up.

There are several other reports on long-term results of aortic valve-sparing operations with similar outcomes to those reported above but shorter follow-up.<sup>29-31</sup> Patients with bicuspid aortic valve seem to enjoy similar results as those with tricuspid aortic valve during the first decade of follow-up.<sup>31,32</sup>

Patients with aortic root aneurysm are usually on their second, third, and fourth decades of life and are frequently associated with inherited disorders such as Marfan syndrome, Loyes-Dietz syndrome, familial aneurysms, and others by the time they come to surgical attention. The aneurysm begins in the aortic sinuses and expands proximally and distally into the aortic annulus and sinotubular junction. Reimplantation of the aortic valve is ideal for these patients as well as those with incompetent bicuspid aortic and dilated aortic annulus because it corrects the annular dilatation and reshapes the aortic annulus by fixing it into the cylindrical Dacron graft. The drawback of the reimplantation procedure is that it places the aortic cusps into a noncompliant structure with consequent increase in mechanical stress on the cusps. Creation of neo-aortic sinuses may reduce the mechanical stresses but it remains uncertain if improves durability.

Patients with primarily ascending aortic aneurysm may have secondarily dilated aortic sinuses but the aortic annulus remains normal. The dilatation of the aortic sinuses is often asymmetrical and the noncoronary aortic sinus is the first one to dilate, followed by the right and left. These patients are older than those with primary aortic root aneurysms and are on their fifth, sixth, and seventh decades of life. Remodeling of the aortic root is ideally suited for these patients.

Aortic valve-sparing operations are an alternative to aortic root replacement with a conduit containing a mechanical or bioprosthetic aortic valve in patients with aortic root aneurysm or ascending aortic aneurysm with dilated aortic sinuses but normal or only mildly diseased aortic cusps. When correctly performed, they provide excellent long-term results and are associated with low rates of valve-related complications. However, they are technically demanding operations and only surgeons with experience in aortic root surgery should perform them. Most failures appear to be related to technical errors.<sup>32</sup> The surgeon must have a sound knowledge of anatomy and pathology of the aortic valve and be able to apply the concepts of functional anatomy to create an anatomically and functionally satisfactory reconstructed aortic root.

# Surgical Treatment of Aortic Valve Endocarditis

Gösta B. Pettersson • Syed T. Hussain

The most common heart valve affected by infective endocarditis (IE) is the aortic valve. Fortunately, significant progress has been made in our understanding and management of aortic valve IE. Clinical manifestations include fever, heart murmur, splenomegaly, embolic events, and bacteremia or fungemia. Early diagnosis is extremely important because progression invariably leads to devastating complications, including acute heart failure, cerebral embolism, and death, if the infection is not treated with antibiotics, surgery, or both. Increasingly, IE has become a “surgical disease,” particularly for aortic valve IE, and during the last decade, more than half of all patients have been operated on during the active phase of the disease (early surgery).<sup>1</sup>

## EPIDEMIOLOGY

Among patients with aortic valve IE, congenitally bicuspid aortic valve is the most common predisposing lesion.<sup>2</sup> Other congenital abnormalities of the aortic valve predisposing to infection are degenerative calcific aortic stenosis, aortic regurgitation due to any cause, and rheumatic aortic valve disease. Occasionally, highly virulent microorganisms infect normal aortic valves. Patients with prosthetic heart valves run a constant higher risk of developing IE.

It is difficult to determine the incidence and prevalence of native aortic valve IE in the general population because the disease is continuously changing.<sup>3,4</sup> The annual incidence is estimated to range from 1.7 to 7.0 episodes per 100,000 person-years in North America,<sup>5-7</sup> and patients with prosthetic aortic valves are reported to have an incidence of 0.2 to 1.4 episodes per 100 patient-years.<sup>8-10</sup> Approximately 1.4% of patients undergoing aortic valve replacement develop prosthetic valve IE during the first postoperative year.<sup>11</sup>

The incidence of nosocomial IE is increasing because more patients are undergoing invasive procedures. IE in hemodialysis patients is fortunately relatively infrequent, but when it happens, it is associated with high mortality.<sup>12</sup> Dental procedures, extractions in particular, have been shown to produce bacteremia. However, daily dental flossing can also produce bacteremia in periodontally healthy individuals at a rate comparable

with that caused by dental procedures for which antibiotic prophylaxis is usually given to patients with valve disease to prevent endocarditis, suggesting that prophylaxis may be futile.<sup>13</sup> Endoscopic procedures may also produce bacteremia. Intravenous drug users using nonsterile syringes and needles most often infect their structurally normal tricuspid valves (see “Prophylaxis of Infective Endocarditis” later in this chapter).

## PATHOGENESIS AND PATHOLOGY

The key to understanding IE is appreciating the pathology progression.<sup>6,14,15</sup> Circulating organisms adhere and attach to areas with endocardial (valve) injury; such damaged areas often have deposition of platelets, fibrin, or clots, facilitating attachment and growth of the organisms. In 1928, Grant and colleagues<sup>16</sup> theorized that platelet-fibrin thrombi on the heart valve serve as a nidus for bacteria to adhere, and in 1963, Angrist and Oka<sup>17</sup> introduced the term *nonbacterial thrombotic endocarditis* to describe such sterile vegetations, providing experimental evidence supporting their role in the pathogenesis of endocarditis.<sup>18</sup> As the organism multiplies, it produces matrix material, and this, together with leukocytes and thrombotic material, accumulates in the area and forms verrucous vegetations. Formation of vegetations means formation of a biofilm, allowing the organisms protection from the host’s defenses and antibiotics.

The infecting organisms produce and release virulence factors and enzymes that promote organism reproduction and survival and kill and disintegrate host tissue, primarily valve cusps and leaflets. The enzymes produced are organism specific with regard to their tissue specificity and efficiency. When tissue disintegration involves the valve annulus, the infection invades extravascular areas (invasive disease). Invasive disease develops in stages: cellulitis, abscess, abscess cavities, and finally, pseudoaneurysm formation. Invasive disease around the aortic root is generally deeper and more extensive than for any other valve because it is constantly highly pressurized. Internal fistulas, perforations, and heart block constitute specific consequences of invasion.<sup>14</sup> IE of the aortic valve not only causes destruction of the aortic cusps, paravalvular

abscesses, and cardiac fistulas, but is also a source of systemic embolization of vegetation material.<sup>19</sup> Strokes and cerebral infarctions caused by embolism of vegetation material are common. An ischemic infarct may convert into a hemorrhagic infarct. However, when an infarct is hemorrhagic, there is a higher probability of a mycotic aneurysm.<sup>20</sup> Rupture of a mycotic aneurysm may cause devastating cerebral bleeding. Mycotic aneurysms, infarcts, and abscesses in other organs, such as the spleen, liver, kidneys, and limbs, are also common.<sup>18</sup> Aortic valve IE with a large vegetation that prolapses into the left ventricle and comes into contact with the anterior mitral valve leaflet causes secondary involvement of this valve (kissing lesions).<sup>14,21</sup> Such kissing lesions are common and manifest themselves as anterior valve leaflet pseudoaneurysms or perforations (windsock lesions).<sup>14</sup>

Infection of a bioprosthetic valve, porcine or pericardial, may involve the cusps, the sewing ring, or both (Fig. 31-1). Infection of aortic valve allografts and pulmonary autografts resembles that of the native aortic valves: It may begin on the aortic cusps and destroy them, causing aortic regurgitation, or it may start at old suture lines and extend into surrounding structures (Fig. 31-2). Infection of a mechanical heart valve is usually located along the sewing ring (Fig. 31-3). Endocarditis after replacement with a prosthesis frequently causes dehiscence of the prosthesis from the annulus, with consequent development of ventricular-aortic separation.

Heart block with aortic valve IE is caused by destruction of the atrioventricular node and the bundle of His. This happens when the infection invades the right atrium and the triangle of Koch (Fig. 31-2).

## MICROBIOLOGY

The microbiology of aortic IE depends on whether the valve is native or prosthetic, and whether the infection is hospital or community acquired. *Staphylococcus aureus* and *Streptococcus*

*viridans* are the most common organisms responsible for native aortic valve endocarditis.<sup>6,22</sup> *S. aureus* is extremely virulent. *S. viridans* and various other streptococci are not as virulent and cause an infection that often follows a more protracted course. Coagulase-negative staphylococci are also less virulent, but have emerged as an important cause of native valve IE in both the community and health care settings.<sup>6,23</sup>

IE caused by Gram-negative bacteria is less common, but these organisms are often resistant to many antibiotics and more difficult to treat and therefore more likely to cause complications. *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella* (the HACEK group) are Gram-negative bacilli grouped together because of their characteristic fastidiousness requiring a prolonged incubation period before growth, although bacteriologic diagnostic methods have improved. Fungal IE is rare but extremely serious and very difficult to eradicate and cure. *Candida albicans* and *Aspergillus fumigatus* are the usual agents. Fungal IE is associated with large, sometimes huge, vegetations (Fig. 31-4).

The microbiology of prosthetic aortic valve IE is somewhat different from that of the native valve.<sup>24,25</sup> Prosthetic valve IE is classified as *early* when it occurs within the first year after surgery and *late* when it occurs after 1 year.<sup>6</sup> Early prosthetic valve IE is likely caused by contamination of the valve by perioperative bacteremia or contamination of the operative field at the time of implantation.<sup>6,11,26,27</sup> This may be particularly true when the infection is caused by coagulase-negative staphylococci and the HACEK group of bacteria. *Staphylococcus epidermidis*, *S. aureus*, and *Enterococcus faecalis* are more common microorganisms responsible for early prosthetic valve IE.<sup>11,27</sup> The sources of late prosthetic valve IE are more difficult to determine. Although streptococci and staphylococci are commonly encountered in these patients, a myriad of microorganisms can cause late prosthetic valve IE.<sup>27</sup> Nosocomial infections are often caused by *S. aureus* or other staphylococci.<sup>6</sup>

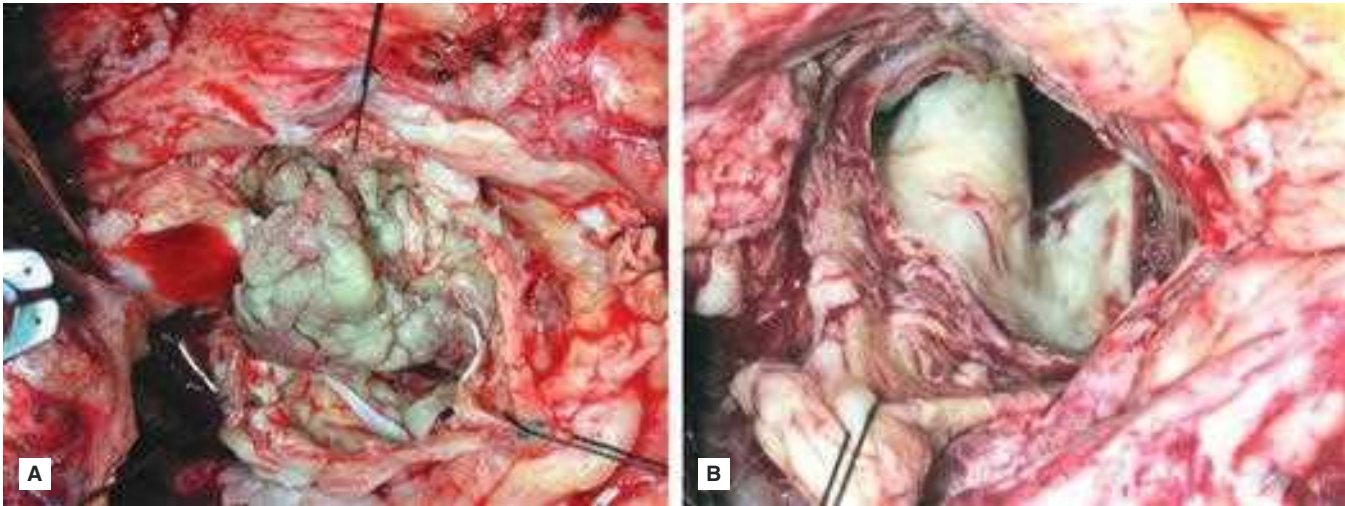

**FIGURE 31-1** Native and prosthetic valve endocarditis. (A) Active aortic native valve endocarditis: Excised aortic valve cusps illustrating vegetations and disintegration, precluding valve repair. (B) Large vegetations attached on an excised aortic valve bioprosthesis in a patient with preoperative embolic stroke. **FIGURE 31-2** Allograft endocarditis with heart block. (A) Endocarditis with sepsis and heart block in patient with a history of aortic allograft root replacement. Allograft cusps are not affected, but vegetations are present on proximal aortic suture line (arrow). (B) Same patient: Cauliflower vegetation (arrow) next to atrioventricular node marking penetration into right atrium. (C) Same cauliflower vegetation (arrow) next to atrioventricular node after opening aortic and right atrial (RA) walls down to vegetation. (D) Complete removal of allograft and debridement discloses extent of peri-allograft infection, which extends from right coronary artery (RCA) counterclockwise to membranous septum and atrioventricular node (arrow). Root is ready for reconstruction. CS, Coronary sinus; LCA, left coronary artery; LVOT, left ventricular outflow tract; TV, tricuspid valve. (Reproduced with permission from Pettersson GB, Hussain ST, Shrestha NK, et al: Infective endocarditis: an atlas of disease progression for describing, staging, coding, and understanding the pathology, *J Thorac Cardiovasc Surg.* 2014 Apr;147(4):1142-1149.e2.)

**FIGURE 31-3** Mechanical prosthesis endocarditis. (A) Infected mechanical aortic valve prosthesis showing circumferential involvement of sewing ring, with some vegetations attaching on both sides of prosthesis. (B) After removal of prosthesis, the vegetations were present both above and beneath the prosthesis, and circumferential invasion is obvious. (C) Although the aortic annulus is disintegrated with atrioventricular discontinuity, the left ventricular outflow tract (LVOT) appears well preserved after debridement. LCA, Left coronary artery; RCA, right coronary artery. (Reproduced with permission from Pettersson GB, Hussain ST, Shrestha NK, et al: Infective endocarditis: an atlas of disease progression for describing, staging, coding, and understanding the pathology, *J Thorac Cardiovasc Surg.* 2014 Apr;147(4):1142-1149.e2.)

**FIGURE 31-4** Fungal endocarditis. (A) Fungal endocarditis with large vegetations on aortic valve. (B) After complete debridement, no destruction or invasion is observed. (Reproduced with permission from Pettersson GB, Hussain ST, Shrestha NK, et al: Infective endocarditis: an atlas of disease progression for describing, staging, coding, and understanding the pathology, *J Thorac Cardiovasc Surg.* 2014 Apr;147(4):1142-1149.e2.)

In a small proportion of cases of aortic valve IE, no microorganism can be cultured from either the blood or surgical specimens.<sup>6</sup> This is called “culture-negative endocarditis,” but in these cases it is important to rule out fastidious microorganisms, and every effort should be made to identify them. Valve sequencing (universal bacterial, mycobacterial, or fungal polymerase chain reaction [PCR]) is successful in identifying the causative organism in most cases.<sup>28</sup>

## CLINICAL PRESENTATION AND DIAGNOSIS

It is helpful to classify IE as acute and subacute, because there are major differences between these two clinical presentations. Originally, before the availability of antibiotics, these concepts of acute, subacute, and chronic IE also described how long it would take patients to die. Subacute and chronic IE are caused by less virulent microorganisms, such as *S. viridans*, and the clinical course is protracted; antibiotics alone cure most cases if treatment is started before important destruction of the cusps or invasion have occurred. On the other hand, acute IE is frequently caused by a virulent and aggressive organism such as *S. aureus*. The clinical course is acute, and destruction and invasion occur fast, with antibiotics alone often failing to cure the infection.

The onset of subacute IE is usually subtle, with low-grade fever and malaise. Patients think they have the “flu,” are often treated with oral antibiotics, and symptoms improve. However, in most cases the symptoms recur a few days after the antibiotics are stopped. In the majority of cases, no extracardiac source of bacteremia is identified. An aortic valve murmur is present in nearly all patients because they have preexisting aortic valve disease. Splenomegaly is common. Clubbing of the fingers and toes may develop in long-standing cases.

Skin and mucous membrane signs occur late in this form of IE. Petechiae appear on any part of the body. Small areas of hemorrhage may be seen in the ocular fundi. Hemorrhages in the nail beds usually have a linear distribution near the distal end, hence the name splinter hemorrhages. Osler nodes are acute, tender, barely palpable nodular lesions in the pulp of the fingers and toes, and bacteria have been cultured from these lesions. Embolization of large vegetation fragments may cause dramatic clinical events such as stroke, acute myocardial infarction, or splenic or hepatic infarcts. Any other organ may also be a target for an embolic event. Destruction of the aortic cusps causes aortic regurgitation and heart failure. The hematologic picture is not distinctive in subacute endocarditis. The leukocyte count is moderately elevated. Anemia without reticulocytosis develops after a few weeks in patients who are untreated. Blood cultures frequently identify the offending microorganism.

Acute IE is defined by a fulminant clinical course. A noncardiac source of bacteremia may often be identified. This form of IE can present with all the symptoms and signs described under subacute IE, but they are more severe and progress rapidly, and patients are often sicker and show signs of sepsis. Early metastatic infections are common. Two physical signs are seen only in acute IE: Janeway lesions (painless red-blue hemorrhagic lesions a few millimeters in diameter found on the palms of the hands and soles of the feet) and Roth spots (an oval pale area surrounded by hemorrhage near the optic disc). In patients with no preexisting aortic valve disease, the presentation is acute. Early extra-aortic infection and cardiac decompensation caused by severe aortic regurgitation is common. Invasion with paravalvular abscesses is also more common, and with invasion behind the central fibrous body, toward the floor of the right atrium and triangle of Koch (Fig. 31-2), the electrocardiogram may show an increased PR interval that within hours or days progresses to

**TABLE 31-1: Modified Duke Criteria for the Diagnosis of Infective Endocarditis**
**Major criteria**

- Blood culture positive for infective endocarditis
  - Typical microorganisms consistent with infective endocarditis from two separate blood cultures: *Streptococcus viridans*, *S. bovis*, HACEK group, *S. aureus*, or community-acquired enterococci, in the absence of a primary focus, or Microorganisms consistent with infective endocarditis from a persistently positive blood culture, defined as follows:
    - At least two positive cultures of blood drawn >12 hours apart, or
    - All of three or a majority of >four separate cultures of blood (with the first and last samples drawn at least 1 hour apart)
    - Single positive blood culture for *Coxiella burnetii* or phase I IgG antibody titer to *C. burnetii* > 1:800
- Evidence of endocardial involvement:
  - Echocardiogram positive for infective endocarditis: TEE recommended in patients with prosthetic valves, rated at least as “possible endocarditis” by clinical criteria, or complicated endocarditis, such as endocarditis with paravalvular abscess; TTE as the first test in other patients as follows:
    - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation
    - Abscess
    - New partial dehiscence of prosthetic valve
    - New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

**Minor criteria**

- Predisposition, predisposing heart condition, or injection drug use
- Fever
- Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
- Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above, or serologic evidence of active infection with an organism consistent with infective endocarditis
- Echocardiographic minor criteria eliminated

Definite endocarditis = two major criteria, or one major + three minor criteria, or five minor criteria

Possible endocarditis = one major + one minor, or three minor criteria

HACEK group = Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, and Kingella; IE = infective endocarditis; TEE = transesophageal echocardiography;

TTE = transthoracic echocardiography

Reproduced with permission from Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis, *Clin Infect Dis*. 2000 Apr;30(4):633-638.

complete heart block. The blood picture is one of acute sepsis. Blood cultures often isolate the infecting agent.

Prosthetic valve IE may present as acute or subacute endocarditis.

Doppler echocardiography is ubiquitous and of fundamental importance in the diagnosis, management, and follow-up of patients with IE.<sup>6,29</sup> Transesophageal echocardiography (TEE) is more sensitive than transthoracic echocardiography (TTE), and multiplane is better than monoplane for diagnosing IE. The sensitivity of TTE ranges from 40 to 63% and that of TEE from 90 to 100%.<sup>6</sup> Echocardiography can detect vegetations as small as 1 or 2 mm, but it is more reliable in native than prosthetic valve IE. It is more useful for tissue than for mechanical valves because of the acoustic shadowing of mechanical heart valves. Echocardiography is also highly sensitive for detecting paravalvular abscesses and cardiac fistulas, but may still miss some.

Clinical investigators from Duke University proposed certain criteria for confirming or rejecting the diagnosis of IE.<sup>29</sup> The Duke criteria have been validated, and their limitations discussed by other investigators.<sup>30,31</sup> A modified version of the Duke criteria has been proposed,<sup>31</sup> and it is shown in Table 31-1.

## TREATMENT

Appropriate antibiotic treatment is the most important aspect of the management of patients with IE.<sup>6,22,27</sup> Timing is important because destruction is progressive, and disintegrated cusps do not heal or regenerate. Once invasive, the infection is less likely to be cured by antibiotics alone.

Antibiotic therapy should be started soon after obtaining at least two blood cultures within a 3- to 6-hour interval taken from different peripheral sites (the modified Duke criteria have as a major criterion “At least two positive blood cultures of blood samples drawn >12 hours apart; or all of three or a majority of  $\geq 4$  separate cultures of blood [with first and last samples drawn at least 1 hour apart]”). The initial choice of antibiotics is based on clinical circumstances and the suspected source of infection. Patients who had recent dental work should receive antibiotics to counteract bacteria from the oral cavity; those who had recent urinary or colonic procedures should be treated with antibiotics that are effective against Gram-negative bacteria. Intravenous drug users are usually infected with *S. aureus* or coagulase-negative staphylococci. Once the microorganism is identified by blood cultures and its sensitivity to specific antibiotics is known, antibiotic therapy is adjusted accordingly.

Higher doses and a combination of two or three antibiotics that potentiate one another are often needed in the treatment of IE. Intravenous antibiotic therapy is continued for 6 weeks. It is difficult to eradicate infection caused by virulent microorganisms with antibiotics alone because these organisms have several mechanisms by which they avoid the patient's defense systems and resist the antibiotics, with the ability to form biofilm perhaps the most important one. Destruction of the aortic valve cusps happens rapidly and causes aortic regurgitation and congestive heart failure. These infections are usually caused by *S. aureus*, *Pseudomonas aeruginosa*, *Serratia marcescens*, or fungi.

Repeat blood cultures are performed 48 hours after starting to monitor the efficacy of antibiotic therapy. The patient must be watched closely for signs of congestive heart failure, coronary and systemic embolization, and unresponsive infection. Daily electrocardiograms and frequent echocardiograms are performed during the first 2 weeks of treatment. With any evidence of increasing aortic regurgitation, enlarging vegetations, recurrent embolism, paravalvular abscess, heart block, or poor response of clinical symptoms to antibiotics, surgery should be immediately considered. It is better to operate on patients before they develop complications, such as intractable heart failure, cardiogenic or septic shock, heart block, extensive aortic root abscesses, or stroke.

Patients with mobile vegetations larger than 10 mm are more likely to suffer serious complications, including stroke, so early surgery may be justified.<sup>6,7,32-34</sup> Anticoagulation is neither indicated nor effective in preventing embolization of vegetations in native or biologic valve IE; rather, it is associated with an increased risk of neurologic complications.<sup>6</sup>

Current guidelines for indications and timing of surgery in native and prosthetic valve IE are presented in Table 31-2. Surgical treatment should be considered in patients with signs of congestive heart failure, acute valve dysfunction, invasion with paravalvular abscess or cardiac fistulas, recurrent systemic embolization, and persistent sepsis despite adequate antibiotic therapy for more than 4 to 5 days. Approximately half of patients with IE develop severe complications that sooner or later will require an operation. In general, our recommendation is that once a surgical indication is present, surgery should not be delayed. Knowing the sensitivity of the causative organism preoperatively is important to ensure appropriate antibiotic coverage at the time of surgery. Once the patient is covered with an antibiotic to which the organism is susceptible, the penalty for operating during the active infection phase is minimized.

Preoperatively, coronary angiography is recommended in patients age 40 years or older, particularly those with at least one cardiovascular risk factor or a history of coronary artery disease or previous revascularization.<sup>6</sup> Exceptions to this recommendation can happen when there are large aortic vegetations that could be dislodged during catheterization, or when emergency surgery is necessary and angiography is not necessary for planning the operation.<sup>6,32</sup> For patients with renal dysfunction, clinical judgment should be exercised. High-resolution computed tomography (CT) imaging to diagnose

coronary artery disease may be useful and acceptable in younger patients, but contrast renal toxicity remains an issue.

All patients scheduled to undergo surgery for IE should have a neurologic evaluation and a CT scan or magnetic resonance imaging of the brain performed preoperatively within a day of the operation to visualize any strokes and to determine if an infarct is ischemic or hemorrhagic. Ischemic strokes are far more common than hemorrhagic, but both are associated with increased mortality and morbidity. Hemorrhagic lesions are associated with a higher probability of mycotic aneurysms, which often require treatment before valve surgery. An angiography is needed to exclude a mycotic aneurysm and should be performed if there is bleeding and a high suspicion. Delay of the heart surgery is usually advised in patients with more serious neurologic complications; we do not operate on unconscious patients or those unable to follow simple commands until they demonstrate neurologic improvement. Patients with ischemic stroke should ideally have surgery delayed by 1 to 2 weeks and those with hemorrhagic stroke by 3 to 4 weeks.<sup>6,7,32</sup> The risk of delaying surgery should always be weighed against patients' hemodynamic condition.<sup>33</sup>

## SURGICAL TREATMENT

We routinely perform surgery for aortic valve IE through a median sternotomy; intraoperative TEE is mandatory. Patients who need emergency or urgent surgery are often very sick and may be in congestive heart failure. For this reason, and because they often require complex and long surgical procedures, myocardial protection is of utmost importance. We achieve this by using initial induction with antegrade and retrograde blood cardioplegia, and repeat retrograde cardioplegia every 15 to 20 minutes. The right atrium is routinely opened to cannulate the coronary sinus directly through a purse-string suture around its orifice. We avoid unnecessary cardiac manipulation before arresting the heart.

Another important aspect of surgery for IE is minimizing residual contamination of the surgical field, instruments, drapes, and gloves with vegetations and pus. Instruments used to debride contaminated areas of the heart are discarded before reconstruction begins. In addition, local drapes, suction equipment, and surgical gloves are changed. The objective is to leave as few organisms as possible in the operative field.

The aortic valve is explored through a transverse aortotomy 1 cm or more above the right coronary artery. When the infection is limited to the cusps of the native aortic valve or a prosthetic valve, complete removal of the valve and implantation of a biologic or mechanical valve prosthesis usually resolves the problem. There is no evidence that a bioprosthesis is better than a mechanical valve in patients with active IE.<sup>6,10,32,35</sup> The choice of prosthesis depends on age of the patient, comorbidities, life expectancy, and compliance with anticoagulation. For native valve infection with limited localized infection, an attempt can be made to repair and preserve the valve using autologous pericardium. History of a hemorrhagic stroke is a reason to avoid a mechanical valve and its associated need for anticoagulation.

 **TABLE 31-2: Indications and Timing of Surgery in Native and Prosthetic Valve Infective Endocarditis**

Indications	Timing*	Class	Level of evidence
<b>Heart failure</b>			
Aortic or mitral IE or PVE with severe acute regurgitation or valve obstruction of fistula causing refractory pulmonary edema or cardiogenic shock	Emergency	I	B
Aortic or mitral IE with severe acute regurgitation or valve obstruction and persisting heart failure or echocardiographic signs of poor hemodynamic tolerance early mitral closure or pulmonary hypertension)	Urgent	I	B
Aortic or mitral IE or severe prosthetic dehiscence with severe regurgitation and no heart failure	Elective	IIa	B
Right heart failure secondary to severe tricuspid regurgitation with poor response to diuretic therapy	Urgent/elective	IIa	C
<b>Uncontrolled infection</b>			
Locally uncontrolled infection (abscess, false aneurysm, fistula, enlarging vegetation)	Urgent	I	B
Persisting fever and positive blood cultures > 7-10 days not related to an extracardiac cause	Urgent	I	B
Infection caused by fungi or multiresistant organisms	Urgent/elective	I	B
PVE caused by staphylococci or Gram negative bacteria (most cases of early PVE)	Urgent/elective	IIa	C
<b>Prevention of embolism</b>			
Aortic or mitral IE or PVE with large vegetations (>10 mm) following one or more embolic episodes despite appropriate antibiotic therapy	Urgent	I	B
Aortic or mitral IE or PVE with large vegetations (>10 mm) and other predictors of complicated course (heart failure, persistent infection, abscess)	Urgent	I	C
Aortic or mitral or PVE with isolated very large vegetations (>15 mm†)	Urgent	Ib	C
Persistent tricuspid valve vegetations > 20 mm after recurrent pulmonary emboli	Urgent/elective	IIa	C

Class I: Evidence and/or general agreement that a given treatment or procedure is beneficial, useful, effective.

Class II: Conflicting evidence and/or divergence of opinion about the usefulness/efficacy of the given treatment or procedure.

Class IIa: Weight of evidence/opinion is in favor of usefulness efficacy.

Class IIb: Usefulness/efficacy is less well established by evidence/opinion.

Class III: Evidence of general agreement that the given treatment or procedure is not useful/effective, and in some cases may be harmful.

Level of evidence A: Data derived from multiple randomized clinical trials or meta-analyses.

Level of evidence B: Data derived from a single randomized clinical trial or large nonrandomized studies.

Level of evidence C: Consensus of opinion of the experts or small studies, retrospective studies, registries.

\*Emergency surgery: Surgery performed within 24 hours, urgent surgery: within a few days, elective surgery, after at least 1 or 2 weeks of antibiotic treatment.

†Surgery may be preferred if procedure preserving the native valve is feasible.

IE, infective endocarditis; PVE, prosthetic valve endocarditis.

Reproduced with permission from Thuny F, Habib G: When should we operate on patients with acute infective endocarditis? *Heart*. 2010 Jun;96(11):892-897.

If the infection is invasive beyond the cusps or leaflets, radical resection of all infected tissues and foreign material (prosthesis, pledgets, and sutures) is necessary, followed by reconstruction (Fig. 31-5).<sup>14,25,27,36,37</sup> The pathology and anatomy of the left ventricular outflow tract (LVOT) must be well understood for complete surgical debridement and reconstruction, particularly in patients with prosthetic valve and advanced invasive aortic root IE. To reconstruct the aortic root, an aortic allograft is usually our preferred choice. Use of an allograft is no substitute for radical removal of infected tissue, as not even allografts are immune to reinfection.<sup>37</sup> After

extensive debridement, the LVOT is almost always preserved to allow direct anastomosis to the allograft. The intervalvular fibrosa corresponding to the base of the anterior mitral valve leaflet and the two trigones on either side are the main landmarks to indicate the level of the proximal suture line. The LVOT is sized with Hegar dilators, and an allograft with an internal diameter 2 to 3 mm less than the diameter of the annulus is chosen. The coronary buttons should be well mobilized. No felt is used to support the suture lines. When patching is required, autologous pericardium is our preference, but need for patching should be uncommon! Aortic

**FIGURE 31-5** Prosthetic valve endocarditis with sepsis and heart block. (A) Infected mechanical prosthesis with vegetations on sewing ring (arrow). (B) Same patient with perforation visible in right atrium (RA; arrow). (C) After debridement, destruction in location of atrioventricular node is seen. This infection has worked its way around the aorta counterclockwise over an extended period, displaying a pseudoaneurysm stage anteriorly and an active cellulitis stage posteriorly and into right atrium. Left ventricular outflow tract (LVOT) is intact and ready for reconstruction. (D) After complete debridement of all infected tissue, RA is reconstructed with autologous pericardium (arrow). (E) Aortic allograft is sutured to LVOT with running monofilament suture. (F) Allograft is tied down and well seated, allowing debrided infected areas to communicate and drain to pericardium. CFB, central fibrous body; CS, coronary sinus; LCA, left coronary artery; RCA, right coronary artery; TV, tricuspid valve. (Reproduced with permission from Pettersson GB, Hussain ST, Shrestha NK, et al: Infective endocarditis: an atlas of disease progression for describing, staging, coding, and understanding the pathology. *J Thorac Cardiovasc Surg.* 2014 Apr;147(4):1142-1149.e2.)

root destruction extending into the intervalvular fibrosa or a prosthetic mitral valve is a difficult and not uncommon issue. An alternative technique some prefer when the aortic annulus is involved is patching the defect after resection of the necrotic or inflamed area, before a prosthetic valve is implanted. Use of fresh autologous pericardium to patch small defects (1 or 2 cm wide) and glutaraldehyde-fixed bovine pericardium for larger defects has been suggested.<sup>37,38</sup> Some surgeons also use polyester fabric to reconstruct the aortic root,<sup>38</sup> and a pulmonary autograft has been used as an alternative to an allograft in young patients.<sup>39,40</sup> Use of freestyle root replacement for complex destructive aortic valve IE has been reported as well.<sup>41,42</sup> Specimens are divided and sent for microbiologic and pathologic examination and also considered for PCR.

Postoperative complications are common after surgery for active IE. Septic patients may be hypotensive and may have severe coagulopathy and bleed excessively after prolonged cardiopulmonary bypass. When extensive debridement and allograft root reconstruction have been done, important surgical bleeders are controlled before protamine administration. Following protamine, the field is packed and suction is avoided, allowing adequate time (usually 20-30 minutes) for clotting to occur before additional surgical hemostasis is attempted. Antifibrinolytic agents such as aminocaproic acid

may be used in reoperations in addition to platelets, cryoprecipitate, and fresh-frozen plasma in patients with coagulopathy. Radical debridement of invasive disease with periaortic cellulitis and necrotic tissue and abscess may in itself cause heart block, for which a permanent pacemaker will be needed postoperatively. Placement of epicardial leads and implantation of the pacemaker during the operation may be considered. Multisystem organ failure may develop postoperatively. However, rapid reversal of renal dysfunction caused by immune complex glomerulonephritis has been observed. Neurologic deterioration may occur in patients with preexisting cerebral emboli.<sup>33</sup> Pulmonary, splenic, hepatic, and other metastatic abscesses seldom, but occasionally, require surgical treatment. Large metastatic abscesses may have to be drained, and in the case of a splenic abscess, splenectomy should be performed to avoid rupture.<sup>6,38</sup>

## CLINICAL RESULTS

The prognosis of aortic valve IE depends largely on when and in what stage the disease is diagnosed, the offending microorganism, and how promptly it is treated.<sup>7,22,43-46</sup> The surgical results depend on many variables, including patient characteristics, timing of surgery,<sup>7,44-46</sup> whether an emergency

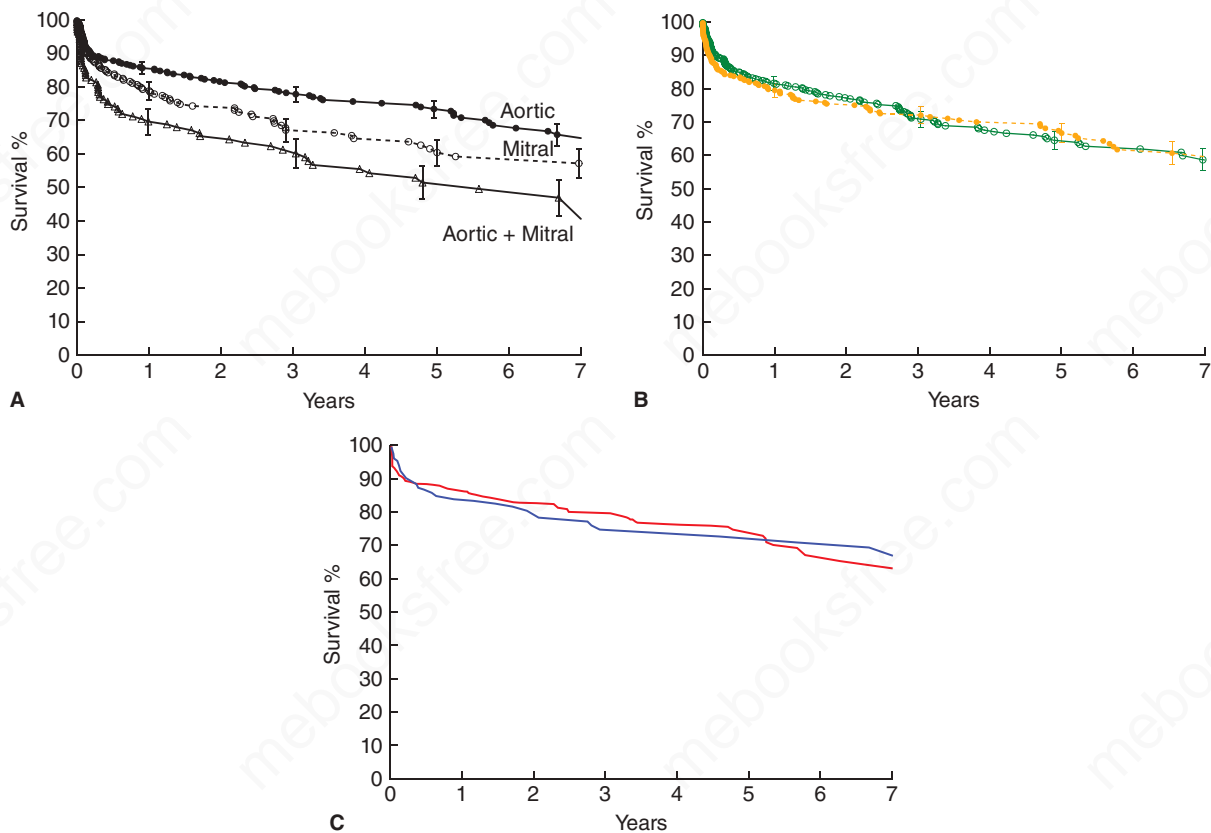

procedure is required,<sup>47</sup> virulence of the organism,<sup>43,46,48</sup> whether the affected valve is native or prosthetic, and whether the infection has extended into and beyond the valve annulus. Until recently, patients with prosthetic aortic valve IE had a worse prognosis than patients with native aortic valve IE.<sup>22,27,48</sup> Nosocomial infections are associated with higher mortality than community-acquired infections.<sup>1</sup> The results of surgery for IE have improved significantly over time, but in-hospital mortality remains high. Variations in outcomes probably reflect variations in institution and surgeon experience in treating IE.

Operative mortality for patients with infection limited to the cusps of the aortic valve is largely dependent on the patient's clinical presentation at the time of surgery, age, and comorbidities. Most reports indicate that operative mortality for patients with noninvasive disease is under 10%.<sup>24,27,48</sup> Reported operative mortality is higher for prosthetic valve IE, ranging from 20 to 30%.<sup>22,25,49</sup> Similarly, surgery for aortic root abscess is associated with higher operative mortality.<sup>27,49</sup>

To provide a context for the surgery, the investigators of the International Collaboration on Endocarditis-Prospective Cohort Study (ICE-PCS), an international and multicenter

database on patients with confirmed IE maintained at the Duke Clinical Research Institute, recently reported on the clinical presentation, etiology, and outcome of IE with a definite diagnosis according to Duke criteria.<sup>22</sup> The ICE-PCS report included a cohort of 2781 patients whose median age was 57.9 years. The IE was native in 72%, prosthetic in 21%, and pacemaker/ICD related in 7%. Approximately one-fourth of the patients had recent health care exposure. The mitral valve was infected in 41.1% and the aortic valve in 37.6%. *S. aureus* was the offending microorganism in 31.2% of all cases. Stroke was diagnosed in 16.9% and other emboli in 22.6%, congestive heart failure developed 32.2%, and paravalvular abscess occurred in 14%. Surgical treatment was common for the entire cohort (48.2%), and overall in-hospital mortality was 17.7%. Prosthetic valve IE, increasing age, pulmonary edema, *S. aureus* infection, coagulase-negative staphylococcal infection, mitral valve vegetation, and paravalvular abscess were associated with increased risk of in-hospital mortality.

In 2014, we published our current results of surgery for IE in 395 consecutive patients with isolated aortic valve active IE (Fig. 31-6).<sup>24</sup> One hundred sixty-three patients had native

**FIGURE 31-6** Survival after surgery for aortic valve endocarditis. (A) Survival after surgery for left-sided infective endocarditis (IE), stratified by the involved valve. Each symbol represents a death, and vertical bars represent the 68% confidence limits, equivalent to  $\pm 1$  standard error in each figure. Filled circles indicate aortic valve IE alone; open circles, mitral valve IE alone; and triangles, aortic and mitral valve IE. Survival was significantly lower in the mitral and combined groups than in the isolated aortic patients ( $p < .0001$ ). (B) Survival after surgery for native (solid green lines) or prosthetic (dashed orange lines) aortic valve IE. (C) Survival after surgery for invasive (solid red lines) versus noninvasive (solid blue lines) aortic valve IE. (Reproduced with permission from Hussain ST, Shrestha NK, Gordon SM, et al: Residual patient, anatomic, and surgical obstacles in treating active left-sided infective endocarditis, *J Thorac Cardiovasc Surg*. 2014 Sep;148(3):981-988.e4.)

valve IE and 232 prosthetic valve IE. Eight-five percent of the prosthetic valve and 44% of the native valve IE patients had invasive disease, and overall operative mortality was 7%. Survival was similar after surgery for prosthetic and native valve IE. There was also no difference in survival between those with invasive versus noninvasive IE. These excellent results reflect our improved ability to master the surgery for invasive aortic valve IE, as we are able to debride the aortic root extensively without fear and reconstruct it with an allograft.

## PROPHYLAXIS OF INFECTIVE ENDOCARDITIS

The American Heart Association guidelines for prophylaxis of IE were updated in 2008.<sup>50</sup> Major changes in the updated recommendations include the following: (1) The committee concluded that only an extremely small number of cases of IE might be prevented by antibiotic prophylaxis for dental procedures, even if such prophylactic therapy was 100% effective. (2) IE prophylaxis for dental procedures is reasonable only for patients with underlying cardiac conditions associated with the highest risk of adverse outcome from IE. (3) For patients with these underlying cardiac conditions, prophylaxis is reasonable for all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. (4) Prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of IE. (5) Administration of antibiotics solely to prevent IE is not recommended for patients who undergo a genitourinary or gastrointestinal tract procedure. These changes are intended to define more clearly when IE prophylaxis is or is not recommended and to provide more uniform and consistent global recommendations.

These new recommendations represent a dramatic shift with regard to which patients benefit and who should receive antibiotic prophylaxis for prevention of IE. However, they are “guidelines,” and physicians caring for patients with organic heart valve disease should advise them according to the perceived risk of IE and potential benefit of antibiotic prophylaxis. With regard to guidelines 2 and 3 above, our recommendation is in support of prophylaxis, and we emphasize to our patients that dental extractions absolutely require prophylaxis. We continue to require “dental clearance” preoperatively for patients scheduled to undergo valve surgery.

# Minimally Invasive Aortic Valve Surgery

Prem S. Shekar • Lawrence S. Lee • Lawrence H. Cohn

Aortic valve surgery started with the implantation of the Hufnagel valve in the descending thoracic aorta in 1956. Its evolution over time has culminated with the establishment of percutaneous catheter-based aortic valve replacement techniques. As a new paradigm in aortic valve replacement is ushered, there will be new challenges for the cardiac surgeons to not only maintain the efficacy and outcomes of conventional valve replacement but to provide it in a less invasive approach. Modern techniques will be measured against conventional procedures, especially in the older patients with multiple comorbidities. Minimally invasive aortic valve surgery holds promise as an effective operation with reduced pain, improved respiratory function, early recovery, and an overall reduction in trauma.

## ESSENTIALS OF MINIMAL ACCESS AORTIC VALVE SURGERY

Reoperative minimal access aortic valve surgery is discussed in detail at the end of this chapter. We will first outline the known benefits and salient principles of and the essential ingredients for the conduct of primary minimal access aortic valve surgery. There are many potential benefits of minimal access aortic valve surgery:

1. It provides a cosmetically superior incision
2. There is reduced postoperative pain
3. There is faster postoperative recovery
4. There is improved postoperative respiratory function from preservation of a part of the sternum and the integrity of the costal margin
5. It can be performed with the same degree of ease and speed as a conventional operation with no difference in mortality
6. It provides access to the relevant parts of the heart and reduces dissection of other areas
7. It greatly facilitates a reoperation at a later date as the lower part of the pericardium remains closed.

There are some salient inviolate principles of minimal access aortic valve surgery:

1. Ability to safely apply a stable aortic cross-clamp
2. Ability to visualize the aortic valve completely and perform a successful replacement with the standard techniques
3. Ability to achieve the same degree of myocardial protection as through a midline sternotomy approach
4. Ability to deal with issues of the aortic root, ascending and arch of the aorta with relative ease and without the need for conversion
5. Ability to quickly convert to a standard midline sternotomy if compromising situations arise

The safety and reproducibility of minimal access aortic valve surgery depend on:

1. Availability of experienced cardiac anesthesiologists
2. Availability of transesophageal echocardiography (TEE) in every case and an experienced echocardiographer to interpret findings
3. Ability to place pulmonary artery catheters with pacing capabilities and transjugular coronary sinus catheters, if and when necessary
4. Ability to place percutaneous arterial and venous cardiopulmonary bypass canulae
5. Ability to use vacuum-assisted venous drainage on cardiopulmonary bypass
6. Availability of minimal access retractors and other relevant instruments that facilitate this operation
7. Ability to remotely monitor myocardial protection and distention by TEE
8. Availability of surgeons experienced with conventional aortic valve surgery and minimal access surgery.

## APPROACHES

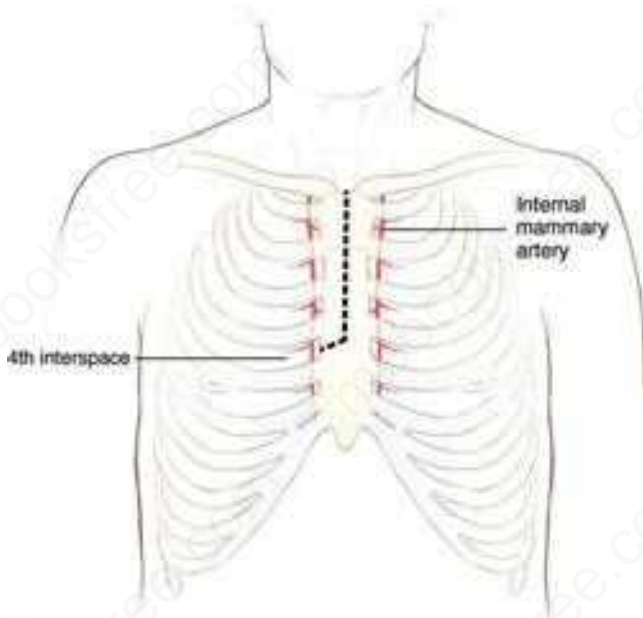

Whatever the surgical approach, today aortic valve replacement is done with the use of cardiopulmonary bypass and diastolic arrest of the heart. There are at least four different minimal access surgical approaches to the aortic valve:

1. Upper hemisternotomy
2. Right parasternal approach
3. Right anterior thoracotomy
4. Transverse sternotomy

## The Upper Hemisternotomy Approach

This is undoubtedly the most popular of all minimal access approaches to the aortic valve.<sup>1,2</sup> This is performed through a 6- to 8-cm vertical midline incision over the upper part of the sternum, starting at or just above the level of the manubrio-sternal angle. The sternotomy is performed with the standard saw starting at the level of the sternal notch up to the level of the third or fourth intercostal space (Fig. 32-1). The sternotomy is then T'd off into the right or left third or fourth intercostal space using a narrow blade oscillating saw, taking care not to dive too deeply with it for risk of injuring mediastinal or pericardial structures. The decision to T into the third or fourth space can be made preoperatively with the chest x-ray being a guide to the amount of exposure that will be needed. We favor the fourth interspace because this almost always produces the ideal exposure. It is very important to ensure that the sternotomy is absolutely midline and that the midline sternotomy is not carried beyond the level of the transverse T. Failure to adhere to these principles will result in either a lateral fracture with resultant three sternal fragments or a continued lower extension of midline fracture which with retraction could result in a slow ongoing intraoperative or postoperative blood loss and also difficulty in closure. There is no need to prophylactically divide the right or left internal mammary arteries with this incision. If care is taken not to damage them, they will usually gently retract away.

A small-blade retractor spreads the sternum. The pericardium is opened in the midline (Fig. 32-2), T'd inferiorly, and at least three pericardial stay sutures are applied to either side and the needles are left on. The retractor is removed and the pericardium is tacked to the dermis of the skin and tied down. This facilitates exposure by elevating the pericardial contents

**FIGURE 32-1** Upper hemisternotomy incision.

**FIGURE 32-2** Midline incision in the pericardium.

forward into the operating field. The retractor is then repositioned. Care must be taken during reopening the retractor because sudden retraction with elevated cardiac structures could impede venous return, causing a sudden drop in cardiac output, and leading to acute refractory decompensation in patients with severe aortic stenosis.

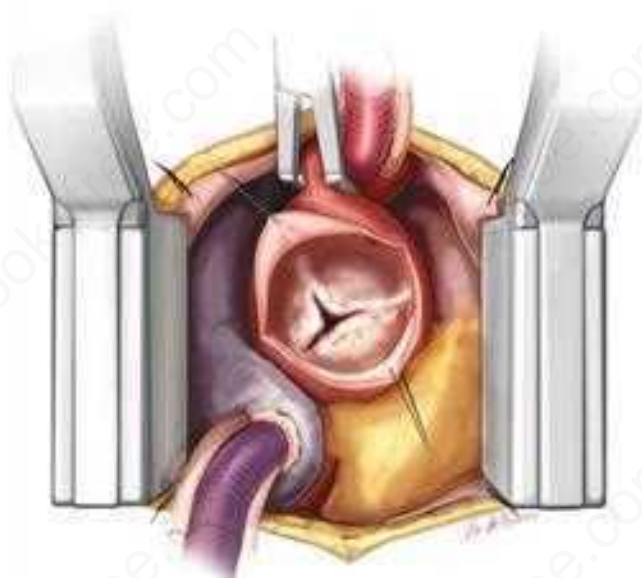

We perform an epiaortic ultrasound to exclude atheromatous disease in the ascending aorta before proceeding to systemic heparinization and ascending aortic cannulation in the standard fashion. Right atrial venous cannulation is accomplished directly through the appendage (when easily accessible) (Fig. 32-3) or with a percutaneous venous cannula inserted via the right or left femoral vein. There are a variety of custom long venous canulae that are available for the same (usually 20- or 22-French), and they are inserted using the Seldinger technique. The cannula is positioned within the right atrium with the tip in the superior vena-cava using transesophageal echocardiographic guidance. The patient is then placed on cardiopulmonary bypass. We use tepid bypass with core cooling to 34 to 35°C. The need for vacuum-assisted venous drainage to facilitate this operation cannot be overemphasized.

A retrograde cardioplegia catheter can be placed in the coronary sinus via the right atrial appendage. This may require a minor adjustment to reduce the angulation of the catheter and its insertion can be facilitated by the use of transesophageal echocardiography. Alternatively, this catheter can be placed by the anesthesiologists before surgical incision via the transjugular route. Although we routinely use a transaortic left ventricular vent, a right superior pulmonary vein or a left atrial dome vent can also be easily placed via this incision.

**FIGURE 32-3** The pericardium has been tacked up and the patient has been cannulated in the standard fashion. Oblique aortotomy has been marked.

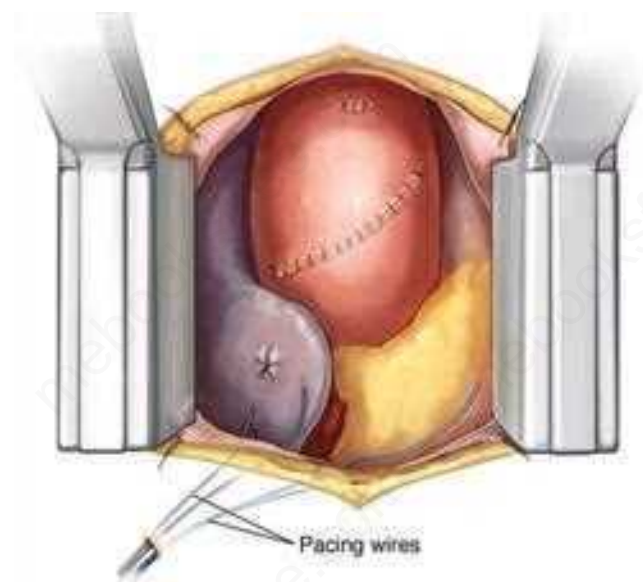

The operation then proceeds as usual. The aorta is cross-clamped and we use 1 L of 8:1 cold blood antegrade cardioplegia. TEE is used to monitor left ventricular distention in patients who may have aortic insufficiency. Retrograde cardioplegia and additional doses of cardioplegia are administered as necessary. Standard aortic valve replacement is then carried through an oblique aortotomy (Fig. 32-4). Upon completion of the procedure, the patient is rewarmed and the aortotomy is closed. A de-airing needle is placed in the ascending aorta before removal of the aortic cross-clamp.

**FIGURE 32-4** The aorta was opened after cross-clamping, exposing a calcified trileaflet aortic valve.

Almost always the heart recovers spontaneous sinus rhythm. When the heart recovers into ventricular fibrillation, it will need to be defibrillated using the external defibrillator pads placed before commencement of the operation. Defibrillation can be facilitated by turning the cardiopulmonary bypass flows down to decompress the heart and other appropriate pharmacologic maneuvers. It is usually quite difficult to introduce internal defibrillator blades through this incision, although pediatric blades can be placed successfully on occasion. Appropriate preoperative placement of external defibrillator pads are of paramount importance. The heart is de-aired using TEE guidance. In the absence of the ability to reach in and agitate the heart, a combination of ventricular filling, table positioning, and external compression is used to successfully de-air the left heart. Although this can always be successfully completed, patience may be an important tool to facilitate this. It is important remember that successful and complete de-airing does not occur until the blood has begun to circulate through the pulmonary and systemic circuits and the heart has started to eject normally.

Before emergence from bypass, pacing wires and drainage tubes will have to be placed (Fig. 32-5). It is very important to perform these placements with the heart decompressed on bypass so as to prevent injury. Invariably, there is an adequate amount of atrial and ventricular myocardium exposed to place pacing wires. We usually bring these wires out in the right inframammary area through the right-sided T. We place fluted silastic drains from a subxiphoid approach. Small incisions are made in the subxiphoid area and long grabbing forceps are used to make two retrosternal tunnels, one of which will puncture the pericardium to facilitate placement of a pericardial drain and the other will remain in the retrosternal plane. These are placed with a combination of tactile and visual control. In cases in which drains were not

**FIGURE 32-5** The aortotomy was closed after valve replacement, and epicardial pacing wires were placed.

placed before separation from bypass and decannulation, we recommend opening the right or left pleural space and placement of transpleural drainage tubes. Placement of subxiphoid drains is not recommended after the heart is full. The wean from cardiopulmonary bypass is then performed in the standard fashion followed by decannulation and protamine administration.

The pericardium is left open. While policing the area for bleeding, some of the important sites are the coronary sinus from the placement of the retrograde catheter (which will need full sternotomy conversion for control), areas of pacing wire placement and drainage tube entry (which may or may not require conversion to full sternotomy and/or institution of bypass for visualization and control), sites of left ventricular vents, the lower edge of the sternotomy/pericardiotomy, and the internal mammary vessels on the side of the T. The sternum is closed using three or four horizontal sternal wires and an oblique wire placed between the lower intact segment of the sternum and the T'd off segment (Fig. 32-6)

Minimally invasive aortic valve replacement via the upper hemisternotomy approach was originally developed by Cosgrove and colleagues at the Cleveland Clinic<sup>1</sup> and soon after by Cohn and colleagues at the Brigham and Women's Hospital in Boston.<sup>2</sup> Johnston and Roselli<sup>3</sup> reported their results involving over 2300 patients undergoing minimally invasive aortic valve surgery over an 18-year period at the Cleveland Clinic, where upper hemisternotomy remains the preferred approach today for isolated aortic valve surgery. Mihaljevic and colleagues<sup>4</sup> from the Brigham group reported their experience with 1000 minimally invasive valve operations, of

which 526 were aortic valve procedures. They reported low levels of morbidity and mortality equal to or better than conventional techniques.

Numerous authors have published their experience with the upper hemisternotomy minimal access aortic valve replacement and most report excellent outcomes. Ghanta et al<sup>5</sup> compared outcomes and cost of minimally invasive aortic valve replacement versus conventional surgery in a multi-institutional regional cohort. They found that 93% of minimally invasive aortic valve operations were performed via upper hemisternotomy with mortality and morbidity equivalent to the full sternotomy approach. Upper hemisternotomy was also associated with decreased ventilator time, decreased blood product use, earlier discharge, and reduced total hospital cost. Gilmanov et al<sup>6</sup> demonstrated excellent outcomes in 853 patients with low overall morbidity, low conversion rate, and comparable long-term survival to that of conventional aortic valve replacement. Upper hemisternotomy for aortic valve replacement has been performed safely in higher risk populations including elderly patients<sup>7</sup> as well as those with left ventricular dysfunction,<sup>8,9</sup> with morbidity and mortality comparable to conventional sternotomy techniques.

Recently, the advent of sutureless aortic prostheses has further kindled interest in minimally invasive aortic valve replacement. Dalen et al<sup>10</sup> reported successful implantation of a sutureless aortic valve bioprosthesis via upper hemisternotomy in 189 patients and found no difference in cross-clamp time, cardiopulmonary bypass time, early postoperative outcomes, or 2-year survival when compared to propensity score matched patients who underwent the operation with full sternotomy. Nonrandomized multicenter clinical trials in Europe also demonstrated safe and successful minimally invasive implantation of a sutureless aortic valve prosthesis through upper hemisternotomy, albeit with slightly longer operative time than with conventional sternotomy but comparable 5-year outcomes.<sup>11</sup>

**FIGURE 32-6** Final closure of the hemisternotomy incision.

## The Right Parasternal Approach

The first foray into the world of minimal access aortic valve surgery was with use of this approach. This approach seemed to be the most logical and elegant at a time when the focus was on the morbidity of the sternotomy and surgeons were compelled to come up with this alternative.

This was performed via a vertical upper right parasternal incision. The second, third, and fourth costal cartilages were removed and the right internal mammary vessels were usually ligated and divided. It provided a similar approach to the aortic valve as an upper hemisternotomy incision described before and techniques of cannulation, cardiopulmonary bypass, myocardial protection, and valve replacement were the same. It soon gave way to the more elegant and simple upper hemisternotomy approach. One particular problem associated with the right parasternal approach was the incidence of lung herniation, which was physiologically disturbing aside from being a cosmetic disaster and

often required a second operation and mesh closure of the defect.

Cohn<sup>12</sup> and Minale et al<sup>13</sup> described their experiences with the right parasternal incision for aortic valve replacement in 1998. They reported fairly low mortality and morbidity rates and had, at that time, recommended the approach for minimal access aortic valve surgery, but soon moved to a hemisternotomy approach because of occasional right lung herniation.

## The Right Anterior Thoracotomy Approach

This is another method to perform minimal access primary aortic valve replacement in adults. The right anterior thoracotomy and the upper hemisternotomy are the most commonly used approaches to minimally invasive aortic valve surgery today.

This technique is usually performed via the second right intercostal space. Owing to the relatively high nature of the thoracotomy, it never reaches around to become a true anterolateral thoracotomy. One can visualize why this would be unappealing for a female patient because the incision would traverse horizontally across the upper part of the right breast, which could lead to scarring and disfigurement. This incision is carried to the right sternal edge and through this incision the right side of the aorta is easily visualized; and with appropriate strategically placed pericardial retraction sutures the area of interest could easily be moved into the operative field. Aortic and venous cannulation could be performed centrally or peripherally, although the latter may be preferable since the operative field is generally smaller and the aortic valve sits deeper within the wound with this approach than with a mini-sternotomy. The rest of the operation is fairly routine for any minimal access aortic valve surgery. Special cross-clamps may be required to facilitate this procedure.

This operation also has some relevance and indication for patients requiring isolated aortic valve surgery in whom sternotomy needs to be avoided at all costs. A unique subset of such patients is those who are disabled and routinely ambulate with the use of shoulder crutches. These patients could be made to ambulate early with the use of their crutches without the risk of sternal dehiscence by the use of this approach. Another possible subset of patients includes those with heavily irradiated or damaged sternum.

The exposure via this incision could be optimized in cases with poor exposure by extending it across the sternum with a transverse sternotomy through the manubrio-sternal angle. Reoperative aortic valve replacement is particularly difficult via this incision and the authors sincerely discourage the approach for a reoperation.

Glauber et al<sup>14</sup> reported their results with minimally invasive aortic valve replacement via the right anterior mini-thoracotomy approach in 138 patients and compared outcomes to a propensity-matched group undergoing full sternotomy. The right anterior mini-thoracotomy group was associated with lower incidence of blood transfusion and

postoperative atrial fibrillation and shorter mechanical ventilation time and hospital length of stay, with comparable perioperative morbidity. Gilmanov et al<sup>15</sup> demonstrated that minimally invasive aortic valve replacement through right anterior thoracotomy can be safely performed with acceptable mortality and morbidity in octogenarians. When compared to propensity-matched patients undergoing full sternotomy, the minimal access group had shorter time to extubation and shorter hospital stay with no difference in perioperative complications or 5-year survival rates.

As with the upper hemisternotomy approach, recently several groups have reported the successful implantation of a sutureless aortic valve prosthesis through a right anterior thoracotomy approach. Vola et al<sup>16</sup> and Gilmanov et al<sup>17</sup> demonstrated in 71 and 515 patients, respectively, that minimally invasive aortic valve replacement with various sutureless prostheses can be safely and reproducibly performed via the right anterior thoracotomy incision. Both groups observed acceptable hemodynamic outcomes and low perioperative complication rates.

## The Transverse Sternotomy Approach

There are anecdotal reports of this incision for minimal access aortic valve surgery.

Typically an 8- to 10-cm transverse incision is made over the manubrio-sternal angle extending onto either side. Bilateral second costal cartilages have to be excised and both internal mammary pedicles have to be ligated and divided. A transverse sternotomy is performed across the sternal angle. The retractor is placed and the sternal edges are retracted in a craniocaudal plane. Adequate exposure is obtained through this incision to permit central aortic cannulation and a routine aortic valve replacement; however, venous cannulation, retrograde coronary sinus catheter placement and vent placement (except transaortic) may have to be performed percutaneously.

For reasons that the mammary arteries are sacrificed, this incision never gained much popularity.

Lee et al,<sup>18</sup> De Amicis et al,<sup>19</sup> and Aris et al,<sup>20</sup> reported their small experiences with the transverse sternotomy approach and good results. However, Bridgewater et al<sup>21</sup> reported an unacceptably high incidence of morbidity (reexploration for bleeding, paravalvular leaks, and longer hospital stay) and mortality with this approach.

Karimov et al<sup>22</sup> reported a series of 85 patients who underwent an upper V-type ministernotomy in the second intercostal space with excellent results.

## REOPERATIVE MINIMAL ACCESS AORTIC VALVE SURGERY

The Brigham and Women's Hospital has pioneered minimal access reoperative aortic valve replacement in patients who previously have undergone coronary artery bypass grafting or other cardiac surgery. We popularized and published our data and have since had more experience with the technique.

According to the STS database, patients requiring a reoperative aortic valve replacement after previous coronary artery bypass grafting have a mortality risk of about 8 to 12% from the procedure. The risks are associated with the performance of a reoperation in an older patient with more comorbidities and patent/diseased bypass grafts.

## The Need for This Operation

1. There is a definite subgroup of patients who have undergone coronary bypass surgery who had mild or no aortic stenosis at the time of their original operation who will eventually progress to have severe aortic stenosis over time. This has sparked off a whole discussion on the management of moderate aortic stenosis with coronary artery disease<sup>23</sup>
2. These patients are older, sicker, and have many comorbid conditions
3. They need a simple, safe, and effective operation
4. The areas of interest are the ascending aorta and aortic root
5. Dissection of the rest of the heart and bypass grafts provide no additional benefit and are potentially harmful
6. Clipping the left internal mammary artery is not mandatory with alternative protection strategies.

## Operative Strategy

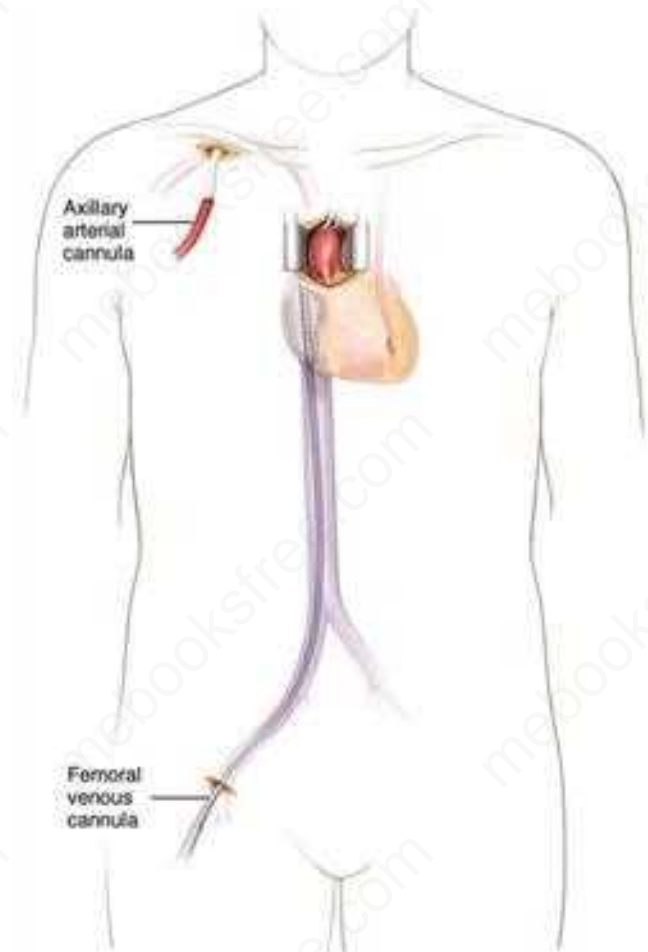

Preoperatively, a computed tomogram of the chest with angiography and three-dimensional reconstruction is performed to ascertain the exact location of the old bypass grafts and their relative location to the sternum (especially the left internal mammary artery).<sup>24</sup> Coronary angiography and percutaneous coronary and graft intervention with drug-eluting stents are done as appropriate to optimize the revascularization as far as possible. Heart failure is controlled medically.

All patients need intraoperative transesophageal echocardiography and a pulmonary artery catheter with atrial and ventricular pacing wire placement capabilities, which should ideally be placed before incision. Accurate placement of external defibrillator pads is emphasized because internal paddles cannot be introduced in these patients.

All patients need peripheral cannulation for cardiopulmonary bypass, either right axillary or percutaneous femoral venous cannulation. Appropriate arterial line placement is needed to facilitate need for circulatory arrest and antegrade cerebral perfusion if required.<sup>25</sup> A standard upper hemisternotomy incision is made with a T into the right fourth intercostal space (Figs. 32-7 and 32-8). The anterior table split is performed with the use of an oscillating saw, whereas the posterior table split is performed on cardiopulmonary bypass using straight Mayo scissors starting from the top down (preferably from the assistant's side of the table). When the left internal mammary artery graft is close to the left side of the sternum, a preplanned one-third to

**FIGURE 32-7** The upper hemisternotomy incision has been marked.

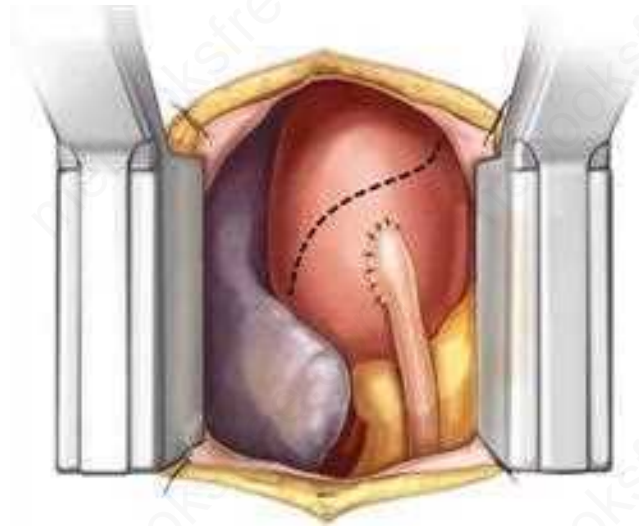

**FIGURE 32-8** Peripheral cannulation for cardiopulmonary bypass.

two-thirds sternotomy to the right is performed. The right pleural space is widely opened. Only 5 to 10 mm dissection is performed underneath the left sternal edge, enough to facilitate the placement of the Kuros-Baxter® retractor. The rest of the mediastinal and aortic dissection is performed on cardiopulmonary bypass. Care is taken not to injure previous saphenous vein or radial arterial bypasses. It is not necessary to visualize the left internal mammary artery graft.

Core cooling should wait until after there is an ability to place an aortic cross-clamp. Moderate-to-deep hypothermia facilitates low flow states and reduces myocardial oxygen demand, which is important because the left internal mammary artery will continue to perfuse the heart for the duration of the operation. A retrograde coronary sinus catheter is placed through the right atrial appendage using TEE guidance. Usually, enough right atrial appendage is seen to place this catheter. Alternatively, a transjugular catheter can be placed before incision. After cross-clamping the aorta, 1 L antegrade cold blood cardioplegia is delivered through the aortic root. Thereafter, 500 cc of cold retrograde blood cardioplegia is used. Simultaneously, systemic hyperkalemia is achieved by instilling 40 mEq of potassium into the cardiopulmonary bypass. Systemic hyperkalemia will achieve diastolic arrest in the left anterior descending artery territory that is perfused by the left internal mammary artery distal to the aortic cross-clamp. All through the operation, frequent doses of antegrade (through the coronaries and grafts using perfusion canulae) and retrograde cardioplegia are delivered. Systemic hyperkalemia is maintained at a level of 6 to 7 mEq/L. This keeps the myocardium fairly quiescent during the procedure. Needless to say, heavy doses of potassium may leave the patient with severe hyperkalemia that may not be cleared in the setting of renal dysfunction. In addition to being judicious in such cases, it is imperative that the perfusion technologists be able to provide ultrafiltration as well.

The aortotomy is dictated by the location of previous bypass grafts. Although in some cases a standard oblique aortotomy can be made, most cases require a modified aortotomy such as a lazy S or a lateral vertical aortotomy (Fig. 32-9). The exposure should be adequate and an expeditious valve replacement is the key to success. We aim to keep the cross-clamp time under 60 minutes. In most cases, there will be continuous back bleeding through the left main orifice from the open left internal mammary artery graft. During debridement and suture placement in the left coronary area, the bypass flows can be reduced or briefly turned off to facilitate exposure. Rewarming is started after the valve is seated. The aortotomy is closed in the standard fashion and a de-airing needle is placed before removal of the aortic cross-clamp. The heart often recovers spontaneous sinus rhythm. Defibrillation is achieved via the external pads if required. The de-airing and wean from cardiopulmonary bypass is as described before.

Drainage tubes are always placed through the right pleural space. Subxiphoid placement is not possible and strongly

**FIGURE 32-9** This is a lazy S oblique aortotomy keeping the grafts to the left.

discouraged. Rarely, when the right pleural space is completely fused, the silastic drain could be brought out in the supraclavicular area. It may be possible to place atrial pacing wires, but placement of ventricular wires is almost always quite difficult. Routine use of pulmonary artery catheter-based pacing leads is also possible. Closure is fairly standard, as described before, and care must be taken during the placement of wires on the left side of the sternum and the oblique lower wire (Fig. 32-10).

**FIGURE 32-10** Final closure, also showing an occasional drainage tube in the supraclavicular space.

# Percutaneous Treatment of Aortic Valve Disease

Stephanie L. Mick • Lars G. Svensson

The history of percutaneous treatment of aortic valve disease began with the work of Danish researcher, H.R. Andersen, who in the late 1980s experimented in an animal lab with a balloon-expandable stented valve.<sup>1</sup> The technology was later acquired by PVT Company, further developed, and later sold to Edwards. Additional early work was done by Alain Cribier<sup>2,3</sup> and subsequently the valve was adopted in the United States and further modified. The initial approach taken by Cribier was to insert the valve via the femoral vein, then snaking the catheter through the mitral valve and into the aortic annulus via transeptal puncture. This turned out to be a fairly cumbersome and difficult procedure with a fairly high mortality rate and an 8.1% stroke rate. At the same time, animal experiments were carried out by Michael Mack, Todd Dewey, and Lars Svensson,<sup>4,5</sup> using the transapical (TA) approach to insert the aortic valve. Concurrently, John Webb et al<sup>6,7</sup> were also developing a TA aortic valve method, and subsequently they introduced the retrograde transfemoral (TF) artery approach. This latter technique became feasible once Edwards developed a catheter that could be flexed to get around the aortic arch to access the aortic valve. At the same time the Edwards balloon-expandable valve was being developed, Medtronic introduced a nitinol-based, self-expanding percutaneous valve system, the CoreValve. Following feasibility studies,<sup>5,8</sup> the safety and effectiveness of both valves were established through the Placement of Aortic Transcatheter Valves (PARTNER) trial and the US CoreValve pivotal trial and both valves are currently approved by US Food and Drug Administration (FDA) for use in patients who are at extreme or high risk (owing to comorbidities or anatomical considerations) for conventional surgery in the United States.<sup>9-11</sup>

## VALVES

At present in the United States, there are only two transcatheter valves approved for use in patients who are at extreme or high risk (owing to comorbidities or anatomical considerations) for conventional surgery.

The balloon-expandable Edwards valves consist of bovine pericardium fashioned into a trileaflet valve within a short cylindrical stent, available in sizes 23, 26, and 29 to treat

annular sizes from 18 to 27 mm. There are three generations of SAPIEN valves (SAPIEN, SAPIEN XT, and SAPIEN 3) that differ by stent material and construction (Fig. 33-1) as well delivery device size (Table 33-1) and other delivery device characteristics. At the time of publication, the commercially available generation is the SAPIEN XT in the United States with the SAPIEN 3 commercially available only in Europe. However, this generation is almost certain to replace the SAPIEN XT in the United States in the coming years. The SAPIEN valves can be delivered via retrograde (eg, TF, trans-aortic, transcarotid, transaxillary/subclavian) and antegrade (TA) approaches. The self-expanding Medtronic CoreValve is constructed of porcine pericardium mounted in a nitinol stent that anchors within the aortic annulus and extends superiorly to anchor in the ascending aorta. It is available in sizes 23, 26, 29, and 31 to fit annulus sizes 18 to 29 mm (Fig. 33-2, Table 33-1). The CoreValve can only be delivered using retrograde approaches.

## PIVOTAL TRIALS

The major landmark trials in the percutaneous treatment of aortic valve disease are the PARTNER and the CoreValve Pivotal Trials. In prospective randomized fashion, the PARTNER Trial compared balloon-expandable (SAPIEN generation) transcatheter aortic valve replacement (TAVR) with valve and medical management in inoperable (combined risk of serious morbidity or mortality exceeding at least 50% and two surgeons agreeing the patient was inoperable) patients in its IB cohort and with surgical valve replacement in high risk (Society of Thoracic Surgeons (STS) >10%) patients in its IA cohort. Likewise, the CoreValve Pivotal Trials compared self-expandable TAVR with medical and surgical treatments in similar cohorts.

## Transcatheter Aortic Valve Replacement Versus Medical Therapy

In the PARTNER IB cohort, inoperable patients were randomly assigned to SAPIEN TAVR or medical management. TAVR was associated with improved 1- and 2-year mortality

**FIGURE 33-1** Three generations of balloon-expandable Edwards SAPIEN valves. (Used with permission from Edwards Lifesciences LLC, Irvine, CA.)

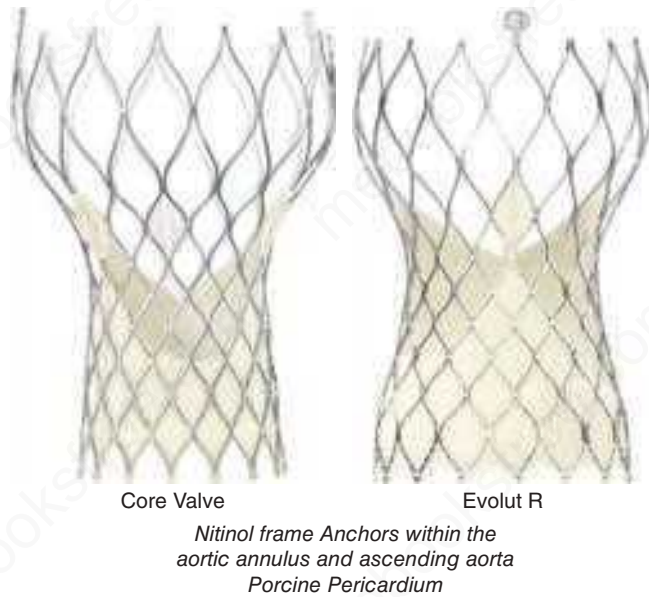

(30.7% 1 year, 43.4% 2 year) compared with medical (including the use of balloon valvuloplasty) management (50.7% 1 year, 68% 2 year). The rate of the composite end point of death or repeat hospitalization was also reduced with TAVR (42.5 vs 71.6%). The stroke rate was significantly higher in the TAVR group than that in the medical therapy group at 30 days (6.7 vs 1.7%) and at 2 years (13.8 vs 5.5%).<sup>10,12</sup> It should be noted that TAVR improved survival in patients with an STS score of <15% but not in those with an STS score of  $\geq 15\%$ .<sup>9</sup>

These very convincing results with the balloon-expandable valve led to the conclusion that a randomized trial comparing self-expanding (CoreValve) TAVR and medical therapy could not ethically be performed. Instead, a prospective single-arm study, the CoreValve Extreme Risk US Pivotal Trial, was used to compare CoreValve TAVR to a prespecified estimate of 12-month mortality or major stroke with medical therapy (43%).<sup>13</sup> Nearly 500 patients underwent attempted treatment with CoreValve. In those patients, the rate of all-cause mortality or major stroke at 1 year was significantly lower

**TABLE 33-1: Characteristics of Balloon-Expandable Edwards SAPIEN Valves and Self-Expanding Medtronic CoreValve**

	SAPIEN	SAPIEN XT	SAPIEN 3	CoreValve EVOLUT	EVOLUT R
Frame	Stainless steel	Cobalt-chromium	Cobalt-chromium	Nitinol	Nitinol
Leaflets	Bovine pericardium	Bovine pericardium	Bovine pericardium	Porcine pericardium	Porcine pericardium
Expansion type	Balloon	Balloon	Balloon	Self-expanding (post-expansion balloon dilation possible)	Recapturable and repositionable prior to final valve release
Special features			Outer skirt to minimize paravalvular leak	Retrievable and repositionable prior to final valve release	Extended sealing skirt
Antegrade access (transapical)	+	+	+	-	-
Retrograde access (eg, transfemoral, transaortic)	+	+	+	+	+
FDA Approval	+	+	+	+	+
Annulus diameters (mm)	18-25	16-27	18-28	18-29	18-26
Valve Sizes	23, 26	20, 23, 26, 29	23, 26, 29	23, 26, 29, 31	23, 26, 29
Delivery sheath sizes	22 Fr (size 23 valve) 24 Fr (size 26 valve)	16 Fr expandable sheath (valve sizes 20, 23) 18 Fr expandable sheath (size 26 valve) 20 Fr expandable sheath (size 29 valve)	14 Fr expandable sheath (valve sizes 23, 26) 16 Fr expandable sheath (size 29 valve)	18 Fr sheath	14 Fr-equivalent System with In-Line™ Sheath

than the prespecified expected rate (26 vs 43%), echoing the results of the PARTNER Trial.<sup>13</sup>

Given the known dismal prognosis of nonsurgically managed severe symptomatic aortic stenosis,<sup>14-16</sup> it was perhaps not surprising that aortic valve replacement was found to be associated with obviously increased survival in inoperable patients. With regard to comparison of TAVR and high-risk aortic valve replacement, the differences are subtler.

## Transcatheter Aortic Valve Replacement Versus Surgery

The PARTNER Trial found similar 30-day (3.4 and 6.5%,  $p = .07$ ), 1-year (24.3 and 26.8%), and 2-year (33.9 and 35.0%) mortality rates between SAPIEN TAVR and surgical valve replacement in patients at high risk for surgery randomized to either SAPIEN TAVR or surgery.

The combined stroke and transient ischemic attack rate was more frequent in the patients assigned to TAVR at 30 days (5.5% TAVR vs 2.4% surgery,  $p = .04$ ) and at 1 year (8.7% TAVR vs 4.3% surgery,  $p = .04$ ). The difference was of borderline significance at 2 years (11.2 vs 6.5%,  $p = .05$ ). More patients undergoing TAVR reported symptom improvement at 30 days, but at 1 year, symptom improvement was similar in the two groups. At 30 days, TAVR was associated with more frequent major vascular complications (11.0 vs 3.2%) and surgery was associated with more frequent major bleeding episodes (19.5 vs 9.3%) and new-onset atrial fibrillation (16.0 vs 8.6%). The rate of new pacemaker requirement at 30 days was similar between the TAVR and surgical groups (3.8 vs 3.6%). Moderate or severe paravalvular aortic regurgitation was more common after TAVR than surgery at 30 days, 1 year, and 2 years and, importantly, was associated with increased late mortality.<sup>10,12</sup>

As in PARTNER, the US CoreValve High Risk Study found no difference in 30-day mortality in patients at high risk for surgery randomized to CoreValve TAVR or surgery (3.3 and 4.5%). However, unlike PARTNER, the 1-year mortality rate was lower in the CoreValve TAVR group than that in the surgical group (14.2 vs 19.1%,  $p < .0001$  for noninferiority,  $p = .04$  for superiority).<sup>13,17</sup> It is to be noted, that diabetes was more common in the surgery group compared with the TAVR cohort (45.4 vs 34.9%;  $p = .003$ ), and this among other factors has led to questions about conclusions regarding the true survival benefit to TAVR over surgery in this trial.<sup>18</sup>

CoreValve TAVR was found to be noninferior to surgery with respect to echocardiographic indices of valve stenosis, functional status and quality of life at 1 year, and exploratory analysis suggested a reduction in the rate of major adverse cardiovascular and cerebrovascular events with TAVR. Unlike PARTNER, no increase in the risk of stroke was observed with CoreValve TAVR at 30 days (4.9% TAVR, 6.2% surgery) or 1 year (8.8% TAVR, 12.6% surgery). Major vascular complications, cardiac perforation, and permanent pacemaker implantation were more frequent after CoreValve TAVR. Life-threatening/disabling hemorrhage, acute kidney injury, and new-onset or worsening atrial fibrillation were more common after surgery.

In the PARTNER 2A trial, TAVR was studied for in intermediate risk populations. There was no difference in disabling stroke but higher risk of need for permanent pacemaker and paravalvular aortic insufficiency in TAVR than in surgical valve replacement. The FDA approved TAVR for use in intermediate risk patients in August 2016. There is interest in extending TAVR to broader, low risk populations. High-quality, randomized control trials are needed prior to such extension, and the PARTNER-3 study comparing TAVR to surgical valve replacement in low-risk patients is currently underway at the time of publication of this chapter.

## COMPARISON OF CURRENTLY AVAILABLE VALVES

There is only one randomized comparison of balloon-expandable and self-expandable valves at this time. In the Comparison of Transcatheter Heart Valves in High Risk Patients With Severe Aortic Stenosis: Medtronic CoreValve versus Edwards SAPIEN XT (CHOICE) trial, 241 patients undergoing TF TAVR were randomized to either the SAPIEN XT or the CoreValve device.

The primary end point of this trial was “device success,” a composite end point of four components: successful vascular access and deployment of the device with retrieval of the delivery system, correct position of the device, intended performance of the valve without moderate or severe insufficiency, and only one valve implanted in the correct anatomical location.

Owing to significantly lower residual more-than-mild aortic regurgitation with the balloon-expandable valve than with the self-expanding valve (4.1 vs 18.3%,  $p < .001$ ) and less frequent need for implantation of more than one valve with the balloon-expandable valve (0.8 vs 5.8%,  $p = .03$ ), the balloon-expandable SAPIEN XT valve showed a significantly higher device success rate than the self-expanding CoreValve.

Placement of a permanent pacemaker also was considerably less frequent in the balloon-expandable valve group (17.3 vs 37.6%,  $p = .001$ ). The all-cause mortality and stroke rate at 30 days in patients receiving either valve were similar; 1 year data are pending.<sup>19</sup>

## INSERTION OF PERCUTANEOUS VALVES: APPROACHES

Possible access routes include TF arterial, TA (not possible for CoreValve, which requires antegrade insertion), transaortic (TAo) via partial J-sternotomy or right anterior thoracotomy,<sup>20-22</sup> transcarotid,<sup>23-25</sup> and transaxillary/subclavian<sup>26,27</sup> approaches. Less commonly, TF-venous routes have been performed using either transseptal<sup>28</sup> or caval-aortic puncture.<sup>29</sup>

The TF approach has been favored as the first choice for patients in most institutions, owing to its ability to be performed in a completely percutaneous manner, at times without intubation and general anesthesia. In certain patients, for instance those with peripheral vascular disease and heavy arterial calcification, TA-TAVR has become an increasingly popular option, with outcomes similar to TF-TAVR after propensity score matching.<sup>30,31</sup> Although a significant learning curve exists,<sup>32</sup> we have found that the procedure can be performed with minimal morbidity and mortality. For instance, in our most recent series of TA-TAVRs, we have shown a 1.2% mortality, 4.7% renal failure, 0% stroke, and 5.9% permanent pacemaker rate.<sup>33</sup> This approach can even be extended to include simultaneous treatment of multiple cardiac pathologic entities, for example, percutaneous coronary intervention (PCI) and transcatheter mitral valve-in-valve implantation.<sup>34-36</sup>

### Transfemoral Approach

The approach we have used for TF insertion is to perform all procedures in a hybrid fluoroscopy operating room with a team consisting of cardiac surgeons, interventional

cardiologists, cardiac anesthesiologists, echocardiographers, perfusionists, surgical scrub nurses trained in transcatheter procedures, circulating nurses, catheterization laboratory technicians, and surgical assistants. We have found this multidisciplinary approach to facilitate rescue in the case of myocardial collapse.<sup>37</sup> The femoral, arterial, and venous lines are introduced percutaneously using a closure device at the end of the procedure. Thus, a venous pacing wire is inserted into the right ventricle and then two arterial wires are inserted into the groins, one for a pigtail catheter for aortography and to mark the location of the lower extent of the noncoronary sinus for valve positioning and the other for the device sheath. Typically, the patient is heparinized so the ACT is between 250 and 350 seconds. The aortic valve is crossed with a 0.035" straight wire and generally an AL1 catheter and advanced into the left ventricle. This is then exchanged with an extra stiff wire that has been fashioned into a curved arc to minimize the risk of ventricular perforation. A balloon is then threaded over the guidewire and positioned across the aortic valve using fluoroscopy and then during rapid pacing, and breath/ventilator holding, expanded to crack the calcified aortic valve in a manner similar to balloon aortic valvuloplasty (Fig. 33-3A).

For the SAPIEN XT, as a rule, patients who need the 23 valve should have an access artery of at least 6 mm; for the size 26 valve, a 6.5 mm artery; and for a 29 valve, a 7 mm artery, depending on the tortuosity of the vessel and degree of calcification. If there is more than 90-degree angulation of the iliac arteries, then generally it would be difficult to insert the sheath unless the vessel straightens very easily with a Lunderquist wire.

Prior to inserting the valve loaded on the delivery balloon, it is checked and confirmed to be correctly oriented and is then threaded over the stiff wire and the loader pushed into the sheath and threaded across the aortic arch with the steerable catheter being flexed to get around the aortic arch and then fed down to the aortic valve. Essentially, the valve with the leading cone is fed across the valve to cross the valve and then the cone is pushed further into

**FIGURE 33-3** Transfemoral artery balloon-expandable valve insertion sequence. (Reproduced with permission from the Cleveland Clinic, Cleveland, OH.)

**FIGURE 33-4** Positioning of balloon-expandable valve during rapid ventricular pacing. Note position of pigtail catheter at the base of the noncoronary sinus and aortography.

the ventricle so that the stent valve is free. Once the balloon is inflated, it can be expanded without limitation from the cone. We consider it very important to carefully check on the positioning of the valve across the hinged point of the native valve using both echocardiography and fluoroscopy and root injections with contrast via the pigtail catheter. The valve is positioned at the valve hinged points, approximately 60 to 70% aortic and 30 to 40% ventricular (Fig. 33-4). Once everybody agrees that the position is correct, the patient's breath is held, the heart is paced at approximately 180 beats per minute, the balloon is inflated in position and then deflated, the pacer is switched off, and ventilation is resumed (Fig. 33-3).

The most common location of perivalvular regurgitation is in the region of the noncoronary-left main leaflet commissure, probably because this is an area of less flexibility and generally calcified. Echocardiography is then used to inspect the function of the valve and aortography to confirm the lack of perivalvular leak. Thereafter, cone is first withdrawn from the left ventricle followed by removal of the catheter and sheath, and lastly the closure device is tied down at the insertion sites. We perform a completion angiogram of the access vessel in nearly all cases to rule out vascular injury (eg, dissection, occlusion, and significant extravasation).

### Transapical Approach

Similar to our practice in the TF cases, we perform all TA procedures in a hybrid operating room with a multidisciplinary team. We position the patient flat supine on pillows

rather than in a traditional left thoracotomy position, so as not to interfere with the positioning of the C-arms. The ideal planes are calculated for imaging the valve with the nadir of each cusp being in the same plane from preoperative computed tomography scans.

Once the patient is positioned, she/he is prepped in the usual manner with exposure of the groin and left chest. The femoral artery and vein are exposed on the right side and the left femoral venous pacing wires are inserted. The femoral artery exposure is performed in case the patient has to be placed on cardiopulmonary bypass and also used for pigtail catheter insertion as in the TF cases.

We continue to have all of our patients undergo general anesthesia but do not use double-lumen endotracheal tubes for the TA valves. Before opening the chest, CT scan images are inspected to find the ideal place to open the left chest. Typically, the fifth intercostal space is entered and the apex of the left ventricle is palpated. Once the apex of the left ventricle has been palpated, a short piece of rib is commonly removed to expose the apex. Originally we did not do this and rather spread the ribs, but we found that some patients had severe postoperative pain as with the MIDCAB experience. We have therefore opted to resect a short piece of rib to obtain both a better exposure and less pain after surgery, particularly because many of these patients have a component of concomitant lung disease. Pericardiotomy is performed over the left ventricular (LV) apex, and heparin is administered aiming to achieve an ACT of 250 to 350. Two concentric purse string sutures reinforced with pledgets are placed as well as and a horizontal mattress suture is placed at the LV apex.

The final entry site is selected by tapping on the LV apex and then looking at the echo to make sure that the LV apex is correctly identified. This is important because the heart can be anywhere from the fourth intercostal space to the seventh or eighth intercostal space. A needle is placed into the apex, followed by soft access wire insertion in the left ventricle through the needle and directed to the aortic valve. A 12-Fr sheath is then delivered into the LV apex; then we insert a balloon-tipped Berman catheter into the left ventricle, through the aortic valve, and across the aortic arch down to the renal arteries. An extra stiff wire is then fed down to this level, the Berman catheter is removed, and the 12-Fr sheath is exchanged for the large-bore TA introduction sheath. Balloon valvuloplasty is performed through this in the same sequence with rapid pacing as for the TF approach. The valve is then loaded onto the sheath and pushed into position and the pusher is retracted into the sheath. With the valve situated approximately 60 to 70% aortic (Fig. 33-5) and with rapid pacing, the balloon is then inflated at this point. The balloon is then withdrawn into the left ventricle before stopping pacing. Both transesophageal echocardiogram (TEE) and aortic root angiography are used to confirm the position and orientation of the prosthetic valve. If all appears well, the sheath is then removed (generally under conditions of rapid pacing), the pursestring sutures are tied down, and protamine is administered.

## THE NORMAL MITRAL VALVE

### Anatomy

The mitral annulus is a pliable zone of discontinuous fibrous and muscular tissue that joins the left atrium and left ventricle and anchors the hinge portions of the anterior and posterior mitral leaflets.<sup>1-3</sup> The annulus has two major collagenous structures: (1) the right fibrous trigone, which is part of the central fibrous body and is located at the intersection of the membranous septum, the tricuspid annulus, and the aortic annulus; and (2) the left fibrous trigone, which is located near the aortic annulus under the left aortic cusp (Fig. 34-1). The anterior mitral leaflet is in direct fibrous continuity with the aortic annulus under the left and noncoronary aortic valve cusps. The posterior half to two-thirds of the annulus, which subtends the posterior leaflet, is primarily muscular with little or no fibrous tissue.<sup>2</sup>

The mitral valve has two major leaflets, the larger anterior (or aortic) leaflet and the smaller posterior (or mural) leaflet; the latter usually contains three or more scallops separated by fetal clefts or *subcommissures*.<sup>4</sup> The three posterior leaflet scallops are termed anterolateral (P1), middle (P2), and posteromedial (P3) scallops<sup>3</sup> (Fig. 34-2). The portions of the leaflets near the free margin on the atrial surface are called the *rough zone*, with the remainder of the leaflet surface closer to the annulus being termed the *smooth* (or *bare* or *membranous*) *zone*. The ratio of the height of the rough zone to the height of the clear zone is 0.6 for the anterior leaflet and 1.4 for the posterior leaflet because the clear zone on the posterior scallops occupies only about 2 mm.<sup>4</sup> The two leaflets are separated by the posteromedial and anterolateral commissures.

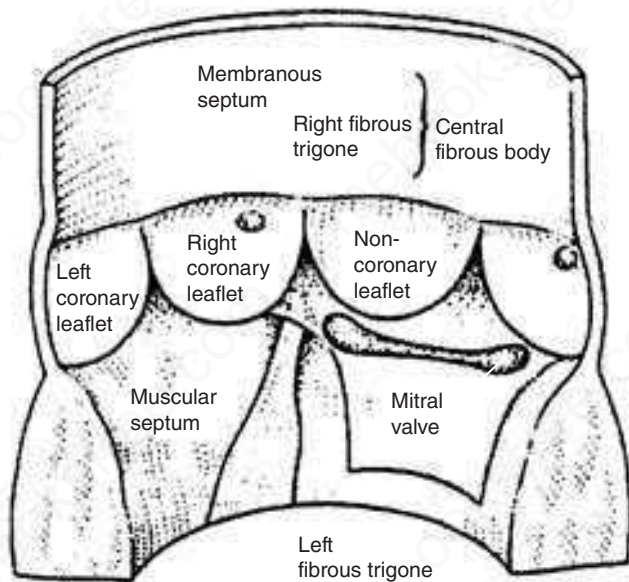

The histologic structure of the leaflets includes three layers: (1) the fibrosa, the solid collagenous core continuous with the chordae tendineae; (2) the spongiosa, which is on the atrial surface and forms the leaflet leading edge (it consists of few collagen fibers but has abundant proteoglycans, elastin, and mixed connective tissue cells); and (3) a thin fibroelastic covering of most of the leaflets.<sup>2</sup> On the atrial aspect of both leaflets, this surface (the atrialis) is rich in elastin. The ventricular side of the fibroelastic cover (the ventricularis) is much thicker and packed with elastin. The fibroelastic layers

become thickened with advancing age as a result of elaboration of more elastin and more collagen formation; accelerated similar changes also accompany progression of myxomatous (degenerative or “floppy”) mitral valvular disease in young patients with Barlow syndrome. In addition to these connective tissue structures, mitral leaflets contain myocardium, smooth muscle, contractile valvular interstitial cells, and blood vessels, as well as both adrenergic and cholinergic afferent and efferent nerves.<sup>5-10</sup> Leaflet contractile tissue is neurally controlled and plays a role in mitral valve function.<sup>11-14</sup> The atrial surface of the anterior leaflet exhibits a depolarizing electrocardiogram spike shortly before the onset of the QRS complex, and the resulting contraction of leaflet muscle (which can be abolished by beta-blockade), along with contraction of smooth muscle and valvular interstitial cells, possibly aids leaflet coaptation before the onset of systole, as well as stiffens the leaflet in response to rising left ventricular (LV) pressure.<sup>6-8,15-23</sup>

### Annular Size, Shape, and Dynamics

The average mitral annular cross-sectional area ranges from 5.0 to 11.4 cm<sup>2</sup> in normal human hearts (average is 7.6 cm<sup>2</sup>).<sup>24</sup> The posterior annulus circumscribes approximately two-thirds of the mitral annulus. Annular area varies during the cardiac cycle and is influenced directly by both left atrial (LA) and LV contraction, size, and pressure.<sup>25,26</sup> Varying by 20 to 40% during the cardiac cycle, annular size increases beginning in late systole and continues through isovolumic relaxation and into diastole; maximal annular area occurs in late diastole.<sup>25,27-29</sup> Importantly, half to two-thirds of the total decrease in annular area occurs during atrial contraction (or *presystolic*); this component of annular area change is smaller when the PR interval is short and is abolished when atrial fibrillation or ventricular pacing is present. Annular area decreases further (if LV end-diastolic volume is not abnormally elevated) to a minimum in early to midsystole.<sup>25-27</sup>

The normal human mitral annulus is roughly elliptical, with greater eccentricity (ie, being less circular) in systole than in diastole.<sup>24-26,30</sup> In three-dimensional (3D) space, the annulus is saddle shaped (or a hyperbolic paraboloid), with

**FIGURE 34-1** Diagram from a pathologic perspective with division of the septum illustrating the fibrous continuity between the mitral and aortic valves. (Reproduced with permission from Wells FC, Shapiro LM: *Mitral Valve Disease*. England: Butterworth-Heinemann; 1996.)

the highest point (farthest from the LV apex) located anteriorly in the middle of the anterior leaflet; this point is termed the *fibrosa* in the echocardiography literature and the *saddle horn* by surgeons. The low points are located posteromedially and anterolaterally in the commissures, and another less prominent high point is located directly posterior.<sup>25,31,32</sup> During the cardiac cycle, annular regions adjacent to the posterior leaflet move toward (during systole) and away (during diastole) from the relatively immobile anterior annulus.<sup>25</sup>

The mitral annulus moves upward into the left atrium in diastole and toward the LV apex during systole; the duration, average rate, and magnitude of annular displacement

correlate with (and perhaps influence) the rate of LA filling and emptying.<sup>25,27,28,33</sup> The annulus moves slightly during late diastole (2 to 4 mm toward the left atrium during atrial systole). This movement does not occur in the presence of atrial fibrillation. The annulus moves a greater distance (3 to 16 mm toward the LV apex) during isovolumic contraction and ventricular ejection. This systolic motion, which aids subsequent LA filling, is related to the extent of ventricular emptying and is likely driven by LV contraction.<sup>25,28,33,34</sup> Subsequently, the annulus moves very little during isovolumic relaxation but then exhibits rapid recoil toward the left atrium in early diastole. This recoiling increases the net velocity of mitral inflow by as much as 20%.<sup>28,35</sup> Annular motion can be responsible for up to 20% of LV filling and ejection.<sup>36</sup>

### Dynamic Leaflet Motion

The posterior mitral leaflet is attached to thinner chordae tendineae than the anterior leaflet, and its motion is restrained by chordae during both systole and diastole.<sup>4,37</sup> Regions of both leaflets are concave toward the left ventricle during systole,<sup>38,39</sup> but leaflet shape is complex, and anterior leaflet curvature near the annulus is convex to the left ventricle during systole, thus resulting in a sigmoid shape.<sup>29,31,32</sup> Leaflet opening does not start with the free margin but rather in the center of the leaflet; leaflet curvature flattens initially and then becomes reversed (making the leaflet convex toward the left ventricle) while the edges are still approximated.<sup>29,39</sup> The leading edge then moves into the left ventricle (like a traveling wave), and the leaflet straightens. The leaflet edges in the middle of the valve appear to separate before those portions closer to the commissures, and posterior leaflet opening occurs approximately 8 to 40 ms later.<sup>39,40</sup> Early leaflet opening (e wave) is very rapid; once reaching maximum opening, the edges exhibit a slow to-and-fro movement (like a flag flapping in a breeze) until another less forceful opening impulse occurs, associated with the a wave.

**FIGURE 34-2** The operative view of the mitral valve is shown (*left*), and the corresponding “surgical view” obtained with real-time three-dimensional transesophageal echocardiography volume rendering (*right*). Images are from patient with type IIIb dysfunction (*see text*). A1, A2, A3, anterior mitral valve scallops; AL, anterolateral; P1, P2, P3, posterior mitral valve scallops; PM, posteromedial. (Reproduced with permission from O’Gara P, Sugeng L, Lang R, et al: The role of imaging in chronic degenerative mitral regurgitation, *JACC Cardiovasc Imaging*. 2008 Mar;1(2):221-237.)

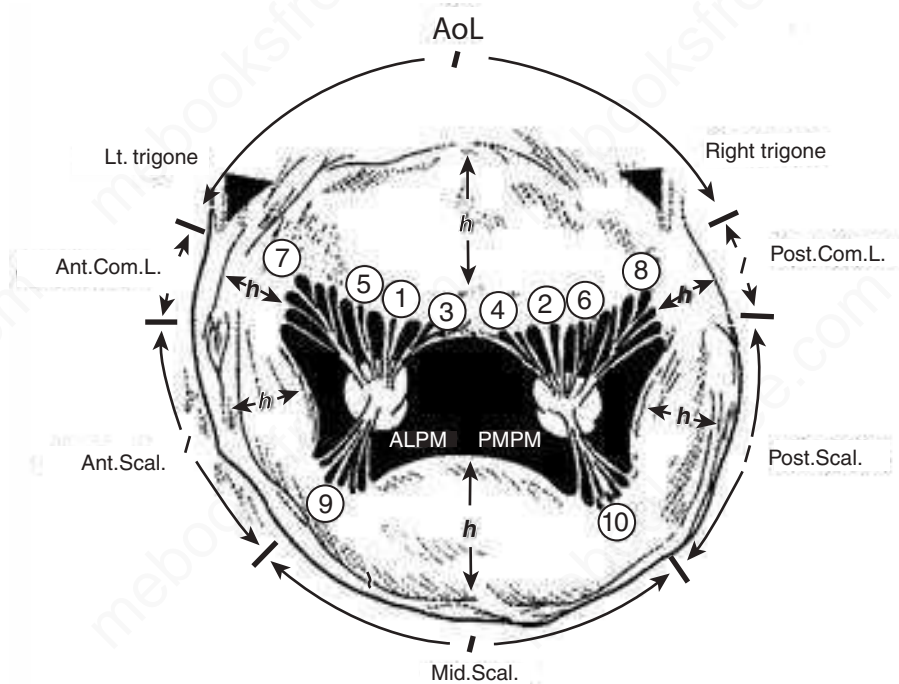

Valve closure starts with the leaflet bulging toward the atrium at its attachment point to the annulus. The closure rate of the anterior leaflet is almost twice that of the posterior leaflet, thereby ensuring arrival of both cusps at their closed positions simultaneously (because the anterior leaflet is opened more widely than the posterior leaflet at the onset of ventricular systole).<sup>40</sup> The anterior leaflet actually arrives at the plane of the annulus in a bulged shape (concave to the ventricle), but as the closing movement proceeds and the leaflet ascends toward the atrium, this curvature appears to run through the whole leaflet, from the annulus toward the edge, in a rolling manner. The leaflet edge is the last part of the leaflet to approach the annular plane.

### Chordae Tendinae and Papillary Muscles

Epicardial fibers in the left ventricle descend from the base of the heart and proceed inward at the apex to form the two papillary muscles, which are characterized by vertically oriented myocardial fibers.<sup>41,42</sup> The anterolateral papillary muscle usually has one major head and is a more prominent structure; the posteromedial papillary muscle can have two or more subheads and is flatter.<sup>4</sup> The posteromedial papillary muscle usually is supplied by the right coronary artery (or a dominant left circumflex artery in 10% of patients); the anterolateral papillary muscle is supplied by blood flow from

both the left anterior descending and circumflex coronary arteries.<sup>3,41,43</sup>

The posteromedial and anterolateral papillary muscles give rise to chordae tendinae going to both leaflets<sup>4,44</sup> (Fig. 34-3). Classically, the chordae are divided functionally into three groups.<sup>41,45</sup> First-order chordae originate near the papillary muscle tips, divide progressively, and insert on the leading edge of the leaflets; these primary chordae prevent valve-edge prolapse during systole. The second-order chordae (including two or more larger and less branched “strut” chordae) originate from the same location and tend to be thicker and fewer in number.<sup>4,45</sup> They insert on the ventricular surface of the leaflets at the junction of the rough and clear zones, which is demarcated by a subtle ridge on the leaflet corresponding to the line of leaflet coaptation. The second-order chordae (including the strut chordae) serve to anchor the valve, are more prominent on the anterior leaflet, and are important for optimal ventricular systolic function. Second-order chordae may arborize from large chordae that also give rise to first-order chordae. The third-order chordae, also called *tertiary* or *basal chordae*, originate directly from the trabeculae carneae of the ventricular wall, attach to the posterior leaflet near the annulus, and can be identified by their fan-shaped patterns.<sup>45</sup> Additionally, distinct commissural chordae and cleft chordae exist in the commissures. In total, about 25 major chordal trunks (range 15 to 32) arise from the papillary muscles in

**FIGURE 34-3** Mitral valve and subvalvular apparatus. (Reproduced with permission from Sakai T, Okita Y, Ueda Y, et al: Distance between mitral annulus and papillary muscles: anatomic study in normal human hearts, *J Thorac Cardiovasc Surg.* 1999 Oct;118(4):636-641.)

humans, equally divided between those going to the anterior and posterior leaflets; on the other end, greater than 100 smaller individual chordae attach to the leaflets.<sup>45</sup>

During diastole, the papillary muscles form an inflow tract. During systole, they create an outflow tract that later becomes obliterated owing to systolic thickening of the papillary muscles, thereby augmenting LV ejection by volume displacement.<sup>42</sup> The contribution of the papillary muscles to LV chamber volume is 5 to 8% during diastole but 15 to 30% during systole.<sup>42,46</sup> The anterolateral and posteromedial papillary muscles contract simultaneously and are innervated by both sympathetic and parasympathetic (vagal) nerves.<sup>47,48</sup> Excited synchronously with adjacent endocardium, the papillary muscles develop tension that significantly lags LV pressure and change length in concert with LV volume<sup>49-51</sup> (Fig. 34-4). At end of isovolumic contraction, therefore, very little papillary tension and/or contraction is available to hold the closed leaflets in place against systolic LV pressure. This has led to the suggestion that the leaflets in the closed valve are virtually self-supporting, which, in turn, has led to the following hypotheses<sup>51</sup>: (1) The chordae, having precise lengths and anchored by papillary tips that maintain a fixed geometric relationship to the mitral annulus, guide the leaflets into precise geometric shapes and positions at the moment of valve closure. If these initial geometric conditions are set properly at this instant (ie, the complex leaflet curvatures are set precisely and all leaflet edges are positioned precisely with respect to one another in the LV chamber), the resulting leaflet assemblage becomes a near-rigid body whose geometry is virtually independent of flow and pressure throughout systole. (2) Subsequent papillary force development, transmitted through secondary chords, contributes about 10% to the total force of LV contraction, particularly in mid-to-late systole. This may underlie the findings, originally by Lillehei and colleagues<sup>52</sup> but validated many times since, that clinical

outcomes are improved by chordal preservation during mitral valve replacement. (3) Papillary muscle force and shortening, continuing during and after ventricular relaxation, plays an active role in valve opening. (4) Anterior leaflet strut chords, always in tension, prevent leaflet intrusion into the outflow tract (ie, systolic anterior motion of the mitral valve) and bias leaflet motion toward closure throughout diastole.<sup>53</sup>

## MITRAL STENOSIS

### Etiology

Mitral stenosis generally is the result of rheumatic heart disease.<sup>54-62</sup> Nonrheumatic causes of mitral stenosis or LV inflow obstruction include severe mitral annular and/or leaflet calcification in the elderly, congenital mitral valve deformities, malignant carcinoid syndrome, neoplasm, LA thrombus, endocarditic vegetations, certain inherited metabolic diseases, and those cases related to previous commissurotomy or an implanted prosthesis.<sup>55-59,63,64</sup> A definite history of rheumatic fever can be obtained in only about 50 to 60% of patients; women are affected more often than men by a 2:1 to 3:1 ratio. Nearly always acquired before age 20, rheumatic valvular disease becomes clinically evident one to three decades later.

Globally, there are approximately 20 million cases of rheumatic fever, the greatest burden of which is evident as rheumatic heart disease with 282,000 new cases and 233,000 deaths annually.<sup>60-62,65</sup> In the United States, Western Europe, and other developed countries, the prevalence of mitral stenosis has decreased markedly. The etiologic agent for acute rheumatic fever is group A beta-hemolytic streptococcus, but the specific immunologic and inflammatory mechanisms leading to the valvulitis are less clear.<sup>61,62,65-68</sup> Streptococcal antigens cross react with human tissues, known as *molecular mimicry*,

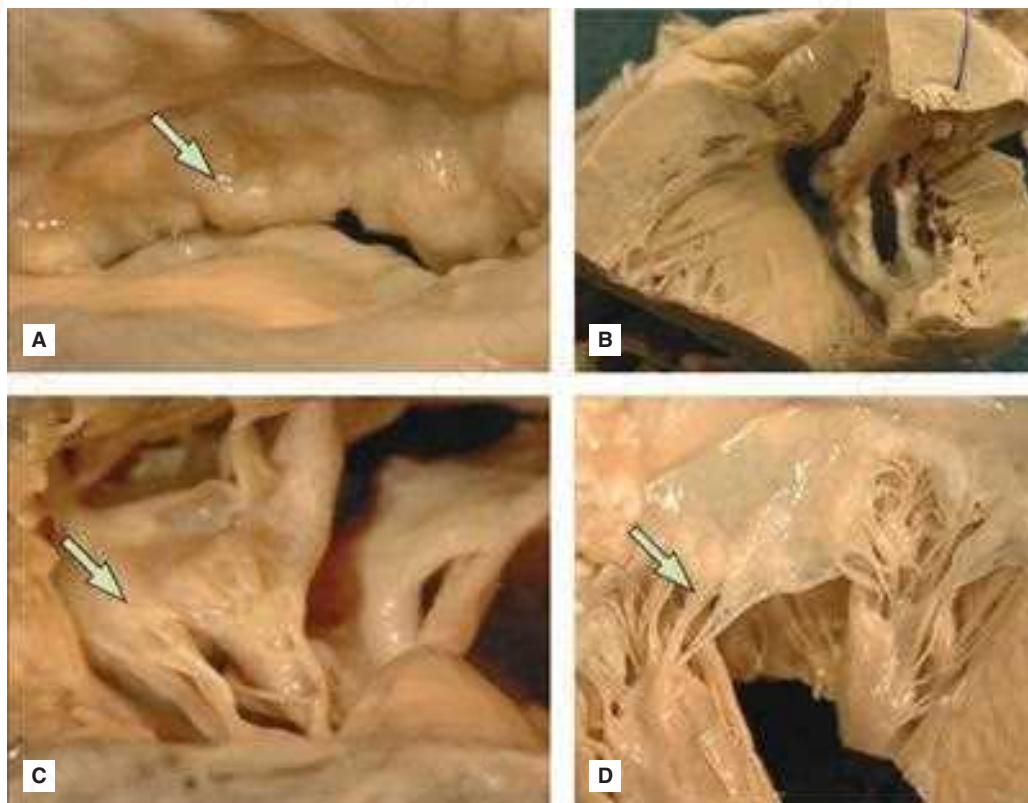

**FIGURE 34-4** (Left panel) Anterior and posterior papillary muscle force in relation to LVP. (Right panel) Anterior and posterior papillary muscle length in relation to LVP. (Reproduced with permission from Ingels NB, Jr. and Karlsson M. *Mitral valve mechanics*. Linköping Sweden: Linköping Press; 2015.)

and may stimulate immunologic responses. Components implicated in the organism's virulence include the hyaluronic acid capsule and the antigenic streptococcal M-protein and its peptides.<sup>61,65-67</sup> Mimicry between streptococcal antigens and heart tissue proteins, combined with high inflammatory cytokine and low interleukin-4 production, leads to the development of autoimmune reactions and cardiac tissue damage.<sup>61,66,67</sup> In acute rheumatic fever and rheumatic heart disease, M-protein can cross react with cardiac myosin, which induces T-cell-mediated injury of cardiac tissue and valves.<sup>61</sup>

In addition to valvular involvement, rheumatic heart disease is a pancarditis affecting to various degrees the endocardium, myocardium, and pericardium<sup>54,58,61</sup> (Fig. 34-5). In rheumatic valvulitis, mitral valve involvement is the most common (isolated mitral stenosis is found in 40% of patients), followed by combined aortic and mitral valve disease, and least frequently, isolated aortic valve disease. Pathoanatomical characteristics of mitral valvulitis include commissural fusion, leaflet fibrosis with stiffening and retraction, and chordal fusion and shortening<sup>59</sup> (Fig. 34-6). Leaflet stiffening and fibrosis can be exacerbated over time by increased flow turbulence. Valvular regurgitation can develop as a result of chordal fusion and shortening. The degree of calcification varies and is more common and of greater severity in men, older patients, and those with a higher transvalvular

**FIGURE 34-5** Intraoperative photograph of mitral stenosis as a result of rheumatic heart disease. The mitral leaflets are markedly restricted. The arrowheads point to the fused anterolateral commissure. (Used with permission from David H. Adams, MD.)

**FIGURE 34-6** Pathology of the mitral valve in mitral stenosis. Thickened, rigid nodular appearance of the mitral valve leaflets viewed from the atria (A) and ventricle (B). Calcium is present in the commissure and the commissures are fused, resulting in a valve shaped like a fish mouth. Subvalvular apparatus is thick, fused, and shortened (B, C). Healthy mitral valve leaflets (D). (Reproduced with permission from Chandrashekar Y, Westaby S, Narula J: Mitral stenosis, *Lancet*. 2009 Oct 10;374(9697):1271-1283.)

gradient.<sup>54</sup> In some cases, rheumatic myocarditis results in LV dilatation and progressive heart failure.

Mitral annular calcification may progress to mitral sclerosis and stenosis in the elderly or those who are dialysis dependent.<sup>59,64</sup> The anterior leaflet can become thick and immobile; LV inflow obstruction also results from calcification of the posterior mitral valve leaflet. Calcific protrusions into the ventricle and extension of the calcium into the leaflets further narrow the valve orifice, resulting in mitral stenosis.<sup>59,64</sup> In these cases, the left ventricle typically is small, hypertrophied, and noncompliant.

## Hemodynamics

In patients with mitral stenosis, an early, middle, and late diastolic transvalvular gradient is present between the left atrium and ventricle; as the degree of mitral stenosis worsens, a progressively higher gradient occurs, especially late in diastole.<sup>55,69,70</sup> The average LA pressure in patients with severe mitral stenosis may be in the range of 15 to 20 mm Hg at rest, with a mean transvalvular gradient of 10 to 15 mm Hg.<sup>69,70</sup> With exercise, the LA pressure and gradient rise substantially.

Another physiologic measurement in patients with mitral stenosis is the (derived) cross-sectional valve area, which is calculated from the mean transvalvular pressure gradient and cardiac output. The transvalvular pressure gradient is a function of the square of the transvalvular flow rate; for example, doubling the flow quadruples the gradient. Mitral transvalvular flow depends on cardiac output and heart rate. An increase in heart rate decreases the duration of transvalvular LV filling during diastole; the transvalvular mean gradient increases, and consequently, so does LA pressure.<sup>71</sup> A high transvalvular gradient may be associated with a normal cardiac output. Conversely, if cardiac output is low, only a modest transvalvular gradient may be present.

Because of effective atrial contraction, the mean LA pressure in patients with mitral stenosis and normal sinus rhythm is lower than that in patients with atrial fibrillation.<sup>72,73</sup> Sinus rhythm further augments flow through the stenotic valve, thereby helping to maintain adequate forward cardiac output. The development of atrial fibrillation decreases cardiac output by 20% or more; atrial fibrillation with a rapid ventricular response can lead to acute dyspnea and pulmonary edema.<sup>72</sup>

## Ventricular Adaptation

In patients with isolated mitral stenosis and restricted LV inflow, LV end-diastolic volume is normal or smaller than normal, and the end-diastolic pressure typically is low.<sup>55,74,75</sup> The peak filling rate is reduced, as is stroke volume. Cardiac output thus is diminished as a result of inflow obstruction leading to underfilling of the ventricle rather than LV pump failure.<sup>76</sup> During exercise, LV ejection fraction (LVEF) may increase slightly; however, LV filling is compromised by the shorter diastolic filling periods at higher heart rates, resulting in a smaller end-diastolic volume (or LV preload). Therefore,

stroke volume and a blunted increase (or even decrease) in cardiac output can occur.<sup>75</sup>

Approximately 25 to 50% of patients with severe mitral stenosis have LV systolic dysfunction as a consequence of associated problems (eg, mitral regurgitation, aortic valve disease, ischemic heart disease, rheumatic myocarditis or pancarditis, and myocardial fibrosis) or internal constraint of a rigid mitral valve, reduced preload, and reflex increase in afterload.<sup>54,59,70,75</sup> In these patients, LV end-systolic and diastolic volumes may be larger than normal. Diastolic dysfunction and abnormal chamber compliance are sometimes evident.<sup>59</sup> Also, because right ventricular afterload increases as pulmonary hypertension develops in these patients, right ventricular systolic performance deteriorates.<sup>55,77</sup>

## Atrial Adaptation

In patients with mitral stenosis who are in normal sinus rhythm, the LA pressure tracing is characterized by an elevated mean LA pressure with a prominent a wave.<sup>73</sup> Because of the stenotic valve, coordinated LA contraction is important in maintaining adequate transvalvular flow.<sup>73</sup> The high LA pressure gradually leads to LA hypertrophy and dilatation, atrial fibrillation, and atrial thrombus formation.<sup>54,75,76</sup> The degree of LA enlargement and fibrosis does not correlate with the severity of the valvular stenosis partly because of the marked variation in duration of the stenotic lesion and atrial involvement by the underlying rheumatic inflammatory process.<sup>75</sup> Disorganized atrial muscle fibers are associated with abnormal conduction velocities and inhomogeneous refractory periods. Premature atrial activation owing to increased automaticity or reentry eventually may lead to atrial fibrillation, which is present in more than half of patients with either pure mitral stenosis or mixed mitral stenosis and regurgitation.<sup>78</sup> Major determinants of atrial fibrillation in patients with rheumatic heart disease include older age and larger LA diameter.<sup>78</sup>

## Pulmonary Changes

In patients with mild-to-moderate mitral stenosis, pulmonary vascular resistance is not increased, and pulmonary arterial pressure may remain normal at rest, rising only with exertion or increased heart rate.<sup>69</sup> In severe chronic mitral stenosis with elevated pulmonary vascular resistance, pulmonary arterial pressure is elevated at rest and can approach systemic pressure with exercise. A pulmonary arterial systolic pressure greater than 60 mm Hg significantly increases impedance to right ventricular emptying and produces high right ventricular end-diastolic and right atrial pressures.

LA hypertension produces pulmonary vasoconstriction, which exacerbates the elevated pulmonary vascular resistance.<sup>54,77</sup> As the mean LA pressure exceeds 30 mm Hg above oncotic pressure, transudation of fluid into the pulmonary interstitium occurs, leading to reduced lung compliance. Pulmonary hypertension develops as a result of passive transmission of high LA pressure, pulmonary venous hypertension, pulmonary arteriolar constriction, and eventually,

pulmonary vascular obliterative changes. Early changes in the pulmonary vascular bed may be considered protective in that the elevated pulmonary vascular resistance protects the pulmonary capillary bed from excessively high pressures. However, the pulmonary hypertension worsens progressively, leading to right-sided heart failure, tricuspid insufficiency, and occasionally, pulmonic valve insufficiency.<sup>55,77,60</sup>

## Clinical Evaluation

Because of the gradual development of mitral stenosis, patients may remain asymptomatic for many years.<sup>59,60,69,79,80</sup> Characteristic symptoms of mitral stenosis eventually develop and are associated primarily with pulmonary venous congestion or low cardiac output, for example, dyspnea on exertion, orthopnea, or paroxysmal nocturnal dyspnea and fatigue. With progressive stenosis (valve area between 1 and 2 cm<sup>2</sup>), patients become symptomatic with less effort. Correspondingly, the transmitral mean gradient is usually between 5 and 10 mm Hg at a normal heart rate.<sup>80</sup> The mean pressure gradient is dependent on the transvalvular flow and diastolic filling period and will vary with changes in heart rate. When mitral valve area decreases to about 1 cm<sup>2</sup>, symptoms become more pronounced. As pulmonary hypertension and right-sided heart failure subsequently develop, signs of tricuspid regurgitation, hepatomegaly, peripheral edema, and ascites can be found.

As a result of high LA pressure and increased pulmonary blood volume, hemoptysis may develop secondary to rupture of dilated bronchial veins (or submucosal varices).<sup>59,77,79</sup> Over time, pulmonary vascular resistance becomes higher, and the likelihood of hemoptysis decreases. Hemoptysis also may result from pulmonary infarction, which is a late complication of chronic heart failure. Acute pulmonary edema with pink frothy sputum can occur as a result of alveolar capillary rupture.

Systemic thromboembolism, occurring in approximately 20% of patients, may be the first symptom of mitral stenosis; recurrent embolization occurs in 25% of patients.<sup>79,81</sup> The incidence of thromboembolic events is higher in patients with mitral stenosis or mixed mitral stenosis-mitral regurgitation than in those with pure mitral regurgitation. At least 40% of all clinically important embolic events involve the cerebral circulation, approximately 15% involve the visceral vessels, and 15% affect the lower extremities.<sup>79,82</sup> Embolization to coronary arteries may lead to angina, arrhythmias, or myocardial infarction; renal embolization can result in hypertension.<sup>79</sup> Factors that increase the risk of thromboembolic events include low cardiac output, LA dilatation, atrial fibrillation, LA thrombus, absence of tricuspid or aortic regurgitation, and the presence of echocardiographic “smoke” in the atrium, an indicator of stagnant flow. Patients with these risk factors should be anticoagulated.<sup>79,81,82</sup> If an episode of systemic embolization occurs in patients in sinus rhythm, infective endocarditis, which is more common in mild than in severe mitral stenosis, should be considered.

Patients with chronic mitral stenosis are often thin and frail (cardiac cachexia), indicative of longstanding low cardiac output, congestive heart failure, and inanition.<sup>79</sup> Heart size usually

is normal, with a normal apical impulse on chest palpation. An apical diastolic thrill may be present. In patients with pulmonary hypertension, a right ventricular lift can be felt in the left parasternal region. Auscultatory findings include a presystolic murmur, a loud S1, an opening snap, and an apical diastolic rumble.<sup>59,79,83,84</sup> The presystolic murmur, which occurs because of closing of the anterior mitral leaflet, is a consistent finding and begins earlier in those in sinus rhythm than in those in atrial fibrillation.<sup>84</sup> S1 is accentuated in mitral stenosis when the leaflets are pliable but diminished in later phases of the disease when the leaflets are thickened or calcified. As pulmonary artery pressure becomes elevated, S2 becomes prominent.<sup>85</sup> With progressive pulmonary hypertension, the normal splitting of S2 narrows because of reduced pulmonary vascular compliance. Other signs of pulmonary hypertension include a murmur of tricuspid and/or pulmonic regurgitation and an S4 originating from the right ventricle. Best heard at the apex, the early diastolic mitral opening snap is caused by sudden tensing of the pliable leaflets during valve opening and is absent when the leaflets are rigid or immobile.<sup>79,83</sup> In mild mitral stenosis, the diastolic rumble is soft and of short duration; a long or holodiastolic murmur indicates severe mitral stenosis. The intensity of the murmur does not necessarily correlate with the severity of the stenosis; indeed, no diastolic murmur may be detectable in patients with severe stenosis, calcified leaflets, or low cardiac output.<sup>84</sup>

On chest radiography, LA enlargement is the earliest change found in patients with mitral stenosis; it is suggested by posterior bulging of the left atrium seen on the lateral view, a double contour of the right heart border seen on the postero-anterior film, and elevation of the left main stem bronchus.<sup>69</sup> The overall cardiac size often is normal. Prominence of the pulmonary arteries coupled with LA enlargement may obliterate the normal concavity between the aorta and left ventricle to produce a straight left heart border. In the lung fields, pulmonary congestion may be recognized as distention of the pulmonary arteries and veins in the upper lung fields and pleural effusions. If mitral stenosis is severe, engorged pulmonary lymphatics are seen as distinct horizontal linear opacities in the lower lung fields (Kerley B lines).

The electrocardiogram is not accurate in assessing the severity of mitral stenosis and in many cases may be completely normal. In patients with severe mitral stenosis and normal sinus rhythm, LA enlargement is the earliest change (a wide notched P wave in lead II and a biphasic P wave in lead V1).<sup>59,69,86</sup> Atrial arrhythmias are common in patients with advanced degrees of mitral stenosis. In those with pulmonary hypertension, right ventricular hypertrophy may develop and is associated with right axis deviation, a tall R wave in V1, and secondary ST-T-wave changes; however, the electrocardiogram is not a sensitive indicator of right ventricular hypertrophy or the degree of pulmonary hypertension.<sup>86</sup>

Echocardiography has become the primary diagnostic method for assessing mitral valve pathology and pathophysiology.<sup>3,59,60,80,87-89</sup> Cross-sectional valve area and LA and LV dimensions can be quantified using two-dimensional (2D) transthoracic echocardiography (TTE).

**FIGURE 34-7** (A) Echocardiogram (long axis) transthoracic view of a patient with leaflet thickening and severe mitral stenosis caused by rheumatic heart disease. A thickened, stenotic valve separates an enlarged left atrium (*right*) and the left ventricle (*left*). (B) The immobility of the posterior leaflet and the doming of the anterior leaflet as typical morphological characteristics of rheumatic mitral valve disease are shown in a three-dimensional transesophageal image. The three-dimensional transesophageal images (left atrial aspect (C) and left ventricular aspect (D)) show the fusion of both commissures (red arrows). AML, anterior mitral leaflet; PML, posterior mitral leaflet. (Reproduced with permission from Wunderlich NC, Beigel R, Siegel RJ: Management of mitral stenosis using 2D and 3D echo-Doppler imaging, *JACC Cardiovasc Imaging*. 2013 Nov;6(11):1191-1205.)

Best appreciated in the parasternal long-axis view, features of rheumatic mitral stenosis include reduced diastolic excursion of the leaflets (Carpentier type IIIa leaflet motion, see below) and thickening or calcification of the valvular and subvalvular apparatus (Fig. 34-7A). M-mode findings include thickening, reduced motion, and parallel movement of the anterior and posterior leaflets during diastole. Doppler echocardiography accurately determines peak and mean transvalvular mitral pressure gradients that correlate closely with cardiac catheterization measurements.<sup>87</sup> To estimate mitral valve area, the pressure half-time (time required for the initial diastolic gradient to decline by 50%) has been employed; the more prolonged the half-time, the

more severe is the reduction in orifice area.<sup>60,87</sup> Using the pressure half-time determination, mitral valve area is equal to 220 (an empirical value) divided by the pressure half-time. Deriving mitral valve area using the pressure half-time method, however, generally has fallen out of favor. The mean mitral gradient at rest and with bicycle or supine exercise measured using Doppler echocardiography is more useful clinically than estimating mitral valve area; the simultaneous increase in right ventricular systolic pressure (estimated from continuous-wave or pulse-wave Doppler envelopes of the tricuspid regurgitation signal) during exercise is also revealing. The mitral separation index, which is the average of the maximum separation of the mitral leaflet

tips in diastole in parasternal and apical four-chamber views, shows good correlation with mitral valve area measured by planimetry and pressure half-time and may be able to discriminate between hemodynamically significant and insignificant mitral stenosis.<sup>90</sup> Transesophageal echocardiography (TEE) is better than the transthoracic approach for visualizing details of valvular pathology, such as valve mobility and thickness, subvalvular apparatus involvement, and extent of leaflet or commissural calcification.<sup>59,60,87,88</sup>

Three-dimensional echocardiography facilitates spatial recognition of intracardiac structures and can evaluate cardiac valvular and congenital heart disease using both real-time 3D TTE and TEE images<sup>60,89,91</sup> (Fig. 34-7B-D). The addition of color-flow Doppler to 3D echocardiography provides better visualization of regurgitant lesions. Measurements of LV volume using 3D echocardiography correlate tightly with measurements obtained using both contrast ventriculography and magnetic resonance imaging (MRI). Cardiac MRI technology remains inferior to echocardiography for depiction of valvular morphology and motion.<sup>92</sup> Multidetector computed tomography (CT) may emerge as a technique that can evaluate both cardiac structure and function. Experience with gated multidetector CT has yielded good visualization of valve leaflet hinges, commissures, and the mitral annulus.<sup>93</sup>

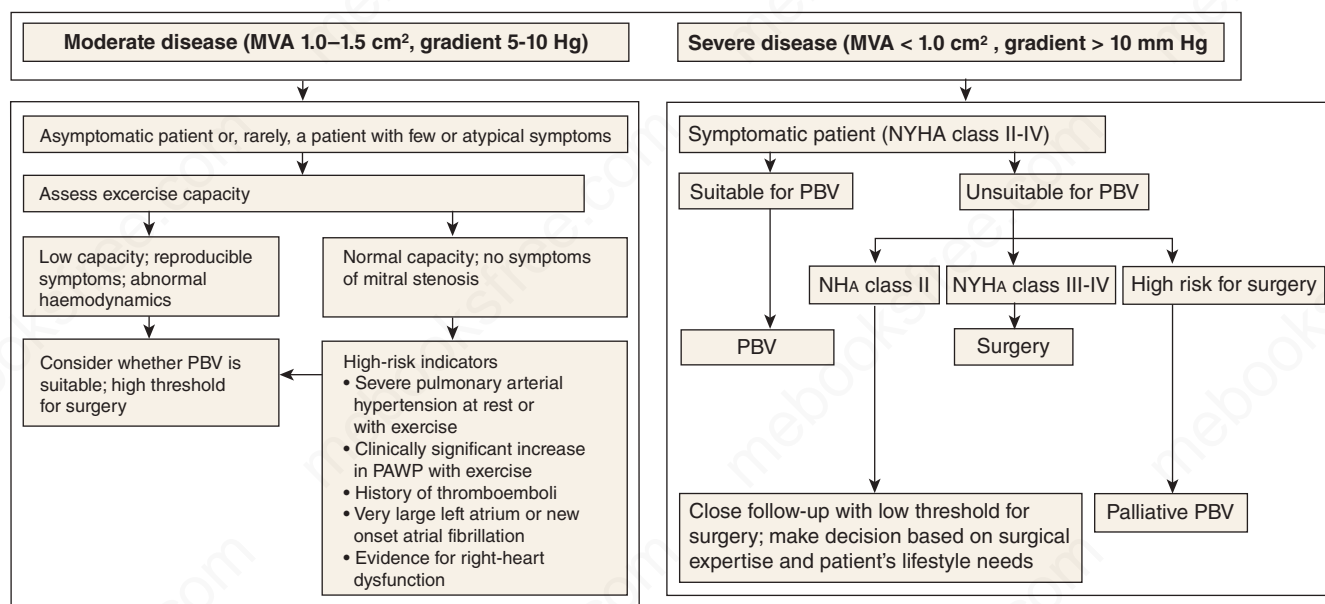

Cardiac catheterization is not necessary to establish the diagnosis of mitral stenosis; however, it provides information regarding coronary artery status in older patients. Left-sided heart catheterization allows determination of LV end-diastolic pressure; right-sided heart catheterization is performed to measure cardiac index and the degree of pulmonary hypertension. Rarely, cardiac catheterization is used

to evaluate the reversibility of severe pulmonary hypertension using pharmacologic interventions, including inhaled nitric oxide when indicated.

## Postprocedure Outcome

Whereas LV systolic function is used to predict the natural history and postoperative prognosis of patients with other valvular lesions, there are few data linking LV function to outcome in patients with mitral stenosis. Not surprisingly, the best indicator is related to the degree of clinical impairment. Untreated mitral stenosis is associated with a poor prognosis once severe symptoms occur.<sup>59</sup> Percutaneous balloon valvuloplasty is the mainstay of treatment of mitral stenosis provided the anatomy is favorable<sup>59,60,80</sup> (Fig. 34-8). Generally, the technique immediately doubles mitral valve area and decreases the gradient substantially in properly selected patients with rheumatic mitral stenosis. Approximately 90% of patients improve clinically if a valve area greater than 1.5 cm<sup>2</sup> without significant regurgitation can be achieved.<sup>94</sup> Surgical intervention (eg, open mitral commissurotomy or mitral valve replacement) substantially improves functional capacity and long-term survival of patients with mitral stenosis; 67 to 90% of patients are alive at 10 years.<sup>86,95-97</sup>

Despite a higher operative risk for patients with severe pulmonary hypertension and right-sided heart failure, these individuals usually improve postoperatively with a reduction in pulmonary vascular pressures.<sup>55,98</sup> If there is not excessive scarring of the subvalvular mitral apparatus, mitral valve replacement using chordal-sparing techniques can be performed in patients with rheumatic mitral valve

**FIGURE 34-8** Treatment strategies for mitral stenosis. MVA, mitral valve area; NYHA, New York Heart Association functional class; PAWP, pulmonary artery wedge pressure; PBV, percutaneous balloon valvuloplasty. Severe mitral stenosis is rarely asymptomatic and, for such patients, we suggest use of the algorithm for assessment of patients with moderate disease. (Reproduced with permission from Chandrashekar Y, Westaby S, Narula J: Mitral stenosis, *Lancet*. 2009 Oct 10;374(9697):1271-1283.)

disease, particularly those with mixed stenotic and regurgitant lesions; this results in a reduction in LV end-systolic and end-diastolic volumes and preservation of LV systolic pump performance.<sup>99,100</sup> Alternatively, the valve and the entire subvalvular apparatus have to be resected during mitral valve replacement when the disease process is very advanced and all structures are densely calcified and extremely scarred, which frequently is the case in older patients.

## Summary

Mitral stenosis generally is caused by rheumatic heart disease. With worsening mitral stenosis, a progressively higher transvalvular pressure gradient develops. Mitral transvalvular flow depends on cardiac output and heart rate; an increase in heart rate decreases the duration of transvalvular filling during diastole and reduces forward cardiac output, causing symptoms. In mild-to-moderate mitral stenosis, pulmonary vascular resistance may not be elevated; pulmonary arterial pressure may be normal at rest and rise only with exercise or increased heart rate. In patients with severe mitral stenosis with elevated pulmonary vascular resistance, the pulmonary arterial pressure usually is high at rest. Characteristic symptoms of mitral stenosis are associated with pulmonary venous congestion and/or low cardiac output. Echocardiography remains the best technique for assessing mitral valve pathology. Percutaneous or surgical intervention can improve functional capacity and long-term survival of patients with mitral stenosis.

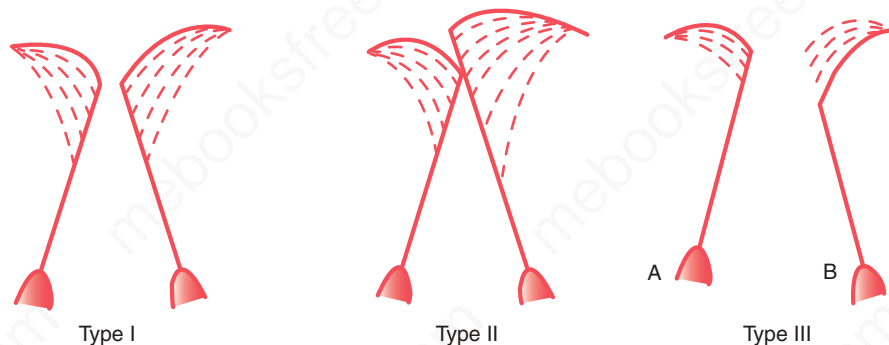

## MITRAL REGURGITATION

### Etiology

The functional competence of the mitral valve relies on proper, coordinated interaction of the mitral annulus and leaflets, chordae tendineae, papillary muscles, left atrium, and left ventricle, known as the *valvular-ventricular complex*.<sup>41,101-104</sup> Normal LV geometry and alignment of the papillary muscles and chordae

tendineae permit leaflet coaptation and prevent prolapse during ventricular systole. Dysfunction of any one or more of the components of this valvular-ventricular complex can lead to mitral regurgitation. Important causes of mitral regurgitation include myxomatous degeneration (“primary” mitral regurgitation), ischemic heart disease with ischemic mitral regurgitation (IMR), dilated cardiomyopathy [for which the general term *functional mitral regurgitation* (FMR) is used], rheumatic valve disease, mitral annular calcification, infective endocarditis, congenital anomalies, endocardial fibrosis, myocarditis, and collagen-vascular disorders.<sup>54,57,58,105-108</sup> IMR is considered a specific subset of FMR, which is now termed “secondary” mitral regurgitation. Acute mitral regurgitation also may be the result of ventricular dysfunction from rapidly developing cardiomyopathy, such as Takotsubo cardiomyopathy, in which the mitral regurgitation is caused by LV outflow tract obstruction and systolic anterior motion of the mitral valve from apical ballooning.<sup>109</sup>

In general, four types of structural changes of the mitral valve apparatus may produce regurgitation: leaflet retraction from fibrosis and calcification, annular dilatation, chordal abnormalities (including rupture, elongation, or shortening), and LV systolic dysfunction with or without papillary muscle involvement.<sup>41,110-116</sup> Carpentier classified mitral regurgitation according to three main pathoanatomic types based on mitral leaflet motion: normal leaflet motion (type I), leaflet prolapse or excessive motion (type II), and restricted leaflet motion (type III).<sup>110,111</sup> Type III is further subdivided into types IIIa and IIIb based on leaflet restriction during diastole (type IIIa), as seen in rheumatic disease, or during systole (type IIIb), which is typically seen in IMR (Fig. 34-9). Mitral regurgitation with normal leaflet motion can result from annular dilatation, often secondary to LV dilatation, for example, patients with dilated cardiomyopathy or ischemic cardiomyopathy. Normal leaflet motion also includes patients with leaflet perforation due to endocarditis or a congenital cleft. Leaflet prolapse typically results from a floppy mitral valve with chordal elongation and/or rupture, but rarely also can be seen in patients with coronary artery disease who have papillary muscle elongation

**FIGURE 34-9** Carpentier's functional classification of the types of leaflet and chordal motion associated with mitral regurgitation. In type I, the leaflet motion is normal. Type II mitral regurgitation is caused by leaflet prolapse or excessive motion. Type III (restricted leaflet motion) is subdivided into restriction during diastole (A) or systole (B). Type IIIb typically is seen in patients with ischemic mitral regurgitation. The course of the leaflets during the cardiac cycle is represented by the dotted lines. (Modified with permission from Carpentier A: Cardiac valve surgery—the “French correction,” *J Thorac Cardiovasc Surg.* 1983 Sep;86(3):323-337.)

or rupture. Mitral regurgitation caused by restricted leaflet motion is associated with rheumatic valve disease (types IIIa and IIIb), ischemic heart disease (IMR with type IIIb restricted systolic leaflet motion secondary to apical tethering or tenting), and dilated cardiomyopathy (type IIIb).<sup>111,112</sup>

### MYXOMATOUS DEGENERATION

Myxomatous degeneration of the mitral valve, also known as *floppy mitral valve* or *mitral valve prolapse* and considered primary mitral regurgitation, is the most common cause of mitral regurgitation in patients undergoing surgical evaluation in the United States.<sup>41,108,117-120</sup> Afflicting 2 to 3% of the general population, mitral valve prolapse is both acquired (*fibroelastic deficiency* in older patients) and congenital or heritable, with excess spongy, weak fibroelastic connective tissue constituting the leaflets and chordae tendineae (*Barlow's valve* in younger patients)<sup>54,80,108,121,122</sup> (Fig. 34-10). Associated with connective tissue disorders, such as Marfan syndrome, Ehlers-Danlos, Loeys-Dietz syndrome, osteogenesis imperfecta, pseudoxanthoma elasticum, and aneurysm-osteoarthritis syndrome, mitral valve prolapse appears to be the result of multiple genetic pathways and can be sporadic or familial with autosomal dominant and X-linked inheritance.<sup>108,123,124</sup> Although three different loci on chromosomes 16, 11, and 13 (autosomal dominant) are linked to mitral valve prolapse, no specific gene has yet been incriminated.<sup>108,123,124</sup> Also, a locus on chromosome X cosegregates with a rare form of mitral valve prolapse called *X-linked myxomatous mitral valve dystrophy*.<sup>108,124</sup> Upregulation of transforming growth factor-beta and the mutations of the cytoplasmic protein filamins appear

to have a pivotal role in various pathways in the pathogenesis of mitral valve prolapse.<sup>108</sup> Because the dysfunctional valve is the disease, myxomatous degeneration of the mitral valve is considered primary mitral regurgitation.<sup>80,125</sup>

Some degree of mitral valve prolapse is seen echocardiographically in 5 to 6% of the female population.<sup>121,126</sup> The risk of endocarditis is increased only if valvular regurgitation is present and accompanied by a murmur. Mitral valve prolapse appears to be more widespread in women, but severe mitral regurgitation resulting from mitral valve prolapse is more common in men. Subtle signs of heart failure, usually manifest as declining stamina and fatigue, may be the presenting complaint in 25 to 40% of symptomatic patients with mitral valve prolapse. As strictly defined originally by John Barlow, "Barlow's syndrome" includes prolapse of the posterior leaflet and chest pain, and occasionally palpitations, syncope, and dyspnea; in younger patients, the initial clinical sign is a midsystolic nonejection click, which later evolves into a click followed by a late systolic murmur.<sup>121</sup> This latter scenario is seen typically in young patients with Barlow's valves, in which large amounts of excessive leaflet tissue and marked annular dilatation are coupled with extensive billowing of both leaflets. Because many patients have had symptoms consistent with mitral valve prolapse syndrome for many years prior to developing significant mitral regurgitation, in certain patients, beta-adrenergic receptor polymorphisms may play a role in the pathogenesis of symptoms.<sup>127</sup>

Pathologically, the atrial aspect of the prolapsing mitral leaflet often is thickened focally, whereas the changes on the ventricular surface of the leaflet consist of connective tissue thickening primarily on the interchordal segments with fibrous proliferation into adjacent chordae and onto the ventricular endocardium.<sup>54,108,121,122</sup> Histologically, elastic fiber and collagen fragmentation and disorganization are present, and acid mucopolysaccharide material accumulates in the leaflets. Myxomatous degeneration commonly involves the annulus, resulting in annular thickening and dilatation. All these changes are pronounced in young patients with Barlow's valves but can be minimal in older subjects with fibroelastic deficiency, in whom the noninvolved posterior leaflet scallops and anterior leaflet are normal and thin.<sup>80</sup> It is important to recognize that these two distinct varieties of mitral valve prolapse exist and can be segregated on clinical grounds, even if pathologists have difficulty discriminating between the two, because the repair techniques differ in major ways. Many centers like the Mayo Clinic encounter mainly elderly patients with coronary artery disease and fibroelastic deficiency (78% of their surgical "flail" leaflet surgical population were greater than 60 years old and/or required concomitant coronary artery bypass grafting), in whom the valvular pathology is limited, and simple repair techniques, such as the small McGoon triangular excision of the middle scallop of the posterior leaflet, are applicable and work well.<sup>128</sup> In contrast, other institutions may attract younger patients who have Barlow's valves or severely myxomatous mitral valves, circumstances that demand much more extensive repair techniques and different expertise.

**FIGURE 34-10** Intraoperative photograph of fibroelastic deficiency (A) and Barlow's disease (B). (Used with permission from David H. Adams, MD.)

Only 5 to 10% of patients with mitral valve prolapse progress to develop severe mitral regurgitation, and they can remain relatively asymptomatic for many years.<sup>121</sup> Mechanisms accounting for severe mitral regurgitation in those with mitral valve prolapse include annular dilatation and rupture or elongation of the first-order chordae (58%), annular dilatation without chordal rupture (19%), and chordal rupture without annular dilatation (19%).<sup>122</sup> Chordal rupture, probably related to defective collagen, underlying papillary muscle fibrosis or dysfunction, or bacterial endocarditis, typically is the culprit when mitral regurgitation develops acutely in patients without any previous symptoms of heart disease or suddenly becomes worse in those with known mitral valve prolapse.<sup>41,54,56,57,106,108,129</sup> Chordal rupture is evident in 14 to 23% of surgically excised purely regurgitant valve specimens; in 73 to 93% of these patients, the underlying pathology is degenerative or floppy mitral valves.<sup>56,57,106</sup> Posterior chordal rupture, usually subtending just the middle scallop, is the most frequent finding, followed by anterior chordal rupture and then combined anterior and posterior chordal rupture.<sup>56,57,106</sup>

### FUNCTIONAL AND ISCHEMIC MITRAL REGURGITATION

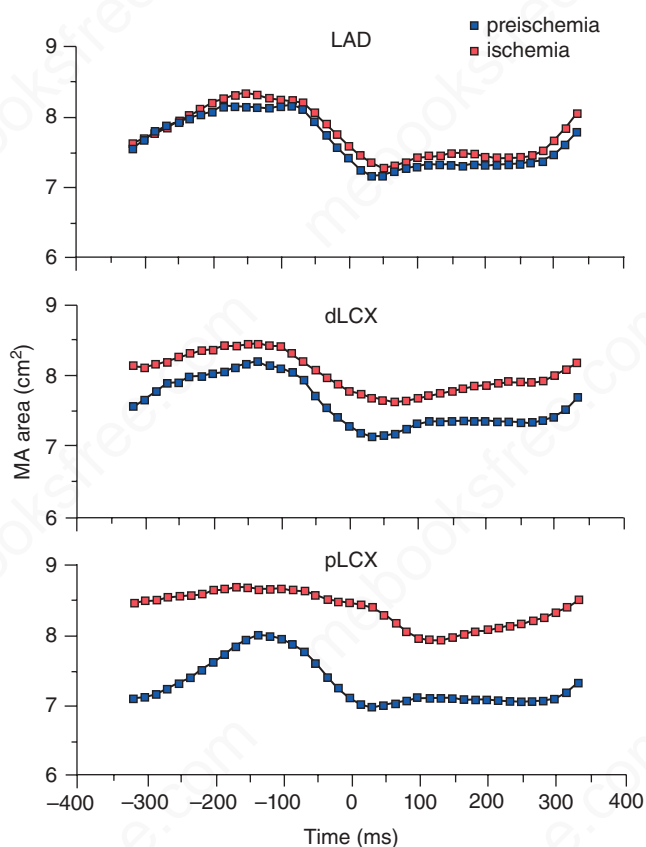

FMR is the result of incomplete mitral leaflet coaptation in the setting of LV systolic dysfunction and dilatation with or without annular dilatation (eg, dilated cardiomyopathy or ischemic cardiomyopathy) and is thus now termed secondary mitral regurgitation.<sup>80,113-116,125</sup> LV systolic dysfunction and dilatation also may be associated with longstanding mitral regurgitation caused by severe chronic LV volume overload. Most commonly, the etiology of nonischemic cardiomyopathy is unknown or idiopathic; the second most common cause is advanced valvular disease. FMR occurs in 40% of patients with heart failure caused by dilated cardiomyopathy.<sup>116</sup>

IMR, a subset of FMR, is becoming widely appreciated as the population ages and more patients survive acute myocardial infarction. In those with acute infarction, IMR occurs in approximately 15% of patients with anterior wall involvement and up to 40% of patients with an inferior infarct.<sup>56,57,130</sup> Generally, the severity of mitral regurgitation is related to the size of the area of LV akinesia or dyskinesia. The pathophysiology of IMR can be attributed to changes in global and regional LV function or geometry, alterations in mitral annular geometry, abnormal leaflet motion and malcoaptation, increased interpapillary distance, and papillary muscle malalignment leading to apical tethering of the leaflets with restricted systolic leaflet motion (type IIIb).<sup>110,113,114,130-139</sup> Because of the interdependence of the elements constituting the valvular-ventricular complex in IMR, perturbation of any component, such as LV systolic function and geometry, annular geometry, leaflet motion and morphology, and papillary and chordal relationship, may result in mitral regurgitation.

**Left Ventricular Systolic Function and Geometry.** Although LV dilatation and dysfunction are less pronounced in the setting of inferior myocardial infarction than that

affecting the anterior wall, the incidence and severity of mitral regurgitation are greater in patients with inferior infarction.<sup>56,57,130,132,134</sup> Over time, as the left ventricle dilates and changes shape after the ischemic event (postinfarction remodeling), the degree of IMR progresses.<sup>115,134,140</sup> Geometric changes associated with ventricular remodeling, such as posteromedial papillary muscle dislocation in the lateral axis, may lead to leaflet tenting, as reflected by a larger distance from the middle of the anterior annulus (saddle horn on echocardiography) to the posteromedial papillary muscle tip, and increased annular diameter.<sup>115,135,136,140</sup> At the ventricular level, myocardial infarction associated with chronic IMR is associated with greater adverse perturbations in LV systolic torsion and diastolic recoil than myocardial infarction without chronic IMR.<sup>141</sup> These abnormalities may be linked to more LV dilatation, which possibly reduces the effectiveness of fiber shortening on torsion generation. Altered LV torsion and recoil may contribute to the “ventricular disease” component of chronic IMR, with increased gradients of myocardial oxygen consumption adversely affecting cardiac efficiency and impaired early diastolic filling.<sup>141</sup> Additionally, in a subacute model of IMR (less than 7 weeks), there is an equivalent increase in LV end-diastolic volume in those with mild mitral regurgitation compared to those with more severe mitral regurgitation, coupled with unchanged end-diastolic and end-systolic remodeling strains, including systolic circumferential, longitudinal, and radial strains; these findings in aggregate argue against an intracellular (cardiomyocyte) mechanism for the LV dysfunction.<sup>142</sup> Instead, differences in subepicardial shear strains suggest a causal role of altered interfiber interactions, and the mechanical impairment may be in extracellular matrix between the fibers and the microtubules in the cytoskeleton that couple cardiomyocyte shortening to LV wall thickening.<sup>142</sup>

**Annular Geometry.** In IMR, there may be increased mitral annular area, annular stretching and flattening (involving both anterior and posterior components of the annulus), increased septal-lateral annular dimension (also termed the *anteroposterior axis*), which is perpendicular to the line of leaflet coaptation), lateral displacement of posteromedial papillary muscle, and apically tethered posterior leaflet with restricted closing motion, any of which may contribute to leaflet malcoaptation<sup>132,133,135,136</sup> (Fig. 34-11). The septal-lateral annular dilatation and diminished LV systolic function determine mitral systolic tenting area, which in turn is predictive of the severity of the IMR.<sup>132</sup> LV dilatation and larger annular dimensions after inferior myocardial infarction require the mitral leaflets to cover more area during closing, exceeding their normal redundancy or “reserve,” which is exacerbated by restricted leaflet closure (type IIIb motion) owing to apical leaflet tenting. Additionally, the distinctive saddle shape of the normal annulus, which becomes accentuated during systole, is eliminated which makes it flatter and suggests an association between maintaining the saddle shape and valvular competence.<sup>132,143,144</sup> Furthermore, in patients with IMR, the anterior and posterior annular perimeters and annular orifice

**FIGURE 34-11** Average mitral annular area (in  $\text{cm}^2$ ) before (blue squares) and during (red squares) acute LV ischemia induced by balloon occlusion of either the LAD artery (top), the dLCx coronary artery (middle), or the pLCx coronary artery (bottom). A 650-ms time interval centered at end-diastole ( $t = 0$ ) is shown. dLCx, distal to second obtuse marginal artery; LAD, proximal left anterior descending artery; MA, mitral annular; pLCx, proximal to second obtuse marginal artery. (Reproduced with permission from Timek TA, Lai DT, Tibayan F, et al: Ischemia in three left ventricular regions: Insights into the pathogenesis of acute ischemic mitral regurgitation, *J Thorac Cardiovasc Surg.* 2003 Mar;125(3):559-569.)

area ( $9.1 \text{ cm}^2$  compared with  $5.7 \text{ cm}^2$  normally) are increased accompanied by an increase in the intertrigonal (anterior) annular distance and restriction of annular motion.<sup>136</sup>

**Leaflet Motion and Morphology.** Acute IMR from proximal left circumflex artery occlusion experimentally results in delayed valve closure in early systole (termed *leaflet loitering*) and increased leaflet edge separation throughout ejection in three leaflet coaptation sites across the valve, specifically near the anterior commissure, the valve center, and near the posterior commissure.<sup>131,133</sup> In addition, there is lateral displacement of the central scallop of the posterior leaflet, suggesting that interscallop malcoaptation and septal-lateral annular dilatation, can contribute to IMR in certain circumstances.<sup>139</sup> Clinically, chronic IMR is associated with apical systolic restriction of the posterior leaflet, thereby effectively preventing competent valve closure; this restriction results in a posteriorly directed eccentric MR jet due to anterior leaflet

“pseudoprolapse.” Chronic IMR is also associated with posterior leaflet displacement in the posterior direction and lateral displacement of both leaflets. When the position of each leaflet edge is assessed independently, the anterior leaflet is not displaced apically after inferior infarction, although with more time and further remodeling, apical restriction of this leaflet may occur.<sup>135</sup> A strong echocardiographic determinant of leaflet tenting height is the distance from the tips of the papillary muscles to the saddle horn of the anterior annulus; LV end-diastolic volume is only weakly correlated with tenting height.<sup>145</sup> Recent human observations have revealed that in some patients with IMR/FMR, there is growth or elongation of the leaflets associated with leaflet thickening that compensates for the larger orifice area and minimizes the amount of mitral regurgitation. In others, however, the leaflets do not become larger and cannot coapt normally across the large orifice, which causes more leaks.<sup>146</sup>

In the past, the leaflet morphology in patients with FMR was considered normal, but further analyses have shown the leaflets to be biochemically different, with extracellular matrix changes associated with altered cardiac dimensions.<sup>147,148</sup> In recipient hearts obtained at time of transplantation, mitral leaflets have up to 78% more deoxyribonucleic acid, 59% more glycosaminoglycans, 15% more collagen, but 7% less water than autopsy control leaflets.<sup>147,148</sup> Radially and circumferentially oriented anterior mitral leaflet strips from failing hearts are 50 to 61% stiffer and less viscous.<sup>148</sup> Thus, the mitral leaflets in heart failure have altered intrinsic structural properties, suggesting that the permanently distended and fibrotic tissue is unable to stretch sufficiently to cover the valve orifice and that mitral regurgitation in these patients is not purely functional.<sup>147,148</sup>

**Papillary Muscle and Chordal Relationships.** The papillary-annular distances in the LV long axis remain relatively constant in normal hearts throughout the cardiac cycle.<sup>114</sup> During acute ischemia, however, these distances change, which reflects repositioning or dislocation of the papillary muscle tips with respect to the mitral annulus. This process can also contribute to apical tenting of the leaflets during systole.<sup>110,114,135,149,150</sup> With proximal circumflex artery occlusion and resulting IMR in an ovine model, the interpapillary distance and LV end-diastolic volume both increase. There is also increased mitral annular area and displacement of both (but predominantly the posteromedial) papillary muscle tips away from the septal annulus throughout ejection and at end-systole.<sup>135,149</sup> Posteromedial papillary muscle tip displacement probably results from failure of the ischemic papillary muscle to shorten during systole, lengthening of the ischemic papillary muscle over time, and dyskinesia of the ischemic LV wall subtending the papillary muscle. Since posterior papillary muscle displacement in the apical and posterior directions also occurs in sheep that did not develop substantial degrees of IMR, the additional posteromedial papillary muscle displacement in the lateral direction is a dominant factor in the development of IMR.<sup>135</sup> In the setting of posterolateral ischemia, a larger distance

from the papillary muscle tips to the midseptal annulus is an important determinant of mitral regurgitant jet area and volume.<sup>130,135</sup> The nonischemic anterolateral papillary muscle may also play a role in apical leaflet restriction because this papillary muscle is displaced apically at end-systole relative to baseline. In sheep with mitral regurgitation, posteromedial papillary muscle tethering distance, papillary muscle depth, and papillary muscle angle are unchanged, and the anterolateral papillary muscle depth and papillary muscle angle decrease with decreasing ejection fraction.<sup>149</sup> Reduced systolic shortening of either papillary muscle in isolation, on the other hand, does not result in mitral regurgitation; thus, the previous notion that “papillary muscle dysfunction” by itself is responsible for IMR is not correct. In fact, papillary muscle dysfunction paradoxically can decrease mitral regurgitation resulting from inferobasal ischemia by reducing leaflet tethering, which improves leaflet coaptation.<sup>151</sup> Further insult to the LV wall underlying the papillary muscles is likely needed before valvular incompetence occurs. Acute IMR induced by experimental posterior LV ischemia is associated with chordal and leaflet tethering at the nonischemic commissural portion of the mitral valve and a paradoxical decrease of the chordal forces and relative prolapse at the ischemic commissural site.<sup>137</sup> Based on cardiac MRI of humans with ischemic heart disease, the loss of lateral shortening of the interpapillary muscle distance tethers the leaflet edges and impairs their systolic closure, resulting in mitral regurgitation.<sup>150</sup> Thus, it may be a combination of systolic annular dilatation and shape change and altered posteromedial and anterolateral papillary muscle position and motion that contributes to incomplete leaflet coaptation and IMR.

**Papillary Muscle Ischemia and Rupture.** Papillary muscle dysfunction in patients with ischemic heart disease has been thought to contribute to mitral regurgitation, although the significance of its role in IMR remains in question.<sup>41,43,56,57,114,135,149,151</sup> The papillary muscles are particularly susceptible to ischemia, more so the posteromedial papillary muscle (supplied only by the posterior descending artery in 63% of cases) than the anterolateral papillary muscle (supplied by both the left anterior descending and the circumflex arteries in 71% of cases).<sup>41,43</sup> Hence, myocardial infarction leading to papillary muscle dysfunction occurs more frequently with the posteromedial papillary muscle after an inferior myocardial infarction. Although papillary muscle necrosis can complicate myocardial infarction, frank rupture of a papillary muscle is rare. Total papillary muscle rupture usually is fatal as a result of severe mitral regurgitation and LV pump failure; survival long enough to reach the operating room in reasonable condition is possible with rupture of one or two of the subheads of a papillary muscle, which is associated with a lesser degree of acute mitral regurgitation. Papillary muscle rupture usually occurs 2 to 7 days after myocardial infarction; without emergency operation, approximately 50 to 75% of such patients may die within 24 hours.<sup>152,153</sup>

## RHEUMATIC DISEASE

With decreasing incidence in the United States, rheumatic fever remains a common cause of mitral regurgitation in developing countries.<sup>41,56-58,105-107,154</sup> It is unknown why rheumatic fever leads to valvular stenosis in some patients and pure regurgitation in others. The pathoanatomical changes of the purely regurgitant rheumatic valve differ from those in a stenotic valve. In chronic rheumatic mitral regurgitation, the valves have diffuse fibrous thickening of the leaflets with minimal calcific deposits and relatively nonfused commissures; chordae tendineae usually are not extremely thickened or fused.<sup>56-58</sup> There also may be shortening of the chordae tendineae, fibrous infiltration of the papillary muscle, and asymmetric annular dilatation primarily in the posteromedial portion. During the first episodes of rheumatic fever (average age is 9 years), patients may develop acute mitral regurgitation, which is more frequently related to annular dilatation and prolapse of the anterior or posterior mitral valve leaflet.<sup>58,154</sup> Those with anterior leaflet prolapse tend to improve with medical management; however, those with prolapse of the posterior leaflet have a less favorable outcome and often require early surgical repair.<sup>154</sup>

## MITRAL ANNULAR CALCIFICATION

Mitral annular calcification is a degenerative disorder that usually is confined to elderly individuals; most patients are older than 60 years of age, and women are affected more often than men.<sup>41,64</sup> The pathogenesis of mitral annular calcification is not known, but it appears to be a stress-induced phenomenon; annular calcification also can be associated with systemic hypertension, hypertrophic cardiomyopathy, aortic stenosis, and occasionally, advanced Barlow's disease. Other predisposing conditions include chronic renal failure and diabetes mellitus. Aortic valve calcification is an associated finding in 50% of patients with severe mitral annular calcification.

The gross appearance of mitral annular calcification may vary from small, localized calcified spicules to massive, rigid crescentic bars up to 2 cm in thickness in the annulus and leaflets.<sup>64</sup> Initially, calcification begins at the midportion of the posterior annulus; as the process progresses, the leaflets become upwardly deformed, stretching the chordae tendineae, and a rigid curved bar of calcium surrounding the entire posterior annulus in a horseshoe shape or even a complete ring of calcium may encircle the entire mitral orifice. The calcific deposit spurs extend into the LV myocardium and the conduction system, which can result in atrioventricular and/or intraventricular conduction defects. Annular calcification causes mitral regurgitation by displacing and immobilizing the mitral leaflets (thereby preventing their normal systolic coaptation) or impairing the presystolic sphincteric action of the annulus.<sup>64</sup> As the degree of mitral regurgitation worsens over time, LV volume overload can lead to heart failure. Systemic embolization can occur if the annular calcific debris is extensive and friable.

## Hemodynamics

The pathophysiology of acute mitral regurgitation differs from that of chronic mitral regurgitation. Acute regurgitation may result from spontaneous chordal rupture, myocardial ischemia or infarction, infective endocarditis, or severe chest trauma.<sup>41,129,152,153</sup> The clinical impact of acute mitral incompetence is modulated largely by the compliance of the left atrium and the pulmonary vasculature. In a normal left atrium with a relatively low compliance, acute mitral regurgitation results in high LA pressure, which can lead rapidly to pulmonary edema. Such is not the situation in patients with chronic mitral regurgitation, in whom compensatory changes over time increase LA and pulmonary bed venous compliance such that symptoms of pulmonary congestion may not occur for many years.

With mitral regurgitation, the impedance to LV emptying is lowered because the mitral orifice is in parallel with the LV outflow tract.<sup>41,70,155</sup> The volume of mitral regurgitation depends on the square root of the systolic pressure gradient between the left ventricle and the atrium, the time duration of the regurgitant leak, and the effective regurgitant orifice (ERO).<sup>41,145,156,157</sup> The ERO is determined echocardiographically using 2D color Doppler imaging to measure the cross-sectional area of the vena contracta (narrowest width of the regurgitant jet) and the proximal isovelocity surface area (PISA), or continuous-wave Doppler measuring the ratio of regurgitant volume to regurgitant time-velocity integral.<sup>145,158</sup> Regurgitation into the left atrium increases LA pressure and reduces forward cardiac output. LA pressure even may remain elevated at end-diastole (transient 5- to 10-mm Hg transvalvular gradient), representing a functional gradient associated with the increased diastolic LV filling rate.

If the mitral annulus is not rigid, various diagnostic and therapeutic interventions can alter ERO. Altered loading conditions (elevated preload and afterload) and decreased contractility result in progressive LV dilatation and a larger ERO.<sup>159</sup> When LV size is reduced by medical management (eg, digoxin, diuretics, and most importantly, systemic arteriolar vasodilators), ERO and regurgitant volume fall.<sup>160,161</sup> Stress echocardiography using an inotropic drug, such as dobutamine, usually decreases ERO and the degree of mitral regurgitation in patients with FMR and IMR because the LV chamber is smaller at the beginning of systole (or end-diastole) and throughout systole secondary to enhanced LV contractility.<sup>162</sup>

## Ventricular Adaptation

The loading conditions induced by mitral regurgitation promote more LV ejection because ventricular preload is increased and afterload is normal or decreased secondary to backward flow across the mitral valve. In terms of cardiac energetics, reduced LV impedance in patients with mitral regurgitation allows a greater proportion of contractile energy to be expended in myocardial fiber shortening than in tension development.<sup>41,155</sup> Because increased fiber shortening

is less of a determinant of myocardial oxygen consumption than other components, such as tension (or pressure) development and heart rate, mitral regurgitation causes only small increases in myocardial oxygen consumption.<sup>155</sup> Reduction in developed tension as a result of lower LV systolic wall stress (LV afterload) permits the ventricle to adapt to the substantial regurgitant volume by increasing LV end-diastolic volume to maintain adequate forward output. Along with lower afterload, this increase in preload (LV end-diastolic volume or, more precisely, LV end-diastolic wall stress) allows the heart to compensate for chronic mitral regurgitation for a long time before symptoms occur.<sup>41,163,164</sup> A fundamental response to increased preload is augmented stroke volume and stroke work, although effective forward stroke volume may be subnormal. High LV preload eventually leads to LV dilatation and shape change, meaning more spherical remodeling, owing to replication of sarcomeres in series as a consequence of chronic elevation of LV end-diastolic wall stress.<sup>163,164</sup> This process is in contrast to LV hypertrophy secondary to chronic pressure overload (elevated systolic wall stress) which leads to sarcomere replication in parallel. In chronic mitral regurgitation, LV mass also increases; however, the degree of hypertrophy correlates with the amount of chamber dilatation so that the ratio of LV mass to end-diastolic volume remains in the normal range (unlike the situation in patients with LV pressure overload).<sup>165-167</sup> The contractile dysfunction that evolves due to chronic LV volume overload is accompanied by increased myocyte length as well as reduced myofibrillar content.<sup>164,165</sup> The basic changes thus are a combination of myofibrillar loss and the absence of significant hypertrophy in response to the progressive decrease in LV pump function. The defect is intrinsic to the myocyte *per se*, but changes in the extracellular matrix also play a role.<sup>142,168</sup> Conversely, in acute mitral regurgitation, the ratio of LV mass to end-diastolic volume is reduced because chamber dilatation occurs suddenly, and the LV wall becomes acutely thinned; this increase in LV end-diastolic volume is associated with sarcomere lengthening along the length-tension curve.<sup>164</sup>

After the initial compensatory phase, LV systolic contractility becomes progressively impaired as mitral regurgitation progresses chronically.<sup>166-169</sup> Because of the low impedance during systole, however, ejection-phase indexes of LV systolic function, such as ejection fraction, stroke volume, and fractional circumferential fiber shortening (%FSc), still can be normal even if LV contractile state has become depressed.<sup>168,170,171</sup> An ejection fraction of less than 55 to 60% or %FSc less than 28% in the presence of severe mitral regurgitation indicates an advanced degree of myocardial dysfunction. It is important to remember that all the ejection-phase indexes commonly used clinically to estimate LV pump performance, for example, ejection fraction, %FSc, cardiac output, stroke volume, stroke work, etc. are all affected by changes in LV preload and afterload.

Because of abnormal LV loading conditions in the setting of mitral regurgitation, load-independent indexes of LV contractility (eg, end-systolic elastance derived from the end-systolic pressure-volume relationship) or preload recruitable

stroke work (PRSW, also termed *linearized Frank-Starling relationship*) are preferred to measure LV systolic function and mechanics.<sup>166-169,172,173</sup> In hypertrophied and dilated hearts, as seen in chronic mitral regurgitation, however, the utility of end-systolic elastance may be limited because of LV chamber shape and size changes. It is necessary to use the end-systolic stress-volume relationship in these circumstances. One other problem inherent in the use of end-systolic elastance or stress-volume data is that end-systole and end-ejection are dissociated in patients with mitral regurgitation. End-ejection is defined as minimum LV volume and end-systole as the instant when LV elastance reaches its maximal value. Because of this temporal dissociation of end-systole from minimal ventricular volume, end-ejection pressure-volume relations do not correlate with maximal elastance values derived using isochronal methods.<sup>172</sup> End-systolic dimension or LV end-systolic volume (LVESV) is less dependent on LV loading conditions than is ejection fraction, and therefore is a better measure of LV systolic contractile function. LVESV varies directly and linearly with afterload, and inversely with contractile state.<sup>169,174-176</sup> The larger the LVESV becomes, the worse LV contractility. Correcting LVESV for chamber geometry, LV wall thickness and afterload (end-systolic wall stress [ESS]), and body size (LV end-systolic volume index [LVESVI]) provides reliable and accurate indexes of LV systolic function that are less influenced by loading conditions and variation in patient size.<sup>174,175</sup> Thus, preoperative LVESV or LVESVI is a better predictor of outcome in terms of post-operative LV systolic performance and cardiac death than is LVEF, end-diastolic volume, or end-diastolic pressure.<sup>176</sup>

Based on load-independent indexes of LV contractility in experimental mitral regurgitation, the normalized end-systolic pressure-volume and end-systolic stress-volume relationships decline after 3 months of mitral regurgitation.<sup>166</sup> PRSW (the relation of stroke work to LV end-diastolic volume) and preload-recrutable pressure-volume area (the relation of stroke work to LV pressure-volume area) also fall, along with a decrease in efficiency of energy transfer from pressure-volume area to external pressure-volume work at matched LV end-diastolic volume. Furthermore, there is deterioration in ventriculoarterial coupling over time; that is, a mismatch develops between the ventricle and the total (forward and regurgitant) vascular load.<sup>166</sup> Although the overall (systemic plus LA) effective arterial elastance is decreased, there is a proportionally greater reduction in LV end-systolic elastance. Thus, LV systolic mechanics become impaired along with deterioration in global LV energetics and efficiency, and a mismatch develops in coupling between the left ventricle and the arterial bed.<sup>166</sup> Additionally, progression from acute to chronic mitral regurgitation (at 3 months) is associated with a decrease in maximum LV systolic torsional deformation from 6.3 to 4.7° and a decrease in early diastolic LV recoil from +3.8 to -1.5°.<sup>177</sup> Because torsion is a mechanism by which the left ventricle equalizes transmural gradients of fiber strain and oxygen demand, a decrease in systolic torsion in chronic mitral regurgitation may play a role in the inexorable and progressive decline of

LV performance.<sup>177</sup> The left ventricle responds to decreased forward cardiac output resulting from mitral regurgitation by dilating; such dilatation equalizes the lengths of the endocardial and epicardial radii and thereby decreases systolic LV torsion. In assessing transmural 3D myocardial deformations in an ovine model of isolated mitral regurgitation, early changes in LV function at 12 weeks was evidenced by alterations in transmural strain (which may be detected before the onset of global LV dysfunction), but not by changes in B-type natriuretic peptide or PRSW.<sup>178</sup> The associated increase in transmural gradient of fiber strain and oxygen supply-demand imbalance results in a further decrease in forward cardiac output, leading to more LV dilatation and continuing the vicious cycle.

Diastolic inflow into the ventricle increases as total stroke volume increases during the evolution of mitral regurgitation and ventricular dilatation.<sup>179-182</sup> Acute mitral regurgitation enhances LV diastolic function by increasing the early diastolic filling rate and decreasing chamber stiffness. Flow across the mitral valve during early diastole is determined by the LA-LV pressure gradient, even though other factors, such as diastolic restoring forces and LV diastolic recoil (creating LV suction) during isovolumic relaxation also influence early LV filling.<sup>179</sup> In middle and late diastole, the lower LV chamber stiffness in patients with acute mitral regurgitation (evidenced by a shift of the LV diastolic pressure dimension or pressure-volume relationship to the right) allows the LV mean and LV end-diastolic pressures (and stresses) to remain in the normal range. In patients with chronic mitral regurgitation and preserved ejection fraction, LV chamber stiffness is also lower, similar to that during acute mitral regurgitation. Conversely, in those with impaired LV systolic function, chamber stiffness usually is normal.<sup>181</sup> In general, chronic mitral regurgitation causes a decrease in LV systolic contractile function but an increase in early diastolic function (as evidenced by an increase in early diastolic filling rate and a decrease in chamber stiffness).<sup>182,183</sup> The reduced chamber stiffness may be the result of altered ventricular geometry (more spherical shape); this shape change can exacerbate the degree of mitral regurgitation by distorting annular dimensions and dislocating the papillary muscles.<sup>181,184</sup> Although the LV chamber stiffness is less owing to the change in geometry, the LV myocardium may be stiffer as a result of myocyte hypertrophy and interstitial fibrosis.<sup>181,182</sup>

## Atrial Adaptation

Regurgitant flow into the left atrium leads to progressive atrial enlargement, the degree of which does not correspond directly with the severity of mitral regurgitation.<sup>74,155</sup> Also, the LA v wave in mitral regurgitation does not correlate with LA volume. Compared with patients with mitral stenosis, LA size can be larger in patients with longstanding mitral regurgitation, but thrombus formation and systemic thromboembolization occur less frequently because of the absence of atrial stasis.<sup>74,77</sup> Atrial fibrillation occurs less often in those with mitral regurgitation than in individuals with mitral stenosis.<sup>77</sup>

LA compliance is an important component of the patient's overall hemodynamic status if mitral regurgitation is present.<sup>41,128,155,185</sup> With sudden development of mitral regurgitation from chordal rupture, papillary muscle infarction, or leaflet perforation, LA compliance is normal or reduced. The left atrium is not enlarged, but the mean LA pressure and v wave are high. Gradually, the LA myocardium becomes hypertrophied, proliferative changes develop in the pulmonary vasculature, and pulmonary vascular resistance rises. As the mitral regurgitation becomes chronic and more severe, the left atrium becomes markedly enlarged, atrial compliance is increased, the atrial wall becomes fibrotic, but LA pressure remains normal or only slightly elevated.<sup>185</sup> In this situation, pulmonary artery pressure and pulmonary vascular resistance usually are still in the normal range or only modestly elevated.

### Pulmonary Changes

Because chronic mitral regurgitation is associated with LA enlargement and only mild elevations in LA pressure, pronounced increases in pulmonary vascular resistance usually do not develop. In patients with acute mitral regurgitation with normal or reduced LA compliance, a sudden increase in LA pressure initially elevates pulmonary vascular resistance, and occasionally acute right-sided heart failure occurs.<sup>41,129</sup> Pulmonary edema is seen less frequently in patients with chronic mitral regurgitation than in those with mitral stenosis because elevated LA pressure is uncommon. In patients with IMR and heart failure, however, acute pulmonary edema is associated with the dynamic changes in IMR and the resulting increase in pulmonary vascular pressure.<sup>186</sup> Exercise-induced changes in ERO, tricuspid regurgitant pressure gradient (estimate of pulmonary artery systolic pressure), and LVEF are independently associated with the development of pulmonary edema.<sup>186</sup> From the standpoint of pulmonary parenchymal function and respiratory mechanics in patients with chronic mitral regurgitation, there is a decline in vital capacity, total lung capacity, forced expiratory volume, and maximal expiratory flow at 50% vital capacity.<sup>186</sup> These patients also may have a positive response to methacholine challenge; this bronchial hyperresponsiveness may result from increased vagal tone owing to longstanding pulmonary congestion.

### Clinical Evaluation

Patients with mild-to-moderate mitral regurgitation may remain asymptomatic for many years as the left ventricle adapts to the increased workload and maintains normal forward cardiac output. Gradually, symptoms reflecting decreased cardiac output with physical activity and/or pulmonary congestion develop insidiously, such as weakness, fatigue, palpitations, and dyspnea on exertion. If right-sided heart failure appears late in the course of the disease, hepatomegaly, peripheral edema, and ascites occur and can be associated with rapid clinical deterioration.<sup>187,188</sup> Conversely, acute mitral regurgitation usually is associated with marked sudden pulmonary congestion and pulmonary edema. Patients with

coronary artery disease can present with myocardial ischemia or infarction and associated mitral regurgitation. Acute papillary muscle rupture may clinically mimic the presentation of a patient with a postinfarction ventricular septal defect.<sup>188,189</sup>

On physical examination, the cardiac impulse in patients with mitral regurgitation is hyperdynamic and displaced laterally; the forcefulness of the apical impulse is indicative of the degree of LV enlargement. In patients with chronic mitral regurgitation, S1 usually is diminished. S2 may be single, closely split, normally split, or even widely split as a consequence of the reduced resistance to LV ejection; a common finding is a widely split S2 that results from shortening of LV systole and early closure of the aortic valve.<sup>108,190</sup> An S3 gallop may be appreciated from the increased transmitral diastolic flow rate during the rapid filling phase. The apical systolic murmur of mitral regurgitation can be blowing, moderately harsh, or even soft and usually radiates to the axilla and left or right sternal border and occasionally to the neck or the vertebral column.<sup>190</sup> With rupture of the posterior leaflet first-order chordae, the mitral regurgitation jet is directed superiorly and impinges on the atrial septum near the base of the aorta, which can produce a murmur heard best along the right sternal border and radiating to the neck.<sup>190,191</sup> In cases of ruptured anterior leaflet first-order chordae, the leakage is aimed laterally and toward the posterior LA wall; the murmur may be transmitted posteriorly. Although there is no correlation between the intensity of the systolic murmur and the hemodynamic severity of the mitral regurgitation, a holosystolic murmur is characteristic of more regurgitant flow. In younger patients with Barlow's valves, early in the disease process, a characteristic midsystolic click is heard followed by a late systolic murmur; as the annulus and left ventricle dilate, the murmur over time becomes holosystolic, and the midsystolic click may become inaudible.

On chest radiography, cardiomegaly indicative of LV and LA enlargement is found commonly in patients with longstanding moderate-to-severe mitral regurgitation. Chest x-ray findings of congested lung fields are less prominent in patients with mitral regurgitation than in those with mitral stenosis, but interstitial edema is seen frequently in individuals with acute mitral regurgitation and those with progressive LV failure secondary to chronic mitral regurgitation.

Changes on the electrocardiogram are not particularly useful and depend on the etiology, severity, and duration of the mitral regurgitation.<sup>86,190</sup> Atrial fibrillation can occur late in the natural history of the disease and usually causes sudden exacerbation of symptoms. In cases of chronic mitral regurgitation, LV volume overload leads to LA and LV dilatation, and eventually to LV hypertrophy. Electrocardiographic evidence of LV enlargement or hypertrophy occurs in one-half of patients, 15% have right ventricular hypertrophy owing to increased pulmonary vascular resistance, and 5% have combined left and right ventricular hypertrophy.<sup>86</sup> In those with acute mitral regurgitation, LA and/or LV dilatation may not be evident, and the electrocardiogram may be normal or show only nonspecific findings, including sinus tachycardia or ST-T-wave alterations.<sup>86</sup> Findings of myocardial ischemia or

infarction, more commonly noted in the inferior leads, may be present when acute mitral regurgitation is related to acute inferior myocardial infarction or myocardial ischemia; in these cases, first-degree AV block is a common coexisting finding.

In the majority of individuals with mitral valve prolapse, particularly those who are asymptomatic, the resting electrocardiogram is normal.<sup>86,126</sup> In symptomatic patients, a variety of ST-T-wave changes, including T-wave inversion and sometimes ST-segment depression, particularly in the inferior leads, can be found.<sup>121,126</sup> QTc prolongation also may be seen. Arrhythmias may be observed on ambulatory electrocardiograms, including premature atrial contractions, supraventricular tachycardia, AV block, bradyarrhythmias, and premature ventricular contractions.<sup>126</sup> Atrial arrhythmias may be present in upward of 14% of patients, and ventricular arrhythmias are present in 30% of patients.<sup>86,126</sup>

TTE is the diagnostic mainstay in patients with valvular heart disease. In those with chronic mitral regurgitation, this modality is used to follow the progression of LA and LV dilatation.<sup>3,41,89,108,192,193</sup> Echocardiography identifies abnormalities in leaflet and chordal morphology and function, including myxomatous degeneration with or without leaflet prolapse, restricted systolic leaflet motion (as in IMR) or diastolic opening motion (as in rheumatic valve disease), lack of adequate coaptation due to annular dilatation or rheumatic valvulitis (fused subvalvular apparatus), and leaflet destruction by endocarditis<sup>3,41,87,89,158,193</sup> (Fig. 34-12). The degree of mitral regurgitation is assessed using 2D color Doppler echocardiography, which permits visualization of the origin, extent, direction, duration, and velocity of disturbed backward flow of the regurgitant leak.<sup>87,158,193</sup> Chordal rupture or elongation causing a flail leaflet is characterized by excessive motion of the leaflet backward into the left atrium beyond the normal leaflet coaptation zone. Papillary muscle rupture after myocardial infarction and annular dilatation can be visualized (Fig. 34-13). In patients with IMR or FMR, apical systolic tethering of the leaflets, tenting area and height, and leaflet opening angles can be quantitated using echocardiography<sup>145,156,158,194</sup> (Fig. 34-14). When the regurgitant leak is

**FIGURE 34-12** Echocardiogram (long-axis) of a patient with mitral regurgitation resulting from floppy mitral valve. The leaflets billow back into the left atrium during systole.

**FIGURE 34-13** Echocardiogram (two-chamber view) of a patient with mitral regurgitation from ruptured papillary muscle.

caused in part or totally by annular dilatation, usually in the septal-lateral dimension, the coaptation height of the anterior and posterior leaflets can be measured.

In mitral regurgitation, ERO and regurgitant volume can be estimated quantitatively in many but not all patients using 2D color Doppler echocardiography.<sup>145,157,158</sup> ERO is an important predictor of outcome in a retrospective Mayo Clinic study of patients with mitral regurgitation and has been proposed as an indicator of when to proceed with mitral repair in asymptomatic patients with prolapse.<sup>157</sup> Accurate quantification of the degree of mitral regurgitation using ERO and regurgitant volume, however, is demanding, time consuming, fraught with error, and may not be available at all institutions. The hemodynamic magnitude or severity of the mitral regurgitation also can be estimated semiquantitatively by calculating mitral and aortic stroke volumes, with regurgitant volume being the difference between these two stroke volumes. Cardiac MRI is an accurate method to measure regurgitant volume and regurgitant fraction by comparing right- with left-sided flow.<sup>92,195,196</sup>

**FIGURE 34-14** Echocardiogram of a patient with ischemic mitral regurgitation and apical systolic leaflet tenting.

Interest in the timing of the regurgitant leak has helped clinicians discern subtle details about the mechanism(s) responsible for the mitral regurgitation, infer information about the overall hemodynamic burden imposed by the LV volume overload, and predict the likelihood of successful and durable mitral repair.<sup>145,156-158,194</sup> IMR is primarily an early systolic leak, FMR occurs during early and middle systole (can be a biphasic pattern), and prolapse is associated with late systolic leaks. Although detected by pulse- and continuous-wave Doppler echocardiography for years, the timing of the mitral regurgitation also can be demonstrated using color Doppler M-mode echocardiography, which has a much faster temporal resolution (sampling frequency) than does 2D color Doppler echocardiography. Cardiac surgeons should study these color Doppler M-mode images carefully because the timing of the regurgitant leak yields important information about the mechanisms responsible for the mitral regurgitation, which in turn aids repair planning.

TTE is usually adequate to learn all that is necessary, but if high-quality TTE images cannot be obtained because of the patient's habitus or advanced emphysema, TEE provides superior image quality and can reveal additional anatomical and pathophysiologic information, including details of the valvular pathoanatomy and the mechanism, origin, direction, timing, and severity of the regurgitant leak.<sup>3,41,108,121,158,192,193,197</sup> TEE can detect small mitral vegetations, ruptured chordae, leaflet perforations or clefts, calcification, and other inflammatory changes and can be useful in patients with annular or leaflet calcification. TEE also is useful in patients with a previously implanted aortic valve prosthesis that can interfere with TTE assessment of mitral regurgitation owing to acoustic shadowing. Although intraoperative TEE during mitral valve repair is essential, a major limitation must always be remembered. The vascular unloading effects (vasodilatation) of general anesthesia downgrade the severity of mitral regurgitation.<sup>198,199</sup> The judgment about how much mitral regurgitation is present must be made on the basis of an awake TTE study when the patient has a normal ambulatory blood pressure. This concept is imperative in assessing the degree of mitral regurgitation in patients with IMR when deciding whether to add a mitral valve procedure at the time of coronary artery bypass grafting. For patients in whom the degree of mitral regurgitation has been minimized by the effects of anesthesia, intraoperative TEE provocative testing using vasoconstrictor drugs with or without volume infusion is mandatory to guide surgical decision making. Testing consists of reproducing the patient's normal awake or active ambulatory hemodynamic condition with preload challenge and afterload augmentation.<sup>198,199</sup> Preload challenge is performed after aortic cannulation for cardiopulmonary bypass by rapidly infusing volume from the pump until the pulmonary capillary wedge pressure reaches 15 to 18 mm Hg. If severe mitral regurgitation is not produced, LV afterload is increased by intravenous boluses of phenylephrine until the arterial systolic pressure climbs to the 150-mm Hg range. In patients undergoing coronary artery bypass grafting, if both tests are negative, or regurgitation is induced but associated with new regional LV systolic wall motion abnormalities (ie, the regurgitation is caused by

acute ischemia of viable myocardium), the valve may not require visual inspection because coronary revascularization usually is all that is necessary if the inferior wall myocardium is viable. If these tests confirm the presence of moderate-to-severe mitral regurgitation, the valve is inspected and usually is repaired at the time of coronary revascularization.

Real-time 3D echocardiography is helpful in the visual assessment of congenital and acquired valvular disease.<sup>3,108,121,194,200,201</sup> (Fig. 34-15). In patients with mitral regurgitation, this modality is fairly accurate in elucidating the dynamic mechanisms of the regurgitant leak(s). The addition of color-flow Doppler to 3D imaging provides improved visualization and may offer improved quantitative assessment of regurgitant valvular lesions.<sup>3,121</sup> Additionally, 3D echocardiography provides insight into the geometric deformities of the mitral leaflets and annulus, maximum tenting site of the mitral leaflet, and quantitative measurements of mitral valve tenting and annular deformity in patients with IMR.<sup>3,121,194,201</sup> Real-time 3D color Doppler echocardiographic imaging provides direct measurement of vena contracta area.<sup>3,200</sup> The quantification of mitral regurgitant flow directly at the lesion using color Doppler echocardiography, however, has been prevented because of multiple aliasing from high flow velocities. Dealiasing of color Doppler flow at the vena contracta is feasible and appears promising for measuring severity of mitral regurgitation. This approach can be readily implemented in current systems to provide regurgitant flow volume and regurgitant fraction.<sup>3,200</sup>

Cardiac catheterization and coronary angiography are needed to determine coronary artery anatomy, but only in older patients with prolapse before repair and those with IMR.<sup>41,85,163</sup> Other techniques, such as calculating mitral regurgitant fraction (regurgitant volume determined as the difference between total LV angiographic stroke volume and the effective forward stroke volume measured by the Fick method), are limited. By measuring rest and exercise (supine bicycle) pulmonary artery pressures and cardiac output, right-sided heart catheterization can be useful occasionally to identify patients with primary myocardial disease who present with LV dilatation and relatively mild degrees of mitral regurgitation (who may not have a high likelihood of benefiting from mitral valve surgery) and those with severe mitral regurgitation who deny symptoms to see if they develop pulmonary hypertension with exercise.

Cardiac MRI can be employed to assess the cardiovascular system, including cardiac structure and function.<sup>92,108,150,195,196,202</sup> Specialized MRI techniques, such as phase contrast velocity mapping, planimetry, or real-time color flow, have been used to evaluate and quantify the degree of mitral regurgitation. The presence of valvular regurgitation can be determined, LV volumes and mitral regurgitant fraction estimated, and information obtained concerning mitral and coronary anatomy. Direct measurement by MRI is a promising method for assessment of the severity of mitral regurgitation; MRI planimetry of the anatomical mitral regurgitant lesion permits quantification of regurgitation with good agreement with cardiac catheterization and echocardiography.<sup>196</sup> Constraints of MRI, such as pacemakers or

implanted defibrillators, morbid obesity, and claustrophobia, hamper the wider use of cardiac MRI. Multidetector CT is an imaging technique that can fully evaluate both cardiac structure and function, including coronary artery anatomy; this technology has yielded good visualization of valve leaflets, commissures, and mitral annulus.<sup>93</sup> Limitations include image noise, requirement for a regular rhythm and a slow heart rate during imaging, time required for postprocessing data analysis, and radiation dose.

## Postoperative LV Function and Surgical Outcomes

### GENERAL

Successful mitral valve surgery usually is associated with clinical improvement, augmented forward stroke volume with lower total stroke volume, smaller LV end-diastolic volume, and regression of LV hypertrophy.<sup>80,97,119,203-207</sup> Correction of

mitral regurgitation can preserve LV contractility, particularly in patients with a normal preoperative ejection fraction who have minimal ventricular dilatation and those without significant coronary artery disease. On the other hand, in patients with LV dysfunction preoperatively, improvement in LV systolic function may not necessarily occur after operation. An LVESVI exceeding 30 mL/m<sup>2</sup> is associated with decreased postoperative LV function.<sup>176,208</sup> Thus, it is proposed that patients with chronic primary mitral regurgitation should be referred for mitral valve surgery before LVESVI exceeds 40 to 50 mL/m<sup>2</sup> or when LV end-systolic dimension (LVESD) reaches 4 cm or greater, consistent with the 2014 American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines<sup>80,176</sup> (Fig. 34-16). Significant determinants of increased operative risk for mitral valve surgery include older age, higher New York Heart Association (NYHA) functional class, associated coronary artery disease, increased LV end-diastolic pressure, elevated LV end-diastolic volume index, elevated LVESD, reduced LV ESS index,

**FIGURE 34-16** Indications for surgery for mitral regurgitation (MR). AF, atrial fibrillation; CAD, coronary artery disease; CRT, cardiac resynchronization therapy; ERO, effective regurgitant orifice; HF, heart failure; LV, left ventricular; LVEF, left ventricular ejection fraction; LVESD, left ventricular end-systolic dimension; MR, mitral regurgitation; MV, mitral valve; MVR, mitral valve replacement; NYHA, New York Heart Association; PASP, pulmonary artery systolic pressure; RF, regurgitant fraction; RVol, regurgitant volume; Rx, therapy. \*Mitral valve repair is preferred over MVR when possible. (Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Thorac Cardiovasc Surg*. 2014 Jul;148(1):e1-e132.)

depressed resting ejection fraction, decreased fractional shortening, reduced cardiac index, elevated capillary wedge or right ventricular end-diastolic pressure, concomitant operative procedures, and previous cardiac surgery.<sup>176,208-212</sup>

The decline in ejection fraction after mitral valve replacement for chronic mitral regurgitation historically was thought to result from an increase in LV afterload as a result of closure of the low-resistance early systolic “pop-off” into the left atrium and the surgical excision of the subvalvular apparatus. A spherical mathematical model defining the relations among LV end-diastolic dimension, systolic wall stress, and ejection fraction, demonstrated that postoperative changes in systolic stress are related directly to changes in chamber size, and LV afterload may decrease postoperatively if chordal-preservation valve replacement techniques are used.<sup>213</sup> In terms of exercise performance after surgery for nonischemic

mitral regurgitation, although patients generally report symptomatic improvement, cardiopulmonary exercise testing at 7 months may not be better than preoperatively, and abnormal neurohumoral activation persists, probably reflective of incomplete recovery of LV contractility.<sup>214</sup> Regarding long-term clinical outcome, risk factors portending postoperative cardiac deterioration include larger LV end-diastolic dimension, increased LVESD, increased LVESV, diminished fractional shortening, reduced LV ESS index, large LA size, decreased LV wall thickness/cavity dimension at end-systole, and associated coronary artery disease.<sup>176,211,215-217</sup>

### PRIMARY MITRAL REGURGITATION

To evaluate the impact of the severity of regurgitation on outcomes in asymptomatic patients with primary mitral

regurgitation, a Mayo Clinic study retrospectively evaluated 456 middle-aged patients with at least mild holosystolic mitral regurgitation defined echocardiographically between 1991 and 2000.<sup>157</sup> Baseline ejection fraction was 70%, LVESD was  $3.4 \pm 6$  cm, LVESD was  $5.6 \pm 8$  cm, LVESVI was  $33 \pm 130$  mL/m<sup>2</sup>, and regurgitant volume was  $66 \pm 40$  mL/beat. At 5 years, 54% of patients had been operated on after an average of  $1.2 \pm 2$  years of medical treatment when symptoms occurred or when worrisome echocardiographic findings were detected (based on the 1998 ACC/AHA practice guidelines). Among those who underwent a mitral valve procedure, 91% received valve repair. The patients were stratified by degree of regurgitation; mild, moderate, and severe were defined as regurgitant volumes of less than 30, 30 to 59, and 60 or more mL/beat, and ERO was defined as less than 20, 20 to 39, and 40 or greater mm<sup>2</sup>, respectively. For the medically treated patients, 5-year survival compared with U.S. Census life tables was significantly inferior for those with moderate regurgitation (ERO of 20 to 39 mm<sup>2</sup>, 66 vs 84%) and severe regurgitation (ERO of 40 mm<sup>2</sup> or more, 58 vs 78%).<sup>157</sup> The influence of ERO also held true for predicting cardiac deaths and all cardiac events. The 5-year cardiac death rate was 36% for patients with an ERO of 40 mm<sup>2</sup> or greater compared with 20% for those with an ERO of 20 to 39 mm<sup>2</sup> and only 3% for those with an ERO of less than 20 mm<sup>2</sup>. Mitral valve operation was an independent determinant of fewer deaths, cardiac deaths, and cardiac events, especially in those with a larger ERO.<sup>157</sup> This important study, which focuses on the predictive effects of the severity of the regurgitation instead of the response of the ventricle, provides the basis for the surgical approach to asymptomatic patients with primary mitral regurgitation. On the other hand, these patients were older and most probably had prolapse due to fibroelastic deficiency; thus, these recommendations cannot safely be generalized to younger patients with Barlow's mitral valve disease or other types of mitral regurgitation.

Managed with medical therapy, mitral regurgitation from a flail leaflet is associated with high annual (6.3%) mortality rates.<sup>120,218,219</sup> In these patients, mitral valve repair is feasible in the large majority of patients in experienced centers and offers excellent early and late functional results.<sup>80,119,219-221</sup> Because fewer complications and lower operative mortality risk are associated with valve repair compared with valve replacement in this patient population, operation should be considered earlier in the natural history of the disease if the pathologic anatomy is judged favorable for valve repair.<sup>80,111,119,120,215,218-220,222</sup>

The 2014 AHA/ACC valve guidelines introduced several new concepts into clinical decision making for patients with mitral regurgitation.<sup>80</sup> The assessment of patients with mitral regurgitation now includes the following clinical stages: (A) at risk for mitral regurgitation, (B) progressive mitral regurgitation, (C) asymptomatic severe mitral regurgitation, and (D) symptomatic severe mitral regurgitation<sup>80</sup> (Table 34-1). For patients with primary mitral regurgitation (intrinsic leaflet disease) the degree of regurgitation is quantified with progressive regurgitation (or stage B) meaning a

vena contracta < 0.7 cm, regurgitant volume < 60 mL, regurgitant fraction < 50%, and ERO < 0.4 cm<sup>2</sup>. Severe regurgitation includes a vena contracta > 0.7 cm, regurgitant volume > 60 mL, regurgitant fraction > 50%, and ERO > 0.4 cm<sup>2</sup>. According to the 2014 ACC/AHA practice guidelines, all asymptomatic patients with chronic primary severe mitral regurgitation should be considered for operation if the LVEF is 30 to 60% or LVESD > 40 mm (class I evidence); asymptomatic patients in whom the LVEF > 60% and LVESD < 40 mm can be considered for early operation (class IIa evidence) if the likelihood of repair is 90% with an expected mortality of < 1% in a referent mitral surgical center.<sup>80</sup> (Fig. 34-16). In healthier patients with LVEF greater than 63% and LVESD less than 39 mm, early mitral valve repair may also result in preserved long-term postoperative LV function.<sup>80,223</sup> The AHA/ACC 2014 valve guidelines for chronic secondary mitral regurgitation (FMR or IMR) have also been modified (see below).

Because many patients with chronic mitral regurgitation report no symptoms, cardiopulmonary exercise testing has been used to evaluate asymptomatic patients with primary mitral regurgitation.<sup>224,225</sup> In a study of asymptomatic patients with severe mitral regurgitation with a regurgitant volume of 68 mL/beat and an ERO of 35 mm<sup>2</sup>, functional capacity was markedly reduced (defined as 84% or less than expected) in 19% of patients.<sup>224</sup> When patients with extraneous, noncardiac reasons for impaired functional capacity were excluded, 14% had a reduced functional capacity. Determinants of reduced functional capacity were impaired LV diastolic function, lower forward stroke volume, and atrial fibrillation; the impact of ERO on functional capacity was only modest.<sup>224</sup> Thus, it was the consequences of chronic mitral regurgitation and not the magnitude of the leak that predicted impaired functional capacity. Follow-up at 3 years revealed that 66% of patients with impaired functional capacity sustained some adverse event or required mitral surgery (vs 29% of those with normal functional capacity).<sup>224</sup> Consistent with the previous study, in patients with primary mitral regurgitation that underwent exercise echocardiography followed by mitral valve surgery, lower achieved metabolic equivalents were associated with worse long-term outcomes.<sup>225</sup> In those with preserved exercise capacity, delaying mitral valve surgery by greater than one year did not adversely affect outcomes.<sup>225</sup> Thus, asymptomatic patients with substantial mitral regurgitation should undergo periodic cardiopulmonary exercise testing to detect subclinical impairment in functional capacity, and repair should be recommended to those with impaired exercise capacity.

Even after mitral valve repair or replacement for chronic mitral regurgitation, some patients continue to be limited by heart failure symptoms and have suboptimal long-term postoperative outcomes. The incidence of congestive heart failure in patients who survive surgery (combined series of valve repair and valve replacement) for pure mitral regurgitation has been 23, 33, and 37% at 5, 10, and 14 years.<sup>226</sup> Patient survival after the first episode of congestive heart failure is dismal, being only 44% at 5 years. Causes of congestive

heart failure include LV dysfunction in two-thirds of patients and valvular problems in the remaining one-third. Predictors of postoperative heart failure are lower preoperative ejection fraction, coronary artery disease, and higher NYHA functional class.<sup>226</sup> Importantly, preoperative functional class III/IV symptoms are associated with markedly decreased postoperative medium- and long-term survival independent of all other baseline characteristics.<sup>227</sup>

## SECONDARY MITRAL REGURGITATION

To risk stratify patients after myocardial infarction, quantifying and staging secondary mitral regurgitation (eg, IMR) are of key importance<sup>80,156,228-230</sup> (Table 34-2). In a report from

the Mayo Clinic, medically managed patients who developed IMR late after myocardial infarction had a very high mortality rate (62% at 5 years) compared with those with an infarction who did not develop IMR (39% at 5 years).<sup>156</sup> Medium-term survival for patients with IMR and LV systolic dysfunction was inversely related to the ERO and regurgitant volume. After 5 years, the survival rate was 47% for patients with an ERO of less than 20 mm<sup>2</sup> and 29% for those with an ERO of 20 mm<sup>2</sup> or greater. Survival at 5 years was 35% when the regurgitant volume was 30 mL/beat or greater compared with 44% for those with a regurgitant volume of less than 30 mL/beat. The relative risk ratio for cardiac death for patients with IMR was 1.56 for patients with an ERO of less than 20 mm<sup>2</sup> versus 2.38 for those with an ERO of greater

**TABLE 34-2: Stages of Secondary Mitral Regurgitation**

2D, 2-dimensional; ERO, effective regurgitant orifice; HF, heart failure; LA, left atrium; LV, left ventricular; MR, mitral regurgitation; TTE, transthoracic echocardiogram. \*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient. Categorization of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence. †The measurement of the proximal isovelocity surface area by 2D TTE in patients with secondary MR underestimates the true ERO due to the crescentic shape of the proximal convergence. Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Thorac Cardiovasc Surg*. 2014 Jul;148(1):e1-e132.

than 20 mm<sup>2</sup>. Note this ERO threshold for secondary IMR if one-half the ERO threshold applied to patients with primary MR.<sup>156,157</sup> In those with myocardial infarction, the incidence of congestive heart failure was also high in patients with IMR.<sup>229</sup> At 5 years, the rate of congestive heart failure was 18% without IMR compared with 53% if IMR was present. If the ERO was less than 20 mm<sup>2</sup>, the incidence of congestive heart failure was 46% compared with 68% when the ERO was 20 mm<sup>2</sup> or greater.<sup>229</sup>

Mitral valve repair or replacement for patients with IMR has been associated with higher operative risk (4 to 30%) than for patients with nonischemic chronic mitral regurgitation, which reflects the concomitant adverse consequences of previous myocardial infarction and ischemia.<sup>205,206,231-237</sup>

Coronary revascularization alone in the setting of moderate or severe IMR leaves many patients with substantial residual mitral regurgitation and heart failure symptoms.<sup>113,238-240</sup> Immediately postoperatively, IMR is absent or mild in 73% and severe in 6%; on the other hand, by 6 weeks, only 40% of patients have absent or mild mitral regurgitation, and 22% have severe mitral regurgitation<sup>239</sup> (Fig. 34-17). Because moderate IMR does not universally resolve with bypass grafting alone, it has been argued that valve repair be considered in these patients because it potentially can reduce cardiac morbidity and may improve long-term survival.<sup>113,228,238</sup> Conversely, some investigators have shown that for patients with moderate or moderately severe IMR, isolated coronary surgery compared to coronary revascularization combined with

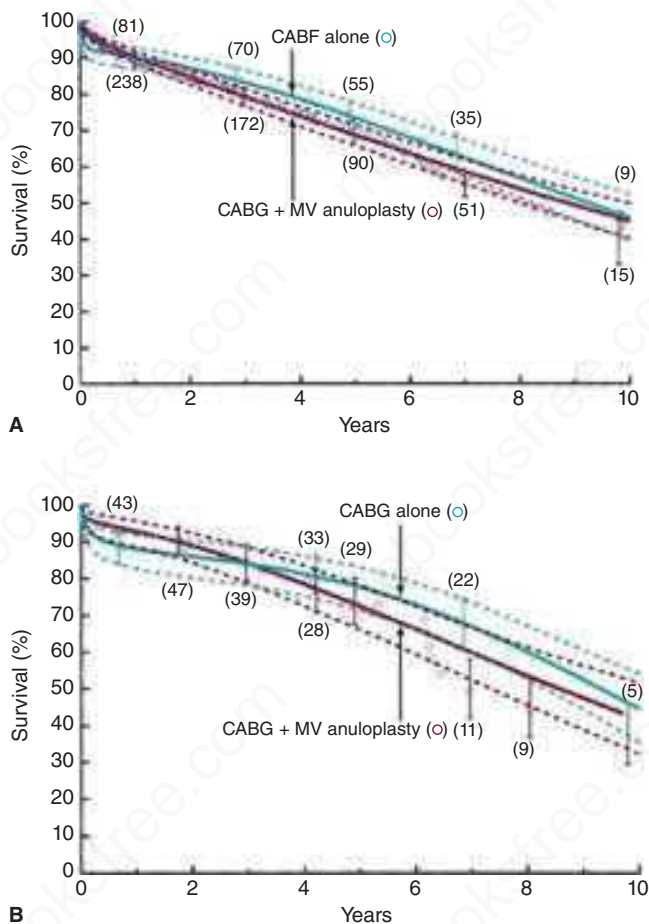

**FIGURE 34-17** Course of mitral regurgitation after isolated coronary revascularization. Horizontal axis is time after coronary artery bypass grafting on a logarithmic scale. 1+ is mild regurgitation, 2+ moderate, 3+ moderately severe, and 4+ severe. (A) All grades of mitral regurgitation. (B) Mitral regurgitation grades 0 or 1+ compared with 2+, 3+, or 4+. Symbols (red circles, green circles) represent aggregated raw echocardiographic values for mitral regurgitation grade. CABG, coronary artery bypass grafting; MR, mitral regurgitation. (Reproduced with permission from Lam BK, Gillinov AM, Blackstone EH, et al: Importance of moderate ischemic mitral regurgitation, *Ann Thorac Surg.* 2005 Feb;79(2):462-470.)

mitral annuloplasty provide similar long-term outcome with survival rates of 82 to 92% at 1 year, 40 to 75% at 5 years, and 37 to 47% at 10 years<sup>232-234,241-243</sup> (Fig. 34-18). Predictors of long-term mortality are older age, prior myocardial infarction, unstable angina, chronic renal failure, atrial fibrillation, absence of an internal mammary artery graft, lack of beta blocker use, lower ejection fraction, smaller LA size, global LV wall motion abnormalities, severe lateral wall motion abnormalities, ST segment elevation in the lateral leads, mitral leaflet restriction, and fewer bypass grafts.<sup>232,234,241</sup> In the experience of some investigators, combined mitral valve repair and coronary revascularization does not emerge as a predictor of long-term survival. Furthermore, in a recent report from the Cardiothoracic Surgical Trials Network of 301 patients with moderate IMR randomized to coronary artery bypass grafting alone or combined coronary artery

bypass grafting with valve repair, the rate of death is 7.3% in and 6.7% at one year.<sup>244</sup> Although moderate or severe regurgitation is less common in the combined group than the coronary artery bypass group alone (11 vs 31%, respectively), the combined group had longer bypass time, longer hospital stay, and more neurologic events. Also, it is sobering that the addition of mitral valve repair does not result in a greater degree of LV reverse remodeling (measured by LVESI) at one year.<sup>244</sup>

To identify preoperatively those that would be more likely to benefit from isolated coronary artery bypass grafting, the Prague group evaluated 135 patients with moderate IMR undergoing isolated coronary artery bypass surgery; of these, 42% of the patients had no or mild mitral regurgitation postoperatively, whereas 47% failed to improve.<sup>245</sup> Preoperatively, the improvement group had significantly more viable myocardium and less dyssynchrony between papillary muscles

**FIGURE 34-18** Survival after coronary artery bypass grafting (CABG) alone or with concomitant mitral valve (MV) annuloplasty for ischemic mitral regurgitation. Vertical bars are 68% confidence limits. Numbers in parentheses are patients alive and remaining at risk. Solid lines are parametric estimates enclosed within 68% confidence limits. (A) Unadjusted survival, based on 37 deaths after CABG alone and 92 after CABG + MV annuloplasty. (B) Propensity-matched survival, based on 19 deaths after CABG alone and 19 after CABG + MV annuloplasty. (Reproduced with permission from Mihaljevic T, Lam BK, Rajeswaran J, et al: Impact of mitral valve annuloplasty combined with revascularization in patients with functional ischemic mitral regurgitation, *J Am Coll Cardiol*. 2007 Jun 5;49(22):2191-2201.)

than the failure group. Thus, reliable improvement in moderate IMR by isolated coronary artery revascularization is likely only in patients with concomitant presence of viable myocardium and absence of dyssynchrony between papillary muscles.<sup>245</sup> In a pilot study of cardiac MRI in patients with IMR and ischemic cardiomyopathy, extensive scarring and severe wall motion abnormalities in the region of posterior papillary muscle correlated with recurrent mitral regurgitation after coronary artery bypass grafting and mitral annuloplasty.<sup>246</sup> Routinely assessing scar burden may identify patients for whom annuloplasty alone is insufficient to eliminate mitral regurgitation. Therefore, although some investigators report

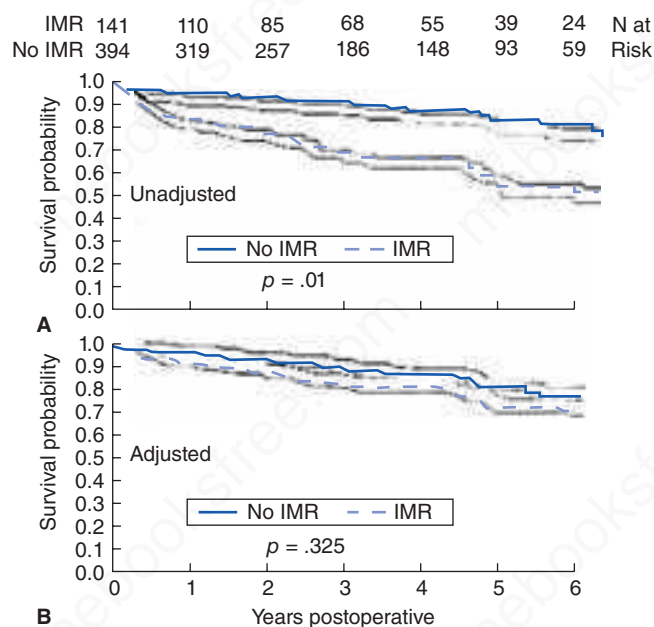

that annuloplasty can be added to coronary grafting in high-risk patients without increasing early mortality, the potential benefit with respect to late survival and functional status is not proved and may be limited because of the underlying ischemic cardiomyopathy.<sup>233-234,247</sup>

In terms of the best type of valve surgery for patients with IMR, it is likely that the clinical condition and LV functional status are more powerful determinants of outcome than whether one undergoes repair or replacement.<sup>231,248-252</sup> In the Brigham and Women's Hospital experience, patients with IMR and annular dilatation who underwent valve repair and coronary revascularization had a worse long-term outcome than those who underwent valve replacement and coronary revascularization.<sup>231</sup> Notably, the pathophysiology or cause of the IMR was a stronger determinant of long-term survival than was the type of valve procedure. In the Cleveland Clinic experience, when patients with severe IMR underwent mitral valve surgery, undersized annuloplasty resulted in less IMR postoperatively in 70 to 85% of cases.<sup>249</sup> Based on propensity score analysis, they found that in the lower-risk quintiles of patients with IMR, valve repair conferred a survival advantage (58% at 5 years) over those who underwent valve replacement (36% at 5 years); however, in the highest-risk patients, late survival rates after valve repair and valve replacement were similarly poor, and valve replacement actually conferred a small survival advantage.<sup>250</sup> At the Laval University in Quebec, 370 patients with IMR underwent either mitral valve repair or mitral valve replacement.<sup>251</sup> The operative mortality was lower in the repair group (10%) compared with the replacement group (17%), but 6-year survival estimates were similar at 73 and 67%, respectively. The type of valve procedure did not emerge as a risk factor for a poor outcome. In the Italian Study on the Treatment of Ischemic Mitral Regurgitation Trial using propensity score matching analysis to evaluate surgical outcomes of patients with chronic IMR and LV dysfunction (ejection fraction less than 40%), those who underwent mitral valve repair had an 8-year survival rate of 82% compared to 80% for those undergoing mitral valve replacement.<sup>237</sup> Further, LV function did not improve in either group postoperatively, and mitral valve repair was a strong predictor of valve-related reoperation. The recent Cardiothoracic Surgical Trials Network multi-institutional randomized trial of 251 patients with severe IMR comparing complete rigid or semirigid ring annuloplasty with mitral valve replacement demonstrated no difference in LV reverse remodeling or survival at 12 months.<sup>252</sup> The rate of recurrent or residual moderate or severe IMR 6 months postoperatively was 32.6% in the annuloplasty group versus 2.3% in the MVR group.<sup>252</sup> Replacement provided a more durable correction of mitral regurgitation with no difference in clinical outcomes at this early follow-up period.<sup>252</sup> These reports emphasize the guarded prognosis of patients with severe IMR and the impact of the patient's preoperative clinical condition and LV functional status (and not the type of procedure *per se*) on outcome. Although mitral valve repair may still be preferred by some for patients with

severe IMR, most surgeons today believe complete chordal-sparing mitral valve replacement is preferable to repair in the most severely ill patients and in those with certain echocardiographic characteristics such as severe bileaflet tethering. Chordal-sparing MVR certainly is more predictable and reliable.

In patients with chronic primary versus secondary mitral regurgitation, the decision to repair or replace the valve should be based on the patient's clinical status and not on whether the regurgitation is degenerative or ischemic in etiology.<sup>235,236,253</sup> In a Mayo Clinic study, older age, ejection fraction of 35% or less, three-vessel coronary disease, mitral valve replacement, and residual mitral regurgitation at discharge were risk factors for death. The cause of the mitral regurgitation, ischemic versus degenerative, was not a predictor of long-term survival, class III or IV congestive heart failure, or recurrent regurgitation.<sup>235</sup> In the Cleveland Clinic experience, analysis of the etiology of the mitral regurgitation (degenerative vs ischemic) in patients with coronary artery disease after combined mitral valve repair and coronary revascularization showed that those with IMR had more extensive coronary disease, worse ventricular function, more comorbidities, and more preoperative symptoms.<sup>253</sup> Unadjusted 5-year survival estimates were 64 and 82% for patients with IMR and degenerative mitral regurgitation, respectively; however, matched pairs had equivalent but poor 5-year survival rates (66 and 65%, respectively). In the Duke database of patients undergoing mitral valve repair with or without coronary artery bypass grafting, the 30-day mortality was 4.3% for those with IMR and 1.3% for nonischemic group; the 5-year survival was 56% for IMR and 84% for those with nonischemic mitral regurgitation.<sup>236</sup> The etiology of mitral regurgitation (ischemic vs degenerative) was not predictive of survival after annuloplasty and coronary artery grafting; importantly, the long-term outcomes were more influenced by advanced age and the number of preoperative comorbidities<sup>236</sup> (Fig. 34-19).

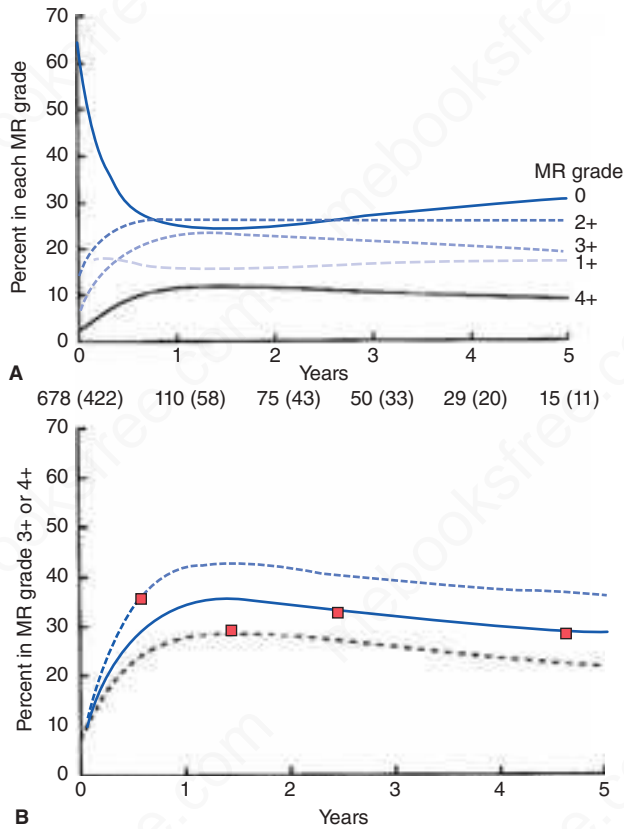

A compelling explanation for the generally poor long-term outcome of patients who undergo mitral valve repair for IMR is the presence of residual and/or recurrent mitral regurgitation postoperatively.<sup>254-259</sup> Persistence of mitral regurgitation after annuloplasty is due predominantly to augmented posterior leaflet apical tethering with no improvement in anterior leaflet tethering and no increase in coaptation length; higher preoperative LVED index may also predict recurrent mitral regurgitation.<sup>256-258</sup> In a Cleveland Clinic report of annuloplasty for IMR (95% with concomitant coronary artery bypass grafting), the proportion of patients with 0 or 1+ mitral regurgitation decreased from 71% preoperatively to 41% postoperatively, but the proportion with 3+ or 4+ residual or recurrent IMR increased from 13 to 28% during the first 6 months after repair<sup>254</sup> (Fig. 34-20). The temporal pattern of development of severe regurgitation was similar for those who received a partial band or a complete ring (25%), but it was substantially worse for those who received a strip of glutaraldehyde-preserved xenograft pericardium for annuloplasty (66%).<sup>254</sup> Others have suggested that the

**FIGURE 34-19** Survival of patients undergoing mitral valve repair with ischemic mitral regurgitation versus nonischemic mitral regurgitation before (A) and after (B) adjustment for differences in baseline patient characteristics. IMR, ischemic mitral regurgitation; NMR, nonischemic mitral regurgitation. (Reproduced with permission from Glower DD, Tuttle RH, Shaw LK, et al: Patient survival characteristics after routine mitral valve repair for ischemic mitral regurgitation, *J Thorac Cardiovasc Surg.* 2005 Apr;129(4):860-868.)

use of smaller, complete, and rigid annuloplasty rings may provide improved freedom from recurrent mitral regurgitation in patient with FMR or IMR.<sup>260</sup> At the Montreal Heart Institute, the operative mortality rate for those undergoing mitral valve repair for IMR was 12.3% and the 5-year survival was 68%.<sup>261</sup> Recurrent moderate mitral regurgitation was seen in 37%, and severe regurgitation was present in 20% at mean follow-up of 28 months. Only age and less marked preoperative posterior tethering were predictive of recurrent mitral regurgitation. Data from the Cardiothoracic Surgical Trials Network severe IMR trial demonstrated a rate of recurrence of moderate regurgitation of 26% and of severe regurgitation of 4% at 6 months after mitral valve repair.<sup>257</sup> The presence of inferior basal aneurysm/dyskinesis was strongly associated with recurrent regurgitation and was a better predictor of recurrence than individual measures of leaflet tethering or LV remodeling, since it integrates both leaflet tethering and LV remodeling measures.<sup>257</sup> The Leiden experience with the use of restrictive mitral semirigid undersized annuloplasty (mean ring size of 26 mm) in patients with FMR and heart failure demonstrated a more satisfactory 19% rate of recurrent regurgitation (grade 2-4) at a mean follow-up of 2.6 years.<sup>259</sup> Based on their method of quantification of preoperative parameters of mitral and LV geometry using echocardiography, distal anterior leaflet tethering and posterior leaflet tethering were independent predictors of recurrent mitral regurgitation<sup>259</sup> (Fig. 34-21). These findings highlight

**FIGURE 34-20** Progression of mitral regurgitation after surgical annuloplasty overall. (A) All grades of mitral regurgitation. Curves for each regurgitation grade represent average temporal prevalence, and they sum up to 100% at each point in time. Numbers below the horizontal axis represent echocardiograms available at various time points, with the number of patients in parentheses. (B) Prevalence of regurgitation grades 3+ or 4+. Dashed lines are 68% confidence limits of average prevalence. MR = mitral regurgitation. (Reproduced with permission from McGee EC, Gillinov AM, Blackstone EH, et al: Recurrent mitral regurgitation after annuloplasty for functional ischemic mitral regurgitation, *J Thorac Cardiovasc Surg.* 2004 Dec;128(6):916-924.)

the need for better patient selection or possibly chordal-sparing mitral valve replacement in certain patients.<sup>254,257,259,261,262</sup>

In brief, because mitral regurgitation is only one component of the disease, the appropriate management of patients with secondary mitral regurgitation or IMR is complicated, since restoring valve competence may not reverse the underlying pathophysiology or improve the prognosis.<sup>80,125</sup> For instance, in those with secondary mitral regurgitation, adverse outcomes are associated with lesser degrees of mitral regurgitation and with a smaller calculated ERO than those with primary mitral regurgitation.<sup>80</sup> ERO, however, may be underestimated by 2D echocardiography-derived flow convergence method due to the crescentic shape of the regurgitant orifice.<sup>80</sup> Importantly, the 2014 ACC/AHA valve guidelines revised the definition of severe **secondary** mitral regurgitation from an ERO of  $>0.4$  to  $>0.2$  cm<sup>2</sup> and a regurgitant volume of  $>60$  to  $>30$  mL.<sup>80,125</sup> However, the new guidelines present clinical challenges because 2D and 3D

echocardiography may generate disparate findings of ERO and regurgitant volume, and the nature of secondary mitral regurgitation may be dynamic depending on medical therapy (loading conditions) and after revascularization or cardiac resynchronization.<sup>125</sup> In terms of decision making, a rebuttal to the 2014 AHA/ACC guidelines focusing so much on ERO in patients with secondary mitral regurgitation was published in 2014 by a group of experienced echocardiographers and cardiac surgeons arguing that an integrated approach based on clinical judgment that incorporates multiple echo Doppler parameters without relying on any single parameter is best.<sup>125</sup> This approach would discount poor quality data (eg, ERO underestimation by PISA) and employ multiple echocardiographic variables, recognize that the definition of “severe” (ERO  $> 0.2$  cm<sup>2</sup> and regurgitant volume  $> 30$  mL) depends on LV size and on the LV-LA pressure gradient, and specify the quantification method (2D, PISA, planimetry, volumetric).<sup>125</sup>

### Mitral Subvalvular Apparatus and LV Systolic Function

Originally proposed by Lillehei and colleagues in 1964, the mitral subvalvular apparatus (or valvular-ventricular complex) including chordal and papillary muscle function is important for optimal postoperative LV geometry and systolic pump function.<sup>101-104,166,167,263-267</sup> After mitral valve replacement with total chordal excision in the experimental and clinical settings, LV performance declines along with depression of regional and global LV elastance, dyssynergy of contraction, and dyskinesia at the papillary muscle insertion sites. Conversely, valve replacement with total or partial chordal preservation maintains LV contractile function.<sup>101-103,183,267</sup> Mitral valve replacement with chordal division is associated with reduced rest and exercise LVEF owing in part to an increase in LV ESS.<sup>266</sup> Mitral valve repair does not perturb rest and exercise ejection indexes of LV function primarily as a consequence of reducing ESS and maintaining a more ellipsoidal chamber geometry. Mitral valve replacement with complete chordal transection results in no postoperative change in LV end-diastolic volume, an increase in LVESV, an increase in ESS, and a decrease in ejection fraction.<sup>265</sup> Patients who undergo chordal-sparing valve replacement, on the other hand, have a smaller LV end-diastolic volume and LVESV, decreased ESS, and unchanged ejection fraction. These findings suggest that smaller chamber size, reduced systolic afterload, and preservation of ventricular contractile function act in concert to maintain ejection performance after chordal-sparing mitral valve replacement. In contrast, increased LV chamber size, increased systolic afterload, and probable reduction in LV contractile function leading to reduced ejection performance occur in patients who undergo valve replacement with chordal transection.<sup>265</sup>

The loss of LV systolic function after mitral valve replacement with chordal division may be caused by heterogeneity of regional LV wall stress and not local depression of regional

**FIGURE 34-21** Method of quantification of basal mitral anterior leaflet angle, distal mitral anterior leaflet angle, and the posterior mitral leaflet angle. Measurements are depicted on echocardiographic image of the mitral valve in apical four-chamber view in mid-systole. The basal mitral anterior leaflet angle is defined as the angle between the annular plane and the basal portion of the anterior leaflet. The distal mitral anterior leaflet angle is defined as the angle between the annular plane and the anterior leaflet tip distance (which corresponds to the distance between the medial part of the mitral annulus and the coaptation point). The posterior mitral leaflet angle is defined as the angle between the annular plane and the posterior leaflet. (Reproduced with permission from Ciarka A, Braun J, Delgado V, et al: Predictors of mitral regurgitation recurrence in patients with heart failure undergoing mitral valve annuloplasty, *Am J Cardiol.* 2010 Aug 1;106(3):395-401.)

contractile function.<sup>268</sup> After valve replacement with chordal transection in an experimental model, outward displacement of the ventricular wall and transverse shearing deformation occurred in the LV region papillary muscle insertion during isovolumic contraction.<sup>268</sup> Circumferential and radial strains during ejection were maintained at the basal LV site and enhanced in the apical LV site. Chordal transection augmented regional myocardial loading at the papillary muscle insertion site; the resulting heterogeneity of regional systolic function might be the mechanism for reduced global LV function and slowed ventricular relaxation. Anterior chordal transection with mitral valve replacement caused impaired regional LV function and also impaired regional right ventricular function,<sup>269</sup> whereas radionuclide angiography before and after mitral valve repair showed that LVEF did not change and right ventricular ejection fraction improved. In the region of the anterolateral papillary muscle insertion, local LV contractile function deteriorated after valve replacement with chordal transection, and right ventricular apico-septal region was similarly impaired.<sup>269</sup>

In patients with chronic IMR, surgical division of the second-order chordae subtending the infarcted wall (usually those originating from the posteromedial papillary muscle) has been proposed to treat IMR by reducing leaflet tethering.<sup>270-272</sup> It is postulated that if the apical systolic tethering is eliminated, the normal redundancy of the mitral leaflet area creates better coaptation with the intact first-order

or marginal chordae preventing leaflet prolapse. Clinically, the Toronto group compared the outcomes of patients who underwent chordal-cutting mitral valve repair (n = 43) and those undergoing conventional mitral valve repair (n = 49) for IMR.<sup>271</sup> The reduction in tenting height before-to-after repair was similar in the two groups of patients, but those undergoing chordal cutting had a greater reduction in tenting area. The chordal-cutting group also had greater mobility of the anterior leaflet, as measured by a reduction in the distance between the free edge of the anterior mitral valve leaflet and the posterior LV wall. Additionally, those undergoing conventional mitral valve repair had a higher incidence of recurrent mitral regurgitation during 2 years of follow-up.<sup>271</sup> Chordal cutting did not adversely affect postoperative LVEF (10% relative increase in EF compared with 11% in the control group). The authors proposed that chordal cutting improves mitral valve leaflet mobility and reduces mitral regurgitation recurrence in patients with IMR, without any obvious deleterious effects on LV function.<sup>271</sup> It is known, however, that division of the chordae, especially the second-order or “strut” chordae, can impair LV systolic function.<sup>273,274</sup> Dividing the second-order chordae in an experimental acute ovine preparation caused regional LV systolic dysfunction near the chordal insertion sites and neither prevents nor decreases the severity of acute IMR, septal-lateral annular dilatation, leaflet tenting area, or leaflet tenting volume.<sup>273</sup> Cutting the anterior mitral leaflet second-order chordae alters LV chamber long-axis and

subvalvular geometry, remodels end-diastolic transmural myocardial architecture in the equatorial lateral LV region, perturbs systolic transmural LV wall-thickening mechanics (thereby decreasing subendocardial “microtorsion”) and wall thickening, changes systolic temporal dynamics with delayed ejection, and impairs global LV systolic function (decreased end-systolic elastance and PRSW).<sup>274</sup> Because of the importance of the chordae for LV structure and function, we believe that caution is necessary when considering procedures that cut second-order chordae to treat patients with IMR because of the resulting compromise in LV systolic function in ventricles that are already impaired.<sup>273,274</sup>

## Summary

The functional competence of the mitral valve relies on the interaction of the mitral annulus and leaflets, chordae tendineae, papillary muscles, left atrium, and left ventricle. Dysfunction of any one or more components of this valvulo-ventricular complex can lead to mitral regurgitation. Important causes of mitral regurgitation include myxomatous degeneration and prolapse (primary mitral regurgitation) due to fibroelastic deficiency in older patients or Barlow’s disease in younger subjects, ischemic heart disease with IMR (secondary mitral regurgitation), dilated cardiomyopathy leading to FMR (secondary mitral regurgitation), rheumatic valve disease, mitral annular calcification, and infective endocarditis. Four structural changes of the mitral valve apparatus may produce regurgitation: leaflet retraction from fibrosis and calcification, annular dilatation, chordal abnormalities, and LV systolic dysfunction with or without papillary muscle involvement. In IMR, changes in global and regional LV function and geometry, alterations in mitral annular geometry, abnormal leaflet (Carpentier type IIIb) motion, leaflet malcoaptation, increased interpapillary distance, and papillary muscle lateral displacement and malalignment all may result in apical tenting of the leaflets and mitral incompetence.

With mitral regurgitation, the impedance to LV emptying is lower because the mitral orifice is parallel with the LV outflow tract. Reduced LV impedance allows a greater proportion of contractile energy to be expended in myocardial fiber shortening than in tension development. After the initial compensatory phase, LV contractility becomes progressively more impaired with chronic mitral regurgitation and chronic LV volume overload. Importantly, because of the low impedance during systole, clinical indexes of systolic function, such as ejection fraction, can be normal even if depressed LV contractility is already present. LVESV is less dependent on preload than is ejection fraction and is a better measure of LV contractile reserve. Preoperative LVESV is a good predictor of postoperative outcome. Surgical mitral valve repair (or, if repair is judged not to be durable, mitral valve replacement with total chordal preservation) for chronic mitral regurgitation can preserve LV contractility, particularly in patients with a normal preoperative ejection fraction who have minimal ventricular dilatation and those without major coronary disease. In patients with impaired preoperative LV contractility,

LV systolic function may not necessarily improve after ring annuloplasty and definitely will not improve if the subvalvular apparatus and chordae are divided during mitral valve replacement.

IMR is generally associated with a higher operative risk than is nonischemic chronic mitral regurgitation. In patients with ischemic cardiomyopathy and mild mitral regurgitation, isolated coronary artery bypass grafting may suffice if the LV inferior wall is still viable. Other argue that coronary revascularization alone in the setting of moderate IMR leaves many patients with substantial residual mitral regurgitation, heart failure symptoms, and a grave prognosis. Because moderate IMR does not resolve reliably with coronary revascularization alone, valve repair should be considered because it can reduce complications and possibly improve long-term survival. Survival after mitral valve surgery and coronary artery bypass grafting is more determined by the extent of coronary artery disease and severity of preoperative LV dysfunction than by the etiology of mitral regurgitation. Because mitral regurgitation is only one component of the disease, the appropriate management of patients with IMR is complicated, since adverse outcomes are associated with lesser degrees of mitral regurgitation (a smaller ERO threshold than those with primary mitral regurgitation). The 2014 ACC/AHA practice guidelines present clinical challenges because 2D and 3D echocardiography may generate disparate findings of ERO and regurgitant volume, and the nature of secondary mitral regurgitation may be dynamic depending on loading conditions and after revascularization or resynchronization. In managing these patients, an integrated approach has been proposed that is based on clinical judgment and that incorporates multiple Doppler parameters without relying on any single parameter.

# Mitral Valve Repair

Dan Loberman • Paul A. Pirundini • John G. Byrne  
• Lawrence H. Cohn

It can be reasonably argued that the very dawn of cardiac surgery began with a mitral valve repair. On May 20, 1923, Dr Elliot Carr Cutler (Fig. 35-1) performed the world's first successful mitral valve repair at the Peter Bent Brigham Hospital in Boston, Massachusetts.<sup>1</sup> Dr Cutler carried out a transventricular mitral valve commissurotomy with a neurosurgical tenotomy knife on a critically ill 12-year-old girl. His choice of instrument was likely influenced by Dr Harvey Cushing who was surgeon-in-chief at the time. A new era in surgery was introduced as well as the reality of mitral valve repair.<sup>2</sup> Cutler had worked assiduously on this problem in the Surgical Research Laboratories of Harvard Medical School before turning his attention to this critically ill patient. Subsequent attempts at this operation using a device to cut out a segment of the diseased mitral valve resulted in several deaths from massive mitral regurgitation and Cutler eventually abandoned the procedure.<sup>3</sup> Of Cutler's contemporaries, Henry Souttar of England performed a single successful transatrial finger commissurotomy in 1925, but received no further referrals.<sup>4</sup> After Souttar, there remained little activity in mitral valve repair until the 1940s when Dwight Harken, then the Chief of Cardiothoracic Surgery at the Peter Bent Brigham Hospital, published his groundbreaking series of valvuloplasty patients for mitral stenosis.<sup>5</sup> Dr Charles Bailey of Philadelphia also published a concomitant series of a similar large group of patients.<sup>6</sup>

That early era focused on mitral stenosis created by rheumatic heart disease, which was extremely common at the time. Surgical treatment of mitral regurgitation for prolapse was first introduced in the 1950s<sup>7-9</sup> but with limited success. Subsequent decades would see the visionary concepts of surgical leaders such as Alain Carpentier, Dwight McGoon, Carlos Duran, and others come to the fore as their visionary ideas for mitral valve reconstruction began to take hold and excellent results were reported. Like many other groundbreaking ideas, their concepts were met with resistance that has gradually dissipated as long-term results by these surgeons have been validated. The concept that repair of mitral regurgitation might serve to further damage a weakened left ventricle (LV) by eliminating the "pop-off" mechanism<sup>16</sup> of the regurgitant valve. This proved a significant barrier to referral that only in the past few decades has been overcome.

What has now become firmly established is the significant contribution to overall left ventricular function of the papillary muscle-annular interaction.<sup>17</sup> As a result of these contributions, mitral valve repair, if technically possible, has now become recognized as the procedure of choice for mitral valve pathology of virtually all etiologies, to the extent that mitral valve repair is always considered first in virtually any clinical situation in which the mitral valve is regurgitant.

## ANATOMY OF THE MITRAL VALVE

The bicuspid mitral valve is one of the most complex structures of the human heart, its complexity lies in its multifaceted anatomy. The concept of "form follows function" is particularly applicable to the mitral valve. Because each part of the valve's anatomy is intimately related to function, there are a variety of pathways whereby regurgitation may be created. If one part of the valvular apparatus fails, regurgitation can result. There are five discrete components to the mitral valve complex: the annulus, the two leaflets (anterior and posterior), the chordae, the papillary muscles, and the LV (Fig. 35-2A).

As part of the fibrous skeleton of the heart, the annulus is the myocardial connective tissue area where the mitral valve leaflets attach to the intersection of the left atrium and LV. It is surrounded by vitally important structures that the cardiac surgeon must avoid for safe surgery: the circumflex coronary artery laterally, the coronary sinus medially, the aortic root superiorly, and the atrioventricular node superior-medially. In myxomatous disease it is the posterior annulus that usually dilates.<sup>18</sup> Previous dictum held that the anterior annulus does not dilate, but recent data suggest that it may dilate a limited amount.<sup>19</sup> Of critical importance to the surgeon are the right and left fibrous trigones. These are intimately related to the anterior annulus and are contiguous with the aortic valve curtain and must be identified during surgery. The trigones, as part of the essential structural framework of the heart, form the anchoring points for ring annuloplasty.

The anterior leaflet of the mitral valve (AML) is in continuity with the left and noncoronary cusps of the aortic valve and is located directly beneath the left ventricular outflow tract (LVOT). It is sometimes referred to as the aortic

**FIGURE 35-1** Elliot Carr Cutler.

leaflet. It typically accounts for approximately one-third of the circumference of the annulus, with the posterior leaflet accounting for the rest.<sup>20</sup> The posterior mitral valve leaflet (PML) is crescent shaped and is more commonly involved in degenerative disease. For surgical decision making and analysis, both the anterior and posterior leaflets are divided into three parts, corresponding to the three scalloped areas of each leaflet (A1, A2, A3 for the anterior leaflet; P1, P2, and P3 for the posterior leaflet; 1 refers to the leftmost, or lateral scallop; 2 the middle scallop; and 3 the rightmost, or medial scallop; Fig. 35-2B).

There are two papillary muscles, the anterolateral and the posteromedial. Each muscle is attached to the leaflets by the chordae tendinae. These chords are composed of string-like fibrous connective tissue. Primary chords are those that attach to the edge of the leaflet. Secondary chords are those that attach to the underside of the leaflets. Tertiary chords, which are only seen on the posterior mitral leaflet, are those that attach to the undersurface of the leaflet directly from the ventricular wall instead of from the papillary muscle. The papillary muscles each give off chordae to both leaflets and correspond to the anterolateral and posteromedial commissures of the mitral valve. The anterolateral papillary muscle receives blood from both the left anterior descending artery as well as the circumflex artery; the posteromedial one receives blood usually from only the posterior descending artery or a branch of the circumflex artery. Because of its single coronary blood supply, the posteromedial papillary

muscle is more susceptible to infarction and rupture than the anterolateral one.

The LV acts in concert with the papillary muscles via the chordae to pull in the leaflet edges during systole, thereby maintaining the line of coaptation and therefore valve competency. If the LV dilates from any etiology, failure of central leaflet coaptation may occur and regurgitation created. Such regurgitation in a valve with *normal leaflets but dilated annulus* is termed *functional* mitral regurgitation (MR).

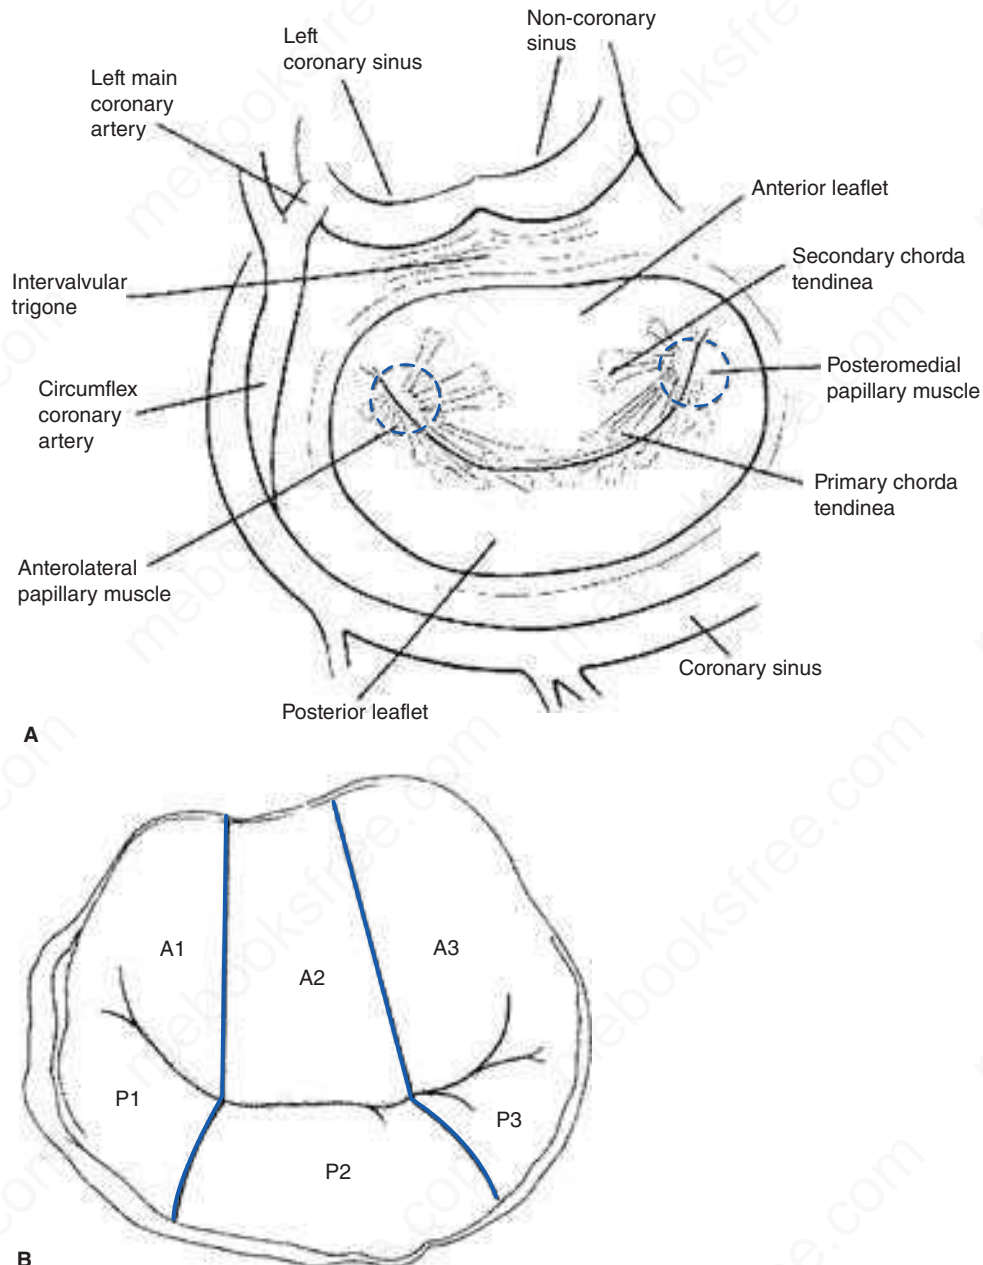

## MYXOMATOUS MITRAL VALVE DISEASE

### Etiology and Pathophysiology

The underlying etiology of myxomatous disease is a defect in the fibroelastic connective tissue of the valvular leaflets, chordae, and annulus.<sup>21</sup> The myxomatous defect leads to an abnormal elongation and redundancy of valve tissue and chordae. Each particular anatomic redundancy creates mitral regurgitation in its own particular manner. Annular dilatation (Fig. 35-3) obliterates the normal coaptation line between the anterior and posterior leaflet, causing regurgitation. If primarily posterior annular dilatation occurs, there is a separation in the middle of the valve between the two leaflets and blood leaks through during ventricular contraction. Leaflet redundancy results in a movement of the redundant leaflet into the left atrium during diastole. If severe enough, that movement leads to a compromised coaptation line and MR then ensues. Elongation of the chordae also causes leaflet tissue to move into the atrium during diastole, also resulting in compromised coaptation. Ruptured or flail leaflets are often the result of systolic stresses fracturing weakened chordae, causing severe regurgitation.

Mitral regurgitation represents pure volume overload for the LV.<sup>22</sup> In myxomatous disease, MR is typically of the chronic compensated variety.<sup>23</sup> A vicious cycle is perpetuated whereby the excess volume load over time results in ventricular failure. Ventricular failure itself implies ventricular dilatation, which results in a greater degree of MR. Thus, MR begets more MR, and a downward spiral is created.<sup>17</sup> MR created by left ventricular failure occurs primarily by ventricular dilatation. Successful repair will result in left ventricular mass reduction.<sup>24</sup> Ventricular dilatation “pulls” or “tethers” the leaflets open, thereby impinging on coaptation. In degenerative disease of the mitral valve, however, the LV itself per se does not primarily cause MR in the early course of the disease.

Carpentier<sup>10</sup> has developed a mitral valve analysis protocol and surgical philosophy for repair of all types of valves (Fig. 35-4). Myxomatous disease has become the pathology responsible for the vast majority of patients with mitral regurgitation in the United States.<sup>25</sup> Currently, mitral valve prolapse, as a part of the spectrum of degenerative disease, is present in about 5% of the general population,<sup>26</sup> with about 10% of these patients exhibiting severe MR requiring surgery.<sup>27</sup> Whatever the ultimate pathologic pathway creating

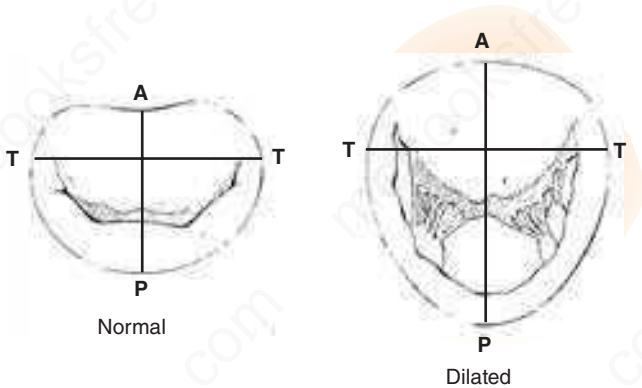

**FIGURE 35-2** Surgical anatomy of the mitral valve. (A) Critical structures that the cardiac surgeon must recognize, including the circumflex coronary artery, the coronary sinus, the atrioventricular node, and aortic root. Note that the left and right trigones are superior to the commissures. (B) The conventional terminology used to describe the pathoanatomic parts of the anterior and posterior leaflets.

regurgitation, more than 95% of all degenerative disease should be amenable to successful repair.

### Diagnostic Work-up and Indications for Operation

Patient presentation is typically quite varied depending on the degree of MR as well as the chronicity of the disease. Patients may be floridly symptomatic or completely asymptomatic. Symptoms can occur in different forms. Heart

failure symptoms are secondary to pulmonary venous hypertension as well as fluid retention. This may include shortness of breath, limited exertional capacity, fluid overload, and in the late stage of the disease, frank heart failure. Embolization sequelae and arrhythmias form a second set of symptoms and include atrial fibrillation and increased stroke risk.<sup>28</sup> Additionally, regurgitation predisposes the valve to infectious endocarditis.<sup>29</sup> Abnormal hemodynamics create pathologic shear stresses and turbulence that generates vulnerability to infection in the valve.

**FIGURE 35-3** Annular dilatation. A, anterior; P, posterior; T, trigone.

## Evaluating MR

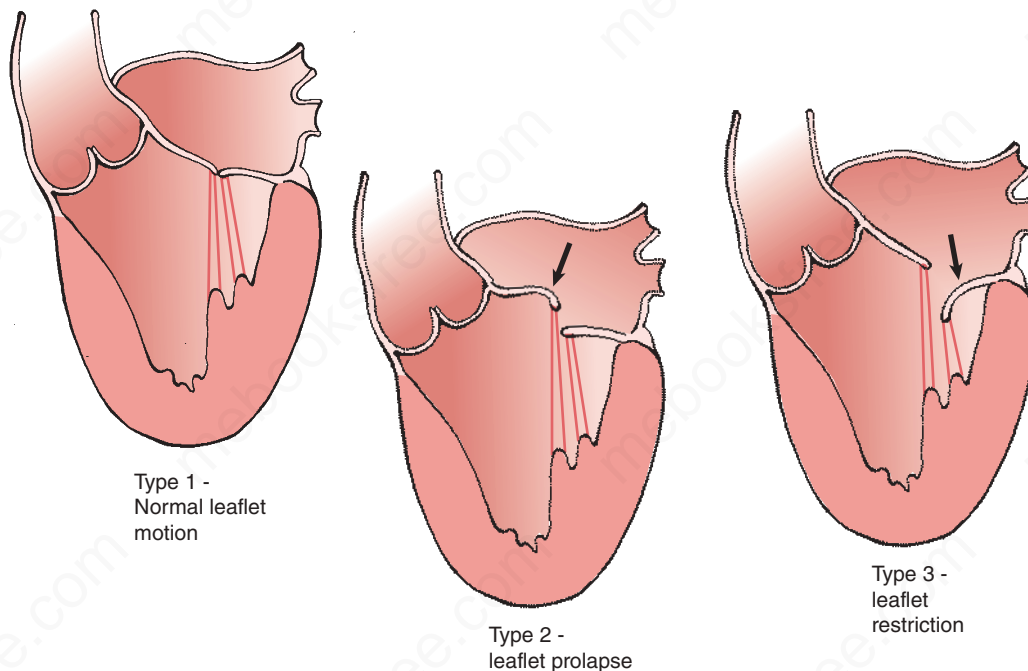

Key information is obtained from echocardiography: the degree of MR, associated pathophysiology, cardiac chamber dimensions, and left ventricular functional analysis. Transthoracic echocardiography is usually the first modality employed. However, if images from transthoracic echocardiography are of insufficient quality, then transesophageal echocardiography (TEE) is required. Mitral regurgitation is graded on a scale from mild to severe, with severe typically referring to a reversal of pulmonary venous blood flow in systole.<sup>30</sup> The methods used to determine the degree of regurgitation commonly include regurgitant volume, regurgitant fraction, and effective regurgitant orifice area.<sup>30</sup> Echocardiographic analysis of the MR (eg, flail leaflet, ruptured chordae, or anterior

or posterior prolapse) is extremely helpful in planning the operative intervention. Other crucial information obtained by the preoperative echo includes left atrial size, ventricular function, ventricular dilatation, aortic valve function, and tricuspid valve function. A large left atrium implies chronic MR. A small LA and hyperdynamic LV implies acute MR. Ventricular function is a key component in assessing operative candidacy; a left ventricular ejection fraction below the norm of 60% indicates some degree of myocardial decompensation secondary to volume overload. Indeed, in the presence of severe MR, the ejection fraction will often decline postoperatively even if the preop ejection fraction is normal. A corollary of this fact is a normal preoperative ejection fraction does not necessarily mean normal ventricular function.

## Timing of Surgery

Once pulmonary hypertension, LV dysfunction/LA dilatation or symptoms appear, the prognosis of MR worsens. Careful surveillance may result in timing of valve surgery before these negative sequelae occur.<sup>30a</sup> An attractive alternative strategy for treating severe chronic primary MR is to perform early mitral repair before these triggers are reached. Early mitral repair avoids the need for intensive surveillance and also obviates the possibility that patients might become lost to follow-up or delay seeing their clinician until advanced LV dysfunction has already ensued. This strategy requires expertise in clinical evaluation and cardiac imaging to evaluate severity and significance of MR.

What, precisely, are the indications for operation? In general, as surgical results improve, the indications for surgery

**FIGURE 35-4** Carpentier's functional classification.

are broadening. The American Heart Association 2014 guidelines state that **“Mitral valve repair is reasonable in asymptomatic patients with chronic severe primary MR (stage C1) with preserved LV function (LVEF > 60% and LVESD 0 40 mm) in whom the likelihood of a successful and durable repair without residual MR is greater than 95% with an expected mortality rate of less than 1% when performed at a Heart Valve Center of Excellence.”**

Patients who would never have been considered for surgery previously are now routinely being offered repair surgery at much earlier stages of their disease. The indications for mitral valve repair have widened as the success of repair has so dramatically improved over the last several years. Better myocardial protection and cardiopulmonary bypass technology, minimally invasive incisions, increased incidence of repair, and better intensive care unit support have all contributed to the phenomenon.<sup>31</sup> The biggest change has been an overall broadening of the indications for mitral valve repair and lowering of the threshold for operation because of these factors,<sup>32</sup> even in the elderly.<sup>33</sup> Increasingly, asymptomatic mitral regurgitation, even without symptoms, is becoming accepted as a reasonable strategy.<sup>34</sup> Repair of the mitral valve, as opposed to replacement, is now accepted as the superior treatment for myxomatous mitral regurgitation. Out of a long laboratory and clinical experience have come the conclusions that repair is associated with better survival, enhanced preservation of ventricular function (by preserving the chordae and papillary muscles), and decreased late thromboembolic complications.<sup>35-42</sup>

For all patients with moderate-to-severe MR and moderately decreased ventricular function (left ventricular ejection fraction < 60%) valve repair is offered, because the ventricle has exhibited signs of decompensation even with a lesser degree of MR; repair in this setting is much more urgent, because severe decompensation can occur in a matter of months as left ventricular function begins to deteriorate.

The standard of care for patients with severe cardiomyopathy and severe MR is unclear presently and is one of the most controversial topics in cardiac surgery. This situation typically does not occur with myxomatous disease but rather ischemia or idiopathic cardiomyopathy and such regurgitation is functional in nature. In longstanding myxomatous disease, however, LV dysfunction may be present.

The intermediate situation of moderate mitral regurgitation and preserved ventricular function is the one in which the most judgment must be exercised. Consider the situation of a structurally normal mitral valve with moderate functional MR, but with concomitant critical aortic stenosis. The patient is to undergo an aortic valve replacement. Should the mitral valve be repaired? Perhaps not, as the moderate MR here is typically exacerbated by the patient's aortic stenosis and volume overload, and correction of the aortic stenosis and euvoemia would likely reduce or eliminate the MR in this structurally normal valve.<sup>39,40</sup> However, should repair be undertaken, ring annuloplasty would be needed to correct the posterior annular dilatation. If the same situation exists, however, with a structurally abnormal valve, such as a prolapsed

P2 or markedly dilated mitral annulus in a myxomatous valve, then mitral repair should always be undertaken, because there is a structural abnormality that aortic valve replacement will not correct. What of moderate MR secondary to myxomatous disease (and not ischemia) in a patient who is to undergo coronary bypass grafting? That patient would likely be offered concomitant valve repair, because bypass grafting would not impact on the pathophysiology of the MR in this case. What of the situation of moderate-to-severe isolated MR secondary to myxomatous disease and borderline normal ventricular function? Even without symptoms of heart failure, this patient should have repair performed on an elective basis. Once left ventricular function begins to deteriorate from the normal 60 to 70% left ventricular ejection fraction, decline may be unpredictably rapid and hence intervention warranted. Increasingly, moderate ischemic, as well as degenerative, MR is thought to be detrimental for long-term survival.<sup>41,42</sup>

In general, no matter what the chronological age is, adequate functional status before valve repair is preferred. If symptoms of heart failure exist before surgery, optimal diuresis should be undertaken before operation. If the procedure involves coronary artery bypass grafting, the conduit status should be determined. Dental clearance on all patients should be obtained before any valvular procedure. If neurologic symptoms exist or if the patient has a history of a previous cerebrovascular disease, then preoperative carotid noninvasive studies are warranted to assess carotid arterial stenosis. All patients older than 40 years should undergo coronary angiography. Patients with MR without coronary artery disease are good candidates for smaller incisions.<sup>43,45</sup>

Whatever the scenario, the decision to operate and repair the valve is a decision made preoperatively as opposed to intraoperatively. Once the patient is under anesthesia, loading conditions are not physiologic and the mitral regurgitation assessed then is inevitably underestimated. Maneuvers used to “bring out the MR,” such as increasing afterload with vasoactive drugs, do not reflect true physiology, but should be used in surgical decision making and may be helpful in some situations. Recent discussions of earlier referral for the treatment of MR clearly depend on a high rate of valve repair in any center.<sup>46,47</sup>

## Operative Philosophy

Clearly, in light of elevated success rates of mitral valve repair in specialized centers but also today in all cardiac surgery programs, the patient with degenerative mitral valve disease with significant MR requires a repair procedure, rather than replacement.<sup>49</sup>

With the increasing numbers of trained surgeons who have absorbed the various mitral valve repair techniques and can apply them safely the percentage of valves that can be repaired and actually are repaired, is improving. Recent STS database interrogation indicates that this percentage may now be as high as 75%.<sup>49</sup>

Beginning in the 1980s, we have developed what we think is a simple, reproducible algorithm that can be used to repair

the degenerative mitral valve in most patients. Overriding this philosophy is the belief that mitral valve repair is not an esoteric “art form” that is difficult to explain, perform, or learn. Rather, we think it is a procedure like any other that should and can be simplified, disseminated, and reproduced with success. In keeping with this philosophy, we have reduced complicated bileaflet prolapse to a competent valve with simplified and straightforward maneuvers that we have found effective with good long-term results. Our overall philosophy and technique are as follows:

1. Expose the valve well through the complete development of Sondergaard's groove, division of pericardial attachments of the superior and inferior venae cavae, and release of the left pericardial retraction stitches
2. Assess the valve through saline injection and corroborate the intraoperative findings with TEE
3. Perform basic, obvious leaflet repair procedures first (eg, quadrangular resections to the posterior leaflet)
4. Implant the annuloplasty ring sized by the height of the anterior leaflet (not the trigones or commissures)
5. Test the repair
6. Perform additional reparative procedures as needed, that is, cleft closure.

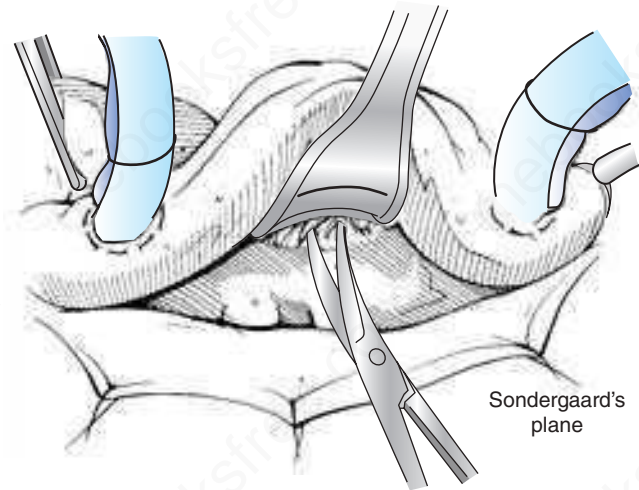

With the above maneuvers, we estimate that approximately 95% of all degenerative valves can be repaired.

Collaborative involvement with cardiac anesthesia colleagues is essential in utilizing the invaluable tool of transesophageal echocardiogram monitoring for pre- and postrepair assessment. In our clinic, standard TEE monitoring (either two- or three-dimensional) is now utilized for every patient undergoing mitral valve repair. In addition to documenting the efficacy of repair, TEE is essential in preventing and assessing the potential or persistence of systolic anterior motion (SAM) of the anterior valve.

## Operative Exposure

Because the mitral valve is such a complex anatomic structure and the maneuvers involved in correcting a regurgitant valve may vary from the simple to the very complex, adequate exposure is an absolute requirement in every operative plan. This becomes more important if minimally invasive techniques are employed. Mitral valve exposure is more challenging than exposure of the aortic or tricuspid valve. Why? From the surgeon's side, the mitral valve is furthest away from the operating surgeon than any other valve. In addition, the valve in its native position naturally faces above and/or toward the surgeon's left shoulder at an oblique angle such that the surgeon does not see the valve en face.

The first critical aspect to the standard valve repair is the complete and thorough development of the Sondergaard plane reflecting the right atrium off the left atrium to the atrial septum, as depicted in Fig. 35-5. This was first described in the 1950s by the Danish surgeon Sondergaard,<sup>50</sup> to expose the atrial septum for noncardiopulmonary bypass treatment of atrial septal defects. In 1990, we stressed the

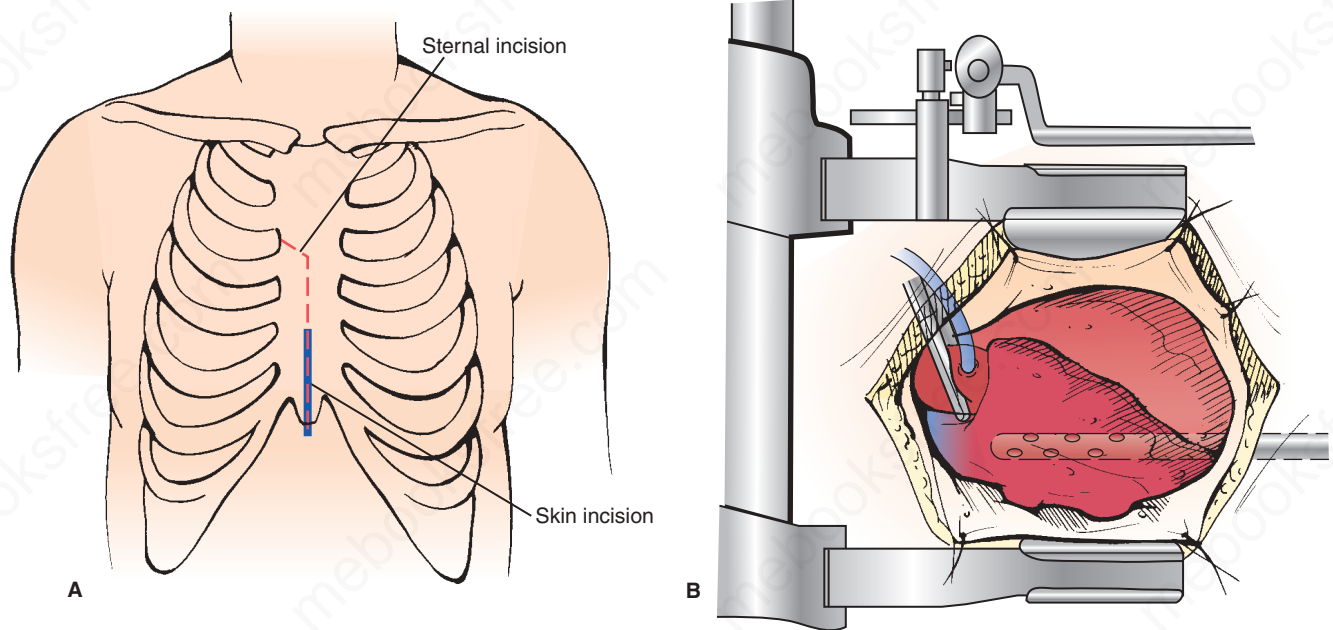

**FIGURE 35-5** Dissection of Sondergaard's plane. Sondergaard's plane should be dissected at least 2 to 4 cm from the right superior pulmonary vein for adequate exposure of the mitral valve.

importance of this particular technique for exposure in mitral valve surgery.<sup>51</sup> Regardless of even previous procedures, it should always be possible to dissect out the groove without significant difficulty. The complete and full development of the groove is a most important aspect to obtain adequate exposure of the mitral valve. With this technique, via blunt and sharp dissection we typically have not needed any other incision for mitral valve repair or replacement, whether for primary surgery or reoperation. This incision usually brings the surgeon very close to the mitral valve. Once the right atrium is dissected off the left atrium, a generous incision in the left atrium is made, avoiding the atrial septum.

The second aspect of exposure is to bring the valve as close to an en face position to the operating surgeon as possible. Pericardial stay sutures are released on the left side. The operating table is maneuvered head up and to the left. If necessary, the left pericardium is opened and the apex of the heart moved laterally to the left pleural space. Exposure of the left trigone can be particularly challenging for stitch placement. This can be facilitated with local epicardial displacement of the midlateral LV wall medially with spongestick (Fig. 35-6).

## Cardiopulmonary Bypass

For cardiopulmonary bypass, we use a 22F percutaneous femoral vein venous catheter placed into the right atrium via the right femoral vein with TEE control. The cannula can even be advanced into the superior vena cava if desired. Because the cannula has multiple holes, is flexible and thus can still drain the inferior vena cava, this one cannula is sometimes all that is needed for drainage of both the superior and inferior vena cava. If performing a concomitant bypass procedure requiring a full sternotomy, then venous cannulation should be bicaval via the atria. One venous cannula should be placed in the superior vena cava above the right atrial/

**FIGURE 35-6** Minimally invasive mitral valve repair. (A) Via a 6- to 8-cm skin incision, a lower hemisternotomy through the right second intercostal space is performed. (B) Venous cannulation is percutaneous with vacuum assist. Aortic cannulation, cross-clamping, and cardioplegia administration are performed in the standard manner.

superior vena caval junction and the other through the lowest part of the right atrium into the mouth of the inferior vena cava. The arterial cannula should be placed directly into the distal ascending aorta.

Once on cardiopulmonary bypass, systemic temperature is allowed to drift to 34°, the ascending aorta is cross-clamped, and the heart arrested by cold blood cardioplegia. For isolated valve repair, some debate still exists regarding the use of retrograde or antegrade blood cardioplegia after cross-clamping. If there is concomitant coronary artery disease, myocardial protection in this circumstance should be antegrade and retrograde, because the coronary artery bypass graft/mitral operation presents one of the highest-risk operative settings in cardiac surgery.<sup>36</sup>

After the heart is arrested, the left atrium is opened well above the right superior pulmonary vein near the septum inferiorly. Retractors are placed (Fig. 35-7). The patient's bed is placed head up with a tilt to the left. A wire-reinforced suction catheter is placed in the left inferior pulmonary vein (the most dependent portion of the left atrium in this position) for drainage of collateral blood flow. Carbon dioxide is infused to minimize intracardiac air.

Alternate exposures can be obtained by the transeptal approach through the right atrium<sup>52</sup> or the superior septal approach.<sup>53</sup> The transeptal approach is a perfectly acceptable incision that allows the cardiac surgeon to be close to the mitral valve by carrying the incision through the fossa ovalis (Fig. 35-8) and up into the superior vena cava. Retraction sutures and other types of retraction devices can be utilized to expose the mitral valve exceedingly well, particularly in these minimally invasive cases. This approach may also be helpful

in patients who have had previous operations on the mitral valve or when concomitant procedures on the tricuspid valve are required.

### Examination of Valve and Valve Analysis

Once exposure is obtained and a self-retaining retractor is in place, inspection of the valve is carried out. Valve analysis takes a few minutes utilizing nerve hooks, forceps, and insufflation of the ventricle with saline to determine and corroborate the pathology already diagnosed by intraoperative TEE. Valve analysis may reveal ruptured chordae or simply a prolapse of the valve with elongated chords and one or more prolapsed sections of the valve. The anterior leaflet, though frequently advertised as part of “bileaflet prolapse,” often has normal length chordae and may be without specific leaflet or subvalvular pathology. Prolapse of the commissures may be found, and calcified nodules may exist that may present difficulty in mitral valve repair and may need excision. There may be healed endocarditic vegetations on one or more parts of the valve. The annulus will almost always appear to be distorted, dilated, or deformed in long-standing cases, particularly in Barlow syndrome.

### Repair Strategy and Overview

After the analysis of the valve is carried out, a detailed reparative strategy can be deduced from the pathologic analysis. In a broad generalization, degenerative disease of the mitral valve creates what amounts to a PML that is too large, with or without flail segments, in an annulus that is functionally too small for the anterior leaflet. In degenerative disease, the

**FIGURE 35-7** Minimally invasive operative exposure. After the retractors are placed, the patient is positioned with head up and the operative bed tilted to the left. Exposure is excellent.

posterior leaflet is typically pathologic, whereas the anterior leaflet usually is not.

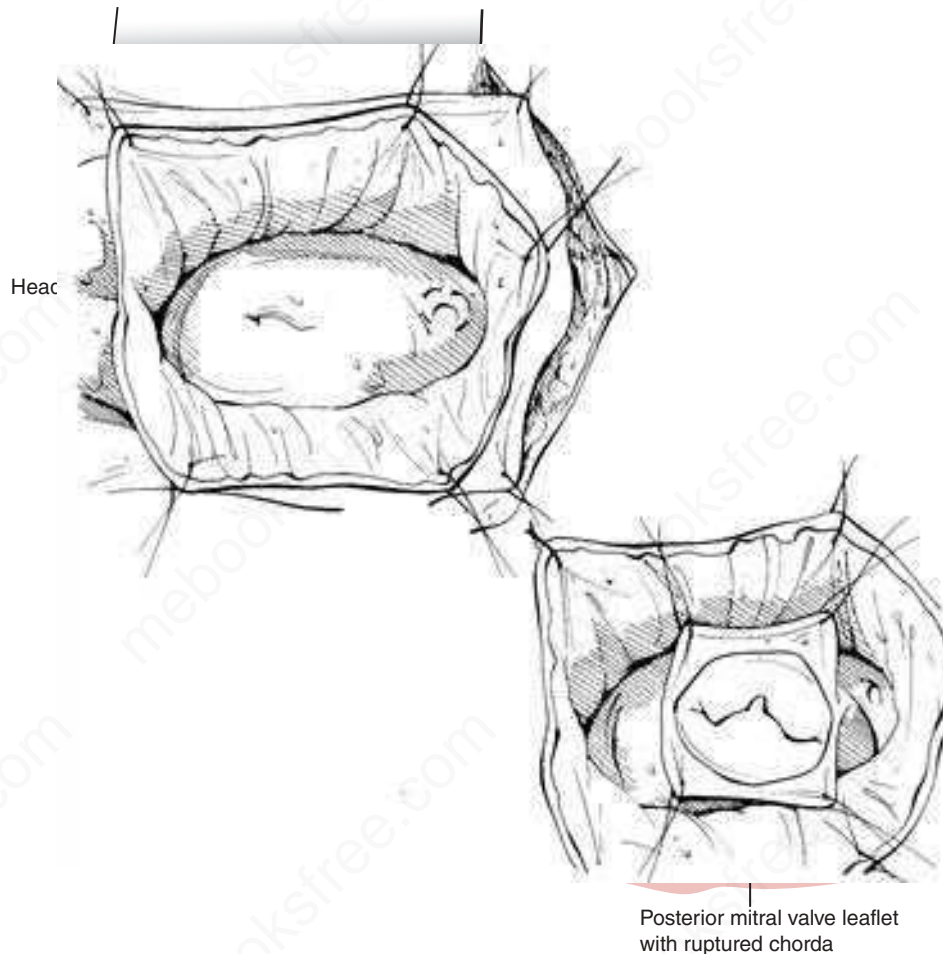

The first principle of the repair is to reduce or obliterate the enlarged segments and to reduce the overall height of the abnormally large posterior leaflet. This reduction reconstructs the correct coaptation line with the anterior leaflet, and, just as importantly, prevents systolic anterior motion (SAM) of the anterior leaflet. If the height of the posterior leaflet is too high, it will push the anterior leaflet into the LVOT and create SAM. In general, the height of the posterior leaflet should be no more than 1 to 1.5 cm in average-sized patients once the repair is complete. The normal sections of the posterior leaflet should be used as a marker to guide the reduction of the redundant parts. Ultimately, the reconstructed posterior leaflet should appear like a “smile.” Once the posterior leaflet reduction is performed, one must ensure that the anterior leaflet coapts with the subsequently reduced posterior leaflet within the correct plane using the saline test. The resulting repair should result in a coaptation line at the level of the annulus during systole. Specific methods to lower the height of the posterior leaflet and anterior leaflet will be addressed below.

A new concept of ‘respect rather than resect’ has become popular in recent years. Instead of resecting the leaflet segment that is flailing, this same segment is brought down back to form a coaptation line using polytetrafluoroethylene (PTFE) suture to form neochords. The excess tissue is displaced into the LV to form a new and durable coaptation

line. This approach is of value especially in small access procedures, in which implementation of more complex resection and repair can be cumbersome. Regardless of the surgeon’s choice regarding whether to ‘respect or resect’, a prosthetic ring or band is mandatory in all repair procedures. The result of avoiding an annuloplasty ring is a significantly higher risk of recurrent moderate-to-severe mitral valve regurgitation.
