

FIFTH EDITION

The cover features a dark background with a red wireframe heart on the left and a surgical scene on the right. The surgical scene shows hands in blue gloves performing a procedure on a patient's chest, with various surgical instruments and a blue drape visible. A semi-transparent blue horizontal band is positioned across the middle of the cover, containing the main title.

### **Notice**

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Lawrence H. Cohn, MD

The 5th edition of *Cardiac Surgery in the Adult* is dedicated to Dr. Lawrence Cohn, Emeritus Chief of the Division of Cardiac Surgery at Brigham and Women's Hospital and Virginia and James Hubbard Professor of Cardiac Surgery at Harvard Medical School, who sadly passed away unexpectedly during the final stages of preparation of this latest edition of "his" reference textbook. Dr. Cohn leaves a legacy of excellence seldom seen in academic surgery, and he will be sorely missed by all of us who knew him, and especially those of us lucky enough to have been mentored by him. Dr. Cohn received his training in cardiothoracic surgery under the tutelage of Dr. Norman Shumway at Stanford University, and after completing his fellowship in 1971 he joined the staff of the Peter Bent Brigham Hospital in Boston. Over the next 45 years he was the driving force behind the success of the Harvard program, and became the Chief of the Division of Cardiac Surgery in 1986. A clinical cardiac surgeon first and foremost, Dr. Cohn performed over 11,000 open heart procedures during his career, and was best known for his pioneering and international leadership in minimally invasive valve surgery. His academic contributions included over 500 peer-reviewed publications, 100 book chapters, and 750 invited lectures on virtually all topics in cardiac surgery, but perhaps his greatest academic legacy was his editorship of the 2nd, 3rd, and 4th editions of *Cardiac Surgery in the Adult*, which under his vision became the most widely referenced international textbook in

adult cardiac surgery. During his career Dr. Cohn earned the highest awards and honors a cardiac surgeon could possibly achieve, serving as the 79th President of the American Association for Thoracic Surgery, receiving an honorary Masters of Medicine from Harvard, and receiving the American Heart Association's Paul Dudley White Award, among numerous others. He would claim his greatest honor, however, was the opportunity to train over 200 residents and fellows from all over the world, many of whom went on to become Division Chiefs, Department Chairs, and leaders in the specialty. His American Association for Thoracic Surgery presidential address "What the Cardiothoracic Surgeon of the 21st Century Ought to Be" personifies the essence of what made him one of the masters of cardiac surgery who will be remembered by generations to come. Through leadership by example in all phases of his career, his unwavering commitment to the individual patient was the foundation of all of his accomplishments, and few surgeons have had such a profound impact on our specialty. Dr. Cohn was my teacher, mentor, and friend, and it was an honor to be asked by his wife of 55 years, Roberta, to assume the role of Co-Editor to complete this 5th edition of his textbook. Dr. Cohn left footprints too large to fill, but with the help of the many authors who contributed chapters and the publisher's leadership, we now present this peer tribute to one of the greatest cardiac surgeons of all time.

# History of Cardiac Surgery

Larry W. Stephenson • Frank A. Baciewicz, Jr.

The development of major surgery was retarded for centuries by a lack of knowledge and technology. Significantly, the general anesthetics ether and chloroform were not developed until the middle of the nineteenth century. These agents made major surgical operations possible, which created an interest in repairing wounds to the heart, leading some investigators in Europe to conduct studies in the animal laboratory on the repair of heart wounds. The first simple operations in humans for heart wounds soon were reported in the medical literature.

## HEART WOUNDS

On July 10, 1893, Dr. Daniel Hale Williams (Fig. 1-1), a surgeon from Chicago, successfully operated on a 24-year-old man who had been stabbed in the heart during a fight. The stab wound was slightly to the left of the sternum and dead center over the heart. Initially, the wound was thought to be superficial, but during the night the patient experienced persistent bleeding, pain, and pronounced symptoms of shock. Williams opened the patient's chest and tied off an artery and vein that had been injured inside the chest wall, likely causing the blood loss. Then he noticed a tear in the pericardium and a puncture wound to the heart "about one-tenth of an inch in length."<sup>1</sup>

The wound in the right ventricle was not bleeding, so Williams did not place a stitch through the heart wound. He did, however, stitch closed the hole in the pericardium. Williams reported this case 4 years later.<sup>1</sup> This operation, which is referred to frequently, is probably the first successful surgery involving a documented stab wound to the heart. At the time Williams' surgery was considered bold and daring, and although he did not actually place a stitch through the wound in the heart, his treatment seems to have been appropriate. Under the circumstances, he most likely saved the patient's life.

A few years after Williams' case, a couple of other surgeons actually sutured heart wounds, but the patients did not survive. Dr. Ludwig Rehn (Fig. 1-2), a surgeon in Frankfurt, Germany, performed what many consider the first successful heart operation.<sup>2</sup> On September 7, 1896, a 22-year-old

man was stabbed in the heart and collapsed. The police found him pale, covered with cold sweat, and extremely short of breath. His pulse was irregular and his clothes were soaked with blood. By September 9, his condition was worsening, as shown in Dr. Rehn's case notes:

Pulse weaker, increasing cardiac dullness on percussion, respiration 76, further deterioration during the day, diagnostic tap reveals dark blood. Patient appears moribund. Diagnosis: increasing hemothorax. I decided to operate entering the chest through the left fourth intercostal space, there is massive blood in the pleural cavity. The mammary artery is not injured. There is continuous bleeding from a hole in the pericardium. This opening is enlarged. The heart is exposed. Old blood and clots are emptied. There is a 1.5 cm gaping right ventricular wound. Bleeding is controlled with finger pressure. ...

I decided to suture the heart wound. I used a small intestinal needle and silk suture. The suture was tied in diastole. Bleeding diminished remarkably with the third suture, all bleeding was controlled. The pulse improved. The pleural cavity was irrigated. Pleura and pericardium were drained with iodoform gauze. The incision was approximated, heart rate and respiratory rate decreased and pulse improved post-operatively.

... Today the patient is cured. He looks very good. His heart action is regular. I have not allowed him to work physically hard. This proves the feasibility of cardiac suture repair without a doubt! *I hope this will lead to more investigation regarding surgery of the heart. This may save many lives.*

Ten years after Rehn's initial repair, he had accumulated a series of 124 cases with a mortality of only 60%, quite a feat at that time.<sup>3</sup>

Dr. Luther Hill was the first American to report the successful repair of a cardiac wound, in a 13-year-old boy who was a victim of multiple stab wounds.<sup>4</sup> When the first doctor arrived, the boy was in profound shock. The doctor remembered that Dr. Luther Hill had spoken on the subject of repair of cardiac wounds at a local medical society meeting in Montgomery, Alabama. With the consent of the boy's parents, Dr. Hill was summoned. He arrived sometime after midnight with six other physicians. One was his brother. The surgery

**FIGURE 1-1** Daniel Hale Williams, a surgeon from Chicago, who successfully operated on a patient with a wound to the chest involving the pericardium and the heart. (Reproduced with permission from Organ CH Jr., Kosiba MM: *The Century of the Black Surgeons: A USA Experience*. Norman, OK: Transcript Press, 1937; p 312.)

took place on the patient's kitchen table in a rundown shack. Lighting was provided by two kerosene lamps borrowed from neighbors. One physician administered chloroform anesthesia. The boy was suffering from cardiac tamponade as a result of a stab wound to the left ventricle. The stab wound to the ventricle was repaired with two catgut sutures. Although the early postoperative course was stormy, the boy made a complete recovery. That patient, Henry Myrick, eventually moved to Chicago, where, in 1942, at the age of 53, he got into a heated argument and was stabbed in the heart again, very close to the original stab wound. This time, Henry was not as lucky and died from the wound.

Another milestone in cardiac surgery for trauma occurred during World War II when Dwight Harken, then a U.S. Army surgeon, removed 134 missiles from the mediastinum, including 55 from the pericardium and 13 from cardiac chambers, without a death.<sup>5</sup> It is hard to imagine this type of elective (and semielective) surgery taking place without sophisticated indwelling pulmonary artery catheters, blood banks, and electronic monitoring equipment.

**FIGURE 1-2** Ludwig Rehn, a surgeon from Frankfurt, Germany, who performed the first successful suture of a human heart wound. (Reproduced with permission from Mead R: *A History of Thoracic Surgery*. Springfield: Charles C Thomas; 1961.)

Rapid blood infusion consisted of pumping air into glass bottles of blood.

## OPERATIVE MANAGEMENT OF PULMONARY EMBOLI

Martin Kirschner reported the first patient who recovered fully after undergoing pulmonary embolectomy in 1924.<sup>6</sup> In 1937, John Gibbon estimated that nine of 142 patients who had undergone the procedure worldwide left the hospital alive.<sup>7</sup> These dismal results were a stimulus for Gibbon to start work on a pump oxygenator that could maintain the circulation during pulmonary embolectomy. Sharp was the first to perform pulmonary embolectomy using cardiopulmonary bypass, in 1962.<sup>8</sup>

## SURGERY OF THE PERICARDIUM

Pericardial resection was introduced independently by Rehn<sup>9</sup> and Sauerbruch.<sup>10</sup> Since Rehn's report, there have been few advances in the surgical treatment of constrictive pericarditis.

Some operations are now performed with the aid of cardiopulmonary bypass. In certain situations, radical pericardiectomy that removes most of the pericardium posterior to the phrenic nerves is done.

## CATHETERIZATION OF THE RIGHT SIDE OF THE HEART

Although cardiac catheterization is not considered heart surgery, it is an invasive procedure, and some catheter procedures have replaced heart operations. Werner Forssmann is credited with the first heart catheterization. He performed the procedure on himself and reported it in *Klinische Wochenschrift*.<sup>11</sup> In 1956 Forssmann shared the Nobel Prize in Physiology or Medicine with Andre F. Cournand and Dickenson W. Richards, Jr. His 1929 paper states, “One often hesitates to use intercardiac injections promptly, and often, time is wasted with other measures. This is why I kept looking for a different, safer access to the cardiac chambers: the catheterization of the right heart via the venous system.”

In this report by Forssmann, a photograph of the x-ray taken of Forssmann with the catheter in his own heart is presented. Forssmann, in that same report, goes on to present the first clinical application of the central venous catheter for a patient in shock with generalized peritonitis. Forssmann concludes his paper by stating, “I also want to mention that this method allows new options for metabolic studies and studies about cardiac physiology.”

In a 1951 lecture Forssmann discussed the tremendous resistance he faced during his initial experiments.<sup>12</sup> “Such methods are good for a circus, but not for a respected hospital” was the answer to his request to pursue physiologic studies using cardiac catheterization. His progressive ideas pushed him into the position of an outsider with ideas too crazy to give him a clinical position. Klein applied cardiac catheterization for cardiac output determinations using the Fick method a half year after Forssmann’s first report.<sup>13</sup> In 1930, Forssmann described his experiments with catheter cardiac angiography.<sup>14</sup> Further use of this new methodology had to wait until Cournand’s work in the 1940s.

## HEART VALVE SURGERY BEFORE THE ERA OF CARDIOPULMONARY BYPASS

The first clinical attempt to open a stenotic valve was carried out by Theodore Tuffier on July 13, 1912.<sup>15</sup> Tuffier used his finger to reach the stenotic aortic valve. He was able to dilate the valve supposedly by pushing the invaginated aortic wall through the stenotic valve. The patient recovered, but one must be skeptical as to what was accomplished. Russell Brock attempted to dilate calcified aortic valves in humans in the late 1940s by passing an instrument through the valve from the innominate or another artery.<sup>16</sup> His results were poor, and he abandoned the approach. During the next several years, Brock<sup>17</sup> and Bailey and colleagues<sup>18</sup> used different

dilators and various approaches to dilate stenotic aortic valves in patients. Mortality for these procedures, which was often done in conjunction with mitral commissurotomy, was high.

Elliott Cutler worked for 2 years on a mitral valvulotomy procedure in the laboratory. His first patient underwent successful valvulotomy on May 20, 1923, using a tetrasomy knife.<sup>19</sup> Unfortunately, most of Cutler’s subsequent patients died because he created too much regurgitation with his valvulotome, and he soon gave up the operation.

In Charles Bailey’s 1949 paper entitled, “The Surgical Treatment of Mitral Stenosis,” he states, “After 1929 no more surgical attempts [on mitral stenosis] were made until 1945. Dr. Dwight Harken, Dr. Horace Smithy, and the author recently made operative attempts to improve mitral stenosis. Our clinical experience with the surgery of the mitral valves has been five cases to date.” He then describes his five patients, four of whom died and only one of whom lived a long life.<sup>20,21</sup>

A few days after Bailey’s success, on June 16 in Boston, Dr. Dwight Harken successfully performed his first valvulotomy for mitral stenosis.<sup>22</sup>

The first successful pulmonary valvulotomy was performed by Thomas Holmes Sellers on December 4, 1947.<sup>23</sup>

Charles Hufnagel reported a series of 23 patients starting September 1952 who had operation for aortic insufficiency.<sup>24</sup> There were four deaths among the first 10 patients and two deaths among the next 13. Hufnagel’s caged-ball valve, which used multiple-point fixation rings to secure the apparatus to the descending aorta, was the only surgical treatment for aortic valvular incompetence until the advent of cardiopulmonary bypass and the development of heart valves that could be sewn into the aortic annulus position.

## CONGENITAL CARDIAC SURGERY BEFORE THE HEART-LUNG MACHINE ERA

Congenital cardiac surgery began when John Strieder at Massachusetts General Hospital first successfully interrupted a ductus on March 6, 1937. The patient was septic and died on the fourth postoperative day. At autopsy, vegetations filled the pulmonary artery down to the valve.<sup>25</sup> On August 16, 1938, Robert Gross, at Boston Children’s Hospital, operated on a 7-year-old girl with dyspnea after moderate exercise.<sup>26</sup> The ductus was ligated and the patient made an uneventful recovery.

Modifications of the ductus operation soon followed. In 1944, Dr. Gross reported a technique for dividing the ductus successfully. The next major congenital lesion to be overcome was coarctation of the aorta. Dr. Clarence Crafoord, in Stockholm, Sweden, successfully resected a coarctation of the aorta in a 12-year-old boy on October 19, 1944.<sup>27</sup> Twelve days later he successfully resected the coarctation of a 27-year-old patient. Dr. Gross first operated on a 5-year-old boy with this condition on June 28, 1945.<sup>28</sup> After he excised the coarctation and rejoined the aorta, the patient’s heart stopped suddenly. The patient died in the operating room. One week

later, however, Dr. Gross operated on a second patient, a 12-year-old girl. This patient's operation was successful. Dr. Gross had been unaware of Dr. Crafoord's successful surgery several months previously, probably because of World War II.

In 1945, Dr. Gross reported the first successful case of surgical relief for tracheal obstruction from a vascular ring.<sup>29</sup> In the 5 years that followed Gross's first successful operation, he reported 40 more cases.

The famous Blalock-Taussig operation also was first reported in 1945. The first patient was a 15-month-old girl with a clinical diagnosis of tetralogy of Fallot with a severe pulmonary stenosis.<sup>30</sup> At age 8 months, the baby had her first cyanotic spell, which occurred after eating. Dr. Helen Taussig, the cardiologist, followed the child for 3 months, and during that time, cyanosis increased, and the child failed to gain weight. The operation was performed by Dr. Alfred Blalock at Johns Hopkins University on November 29, 1944. The left subclavian artery was anastomosed to the left pulmonary artery in an end-to-side fashion. The postoperative course was described as stormy; the patient was discharged 2 months postoperatively. Two additional successful cases were done within 3 months of that first patient.

Thus, within a 7-year period, three congenital cardiovascular defects, patent ductus arteriosus, coarctation of the aorta, and vascular ring, were attacked surgically and treated successfully. However, the introduction of the Blalock-Taussig shunt probably was the most powerful stimulus to the development of cardiac surgery because this operation palliated a complex intracardiac lesion and focused attention on the pathophysiology of cardiac disease.

Anomalous coronary artery in which the left coronary artery communicates with the pulmonary artery was the next surgical conquest. The surgery was performed on July 22, 1946, and was reported by Gunnar Biorck and Clarence Crafoord.<sup>31</sup> The anomalous coronary artery was identified and doubly ligated. The patient made an uneventful recovery.

Muller<sup>32</sup> reported successful surgical treatment of transposition of the pulmonary veins in 1951, but the operation addressed a partial form of the anomaly. Later in the 1950s, Gott, Varco, Lillehei, and Cooley reported successful operative variations for anomalous pulmonary veins.

Another of Gross's pioneering surgical procedures was surgical closure of an aortopulmonary window on May 22, 1948.<sup>33</sup> Cooley and colleagues<sup>34</sup> were the first to report on the use of cardiopulmonary bypass to repair this defect and converted a difficult and hazardous procedure into a relatively straightforward one.

Glenn<sup>35</sup> reported the first successful clinical application of the cavopulmonary anastomosis in the United States in 1958 for what has been termed the *Glenn shunt*. Similar work was done in Russia during the 1950s by several investigators. On January 3, 1957, Galankin,<sup>36</sup> a Russian surgeon, performed a cavopulmonary anastomosis in a 16-year-old patient with tetralogy of Fallot. The patient made a good recovery with significant improvement in exercise tolerance and cyanosis.

## THE DEVELOPMENT OF CARDIOPULMONARY BYPASS

The development of the heart-lung machine made repair of intracardiac lesions possible. To bypass the heart, one needs a basic understanding of the physiology of the circulation, a method of preventing the blood from clotting, a mechanism to pump blood, and finally, a method to ventilate the blood.

One of the key requirements of the heart-lung machine was anticoagulation. Heparin was discovered in 1915 by a medical student, Jay McLean, working in the laboratory of Dr. William Howell, a physiologist at Johns Hopkins.<sup>37</sup>

John Gibbon contributed more to the success of the development of the heart-lung machine than anyone else.

Gibbon's work on the heart-lung machine took place over 20 years in laboratories at Massachusetts General Hospital, the University of Pennsylvania, and Thomas Jefferson University. In 1937, Gibbon reported the first successful demonstration that life could be maintained by an artificial heart and lung and that the native heart and lungs could resume function. Unfortunately, only three animals recovered adequate cardiorespiratory function after total pulmonary artery occlusion and bypass, and even they died a few hours later.<sup>38</sup> Gibbon's work was interrupted by World War II; afterward, he resumed his work at Thomas Jefferson Medical College in Philadelphia (Table 1-1).

Forest Dodrill and colleagues used the mechanical blood pump they developed with General Motors on a 41-year-old man<sup>43</sup> (Fig. 1-3). The machine was used to substitute for the left ventricle for 50 minutes while a surgical procedure was carried out to repair the mitral valve; the patient's own lungs were used to oxygenate the blood. This, the first clinically successful total left-sided heart bypass in a human, was performed on July 3, 1952, and followed from Dodrill's experimental work with a mechanical pump for univentricular, biventricular, or cardiopulmonary bypass. Although Dodrill and colleagues had used their pump with an oxygenator for total heart bypass in animals,<sup>54</sup> they felt that left-sided heart bypass was the most practical method for their first clinical case.

Later, on October 21, 1952, Dodrill and colleagues used their machine in a 16-year-old boy with congenital pulmonary stenosis to perform a pulmonary valvuloplasty under direct vision; this was the first successful right-sided heart bypass.<sup>44</sup> Between July 1952 and December 1954, Dodrill performed approximately 13 clinical operations on the heart and thoracic aorta using the Dodrill—General Motors machine, with at least five hospital survivors.<sup>55</sup> Although he used this machine with an oxygenator in the animal laboratory, he did not start using an oxygenator with the Dodrill—General Motors mechanical heart clinically until early 1955.

Hypothermia was another method to stop the heart and allow it to be opened.<sup>44</sup>

John Lewis closed an atrial septal defect (ASD) in a 5-year-old girl on September 2, 1952 using a hypothermic technique.<sup>44</sup>

**TABLE 1-1: Twilight Zone: Clinical Status of Open-Heart Surgery, 1951–1955**

- 1951 *April 6:* Clarence Dennis at the University of Minnesota used a heart-lung machine to repair an ostium primum or AV canal defect in a 5-year-old girl. Patient could not be weaned from cardiopulmonary bypass.<sup>39</sup>  
*May 31:* Dennis attempted to close an atrial septal defect using heart-lung machine in a 2-year-old girl who died intraoperatively of a massive air embolus.<sup>40</sup>  
*August 7:* Achille Mario Digliotti at the University of Turino, Italy, used a heart-lung machine of his own design to partially support the circulation (flow at 1 L/min for 20 minutes) while he resected a large mediastinal tumor compressing the right side of the heart.<sup>41</sup> The cannulation was through the right axillary vein and artery. The patient survived. This was the first successful clinical use of a heart-lung machine, but the machine was not used as an adjunct to heart surgery.
- 1952 *February* (1952 or 1953 John Gibbon; see February 1953)  
*March:* John Gibbon used his heart-lung machine for right-sided heart bypass only while surgeon Frank Allbritten at Pennsylvania Hospital, Philadelphia, operated to remove a large clot or myxomatous tumor suspected by angiography.<sup>42</sup> No tumor or clot was found. The patient died of heart failure in the operating room shortly after discontinuing right-sided heart bypass.  
*April 3:* Helmsworth in Cincinnati used a pump oxygenator of his own design connecting it in a veno-veno bypass mode to temporarily treat a patient with end-stage lung disease. The patient's symptoms improved but recurred shortly after bypass was discontinued.<sup>60</sup>  
*July 3:* Dodrill used the Dodrill-GMR pump to bypass the left side of the heart while he repaired a mitral valve.<sup>43</sup> The patient survived. This was the first successful use of a mechanical pump for total substitution of the left ventricle in a human being.  
*September 2:* John Lewis, at the University of Minnesota, closed an atrial septal defect under direct vision in a 5-year-old girl. The patient survived. This was the first successful clinical heart surgery procedure using total-body hypothermia. A mechanical pump and an oxygenator were not used. Others, including Dodrill, soon followed, using total-body hypothermia techniques to close atrial septal defects (ASDs) and perform pulmonary valvulotomies. By 1954, Lewis reported on 11 ASD closures using hypothermia with two hospital deaths.<sup>44</sup> He also operated on two patients with ventricular septal defect (VSD) in early 1954 using this technique. Both resulted in intraoperative deaths.  
*October 21:* Dodrill performed pulmonary valvulotomy under direct vision using Dodrill-GMR pump to bypass the right atrium, ventricle, and main pulmonary artery.<sup>45</sup> The patient survived.  
 Although Dr. William Mustard in Toronto would describe a type of “corrective” surgical procedure for transposition of the great arteries (TGA) in 1964, which, in fact, for many years, would become the most popular form of surgical correction of TGA, his early results with this lesion were not good. In 1952, he used a mechanical pump coupled to the lung that had just been removed from a monkey to oxygenate the blood in seven children while attempts were made to correct their TGA defect.<sup>46</sup> There were no survivors.
- 1953 *February* (or 1952): Gibbon at Jefferson Hospital in Philadelphia operated to close an ASD. No ASD was found. The patient died intraoperatively. Autopsy showed a large patent ductus arteriosus.<sup>47</sup>  
*May 6:* Gibbon used his heart-lung machine to close an ASD in an 18-year-old woman with symptoms of heart failure.<sup>47,57</sup> The patient survived the operation and became the first patient to undergo successful open-heart surgery using a heart-lung machine.  
*July:* Gibbon used the heart-lung machine on two 5-year-old girls to close atrial septal defects.<sup>47</sup> Both died intraoperatively. Gibbon was extremely distressed and declared a moratorium on further cardiac surgery at Jefferson Medical School until more work could be done to solve problems related to heart-lung bypass. These were probably the last heart operation he performed using the heart-lung machine.
- 1954 *March 26:* C. Walton Lillehei and associates at the University of Minnesota closed a VSD under direct vision in a 15-month-old boy using a technique to support the circulation that they called *controlled cross-circulation*. An adult (usually a parent) with the same blood type was used more or less as the heart-lung machine. The adult's femoral artery and vein were connected with tubing and a pump to the patient's circulation. The adult's heart and lungs were oxygenated and supported the circulation while the child's heart defect was corrected. The first patient died 11 days postoperatively from pneumonia, but six of their next seven patients survived.<sup>48</sup> Between March 1954 and the end of 1955, 45 heart operations were performed by Lillehei on children using this technique before it was phased out. Although controlled cross-circulation was a short-lived technique, it was an important stepping stone in the development of open-heart surgery.  
*July:* Clarence Crafoord and associates at the Karolinska Institute in Stockholm, Sweden, used a heart-lung machine of their own design coupled with total-body hypothermia (patient was initially submerged in an ice-water bath) to remove a large atrial myxoma in a 40-year-old woman.<sup>49</sup> She survived.
- 1955 *March 22:* John Kirklin at the Mayo Clinic used a heart-lung machine similar to Gibbon's, but with modifications his team had worked out over 2 years in the research laboratory, to successfully close a VSD in a 5-year-old patient. By May of 1955, they had operated on eight children with various types of VSDs, and four were hospital survivors. This was the first successful series of patients (ie, more than one) to undergo heart surgery using a heart-lung machine.<sup>50</sup>  
*May 13:* Lillehei and colleagues began using a heart-lung machine of their own design to correct intracardiac defects. By May of 1956, their series included 80 patients.<sup>48</sup> Initially they used their heart-lung machine for lower-risk patients and used controlled cross-circulation, with which they were more familiar, for the higher-risk patients. Starting in March 1955, they also tried other techniques in patients to oxygenate blood during heart surgery, such as canine lung, but with generally poor results.<sup>48</sup>

(Continued)

**TABLE 1-1: Twilight Zone: Clinical Status of Open-Heart Surgery, 1951–1955 (Continued)**

1955 Dodrill had been performing heart operations with the GM heart pump since 1952 and used the patient's own lungs to oxygenate the blood. Early in the year 1955, he attempted repairs of VSDs in two patients using the heart pump, but with a mechanical oxygenator of his team's design both died. On December 1, he closed a VSD in a 3-year-old girl using his heart-lung machine. She survived. In May 1956 at the annual meeting of the American Association for Thoracic Surgery, he reported on six children with VSDs, including one with tetralogy of Fallot, who had undergone open-heart surgery using his heart-lung machine. All survived at least 48 hours postoperatively.<sup>51</sup> Three were hospital survivors, including the patient with tetralogy of Fallot.

*June 30:* Clarence Dennis, who had moved from the University of Minnesota to the State University of New York, successfully closed an ASD in a girl using a heart-lung machine of his own design.<sup>52</sup>

Mustard successfully repaired a VSD and dilated the pulmonary valve in a 9-month-old with a diagnosis of tetralogy of Fallot using a mechanical pump and a monkey lung to oxygenate the blood.<sup>53</sup> He did not give the date in 1955, but the patient is listed as Human Case 7. Unfortunately, in the same report, cases 1–6 and 8–15 operated on between 1951 and the end of 1955 with various congenital heart defects did not survive the surgery using the pump and monkey lung, nor did another seven children in 1952, all with TGA (see timeline for 1952) using the same bypass technique.

Note: This list is not all-inclusive but likely includes most of the historically significant clinical open-heart events in which a blood pump was used to support the circulation during this period. (A twilight zone can mean an ill-defined area between two distinct conditions, such as the area between darkness and light.)

The use of systemic hypothermia for open intracardiac surgery was relatively short-lived; after the heart-lung machine was introduced clinically, it appeared that deep hypothermia was obsolete. However, during the 1960s it became apparent that operative results in infants under 1 year of age using

cardiopulmonary bypass were poor. In 1967, Hikasa and colleagues,<sup>56</sup> from Kyoto, Japan, published an article that reintroduced profound hypothermia for cardiac surgery in infants and used the heart-lung machine for rewarming. Their technique involved surface cooling to 20°C, cardiac

**FIGURE 1-3** Blueprints by General Motors engineers of the Dodrill-GMR mechanical heart. (Used with permission from Calvin Hughes.)

surgery during circulatory arrest for 15 to 75 minutes, and rewarming with cardiopulmonary bypass. At the same time, other groups reported using profound hypothermia with circulatory arrest in infants with the heart-lung machine for cooling and rewarming. Results were much improved, and subsequently the technique also was applied for resection of aortic arch aneurysms.

After World War II, John Gibbon resumed his research. He eventually met Thomas Watson, chairman of the board of the International Business Machines (IBM) Corporation. Watson was fascinated by Gibbon's research and promised help. Soon afterward, six IBM engineers arrived and built a machine that was similar to Gibbon's earlier machine, which contained a rotating vertical cylinder oxygenator and a modified DeBakey rotary pump. Gibbon operated on a 15-month-old girl with severe congestive heart failure (CHF). The preoperative diagnosis was ASD, but at operation, none was found. She died, and a huge patent ductus was found at autopsy. The next patient was an 18-year-old girl with CHF owing to an ASD. This defect was closed successfully on May 6, 1953, with the Gibbon-IBM heart-lung machine.

The patient recovered, and several months later the defect was confirmed closed at cardiac catheterization.<sup>57</sup> Unfortunately, Gibbon's next two patients did not survive intracardiac procedures when the heart-lung machine was used. These failures distressed Dr. Gibbon, who declared a 1-year moratorium for the heart-lung machine until more work could be done to solve the problems causing the deaths.

During this period, C. Walton Lillehei and colleagues at the University of Minnesota studied a technique called *controlled cross-circulation*.<sup>58</sup> With this technique, the circulation of one dog was used temporarily to support that of a second dog while the second dog's heart was stopped temporarily and opened. After a simulated repair in the second dog, the animals were disconnected and allowed to recover.

Lillehei and colleagues<sup>58</sup> used their technique at the University of Minnesota to correct a ventricular septal defect (VSD) in a 12-month-old infant on March 26, 1954 (Fig. 1-4). Either a parent or a close relative with the same blood type was connected to the child's circulation. In Lillehei's first clinical case, the patient made an uneventful recovery until death on the eleventh postoperative day from a

**FIGURE 1-4** A depiction of the method of direct-vision intracardiac surgery using extracorporeal circulation by controlled cross-circulation. (A) The patient, showing sites of arterial and venous cannulations. (B) The donor, showing sites of arterial and venous (superficial femoral and great saphenous) cannulations. (C) The Sigma motor pump controlling precisely the reciprocal exchange of blood between the patient and donor. (D) Close-up of the patient's heart, showing the vena caval catheter positioned to draw venous blood from both the superior and inferior vena cavae during the cardiac bypass interval. The arterial blood from the donor circulated to the patient's body through the catheter that was inserted into the left subclavian artery. (Reproduced with permission from Lillehei CW, Cohen M, Warden HE, et al: The results of direct vision closure of ventricular septal defects in eight patients by means of controlled cross circulation, *Surg Gynecol Obstet.* 1955 Oct;101(4):446-466.)

rapidly progressing tracheal bronchitis. At autopsy, the VSD was closed, and the respiratory infection was confirmed as the cause of death. Two weeks later, the second and third patients had VSDs closed by the same technique 3 days apart. Both remained long-term survivors with normal hemodynamics confirmed by cardiac catheterization.

In 1955, Lillehei and colleagues<sup>59</sup> published a report of 32 patients that included repairs of VSDs, tetralogy of Fallot, and atrioventricularis communis defects. By May of 1955, the blood pump used for systemic cross-circulation by Lillehei and colleagues was coupled with a bubble oxygenator developed by Drs. DeWall and Lillehei, and cross-circulation was soon abandoned after use in 45 patients during 1954 and 1955. Although its clinical use was short-lived, cross-circulation was an important steppingstone in the development of cardiac surgery.

Meanwhile, at the Mayo Clinic only 90 miles away, John W. Kirklin and colleagues launched their open-heart program on March 5, 1955.<sup>50</sup> They used a heart-lung machine based on the Gibbon-IBM machine but with their own modifications. Kirklin wrote:<sup>61</sup>

We investigated and visited the groups working intensively with the mechanical pump oxygenators. We visited Dr. Gibbon in his laboratories in Philadelphia, and Dr. Forest Dodrill in Detroit, among others. The Gibbon pump oxygenator had been developed and made by the International Business Machine Corporation and looked quite a bit like a computer. Dr. Dodrill's heart-lung machine had been developed and built for him by General Motors and it looked a great deal like a car engine. We came home, reflected and decided to try to persuade the Mayo Clinic to let us build a pump oxygenator similar to the Gibbon machine, but somewhat different. We already had had about a year's experience in the animal laboratory with David Donald using a simple pump and bubble oxygenator when we set about very early in 1953, the laborious task of building a Mayo-Gibbon pump oxygenator and continuing the laboratory research.

Most people were very discouraged with the laboratory progress. The American Heart Association and the National Institutes of Health had stopped funding any projects for the study of heart-lung machines, because it was felt that the problem was physiologically insurmountable. David Donald and I undertook a series of laboratory experiments lasting about 1½ years during which time the engineering shops at the Mayo Clinic constructed a pump oxygenator based on the Gibbon model.

... In the winter of 1954 and 1955 we had nine surviving dogs out of 10 cardiopulmonary bypass runs. With my wonderful colleague and pediatric cardiologist, Jim DuShane, we had earlier selected eight patients for intracardiac repair. Two had to be put off because two babies with very serious congenital heart disease came along and we decided to fit them into the schedule. We had determined to do all eight patients even if the first seven died. All of this was planned with the knowledge and approval of the governance of the Mayo Clinic. Our plan was then to return to the laboratory and spend the next 6 to 12 months solving the problems that had arisen in the first planned clinical trial of a pump oxygenator. ... We did our first open-heart operation on a Tuesday in March 1955.

Kirklin continued:<sup>61</sup>

Four of our first eight patients survived, but the press of the clinical work prevented our ever being able to return to the laboratory with the force that we had planned. By now, Walt Lillehei and I were on parallel, but intertwined paths.

By the end of 1956, many university groups around the world had launched into open-heart programs. Currently, it is estimated that more than 1 million cardiac operations are performed each year worldwide with use of the heart-lung machine. In most cases, the operative mortality is quite low, approaching 1% for some operations. Little thought is given to the courageous pioneers in the 1950s whose monumental contributions made all this possible.

## Extracorporeal Life Support

Extracorporeal life support (ECLS) is an extension of cardiopulmonary bypass. Cardiopulmonary bypass was limited initially to no more than 6 hours. The development of membrane oxygenators in the 1960s permitted longer support. Donald Hill and colleagues in 1972 treated a 24-year-old man who developed shock lung after blunt trauma.<sup>62</sup> The patient was supported for 75 hours using a heart-lung machine with a membrane oxygenator, cannulated via the femoral vein and artery. The patient was weaned and recovered. Hill's second patient was supported for 5 days and recovered. This led to a randomized trial supported by the National Institutes of Health to determine the efficacy of this therapy for adults with respiratory failure. The study was conducted from 1972 to 1975 and showed no significant difference in survival between patients managed by ECLS (9.5%) and those who received conventional ventilatory therapy (8.3%).<sup>63</sup> Because of these results, most U.S. centers abandoned efforts to support adult patients using ECLS, also known as *extracorporeal membrane oxygenation* (ECMO).

One participant in the adult trial decided to study neonates. The usual causes of neonatal respiratory failure have in common abnormal postnatal blood shunts known as *persistent fetal circulation* (PFC). This is a temporary, reversible phenomenon. In 1976, Bartlett and colleagues at the University of Michigan were the first to treat a neonate successfully using ECLS. More than 8000 neonatal patients have been treated using ECLS worldwide, with a survival rate of 82% (ELSO registry data).

## MYOCARDIAL PROTECTION

Melrose and colleagues<sup>64</sup> in 1955 presented the first experimental study describing induced arrest by potassium-based cardioplegia. Blood cardioplegia was used "to preserve myocardial energy stores at the onset of cardiac ischemia." Unfortunately, the Melrose solution proved to be toxic to the myocardium, and as a result cardioplegia was not used widely for several years.

Gay and Ebert<sup>65</sup> and Tyres and colleagues<sup>66</sup> demonstrated that cardioplegia with lower potassium concentrations was

safe. Studies by Kirsch and colleagues,<sup>67</sup> Bretschneider and colleagues,<sup>68</sup> and Hearse and colleagues<sup>69</sup> demonstrated the effectiveness of cardioplegia with other constituents and renewed interest in this technique. Gay and Ebert in 1973 demonstrated a significant reduction in myocardial oxygen consumption during potassium-induced arrest when compared with that of the fibrillating heart.<sup>65</sup> They also showed that the problems in the use of the Melrose solution in the early days of cardiac surgery probably were caused by its hyperosmolar properties and perhaps not the high potassium concentration.

In a 1978 publication by Follette and colleagues,<sup>70</sup> the technique of blood cardioplegia was reintroduced. In experimental and clinical studies, these authors demonstrated that hypothermic, intermittent blood cardioplegia provided better myocardial protection than normothermic, continuous coronary perfusion and/or hypothermic, intermittent blood perfusion without cardioplegia solution. The composition of the best cardioplegia solution remains controversial, and new formulations, methods of delivery, and recommended temperatures continue to evolve.

## EVOLUTION OF CONGENITAL CARDIAC SURGERY DURING THE ERA OF CARDIOPULMONARY BYPASS

With the advent of cardiopulmonary bypass using either the cross-circulation technique of Lillehei and colleagues or the version of the mechanical heart-lung machine used by Kirklin and colleagues, the two groups led the way for intracardiac repairs for many of the commonly occurring congenital heart defects. Because of the morbidity associated with the heart-lung machine, palliative operations also were developed to improve circulatory physiology without directly addressing the anatomic pathology. These palliative operations included the Blalock-Taussig subclavian–pulmonary arterial shunt<sup>30</sup> with modifications by Potts and colleagues<sup>71</sup> and Waterston,<sup>72</sup> the Blalock-Hanlon operation to create an ASD,<sup>73</sup> and the Galankin-Glenn superior vena cava–right pulmonary arterial shunt.<sup>35,36</sup>

As the safety of cardiopulmonary bypass improved steadily, surgeons addressed more and more complex abnormalities of the heart in younger and younger patients. Some of the milestones in the development of operations to correct congenital heart defects using cardiopulmonary bypass appear in Table 1-2.

## VALVULAR SURGERY: CARDIOPULMONARY BYPASS ERA

Cardiac valve repair or replacement under direct vision awaited the development of the heart-lung machine. The first successful aortic valve replacement (AVR) in the subcoronary position was performed by Dr. Dwight Harken and associates.<sup>91</sup> A caged-ball valve was used. Many of the techniques described in Harken's 1960 report are similar to those used today for AVR.

That same year, Starr and Edwards<sup>92</sup> successfully replaced the mitral valve using a caged-ball valve of their own design.

By 1967, nearly 2000 Starr-Edwards valves had been implanted, and the caged-ball-valve prosthesis was established as the standard against which all other mechanical prostheses would be compared.

In 1964, Starr and colleagues reported 13 patients who had undergone multiple valve replacement.<sup>93</sup> One patient had the aortic, mitral, and tricuspid valves replaced on February 21, 1963. Cartwright and colleagues, however, on November 1, 1961, were the first to replace both the aortic and mitral valves successfully with ball-valve prostheses that they had developed.<sup>94</sup> Knott-Craig and colleagues,<sup>95</sup> from the Mayo Clinic, successfully replaced all four heart valves in a patient with carcinoid involvement.

In 1961, Andrew Morrow and Edwin Brockenbrough<sup>96</sup> reported a treatment for idiopathic hypertrophic subaortic stenosis by resecting a portion of the thickened ventricular septum. They referred to this as *subaortic ventriculomyotomy*. They gave credit to William Cleland and H.H. Bentall in London, who had encountered this condition unexpectedly at operation and resected a small portion of the ventricular mass. The patient improved, but no postoperative hemodynamic studies had been reported. The subaortic ventriculomyotomy became the standard surgical treatment for this cardiac anomaly, although in some patients systolic anterior motion (SAM) of the anterior leaflet of the mitral valve necessitates mitral valve replacement with a low-profile mechanical valve.

An aortic homograft valve was used clinically for the first time by Heimbecker and colleagues in Toronto for replacement of the mitral valve in one patient and an aortic valve in another.<sup>97</sup> Survival was short, 1 day in one patient and 1 month in the other. Donald Ross reported on the first successful aortic valve placement with an aortic valve homograft.<sup>98</sup> He used a technique of subcoronary implantation developed in the laboratory by Carlos Duran and Alfred Gunning in Oxford.

The technique of AVR with a pulmonary autograft described initially by Ross in 1967 is advocated by some groups for younger patients who require AVR.<sup>99</sup> An aortic or pulmonary valve homograft is used to replace the pulmonary valve that has been transferred to the aortic position.

Other autogenous materials that have been used to manufacture valve prostheses include pericardium, fasciae latae, and dura mater. In the 1960s, Binet and colleagues<sup>100</sup> began to develop and test tissue valves. In 1964, Duran and Gunning in England replaced an aortic valve in a patient using a xenograft porcine aortic valve. Early results with formaldehyde-fixed xenografts were good,<sup>100</sup> but in a few years these valves began to fail because of tissue degeneration and calcification.<sup>101</sup> Carpentier and colleagues revitalized interest in xenograft valves by fixating porcine valves with glutaraldehyde. Carpentier also mounted his valves on a stent to produce a bioprosthesis. Carpentier-Edwards porcine valves and Hancock and Angell-Shiley bioprostheses became popular and were implanted in large numbers of patients.<sup>102,103</sup>

With the development of cardiopulmonary bypass, valves could be approached under direct vision, and for the first

**TABLE 1-2: First Successful Intracardiac Repairs Using Cardiopulmonary Bypass or Cross-Circulation**

Lesion	Year	Reference	Comment

Pediatric heart transplantation	1985	Bailey et al <sup>90</sup>	

time, mitral insufficiency could be attacked by reparative techniques. Techniques for mitral annuloplasty were described by Wooler and colleagues,<sup>104</sup> Reed and colleagues,<sup>105</sup> and Kay and colleagues.<sup>106</sup> The next step forward was development of annuloplasty rings by Carpentier and Duran. In the 1970s, few groups were involved in valve repairs. Slowly, techniques evolved, were tested clinically, and were followed over the years. Carpentier led the field by establishing the importance of careful analysis of valve pathology, describing in detail several techniques of valve repair, and reporting good results after early and late follow-up, especially with concomitant use of annuloplasty rings.<sup>107</sup>

From 1966 to 1968, a small epidemic of infective endocarditis in Detroit among heroin addicts broke out. Patients were dying of intractable gram-negative tricuspid valve endocarditis, often caused by *Pseudomonas aeruginosa*. Long-term antibiotic administration in combination with tricuspid valve replacement was 100% fatal. Starting in 1970, Arbulu operated on 55 patients; in 53, the tricuspid valve was removed without replacing it.<sup>108,109</sup> At 25 years, the actuarial survival is 61%.

Alan Cribier in Rouen France was first to successfully perform a transcatheter aortic valve insertion in a patient on

April 16, 2002.<sup>110</sup> Prospective clinical trials soon followed, which demonstrated that percutaneous aortic valve insertion improved 1 year survival compared to medically treated patients with critical aortic stenosis, and that this procedure had similar 30-day and 1-year mortalities when compared to the standard surgical procedure. There was, however, an increased rate of stroke/transient ischemic attack (TIA) with percutaneous approach.<sup>111, 112</sup>

## CORONARY ARTERY SURGERY

Selective coronary angiography was developed by Sones and Shirey at the Cleveland Clinic and reported in their 1962 classic paper entitled, "Cine Coronary Arteriography."<sup>113</sup> They used a catheter to inject contrast material directly into the coronary artery ostia. This technique gave a major impetus to direct revascularization of obstructed coronary arteries.

From 1960 to 1967, several sporadic instances of coronary grafting were reported. All were isolated cases and, for uncertain reasons, were not reproduced. None had an impact on the development of coronary surgery. Dr. Robert H. Goetz performed what appears to be the first clearly documented coronary artery bypass operation in a human, which was

successful. The surgery took place at Van Etten Hospital in New York City on May 2, 1960.<sup>114</sup> He operated on a 38-year-old man who was severely symptomatic and used a nonsuture technique to connect the right internal mammary artery to a right coronary artery. It took him 17 seconds to join the two arteries using a hollow metal tube. The right internal mammary artery–coronary artery connection was confirmed patent by angiography performed on the 14th postoperative day. The patient remained asymptomatic for about a year and then developed recurrent angina and died of a myocardial infarction on June 23, 1961. Goetz was severely criticized by his medical and surgical colleagues for this procedure, although he had performed it successfully many times in the animal laboratory. He never attempted another coronary bypass operation in a human.

Another example involved a case of autogenous saphenous vein bypass grafting performed on November 23, 1964, in a 42-year-old man who was scheduled to have endarterectomy of his left coronary artery.<sup>115</sup> Because the lesion involved the entire bifurcation, endarterectomy with venous patch graft was abandoned as too hazardous. The authors, Garrett, Dennis, and DeBakey, however, did not report this case until 1973. The patient was alive at that time, and angiograms showed the vein graft to be patent.

Shumaker<sup>116</sup> credits Longmire with the first internal mammary–coronary artery anastomosis. “It was almost surely Longmire, long-time chairman at UCLA, and his associate, Jack Cannon, who first performed an anastomosis between the internal mammary artery and a coronary branch, probably in early 1958.”

The reference that Shumaker gives for this quotation from Longmire is a personal communication to Shumaker in 1990, which was 32 years after the fact!

As early as 1952, Vladimir Demikhov, the renowned Soviet surgeon, was anastomosing the internal mammary artery to the left coronary artery in dogs.<sup>117</sup> In 1967, at the height of the Cold War, a Soviet surgeon from Leningrad, V. I. Kolessov, reported his experience with mammary artery–coronary artery anastomoses for the treatment of angina pectoris in six patients in an American surgical journal.<sup>118</sup> The first patient in that series was done in 1964. Operations were performed through a left thoracotomy without extracorporeal circulation or preoperative coronary angiography. The following year, Green and colleagues<sup>119</sup> and Bailey and Hirose<sup>120</sup> separately published reports in which the internal mammary artery was used for coronary artery bypass in patients.

Rene Favalaro from the Cleveland Clinic used saphenous vein for bypassing coronary obstructions.<sup>121</sup> Favalaro’s 1968 article focused on 15 patients, who were part of a larger series of 180 patients who had undergone the Vineberg procedure. In these 15 patients with occlusion of the proximal right coronary artery, an interpositional graft of saphenous vein also was placed between the ascending aorta and the right coronary artery distal to the blockage. The right coronary artery was divided, and the vein graft was anastomosed end to end. Favalaro states that this procedure was done because of the unfavorable results with pericardial patch reconstruction

of the coronary artery. In an addendum to that paper, 55 patients were added, 52 for segmental occlusion of the right coronary and 3 others for circumflex disease.

The contributions by Favalaro, Kolessov, Green and colleagues, and Bailey and Hirose all were important, but arguably the official start of coronary bypass surgery as we know it today happened in 1969 when W. Dudley Johnson and coworkers from Milwaukee reported their series of 301 patients who had undergone various operations for coronary artery disease (CAD) since February of 1967.<sup>122</sup> In that report, the authors presented their results with direct coronary artery surgery during a 19-month period. They state:

After two initial and successful patch grafts, the vein bypass technique has been used exclusively. Early results were so encouraging that last summer the vein graft technique was expanded and used to all major branches. Vein grafts to the left side of the arteries run from the aorta over the pulmonary artery and down to the appropriate coronary vessel. Right-sided grafts run along the atrioventricular groove and also attach directly to the aorta. There is almost no limit of potential (coronary) arteries to use. Veins can be sutured to the distal anterior descending or even to posterior marginal branches. Double vein grafts are now used in more than 40% of patients and can be used to any combination of arteries.

Johnson goes on to say:

Our experience indicates that five factors are important to direct surgery. One: Do not limit grafts to proximal portions of large arteries. ... Two: Do not work with diseased arteries. Vein grafts can be made as long as necessary and should be inserted into distal normal arteries. Three: Always do end-to-side anastomoses. ... Four: Always work on a dry, quiet field. Consistently successful fine vessel anastomoses cannot be done on a moving, bloody target. ... Five: Do not allow the hematocrit to fall below 35.

In discussing Dr. Johnson’s presentation, Dr. Frank Spencer commented:

I would like to congratulate Dr. Johnson very heartily. We may have heard a milestone in cardiac surgery today. Because for years, pathologists, cardiologists, and many surgeons have repeatedly stated that the pattern of coronary artery disease is so extensive that direct anastomosis can be done in only 5 to 7% of patients. If the exciting data by Dr. Johnson remain valid and the grafts remain patent over a long period of time, a total revision of thinking will be required regarding the feasibility of direct arterial surgery for CAD.<sup>122</sup>

The direct anastomosis between the internal mammary artery and the coronary artery was not as popular initially as the vein-graft technique; however, owing to the persistence of Drs. Green, Loop, Grondin, and others, internal mammary artery grafts eventually became the conduit of choice when their superior long-term patency became known.<sup>123</sup>

Andreas Gruntzig working in Zurich, Switzerland, was the first to successfully dilate a stenotic coronary artery in a patient, percutaneously and used a balloon-tip catheter he had developed. The procedure was performed on September 16, 1977, on a 38-year-old woman with an 85% stenosis of the

left anterior descending coronary artery. In 1979, he reported on the first 50 patients to undergo percutaneous transluminal coronary angioplasty (PTCA).<sup>124</sup> However despite the almost instant popularity of this procedure in the Western world, it was soon found that the restenosis rate was relatively high when compared with that of coronary bypass surgery, and there was also risk of sudden closure of the artery in the area that had been dilated.

Research in the animal laboratory with stents was carried out in the hope of solving these problems.

Jacque Puel in Toulouse, France, and shortly afterward, Ulrich Sigwart in Lausanne, Switzerland, were first to implant stents in patient's coronary arteries in the spring of 1986.<sup>125-128</sup> Although stents improved the results of PTCA and significantly decreased the incidence of acute coronary closure, the long-term patency rates in general were not as good as those in coronary bypass surgery. Therefore, stents that were impregnated with drugs or other chemicals were developed, which would be slowly released with hopes of decreasing the restenosis rate. Clinical trials with these drug-eluting types of stents began in 2003 and indicate they are associated with a decrease in restenosis rates.

Denton Cooley and colleagues made two important contributions to the surgery for ischemic heart disease.<sup>129</sup> In 1956, with the use of cardiopulmonary bypass, they were the first to repair a ruptured interventricular septum following acute myocardial infarction. The patient did well initially but died of complications 6 weeks after the operation. Cooley and colleagues also were the first to report the resection of a left ventricular aneurysm with the use of cardiopulmonary bypass.<sup>130</sup>

## ARRHYTHMIC SURGERY

Cobb and colleagues at Duke University developed the first successful surgical treatment for cardiac arrhythmias.<sup>131</sup> A 32-year-old fisherman was referred for symptomatic episodes of atrial tachycardia that caused CHF. On May 2, 1968, after epicardial mapping, a 5- to 6-cm cut was made extending from the base of the right atrial appendage to the right border of the right atrium during cardiopulmonary bypass. The incision transected the conduction pathway between the atrium and ventricle. Subsequent epicardial mapping indicated eradication of the pathway. Six weeks after the operation, heart size had decreased and lung fields had cleared. The patient eventually returned to work.

A year earlier, Dr. Dwight McGoon at the Mayo Clinic closed an ASD in a patient who also had Wolff-Parkinson-White (WPW) syndrome.<sup>132</sup> At operation, Dr. Birchell mapped the epicardium of the heart and localized the accessory pathway to the right atrioventricular groove. Lidocaine was injected into the site, and the delta wave disappeared immediately. Unfortunately, conduction across the pathway reappeared a few hours later. This probably was the first attempt to treat the WPW syndrome surgically. As a result of knowledge gained from the surgical treatment for WPW syndrome, more than 95% of

all refractory clinical cases now are treated successfully by nonsurgical means.<sup>132</sup>

Ross and colleagues<sup>133</sup> in Sydney, Australia, and Cox and colleagues<sup>134</sup> in St. Louis, Missouri, used cryosurgical treatment of atrial ventricular node re-entry tachycardia. Subsequently, James L. Cox, after years of laboratory research, developed the Maze operation for atrial fibrillation.<sup>135</sup> That technique, with his subsequent modifications, is now known as the *Cox Maze procedure* and has become the world standard with which other techniques used to treat atrial fibrillation, either surgically or with catheters, are compared.<sup>136</sup>

Guiraudon and colleagues,<sup>136</sup> from Paris, reported their results with an encircling endomyocardial ventriculotomy for the treatment of malignant ventricular arrhythmias. The following year, in 1979, Josephson and colleagues<sup>137</sup> described a more specific procedure for treatment of malignant ventricular arrhythmias. After endocardial mapping, the endocardial source of the arrhythmia was excised. Although the Guiraudon technique usually isolated the source of the arrhythmia, the incision also devascularized healthy myocardium and was associated with high mortality. Endocardial resection was safer and more efficacious and became the basis of all approaches for the treatment of ischemic ventricular tachycardia.<sup>137</sup>

Stimulated by the death of a close personal friend from ventricular arrhythmias, Dr. Mirowski developed a prototype defibrillator over a 3-month period in 1969. In 1980, Mirowski and colleagues described three successful cases using their implantable myocardial stimulator at Johns Hopkins.<sup>138</sup>

Soon a version of Mirowski's defibrillator was commercially available. Initially centers implanting them were part of the clinical trials being conducted and required Food and Drug Administration (FDA) approval. The chest needed to be opened to place the relatively large electrodes directly on the ventricles. The battery used to power the device and generate the electrical shock was also large and was usually placed in the abdominal wall. Within 10 years, smaller, more advanced ventricular leads were developed and inserted percutaneously through the venous system. The battery was made much smaller in size. During the 1990s, clinical trials were conducted, which showed the automatic implantable cardiac defibrillators decreased mortality when compared to medically treated patients in subsets of patients prone to ventricular tachycardia and fibrillation. As a result of these findings, the use of these devices has increased significantly.<sup>139, 140</sup>

## PACEMAKERS

In 1952, Paul Zoll applied electric shocks 2 ms in duration that were transmitted through the chest wall at frequencies from 25 to 60 per minute and increased the intensity of the shock until ventricular responses were observed. However, after 25 minutes of intermittent stimulation the patient died, although many subsequent patients recovered.<sup>141</sup> The next step came when Lillehei and colleagues reported a series of patients who had external pacing after open-heart surgery during the 1950s.<sup>142</sup> The field of open-heart

surgery gave a major impetus to the development of pacemakers because there was a high incidence of heart block following many intracardiac repairs. The major difference between Zoll's pacing and that of Lillehei and colleagues was that Zoll used external electrodes placed on the chest wall, whereas Lillehei and colleagues attached electrodes directly to the heart at operation. Lillehei and colleagues used a relatively small external pacemaker to stimulate the heart and much less electric current. This form of heart pacing was better tolerated by the patient and was a more efficient way to stimulate the heart. The survival rate of Lillehei's patients with surgically induced heart block was improved significantly.

During this period, progress was made toward a totally implantable pacemaker. Elmquist and Senning<sup>143</sup> developed a pacer battery that was small enough for an epigastric pocket with electrodes connected to the heart. They implanted the unit in a patient with atrioventricular block in 1958. Just before implantation, the patient had 20 to 30 cardiac arrests a day. The first pacemaker that was implanted functioned only 8 hours; the second pacemaker implanted in the same patient had better success. The patient survived until January 2002 and had many additional pacemakers. Chardack and colleagues are perhaps better known for their development of the totally implantable pacemaker.<sup>144</sup> In 1961, they reported a series of 15 patients who had pacemakers that they had developed implanted.

Early implantable pacemakers were fixed-rate, asynchronous devices that delivered an impulse independent of the underlying cardiac rhythm. During the past 40 years, enormous progress has been made in the field of pacing technology. The number of individuals with artificial pacemakers is unknown; however, estimates indicate that approximately 500,000 Americans are living with a pacemaker and that each year another 100,000 or more patients require permanent pacemakers in the United States.

## HEART, HEART-LUNG, AND LUNG TRANSPLANTATION

Alexis Carrel and Charles Guthrie reported transplantation of the heart and lungs while at the University of Chicago in 1905.<sup>145</sup> The heart of a small dog was transplanted into the neck of a larger one by anastomosing the caudad ends of the jugular vein and carotid artery to the aorta and pulmonary artery. The animal was not anticoagulated, and the experiment ended about 2 hours after circulation was established because of blood clot in the cavities of the transplanted heart.

Vladimir Demikhov, from Russia, described more than 20 different techniques for heart transplantation in 1950.<sup>146</sup> He also published various techniques for heart and lung transplantation. He was even able to perform an orthotopic heart transplant in a dog before the heart-lung machine was developed. This was accomplished by placing the donor heart above the dog's own heart, and then with a series of tubes and connections, he rerouted the blood from one heart to the

other until he had the donor heart functioning in the appropriate position and the native heart removed. One of his dogs climbed the steps of the Kremlin on the sixth postoperative day but died shortly afterward of rejection.

Richard Lower and Norman Shumway established the technique for heart transplantation as it is performed today.<sup>147</sup> Preservation of the cuff of recipient left and right atria with part of the atrial septum was described earlier by Brock<sup>148</sup> in England and Demikhov<sup>117</sup> in Russia,<sup>149</sup> but it became popular only after Shumway and Lower reported it in their 1960 paper.

The first attempt at human heart transplantation was made by Hardy and colleagues<sup>150</sup> at the University of Mississippi. Because no human donor organ was available at the time, a large chimpanzee's heart was used; however, it was unable to support the circulation because of hyperacute rejection.

The first human-to-human heart transplant occurred on December 3, 1967, in Capetown, South Africa.<sup>151</sup> The surgical team, headed by Christiaan Barnard, transplanted the heart of a donor who had been certified dead after the electrocardiogram showed no activity for 5 minutes into a 54-year-old man whose heart was irreparably damaged by repeated myocardial infarctions. The second human heart transplant using a human donor was performed on a child 3 days after the first on December 6, 1967, by Adrian Kantrowitz in Brooklyn, New York. Dr. Kantrowitz's patient died of a bleeding complication within the first 24 hours.<sup>152</sup> Barnard's patient, Lewis Washkansky, died on the 18th postoperative day. At autopsy, the heart appeared normal, and there was no evidence of chronic liver congestion, but bilateral pneumonia was present, possibly owing to severe myeloid depression from immunosuppression.<sup>153</sup>

On January 2, 1968, Barnard performed a second heart transplant on Phillip Blaiberg, 12 days after Washkansky's death.<sup>154</sup> Blaiberg was discharged from the hospital and became a celebrity during the several months he lived after the transplant. Blaiberg's procedure indicated that a heart transplant was an option for humans suffering from end-stage heart disease. Within a year of Barnard's first heart transplant, 99 heart transplants had been performed by cardiac surgeons around the world. However, by the end of 1968, most groups abandoned heart transplantation because of the extremely high mortality related to rejection. Shumway and Lower, Barnard, and a few others persevered both clinically and in the laboratory. Their efforts in discovering better drugs for immunosuppression eventually established heart transplantation as we know it today.

A clinical trial of heart-lung transplantation was commenced at Stanford University in 1981 by Reitz and colleagues.<sup>155</sup> Their first patient was treated with a combination of cyclosporine and azathioprine. The patient was discharged from the hospital in good condition and was well more than 5 years after the transplant.

The current success with heart, heart-lung, and lung transplantation is related in part to the discovery of cyclosporine by workers at the Sandoz Laboratory in Basel, Switzerland, in 1970. In December of 1980, cyclosporine was introduced

at Stanford for cardiac transplantation. The incidence of rejection was not reduced, nor was the incidence of infection. However, these two major complications of cardiac transplantation were less severe when cyclosporine was used. Availability of cyclosporine stimulated many new programs across the United States in the mid-1980s.

The first human lung transplant was performed by Hardy and colleagues<sup>156</sup> at the University of Mississippi on June 11, 1964. The patient died on the 17th postoperative day. In 1971, a Belgian surgeon, Fritz Derom, achieved a 10-month survival in a patient with pulmonary silicosis.<sup>157</sup>

Much of the credit, however, for the success of lung transplantation belongs to the Toronto group, whose efforts were headed by Joel Cooper. Their successes were based on laboratory experimentation and the discovery of cyclosporine. After losing an early patient to bronchial anastomotic dehiscence in 1978, the group substituted cyclosporine for cortisone and wrapped the bronchial suture line with a pedicle of omentum. They also developed a comprehensive preoperative preparation program that increased the strength and nutritional status of the recipients. In 1986, Cooper and associates presented their first two successful patients, who had returned to normal activities and were alive 14 and 26 months after operation.<sup>158</sup>

## HEART ASSIST AND ARTIFICIAL HEARTS

In 1963, Kantrowitz and colleagues reported the first use of the intra-aortic balloon pump (IABP) in three patients.<sup>159</sup> All were in cardiogenic shock but improved during balloon pumping. One survived to leave the hospital.

In 1963, Liotta and colleagues reported a 42-year-old man who had a stenotic aortic valve replaced but suffered a cardiac arrest the following morning.<sup>160</sup> The patient was resuscitated but developed severe ventricular failure. An artificial intrathoracic circulatory pump was implanted. The patient's pulmonary edema cleared, but he died 4 days later with the pump working continuously. In 1966, the same group used a newer intrathoracic pump to support another patient who could not be weaned from cardiopulmonary bypass. This pump maintained the circulation. The patient eventually died before the pump could be removed.<sup>161</sup> Later that year, the same group used a left ventricular assist device (LVAD) in a woman who could not be weaned from cardiopulmonary bypass after double valve replacement.<sup>162</sup> After 10 days of circulatory assistance, the patient was weaned successfully from the device and recovered. This woman was probably the first patient to be weaned from an assist device and leave the hospital.

The first human application of a totally artificial heart was by Denton Cooley and colleagues as a "bridge" to transplantation.<sup>163</sup> They implanted a totally artificial heart in a patient who could not be weaned from cardiopulmonary bypass. After 64 hours of artificial heart support, heart transplantation was performed, but the patient died of *Pseudomonas* pneumonia 32 hours after transplantation. The first two patients bridged successfully to transplantation were reported

at almost the same time and in the same location by different groups. On September 5, 1984, in San Francisco,<sup>164</sup> Donald Hill implanted a Pierce-Donachy LVAD in a patient in cardiogenic shock. The patient received a successful transplant 2 days later and was discharged subsequently. The assist device used by Hill was developed at Pennsylvania State University by Pierce and Donachy. Phillip Oyer and colleagues at Stanford University placed an electrically driven Novacor LVAD in a patient in cardiogenic shock on September 7, 1984.<sup>165</sup> The patient was transplanted successfully and survived beyond 3 years. The device used by the Stanford group was developed by Peer Portner.

The first implantation of a permanent totally artificial heart (Jarvik-7) was performed by DeVries and colleagues at the University of Utah in 1982.<sup>166</sup> By 1985, they had implanted the Jarvik in four patients, and one survived for 620 days after implantation. This initial clinical experience was based heavily on the work of Kolff and colleagues.

## THORACIC AORTA SURGERY

Alexis Carrel was responsible for one of the great surgical advances of the twentieth century: techniques for suturing and transplanting blood vessels.<sup>167</sup> Although Carrel initially developed his methods of blood vessel anastomosis in Lyon, France, his work with Charles Guthrie in Chicago led to many major advances in vascular, cardiac, and transplantation surgery. In a short period of time, these investigators perfected techniques for blood vessel anastomoses and transposition of arterial and venous segments using both fresh and frozen grafts. After leaving Chicago, Carrel continued to expand his work on blood vessels and organ transplantation and in 1912 received the Nobel Prize. Interestingly, Carrel's work did not receive immediate clinical application.

Rudolph Matas pioneered clinical vascular surgery. Matas' work took place before drugs were available to prevent blood clotting, before antibiotics, and without reliable blood vessel substitutes.<sup>168</sup> Matas performed 620 vascular operations between 1888 and 1940. Only 101 of these were attempts to repair arteries; most involved ligation. Matas developed three variations of his well-known endoaneurysmorrhaphy procedure. The most advanced was to reconstruct the wall of the blood vessel from within while using a rubber tube as a stent.

Vascular surgery advanced tentatively during World War II as traumatic injuries to major blood vessels were repaired in some soldiers with results significantly better than with the standard treatment of ligation.<sup>169</sup> The successful treatment of coarctation of the aorta by Crafoord and Gross added a major boost to the reconstructive surgery of arteries.

Shumaker reported the excision of a small descending thoracic aortic aneurysm with reanastomosis of the aorta in 1948.<sup>170</sup> Swan and colleagues<sup>171</sup> repaired a complex aneurysmal coarctation and used aortic homograft for reconstruction in 1950. Gross<sup>172</sup> reported a series of similar cases using homograft replacement. In 1951, DuBost and colleagues<sup>173</sup> in Paris resected an intra-abdominal aortic aneurysm with homograft replacement.

In 1953, Henry Bahnson,<sup>174</sup> from Johns Hopkins, successfully resected six saccular aneurysms of the aorta in eight patients. In the same year, DeBakey and Cooley<sup>175</sup> reported a 46-year-old man who had resection of a huge aneurysm of the descending thoracic aorta that measured approximately 20 cm in length and in greatest diameter. The aneurysm was resected and replaced with an aortic homograft approximately 15 cm in length.

During the Korean War, the arterial homograft and autogenous vein graft were used to reconstruct battlefield arterial injuries and reduce the overall amputation rate to 11.1%<sup>176</sup> compared with the rate of 49.6% reported in World War II. Although the vein autograft remains the first-choice peripheral vascular conduit today, the arterial homograft was superseded by the development of synthetic vascular grafts by Arthur Voorhees at Columbia University in 1952. Voorhees and colleagues developed Vinyon-N cloth tubes to substitute for diseased arterial segments.<sup>177</sup>

Another advance in aortic surgery appeared in 1955 when DeBakey and colleagues<sup>178</sup> reported six cases of aortic dissection treated by aggressive surgery. Because mortality of operation for acute dissections remained high, Myron Wheat Jr. introduced medical therapy for the disease.<sup>179</sup>

During the late 1950s, the Houston group, consisting of Michael DeBakey, Denton Cooley, Stanley Crawford, and their other associates, systematically developed operations for resection and graft replacement of the ascending aorta,<sup>180</sup> descending aorta, and thoracoabdominal aorta.<sup>181</sup> Cardiopulmonary bypass was used for the ascending aortic resections. The high risk of paraplegia highlighted a major complication of thoracoabdominal aortic resections. The Houston group was the first to resect an aortic arch with the use of cardiopulmonary bypass in 1957 and replace the arch with a reconstituted aortic arch homograft.<sup>182</sup> More interesting is that Cooley and colleagues, using great ingenuity, resected a large aortic arch aneurysm that also involved a portion of the descending aorta in a 49-year-old patient on June 24, 1955. The surgery was done, without the use of cardiopulmonary bypass, by first sewing in a temporary graft from the ascending aorta to the distal descending aorta and sewing in two more temporary limbs off that graft, which were anastomosed to the left and right carotid arteries, while the aneurysm was resected and a permanent graft was placed.<sup>183</sup>

In 1968, Bentall and De Bono<sup>184</sup> introduced replacement of the ascending aorta and aortic valve with reanastomoses of the coronary ostia to the replacement graft. They described the composite-graft technique for replacement of the ascending aorta with reimplantation of the coronary arteries into the composite Dacron graft containing the prosthetic aortic valve. As mentioned, Cooley and DeBakey were the first to replace the supracoronary ascending aorta in 1956. In 1963, Starr and colleagues<sup>185</sup> reported replacing the supracoronary ascending aorta and the aortic valve at the same sitting. The technique of fashioning "buttons" of aortic tissue adjacent to the coronary ostia and then incorporating these buttons into the aortic graft along with the AVR was described by Wheat and colleagues<sup>186</sup> in 1964. Bentall and De Bono incorporated

the aortic prosthesis into the tube graft and used the Wheat technique for implanting the coronary arteries into the composite graft.

Since the early 1990s, stents also have been used for the treatment of aneurysms in both the descending aorta and the abdominal aortas.<sup>187, 188</sup>

The first thoracic stent placed in a patient's thoracic aorta was performed to treat a false aneurysm after a coarctation of the aorta repair.<sup>189</sup> The procedure was carried out at Stanford University Hospital in July 1992 by Michael Drake and D. Craig Miller. Since then, the indications for using thoracic stent grafts have gradually expanded and include transected aortas, aneurysms, penetrating atherosclerotic ulcers, and intramural hematomas of the descending aorta. The long-term follow-up with these stents still needs to be better defined.<sup>190-193</sup>

# Surgical Anatomy of the Heart

Michael R. Mill • Robert H. Anderson • Lawrence H. Cohn

A thorough knowledge of the anatomy of the heart is a prerequisite for the successful completion of the myriad procedures performed by the cardiothoracic surgeon. This chapter describes the normal anatomy of the heart, including its position and relationship to other thoracic organs. It also describes the incisions used to expose the heart for various operations and discusses in detail the cardiac chambers and valves, coronary arteries and veins, and the important but surgically invisible conduction tissues.

## OVERVIEW

### Location of the Heart Relative to Surrounding Structures

The overall shape of the heart is that of a three-sided pyramid located in the middle mediastinum (Fig. 2-1). When viewed from the heart's apex, the three sides of the ventricular mass are readily apparent (Fig. 2-2). Two of the edges are named. The *acute margin* lies inferiorly and describes a sharp angle between the sternocostal and diaphragmatic surfaces. The *obtuse margin* lies superiorly and is much more diffuse. The posterior margin is unnamed but is also diffuse in its transition.

One-third of the cardiac mass lies to the right of the midline and two-thirds to the left. The long axis of the heart is oriented from the left epigastrium to the right shoulder. The short axis, which corresponds to the plane of the atrioventricular groove, is oblique and is oriented closer to the vertical than the horizontal plane (see Fig. 2-1).

Anteriorly, the heart is covered by the sternum and the costal cartilages of the third, fourth, and fifth ribs. The lungs contact the lateral surfaces of the heart, whereas the heart abuts onto the pulmonary hila posteriorly. The right lung overlies the right surface of the heart and reaches to the midline. In contrast, the left lung retracts from the midline in the area of the cardiac notch. The heart has an extensive diaphragmatic surface inferiorly. Posteriorly, the heart lies on the esophagus and the tracheal bifurcation and bronchi that extend into the lung. The sternum lies anteriorly and provides rigid protection

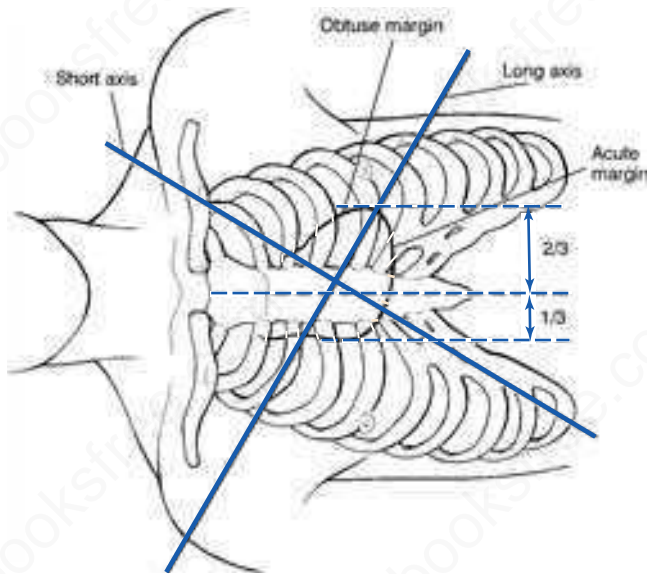

to the heart during blunt trauma and is aided by the cushioning effects of the lungs.

### The Pericardium and Its Reflections

The heart lies within the pericardium, which is attached to the walls of the great vessels and the diaphragm. The pericardium can be visualized best as a bag into which the heart has been placed apex first. The inner layer, in direct contact with the heart, is the *visceral epicardium*, which encases the heart and extends several centimeters back onto the walls of the great vessels. The outer layer forms the *parietal pericardium*, which lines the inner surface of the tough fibrous pericardial sack. A thin film of lubricating fluid lies within the pericardial cavity between the two serous layers. Two identifiable recesses lie within the pericardium and are lined by the serous layer. The first is the *transverse sinus*, which is delineated anteriorly by the posterior surface of the aorta and pulmonary trunk and posteriorly by the anterior surface of the interatrial groove. The second is the *oblique sinus*, a cul-de-sac located behind the left atrium, delineated by serous pericardial reflections from the pulmonary veins and the inferior vena cava.

### Mediastinal Nerves and Their Relationships to the Heart

The vagus and phrenic nerves descend through the mediastinum in close relationship to the heart (Fig. 2-3). They enter through the thoracic inlet, with the phrenic nerve located anteriorly on the surface of the anterior scalene muscle and lying just posterior to the internal thoracic artery (internal mammary artery) at the thoracic inlet. In this position, the phrenic nerve is vulnerable to injury during dissection and preparation of the internal thoracic artery for use in coronary arterial bypass grafting. On the right side, the phrenic nerve courses on the lateral surface of the superior vena cava, again in harm's way during dissection for venous cannulation for cardiopulmonary bypass. The nerve then descends anterior to the pulmonary hilum before reflecting onto the

**FIGURE 2-1** This diagram shows the heart within the middle mediastinum with the patient supine on the operating table. The long axis lies parallel to the interventricular septum, whereas the short axis is perpendicular to the long axis at the level of the atrioventricular valves.

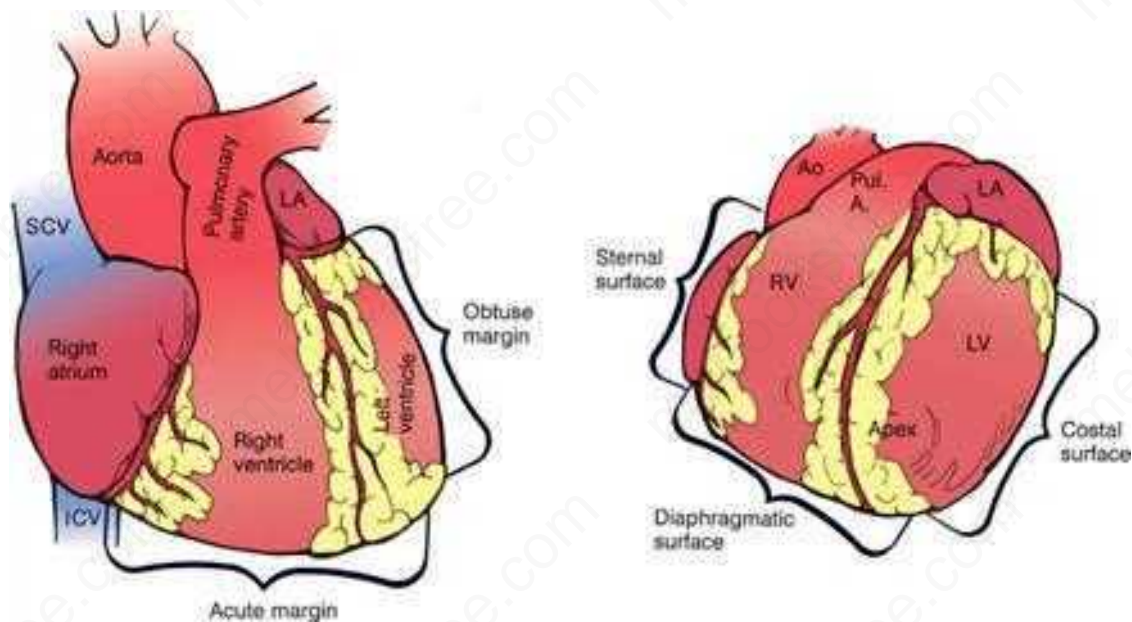

right diaphragm, where it branches to provide its innervation. In the presence of a left-sided superior vena cava, the left phrenic nerve is applied directly to its lateral surface. The nerve passes anterior to the pulmonary hilum and eventually branches on the surface of the diaphragm. The vagus nerves enter the thorax posterior to the phrenic nerves and course along the thoracic arteries. On the right side, the vagus gives off the recurrent laryngeal nerve that passes around the right

subclavian artery before ascending out of the thoracic cavity. The right vagus nerve continues posterior to the pulmonary hilum, gives off branches of the right pulmonary plexus, and exits the thorax along the esophagus. On the left, the vagus nerve crosses the aortic arch, where it gives off the recurrent laryngeal branch. The recurrent nerve passes around the arterial ligament before ascending in the tracheoesophageal groove. The vagus nerve continues posterior to the pulmonary hilum, gives rise to the left pulmonary plexus, and then continues inferiorly out of the thorax along the esophagus. A delicate nerve trunk known as the *subclavian loop* carries fibers from the stellate ganglion to the eye and head. This branch is located adjacent to the subclavian arteries bilaterally. Excessive dissection of the subclavian artery during shunt procedures may injure these nerve roots and cause Horner syndrome.

## SURGICAL INCISIONS

### Median Sternotomy

The most common approach for operations on the heart and aortic arch is the median sternotomy. The skin incision is made from the jugular notch to just below the xiphoid process. The subcutaneous tissues and presternal fascia are incised to expose the periosteum of the sternum. The sternum is divided longitudinally in the midline. After placement of a sternal spreader, the thymic fat pad is divided up to the level of the brachiocephalic vein. An avascular midline plane is identified easily but is crossed by a few thymic veins that are divided between fine silk ties or hemoclips. Either the left or right or, occasionally, both lobes of the thymus gland are removed in infants and young children to improve exposure

**FIGURE 2-2** This diagram shows the surfaces and margins of the heart as viewed anteriorly with the patient supine on the operating table (*left*) and as viewed from the cardiac apex (*right*).

**FIGURE 2-3** Diagram of the heart in relation to the vagus and phrenic nerves as viewed through a median sternotomy.

and minimize compression on extracardiac conduits. If a portion of the thymus gland is removed, excessive traction may result in injury to the phrenic nerve. The pericardium is opened anteriorly to expose the heart. Through this incision, operations within any chamber of the heart or on the surface of the heart and operations involving the proximal aorta, pulmonary trunk, and their primary branches can be performed. Extension of the superior extent of the incision into the neck along the anterior border of the right sternocleidomastoid muscle provides further exposure of the aortic arch and its branches for procedures involving these structures. Exposure of the proximal descending thoracic aorta is facilitated by a perpendicular extension of the incision through the third intercostal space.

### Bilateral Transverse Thoracosternotomy (Clamshell Incision)

The bilateral transverse thoracosternotomy (clamshell incision) is an alternative incision for exposure of the pleural spaces and heart. This incision may be made through either the fourth or fifth intercostal space, depending on the intended procedure. After identifying the appropriate interspace, a bilateral submammary incision is made. The incision is extended down

through the pectoralis major muscles to enter the hemithoraces through the appropriate intercostal space. The right and left internal thoracic arteries are dissected and ligated proximally and distally prior to transverse division of the sternum. Electrocautery dissection of the pleural reflections behind the sternum allows full exposure of both hemithoraces and the entire mediastinum. Bilateral chest spreaders are placed to maintain exposure. Morse or Haight retractors are particularly suitable with this incision. The pericardium may be opened anteriorly to allow access to the heart for intracardiac procedures. When required, standard cannulation for cardiopulmonary bypass is achieved easily. This incision is popular for bilateral sequential double-lung transplants and heart-lung transplants because of enhanced exposure of the apical pleural spaces. When made in the fourth intercostal space, the incision is useful for access to the ascending aorta, aortic arch, and descending thoracic aorta.

### Anterolateral Thoracotomy

The right side of the heart can be exposed through a right anterolateral thoracotomy. The patient is positioned supine, with the right chest elevated to approximately 30 degrees by a roll beneath the shoulder. An anterolateral thoracotomy

incision can be made that can be extended across the midline by transversely dividing the sternum if necessary. With the lung retracted posteriorly, the pericardium can be opened just anterior to the right phrenic nerve and pulmonary hilum to expose the right and left atria. The incision provides access to both the tricuspid and mitral valves and the right coronary artery. Cannulation may be performed in the ascending aorta and the superior and inferior venae cavae. Aortic cross-clamping, administration of cardioplegia, and removal of air from the heart after cardiotomy are difficult with this approach. This incision is particularly useful nonetheless for performance of the Blalock-Hanlon atrial septectomy or valve replacement after a previous procedure through a median sternotomy. A left anterolateral thoracotomy performed in a similar fashion to that on the right side may be used for isolated bypass grafting of the circumflex coronary artery or for left-sided exposure of the mitral valve.

### Posterolateral Thoracotomy

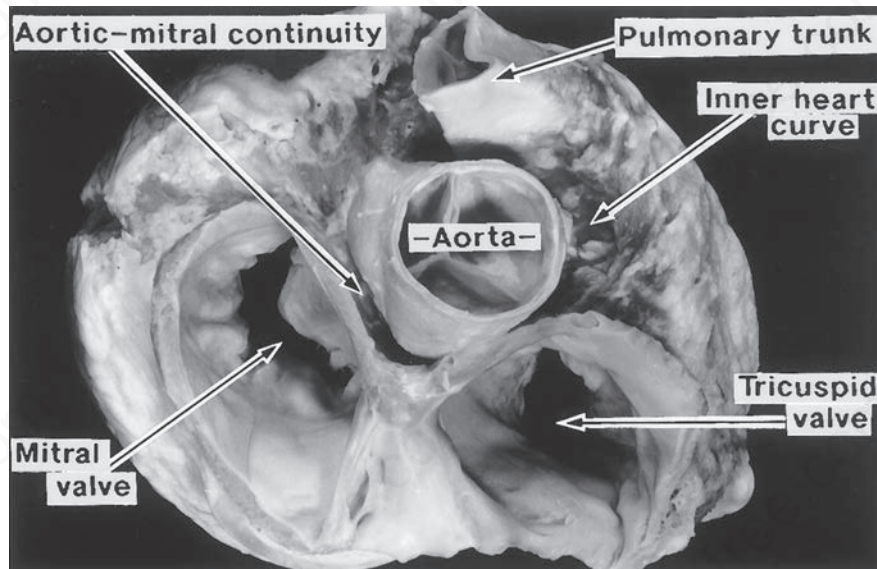

A left posterolateral thoracotomy is used for procedures involving the distal aortic arch and descending thoracic aorta. With left thoracotomy, cannulation for cardiopulmonary bypass must be done through the femoral vessels. A number of variations of these incisions have been used for minimally invasive cardiac surgical procedures. These include partial sternotomies, parasternal incisions, and limited thoracotomies.

### RELATIONSHIP OF THE CARDIAC CHAMBERS AND GREAT ARTERIES

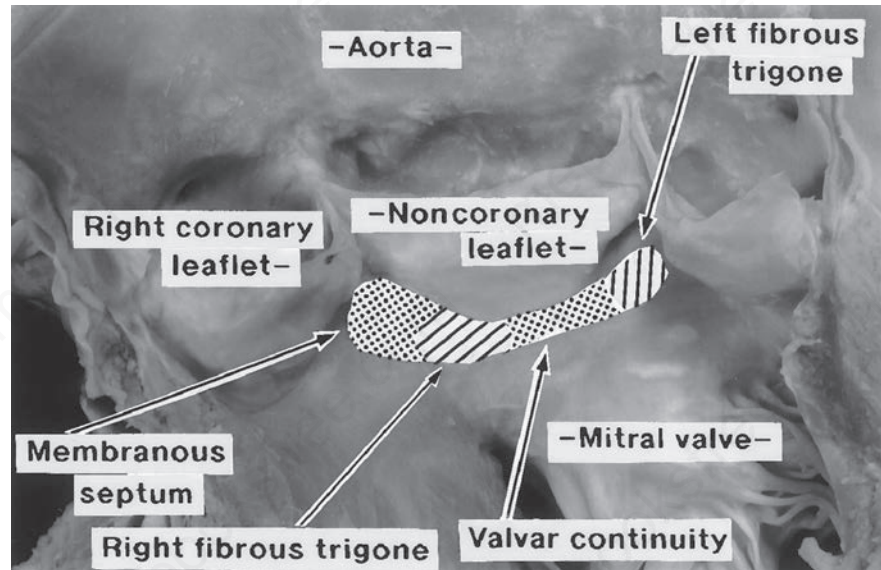

The surgical anatomy of the heart is best understood when the position of the cardiac chambers and great vessels is known in relation to the cardiac silhouette. The atrioventricular

junction is oriented obliquely, lying much closer to the vertical than to the horizontal plane. This plane can be viewed from its atrial aspect (Fig. 2-4) if the atrial mass and great arteries are removed by a parallel cut just above the junction. The tricuspid and pulmonary valves are widely separated by the inner curvature of the heart lined by the transverse sinus. Conversely, the mitral and aortic valves lie adjacent to one another, with fibrous continuity of their leaflets. The aortic valve occupies a central position, wedged between the tricuspid and pulmonary valves. Indeed, there is fibrous continuity between the leaflets of the aortic and tricuspid valves through the central fibrous body.

With careful study of this short axis, several basic rules of cardiac anatomy become apparent. First, the atrial chambers lie to the right of their corresponding ventricles. Second, the right atrium and ventricle lie anterior to their left-sided counterparts. The septal structures between them are obliquely oriented. Third, by virtue of its wedged position, the aortic valve is directly related to all the cardiac chambers. Several other significant features of cardiac anatomy can be learned from the short-axis section. The position of the aortic valve minimizes the area of septum where the mitral and tricuspid valves attach opposite to each other. Because the tricuspid valve is attached to the septum further toward the ventricular apex than the mitral valve, it seems that a muscular atrioventricular septum interposes between the right atrium and the left ventricle. We now know that a continuation of the inferior atrioventricular groove interposes between the atrial and ventricular walls in this area, so that it is a sandwich rather than a true septum, with the fibro-adipose tissue of the atrioventricular groove forming the “meat” in the sandwich. The central fibrous body, where the leaflets of the aortic, mitral, and tricuspid valves all converge, lies cephalad and anterior to the muscular atrioventricular sandwich. The central fibrous body is the main component of the fibrous skeleton of the heart

**FIGURE 2-4** This dissection of the cardiac short axis, seen from its atrial aspect, reveals the relationships of the cardiac valves.

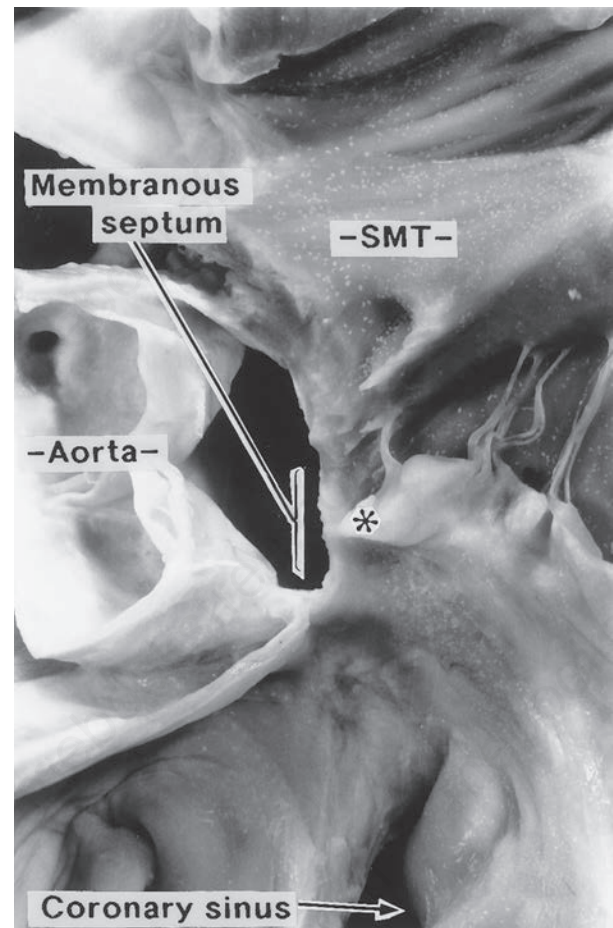

**FIGURE 2-5** This view of the left ventricular outflow tract, as seen from the front in anatomical orientation, shows the limited extent of the fibrous skeleton of the heart.

and is made up in part by the right fibrous trigone, a thickening of the right side of the area of fibrous continuity between the aortic and mitral valves, and in part by the membranous septum, the fibrous partition between the left ventricular outflow tract and the right-sided heart chambers (Fig. 2-5). The membranous septum itself is divided into two parts by the septal leaflet of the tricuspid valve, which is directly attached across it (Fig. 2-6). Thus the membranous septum has an atrioventricular component between the right atrium and left ventricle, as well as an interventricular component. Removal of the noncoronary leaflet of the aortic valve demonstrates the significance of the wedged position of the left ventricular outflow tract in relation to the other cardiac chambers. The subaortic region separates the mitral orifice from the ventricular septum; this separation influences the position of the atrioventricular conduction tissues and the position of the leaflets and tension apparatus of the mitral valve (Fig. 2-7).

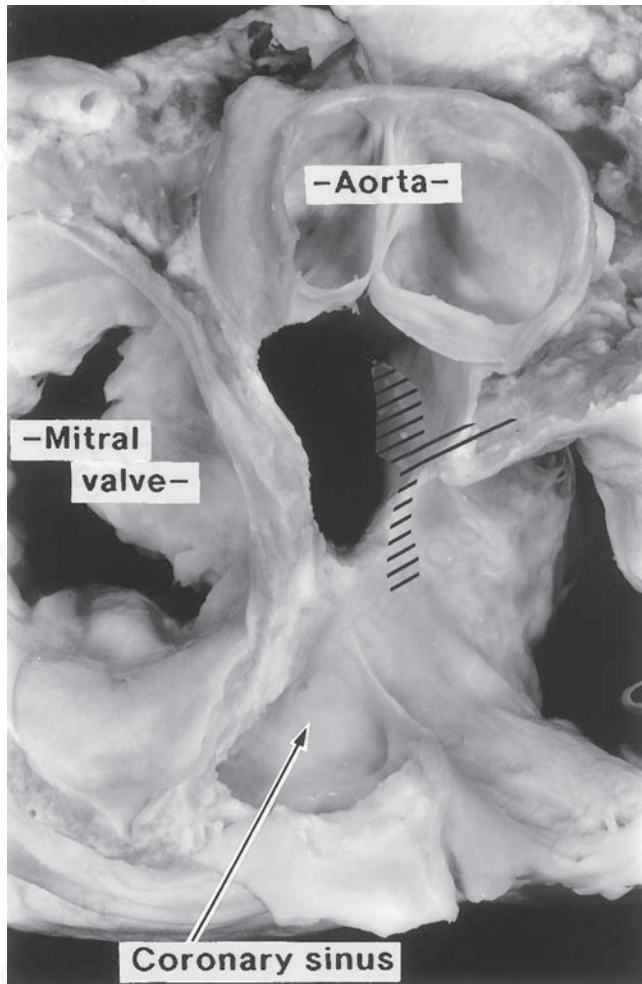

## THE RIGHT ATRIUM AND TRICUSPID VALVE

### Appendage, Vestibule, and Venous Component

The right atrium has three basic parts: the appendage, the vestibule, and the venous component (Fig. 2-8). Externally, the right atrium is divided into the appendage and the venous component, which receives the systemic venous return. The junction of the appendage and the venous component is identified by a prominent groove, the *terminal groove*. This corresponds internally to the location of the terminal crest. The right atrial appendage has the shape of a blunt triangle, with a wide junction to the venous component across the terminal groove. The appendage also has an extensive junction with the vestibule of the right atrium; the latter structure is

**FIGURE 2-6** This dissection, made by removing the right coronary sinus of the aortic valve, shows how the septal leaflet of the tricuspid valve (*asterisk*) divides the membranous septum into its atrioventricular and interventricular components. SMT = septomarginal trabeculation.

**FIGURE 2-7** This dissection, made by removing the noncoronary aortic sinus (compare with Figs. 2-4 and 2-6), shows the approximate location of the atrioventricular conduction axis (*hatched area*) and the relationship of the mitral valve to the ventricular septum.

the smooth-walled atrial myocardium that inserts into the leaflets of the tricuspid valve. The most characteristic and constant feature of the morphology of the right atrium is that the pectinate muscles within the appendage extend around the entire parietal margin of the atrioventricular junction (Fig. 2-9). These muscles originate as parallel fibers that course at right angles from the terminal crest. The venous component of the right atrium extends between the terminal groove and the interatrial groove. It receives the superior and inferior venae cavae and the coronary sinus.

## Sinus Node

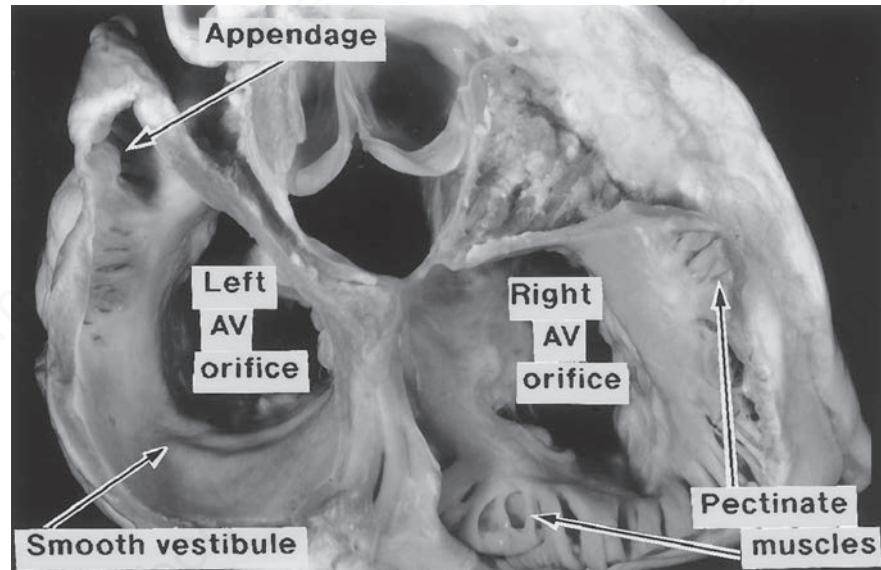

The sinus node lies at the anterior and superior extent of the terminal groove, where the atrial appendage and the superior vena cava are juxtaposed. The node is a spindle-shaped structure that usually lies to the right or lateral to the superior cavoatrial junction (Fig. 2-10). In approximately 10% of

**FIGURE 2-8** This view of the right atrium, seen in surgical orientation, shows the pectinate muscles lining the appendage, the smooth vestibule (*circles*) surrounding the orifice of the tricuspid valve, and the superior vena cava (SCV), inferior vena cava (ICV), and coronary sinus joining the smooth-walled venous component. Note the prominent rim enclosing the oval fossa, which is the true atrial septum (see Fig. 2-11).

cases, the node is draped across the cavoatrial junction in horseshoe fashion.<sup>1</sup>

The blood supply to the sinus node is from a prominent nodal artery that is a branch of the right coronary artery in approximately 55% of individuals and a branch of the circumflex artery in the remainder. Regardless of its artery of origin, the nodal artery usually courses along the anterior interatrial groove toward the superior cavoatrial junction, frequently within the atrial myocardium. At the cavoatrial junction, its course becomes variable and may circle either anteriorly or posteriorly or, rarely, both anteriorly and posteriorly around the cavoatrial junction to enter the node. Uncommonly, the artery arises more distally from the right coronary artery and courses laterally across the atrial appendage. This places it at risk of injury during a standard right atriotomy. The artery also may arise distally from the circumflex artery to cross the

**FIGURE 2-9** This dissection of the short axis of the heart (compare with Fig. 2-4) shows how the pectinate muscles extend around the parietal margin of the tricuspid valve. In the left atrium, the pectinate muscles are confined within the tubular left atrial appendage, leaving the smooth vestibule around the mitral valve confluent with the pulmonary venous component of the left atrium.

dome of the left atrium, where it is at risk of injury when using a superior approach to the mitral valve. Incisions in either the right or left atrial chambers always should be made with this anatomical variability in mind. In our experience, these vessels can be identified by careful gross inspection, and prompt modification of surgical incisions can be made accordingly.

## Atrial Septum

The most common incision into the right atrium is made into the atrial appendage parallel and anterior to the terminal groove. Opening the atrium through this incision confirms that the terminal groove is the external marking of the prominent terminal crest. Anteriorly and superiorly, the crest curves in front of the orifice of the superior vena cava to become continuous with the so-called septum secundum, which, in reality, is the superior rim of the oval fossa. When the right atrium is inspected through this incision, there appears to be an extensive septal surface between the tricuspid valve and the orifices of the venae cavae. This septal surface includes the opening of the oval fossa and the orifice of the coronary sinus. The apparent extent of the septum is spurious because the true septum between the atrial chambers is virtually confined to the oval fossa<sup>2,3</sup> (Fig. 2-11). The superior rim of the fossa, although often referred to as the *septum secundum*, is an extensive infolding between the venous component of the right atrium and the right pulmonary veins. The inferior rim is directly continuous with the so-called sinus septum that separates the orifices of the inferior caval vein and the coronary sinus (Fig. 2-12).

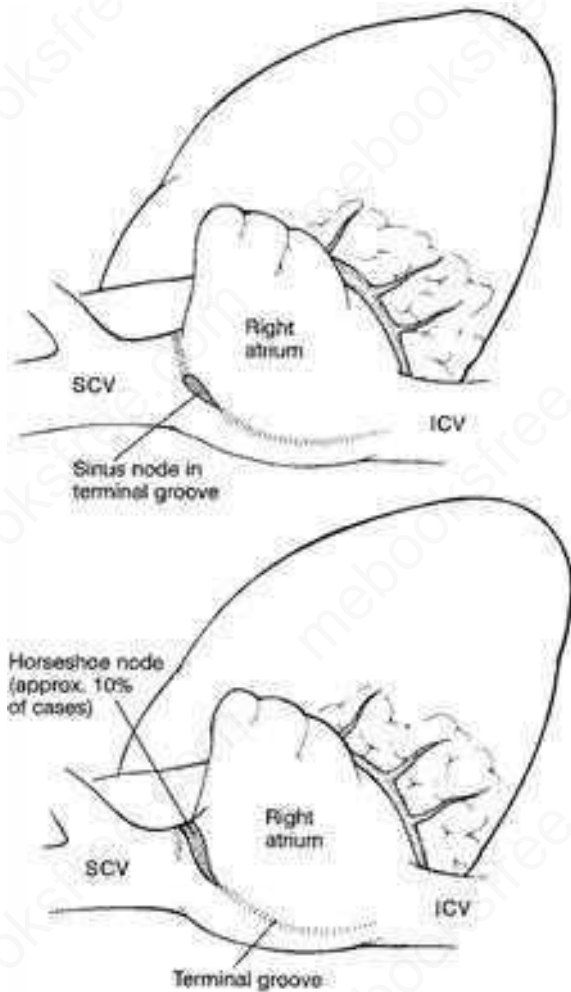

The atrial wall surrounding the mouth of the coronary sinus is continuous anteriorly and superiorly with the atrial

component of the atrioventricular muscular sandwich. Removing the floor of the coronary sinus reveals the anterior extension of the atrioventricular groove in this region. The inferior component of the anterior rim of the oval fossa is a true septal structure. It is continuous superiorly with the anterior atrial wall overlying the aortic root. Thus dissection outside the limited margins of the oval fossa will penetrate the heart to the outside rather than provide access to the left atrium via the septum.

## Atrioventricular Septum and Node: Triangle of Koch

In addition to the sinus node, another major area of surgical significance is occupied by the atrioventricular node. This structure lies within the triangle of Koch, which is demarcated by the tendon of Todaro, the septal leaflet of the tricuspid valve, and the orifice of the coronary sinus (Fig. 2-13). The floor of the triangle of Koch is made up of the atrial wall of the atrioventricular muscular sandwich. The tendon of Todaro is a fibrous structure formed by the junction of the eustachian valve and thebesian valve (the valves of the inferior vena cava and the coronary sinus, respectively). The entire atrial component of the atrioventricular conduction tissues is contained within the triangle of Koch, which must be avoided to prevent surgical damage to atrioventricular conduction. The atrioventricular bundle (of His) penetrates directly at the apex of the triangle of Koch before it continues to branch on the crest of the ventricular septum (Fig. 2-14). The key to avoiding atrial arrhythmias is careful preservation of the sinus and atrioventricular nodes and their blood supply.

**FIGURE 2-10** This diagram shows the location of the sinus node at the superior cavoatrial junction. The node usually lies to the right (*lateral*) side of the junction but may be draped in horseshoe fashion across the anterior aspect of the junction. ICV = inferior vena cava; SCV = superior vena cava.

No advantage is gained in attempting to preserve nonexistent tracts of specialized atrial conduction tissue, although it makes sense to avoid prominent muscle bundles where parallel orientation of atrial myocardial fibers favors preferential conduction (Fig. 2-15).

## Tricuspid Valve

The vestibule of the right atrium converges into the tricuspid valve. The three leaflets reflect their anatomical location, being septal, anterosuperior, and inferior (or mural). The leaflets join together over three prominent zones of apposition; the peripheral ends of these zones usually are described as *commissures*. The leaflets are tethered at the commissures by fan-shaped cords arising from prominent papillary muscles. The anterosseptal commissure is supported by the medial papillary muscle. The major leaflets of the valve extend from this

position in anterosuperior and septal directions. The third leaflet is less well defined. The anteroinferior commissure is usually supported by the prominent anterior papillary muscle. Often, however, it is not possible to identify a specific inferior papillary muscle supporting the inferoseptal commissure. Thus the inferior leaflet may seem duplicated. There is no well-formed collagenous annulus for the tricuspid valve. Instead, the atrioventricular groove more or less folds directly into the tricuspid valvar leaflets at the vestibule, and the atrial and ventricular myocardial masses are separated almost exclusively by the fibrofatty tissue of the groove. The entire parietal attachment of the tricuspid valve usually is encircled by the right coronary artery running within the atrioventricular groove.

## THE LEFT ATRIUM AND MITRAL VALVE

### Appendage, Vestibule, and Venous Component

Like the right atrium, the left atrium has three basic components: the appendage, the vestibule, and the venous component (Fig. 2-16). It also possesses a large smooth-walled body, which represents the larger part of the atrial component of the developing heart tube. Unlike the right atrium, the venous component is considerably larger than the appendage and has a narrow junction with it that is not marked by a terminal groove or crest. There also is an important difference between the relationship of the appendage and vestibule between the left and right atria. As shown, the pectinate muscles within the right atrial appendage extend all around the parietal margin of the vestibule. In contrast, the left atrial appendage has a limited junction with the vestibule, and the pectinate muscles are located almost exclusively within the appendage (see Fig. 2-8). The larger part of the vestibule that supports and inserts directly into the mural leaflet of the mitral valve is directly continuous with the smooth atrial wall of the pulmonary venous component.

Because the left atrium is posterior to and tethered by the four pulmonary veins, the chamber is relatively inaccessible. Surgeons use several approaches to gain access. The most common is an incision just to the right of and parallel to the interatrial groove, anterior to the right pulmonary veins. This incision can be carried beneath both the superior and inferior venae cavae parallel to the interatrial groove to provide wide access to the left atrium. A second approach is through the dome of the left atrium. If the aorta is pulled anteriorly and to the left, an extensive trough may be seen between the right and left atrial appendages. An incision through this trough, between the pulmonary veins of the upper lobes, provides direct access to the left atrium. When this incision is made, it is important to remember the location of the sinus node artery, which may course along the roof of the left atrium if it arises from the circumflex artery. The left atrium also can be reached via a right atrial incision and an opening in the atrial septum.

When the interior of the left atrium is visualized, the small size of the mouth of the left atrial appendage is apparent.

**FIGURE 2-11** This transection across the middle of the oval fossa (*asterisk*) shows how the so-called septum secundum, the rim of the fossa, is made up of the infolded atrial walls (*arrows*). ICV = inferior vena cava; SCV = superior vena cava.

It lies to the left of the mitral orifice as viewed by the surgeon. The majority of the pulmonary venous atrium usually is located inferiorly away from the operative field. The vestibule of the mitral orifice dominates the operative view. The septal surface is located anteriorly, with the true septum relatively inferior (Fig. 2-17).

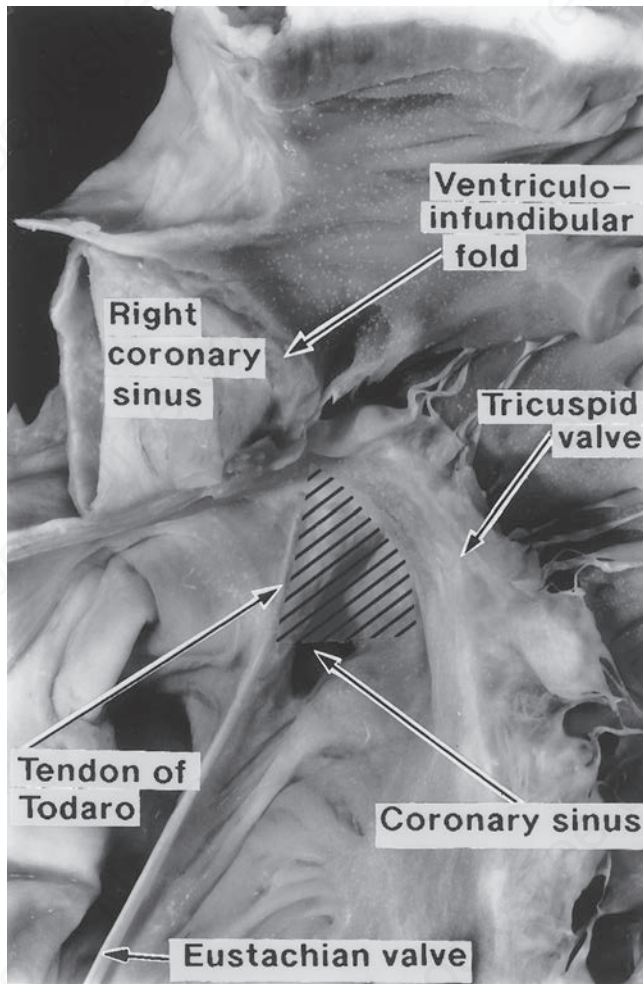

### Mitral Valve

The mitral valve is supported by two prominent papillary muscles located in supero-lateral and infero-septal positions. The two leaflets of the mitral valve have markedly

different appearances (Fig. 2-18). The aortic (or anterior) leaflet is short and relatively square, and guards approximately one-third of the circumference of the valvar orifice. This leaflet is in fibrous continuity with the aortic valve and, because of this, is best referred to as the *aortic leaflet* because it is neither strictly anterior nor superior in position. The other leaflet is much shallower but guards approximately two-thirds of the circumference of the mitral orifice. Because it is connected to the parietal part of the atrioventricular junction, it is most accurately termed the *mural leaflet* but often is termed the *posterior leaflet*. It is divided into a number of subunits that fold against the

**FIGURE 2-12** This diagram demonstrates the components of the atrial septum. The only true septum between the two atria is confined to the area of the oval fossa. ICV = inferior vena cava; SCV = superior vena cava.

**FIGURE 2-13** This dissection, made by removing part of the subpulmonary infundibulum, shows the location of the triangle of Koch (*shaded area*).

aortic leaflet when the valve is closed. Although generally there are three, there may be as many as five or six scallops in the mural leaflet.

Unlike the tricuspid valve, the mitral valve leaflets are supported by a rather dense collagenous annulus, although it may take the form of a sheet rather than a cord. This annulus usually extends parietally from the fibrous trigones, the greatly thickened areas at either end of the area of fibrous continuity between the leaflets of the aortic and mitral valves (see Fig. 2-6). The area of the valvar orifice related to the right fibrous trigone and central fibrous body is most vulnerable with respect to the atrioventricular node and penetrating bundle (see Fig. 2-7). The midportion of the aortic leaflet of the mitral valve is related to the commissure between the noncoronary and left coronary cusps of the aortic valve. An incision through the atrial wall in this area may be extended into the subaortic outflow tract and may be useful for enlarging the aortic annulus during replacement of the aortic valve (Fig. 2-19). The circumflex coronary artery is adjacent to the left half of the mural leaflet,

**FIGURE 2-14** Further dissection of the heart shown in Fig. 2-13 reveals that a line joining the apex of the triangle of Koch to the medial papillary muscle marks the location of the atrioventricular conduction axis.

whereas the coronary sinus is adjacent to the right half of the mural leaflet (Fig. 2-20). These structures can be damaged during excessive dissection or by excessively deep placement of sutures during replacement or repair of the mitral valve. When the circumflex artery is dominant, the entire attachment of the mural leaflet may be intimately related to this artery (Fig. 2-21).

## THE RIGHT VENTRICLE AND PULMONARY VALVE

### Inlet and Apical Trabecular Portions

The morphology of both the right and left ventricles can be understood best by subdividing the ventricles into three anatomically distinct components: the inlet, apical trabecular, and outlet portions.<sup>2</sup> This classification is more helpful than the traditional division of the right ventricle into the sinus and conus parts. The inlet portion of the right ventricle surrounds the tricuspid valve and its tension apparatus. A distinguishing feature of the tricuspid valve is the direct attachment of its septal leaflet. The apical trabecular portion of the right ventricle extends out to the apex. Here, the wall

**FIGURE 2-15** This dissection, made by careful removal of the right atrial endocardium, shows the ordered arrangement of myocardial fibers in the prominent muscle bundles that underscore preferential conduction. There are *no* insulated tracts running within the internodal atrial myocardium. (Used with permission from Prof. Damian Sanchez-Quintana.)

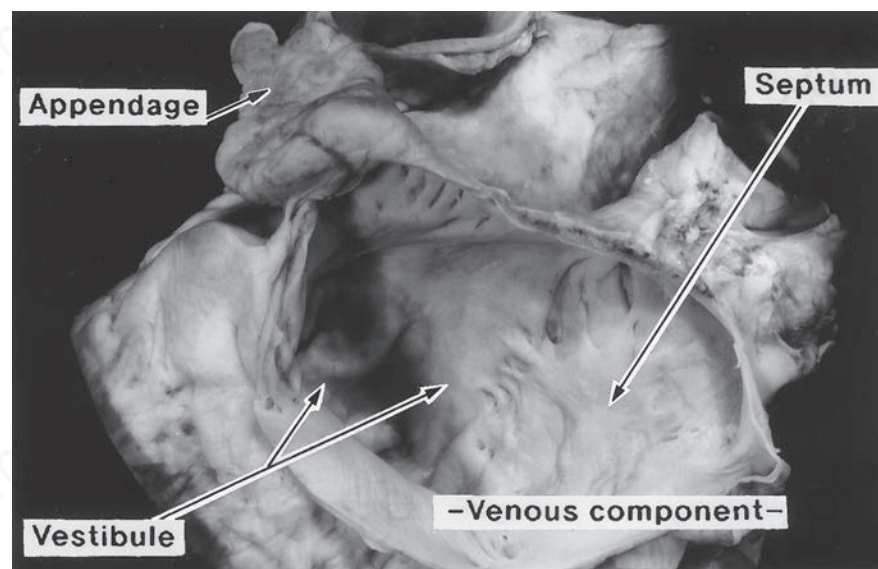

of the ventricle is quite thin and vulnerable to perforation by cardiac catheters and pacemaker electrodes.

### Outlet Portion and Pulmonary Valve

The outlet portion of the right ventricle consists of the infundibulum, a circumferential muscular structure that supports the leaflets of the pulmonary valve. Because of the semilunar shape of the pulmonary valvar leaflets, this valve does not have an annulus in the traditional sense of a ringlike attachment. The leaflets have semilunar attachments that cross the musculoarterial junction in a corresponding semilunar fashion (Fig. 2-22). Therefore, instead of a single annulus, three rings can be distinguished anatomically in relation to the pulmonary valve. Superiorly, the sinotubular ridge of the pulmonary trunk marks the level of peripheral apposition of the leaflets (the commissures). A second ring exists at the ventriculoarterial junction. A third ring can be constructed by joining together the basal attachments of the three leaflets to the infundibular muscle. None of these rings, however, corresponds to the attachments of the leaflets, which must be semilunar to permit the valve to open and close competently. In fact, these semilunar attachments, which mark the hemodynamic ventriculoarterial junction, extend from the first ring, across the second, down to the third, and back in each cusp (Fig. 2-23).

### Supraventricular Crest and Pulmonary Infundibulum

A distinguishing feature of the right ventricle is a prominent muscular shelf, the supraventricular crest, which separates the

**FIGURE 2-16** Like the right atrium, the left atrium (seen here in anatomical orientation) has an appendage, a venous component, and a vestibule. It is separated from the right atrium by the septum.

**FIGURE 2-17** This view of the opened left atrium shows how the septal aspect is dominated by the flap valve, which is attached by its horns (*asterisks*) to the infolded atrial groove.

tricuspid and pulmonary valves (Fig. 2-24). In reality, this muscular ridge is the posterior part of the subpulmonary muscular infundibulum that supports the leaflets of the pulmonary valve. In other words, it is part of the inner curve of the heart. Incisions through the supraventricular crest run into the transverse septum and may jeopardize the right coronary artery. Although this area is often considered the outlet component of the interventricular septum, in fact the entire subpulmonary infundibulum, including the ventriculo-infundibular fold, can be removed without entering the left ventricular cavity. This is possible because the leaflets of the pulmonary and aortic valves are supported on separate sleeves of right and left ventricular outlet muscles. There is an extensive external tissue plane between the walls of the aorta and the pulmonary trunk (Fig. 2-25), and the leaflets of the pulmonary and aortic valves have markedly different levels of attachments within their respective ventricles. This feature enables enucleation of the pulmonary valve, including its basal attachments within the infundibulum, during the Ross procedure without creating a ventricular septal defect. When the infundibulum is removed from the right ventricle, the insertion of the supraventricular crest between the limbs of the septomarginal trabeculation is visible (Fig. 2-26). This

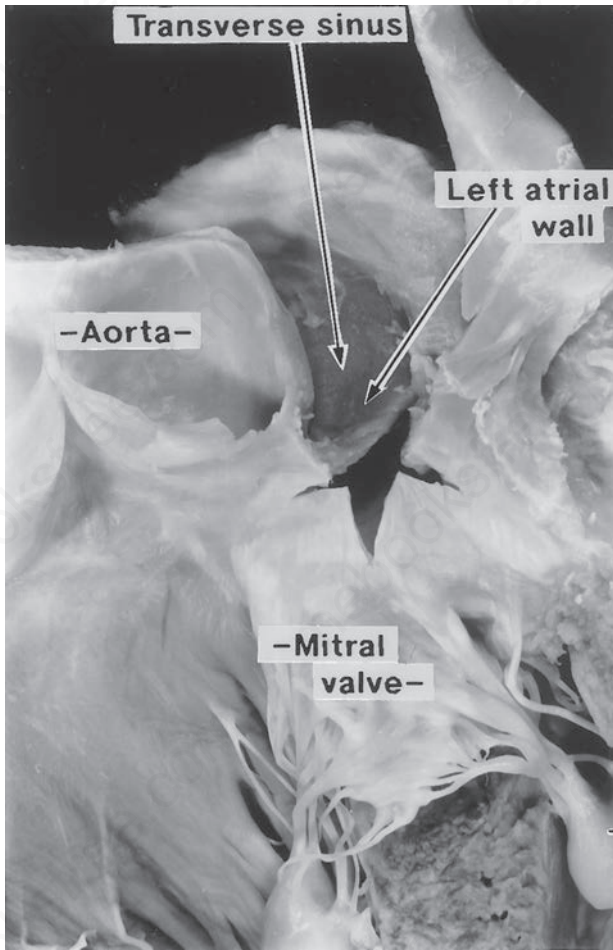

**FIGURE 2-18** This view of the opened left atrium shows the leaflets of the mitral valve in closed position. There is a concave zone of apposition between them (*between asterisks*) with several slits seen in the mural leaflet (MuL). Note the limited extent of the aortic leaflet (AoL) in terms of its circumferential attachments.

trabeculation is a prominent muscle column that divides superiorly into anterior and posterior limbs. The anterior limb runs superiorly into the infundibulum and supports the leaflets of the pulmonary valve. The posterior limb extends backward beneath the ventricular septum and runs into the inlet portion of the ventricle. The medial papillary muscle arises from this posterior limb. The body of the septomarginal trabeculation runs to the apex of the ventricle, where it divides into smaller trabeculations. Two of these trabeculations may be particularly prominent. One becomes the anterior papillary muscle, and the other crosses the ventricular cavity as the moderator band (Fig. 2-27).

## THE LEFT VENTRICLE AND AORTIC VALVE

### Inlet and Apical Trabecular Portions

The left ventricle can be subdivided into three components, similar to the right ventricle. The inlet component surrounds

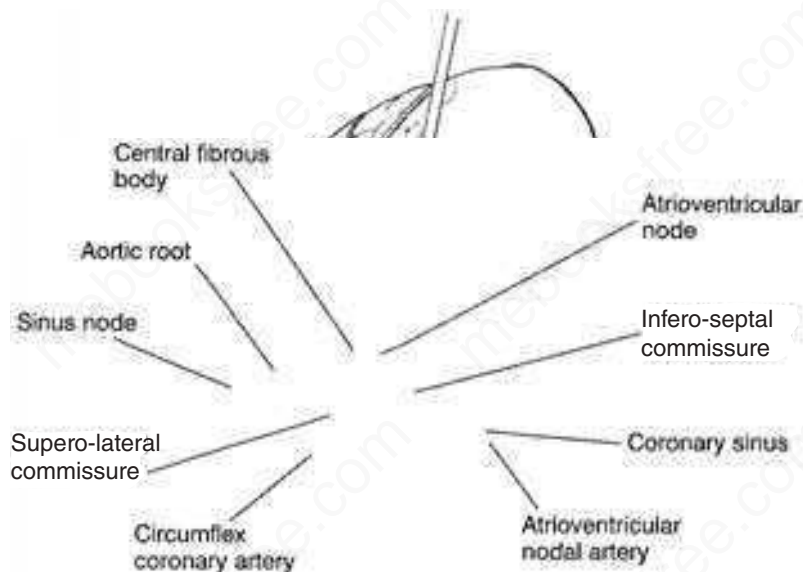

**FIGURE 2-19** This dissection simulates the incision made through the aortic-mitral fibrous curtain to enlarge the orificial diameter of the subaortic outflow tract in a normal heart.

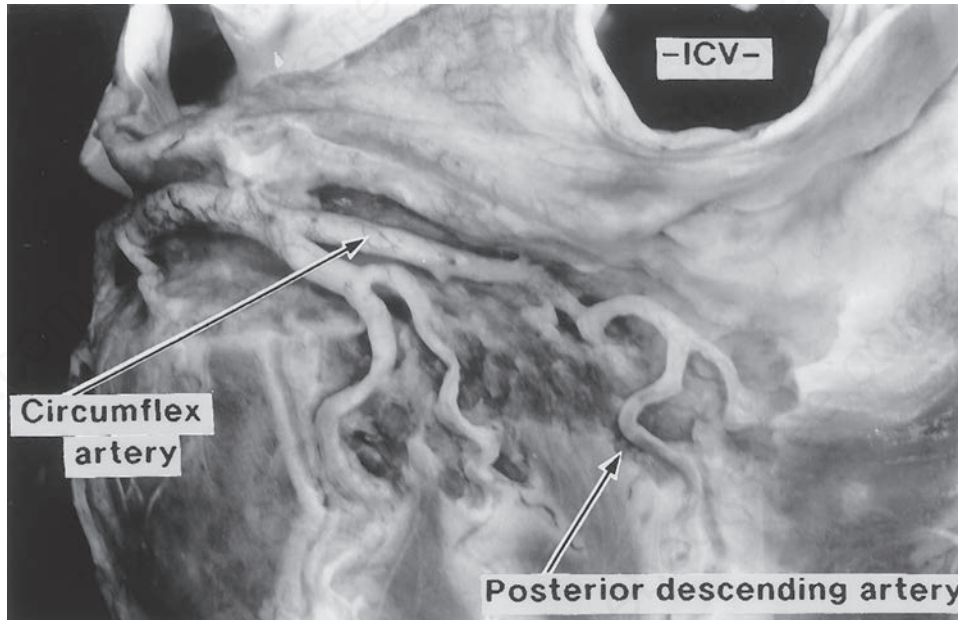

and is limited by the mitral valve and its tension apparatus. The two papillary muscles occupy superolateral and inferoseptal positions and are positioned rather close to each other. The leaflets of the mitral valve have no direct septal attachments because the deep posterior diverticulum of the left ventricular outflow tract displaces the aortic leaflet away from the inlet septum. The apical trabecular component of the left ventricle extends to the apex, where the myocardium is surprisingly thin. The trabeculations of the left ventricle are quite fine compared with those of the right ventricle (Fig. 2-28). This characteristic is useful for defining ventricular morphology on diagnostic ventriculograms.

### Outlet Portion

The outlet component supports the aortic valve and consists of both muscular and fibrous portions. This is in contrast to the infundibulum of the right ventricle, which consists entirely of muscle. The septal portion of the left ventricular outflow tract, although primarily muscular, also includes the membranous portion of the ventricular septum. The posterior quadrant of the outflow tract consists of an extensive fibrous curtain that extends from the fibrous skeleton of the heart across the aortic leaflet of the mitral valve and supports the leaflets of the aortic valve in the area of aortomitral continuity (see Fig. 2-5). The lateral quadrant of the outflow tract again is muscular and consists of the lateral margin of the inner curvature of the heart, delineated externally by the transverse sinus. The left bundle of the cardiac conduction system enters the left ventricular outflow tract posterior to the membranous septum and immediately beneath the commissure between the right and noncoronary leaflets of the aortic valve. After traveling a short distance down the septum, the left bundle divides into anterior, septal, and posterior divisions.

**FIGURE 2-20** This diagram depicts the mitral valve in relationship to its surrounding structures as viewed through a left atriotomy.

**FIGURE 2-21** The extensive course of a dominant circumflex artery within the left atrioventricular groove shown in anatomic orientation. ICV = inferior vena cava.

## Aortic Valve

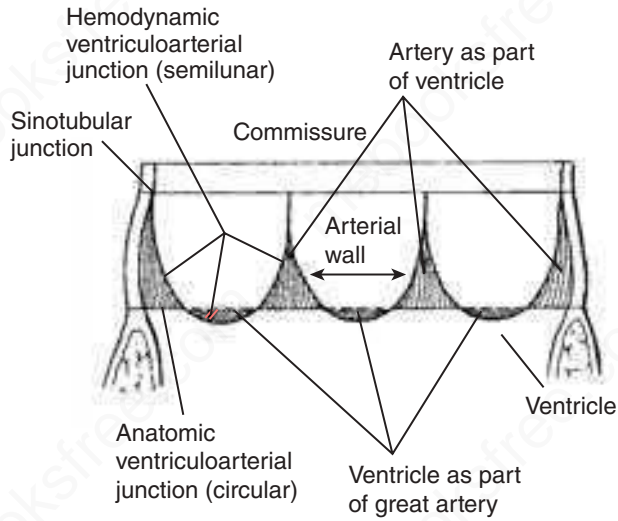

The aortic valve is a semilunar valve that is quite similar morphologically to the pulmonary valve. Likewise, it does not have a discrete annulus. Because of its central location, the aortic valve is related to each of the cardiac chambers and valves (see Fig. 2-4). A thorough knowledge of these relationships is essential to understanding aortic valve pathology and many congenital cardiac malformations.

The aortic valve consists primarily of three semilunar leaflets. As with the pulmonary valve, attachments of the leaflets extend across the ventriculoarterial junction in a curvilinear fashion. Each leaflet therefore has attachments to the aorta

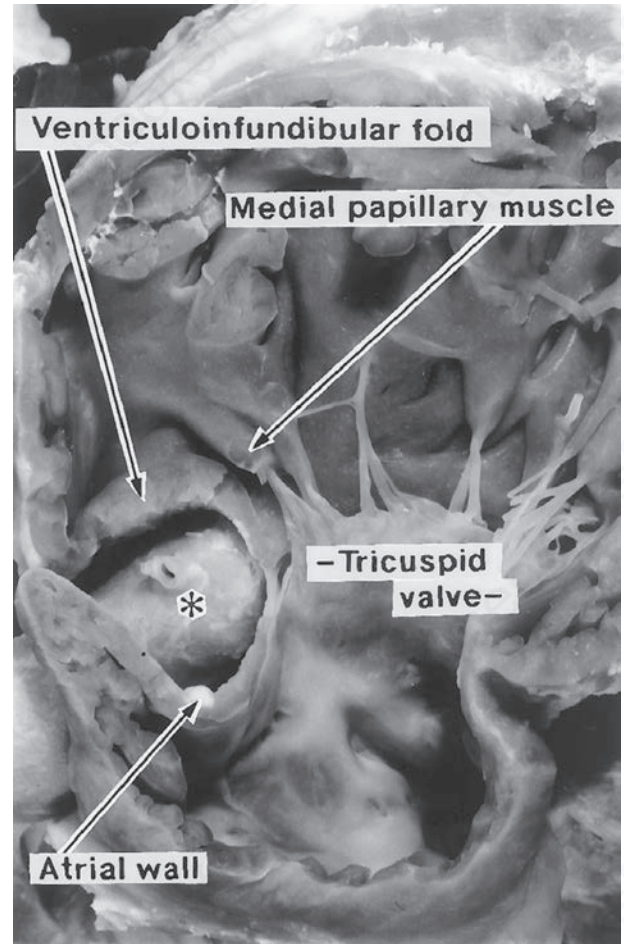

and within the left ventricle (Fig. 2-29). Behind each leaflet, the aortic wall bulges outward to form the sinuses of Valsalva. The leaflets themselves meet centrally along a line of coaptation, at the center of which is a thickened nodule called the *nodule of Arantius*. Peripherally, adjacent to the commissures, the line of coaptation is thinner and normally may contain small perforations. During systole the leaflets are thrust upward and away from the center of the aortic lumen, whereas during diastole they fall passively into the center of the aorta. With normal valvar morphology, all three leaflets meet along lines of coaptation and support the column of blood within the aorta to prevent regurgitation into the ventricle. Two of the three aortic sinuses give rise to coronary

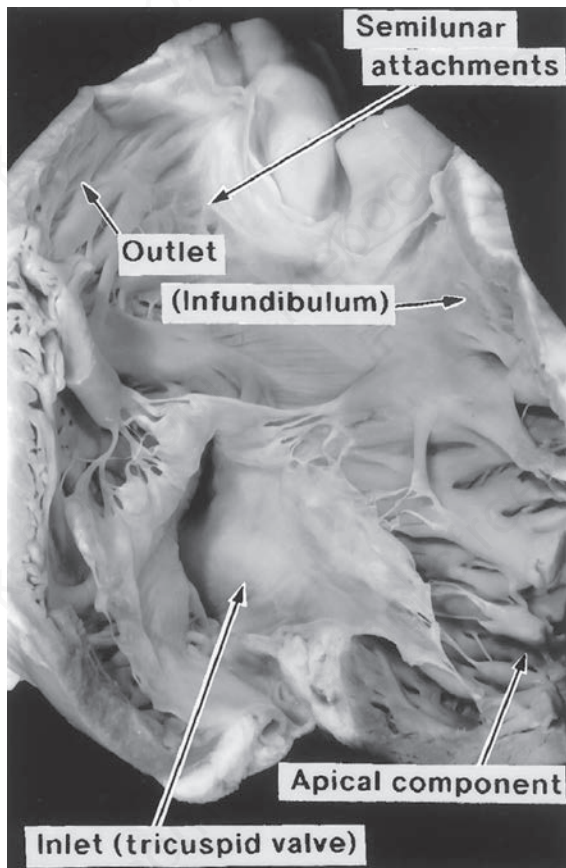

**FIGURE 2-22** The semilunar valves do not have an annulus in the traditional sense. Rather, three rings can be identified anatomically, at the (1) sinotubular junction, (2) musculoarterial junction, and (3) base of the sinuses within the ventricle.

**FIGURE 2-23** The hemodynamic ventriculoarterial junction of the semilunar valves extends from the sinotubular junction across the anatomical ventriculoarterial junction to the basal ring and back in each leaflet (see Fig. 2-22). This creates a portion of ventricle as part of the great artery in each sinus and a triangle of artery as part of the ventricle between each leaflet.

**FIGURE 2-25** This dissection, viewed in surgical orientation, shows how the greater part of the supraventricular crest is formed by the freestanding subpulmonary infundibulum in relation to the right coronary aortic sinus (*asterisk*).

**FIGURE 2-24** View of the opened right ventricle, in anatomical orientation, showing its three component parts and the semilunar attachments of the pulmonary valve. These are supported by the supraventricular crest.

arteries, from which arise their designations as *right*, *left*, and *noncoronary sinuses*.

By sequentially following the line of attachment of each leaflet, the relationship of the aortic valve to its surrounding structures can be clearly understood. Beginning posteriorly, the commissure between the noncoronary and left coronary leaflets is positioned along the area of aortomitral valvar continuity. The fibrous subaortic curtain is beneath this commissure (see Fig. 2-29). To the right of this commissure, the noncoronary leaflet is attached above the posterior diverticulum of the left ventricular outflow tract. Here, the valve is related to the right atrial wall. As the attachment of the noncoronary leaflet ascends from its nadir toward the commissure between the noncoronary and right coronary leaflets, the line of attachment is directly above the portion of the atrial septum containing the atrioventricular node. The commissure between the noncoronary and right coronary leaflets is located directly above the penetrating atrioventricular bundle and the membranous ventricular septum (Fig. 2-30). The attachment of the right coronary leaflet then descends

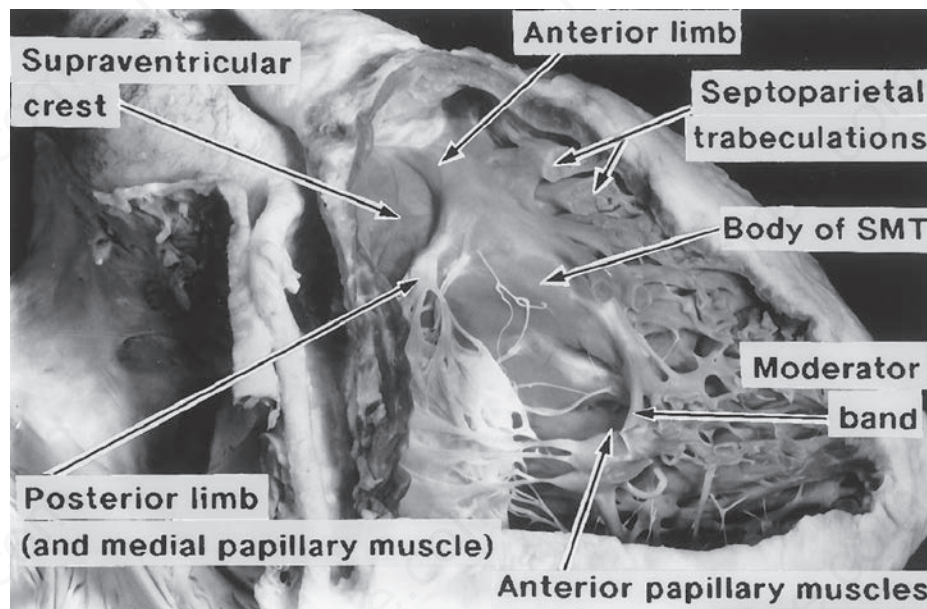

**FIGURE 2-26** Removal of the freestanding subpulmonary infundibulum reveals the insertion of the supraventricular crest between the limbs of the septomarginal trabeculation and shows the aortic origin of the coronary arteries (anatomical orientation).

across the central fibrous body before ascending to the commissure between the right and left coronary leaflets. Immediately beneath this commissure, the wall of the aorta forms the uppermost part of the subaortic outflow. An incision through this area passes into the space between the facing surfaces of the aorta and pulmonary trunk (see Fig. 2-30). As the facing left and right leaflets descend from this commissure, they

are attached to the outlet muscular component of the left ventricle. Only a small part of this area in the normal heart is a true outlet septum because both pulmonary and aortic valves are supported on their own sleeves of myocardium. Thus, although the outlet components of the right and left ventricles face each other, an incision below the aortic valve enters low into the infundibulum of the right ventricle. As

**FIGURE 2-27** This dissection of the right ventricle, in anatomical orientation, shows the relations of supraventricular crest and septomarginal (SMT) and septoparietal trabeculations.

**FIGURE 2-28** This dissection of the left ventricle shows its component parts and characteristically fine apical trabeculations (anatomical orientation).

the lateral part of the left coronary leaflet descends from the facing commissure to the base of the sinus, it becomes the only part of the aortic valve that is not intimately related to another cardiac chamber.

Knowledge of the anatomy of the aortic valve and its relationship to surrounding structures is important to successful replacement of the aortic valve, particularly when

enlargement of the aortic root is required. The Konno-Rastan aortoventriculoplasty involves opening and enlarging the anterior portion of the subaortic region.<sup>4,5</sup> The incisions for this procedure begin with an anterior longitudinal aortotomy that extends through the commissure between the right and left coronary leaflets. Anteriorly, the incision is extended across the base of the infundibulum. The differential level of

**FIGURE 2-29** This dissection in anatomic orientation, made by removing the aortic valvar leaflets, emphasizes the semilunar nature of the hinge points (see Figs. 2-22 and 2-23). Note the relationship to the mitral valve (see Fig. 2-5).

**FIGURE 2-30** Dissection made by removing the right and part of the left aortic sinuses to show the relations of the fibrous triangle between the right and noncoronary aortic leaflets (anatomical orientation).

attachment of the aortic and pulmonary valve leaflets permits this incision without damage to the pulmonary valve (Fig. 2-31). Posteriorly, the incision extends through the most medial portion of the supraventricular crest into the left ventricular outflow tract. By closing the resulting ventricular septal defect with a patch, the aortic outflow tract is widened to allow implantation of a larger valve prosthesis. A second patch is used to close the defect in the right ventricular outflow tract.

Alternative methods to enlarge the aortic outflow tract involve incisions in the region of aortomitral continuity. In the Manouguian procedure (see Fig. 2-19), a curvilinear aortotomy is extended posteriorly through the commissure between the left and noncoronary leaflets down to and occasionally into the aortic leaflet of the mitral valve.<sup>6</sup> A patch is used to augment the incision posteriorly. When the posterior diverticulum of the outflow tract is fully developed, this incision can be made without entering other cardiac chambers, although not uncommonly the roof of the left atrium is opened. The Nicks procedure for enlargement of the aortic

**FIGURE 2-31** This incision, made in a normal heart, simulates the Konno-Rastan procedure for enlargement of the aortic root.

root involves an aortotomy that passes through the middle of the noncoronary leaflet into the fibrous subaortic curtain and may be extended into the aortic leaflet of the mitral valve.<sup>7</sup> This incision also may open the roof of the left atrium. When these techniques are used, any resulting defect in the left atrium must be closed carefully.

As discussed previously, the differential level of attachment of aortic and pulmonary valves, as well as the muscular nature of their support, allows the pulmonary valve to be harvested and used as a replacement for the aortic valve in the Ross procedure.<sup>8,9</sup> This procedure can be combined with the incisions of the Konno-Rastan aortoventriculoplasty to repair left ventricular outflow tract obstructions in young children with a viable autograft that has potential for growth and avoids the need for anticoagulation.

Accurate understanding of left ventricular outflow tract anatomy is also important in the treatment of aortic valvar endocarditis.<sup>10,11</sup> Because of the central position of the aortic valve relative to the other valves and cardiac chambers (see Fig. 2-4), abscess formation can produce fistulas between the aorta and any of the four chambers of the heart. Therefore, patients may present with findings of left-sided heart failure, left-to-right shunting, and/or complete heart

block in addition to the usual signs of sepsis and systemic embolization.

## THE CORONARY ARTERIES<sup>12-14</sup>

The right and left coronary arteries originate behind their respective aortic valvar leaflets (see Fig. 2-26). The orifices usually are located in the upper third of the sinuses of Valsalva, although individual hearts may vary markedly. Because of the oblique plane of the aortic valve, the orifice of the left coronary artery is superior and posterior to that of the right coronary artery. The coronary arterial tree is divided into three segments; two (the left anterior descending artery and the circumflex artery) arise from a common stem. The third segment is the right coronary artery. The dominance of the coronary circulation (right vs left) usually refers to the artery from which the inferior interventricular artery originates, not the absolute mass of myocardium perfused by the left or right coronary artery. Right dominance occurs in 85 to 90% of normal individuals. Left dominance occurs slightly more frequently in males than in females.

### Main Stem of the Left Coronary Artery

The main stem of the left coronary artery courses from the left sinus of Valsalva anteriorly, inferiorly, and to the left between the pulmonary trunk and the left atrial appendage (Fig. 2-32). Typically, it is 10 to 20 mm in length, but can extend to a length of 40 mm. The left main stem can be absent, with separate orifices in the sinus of Valsalva for

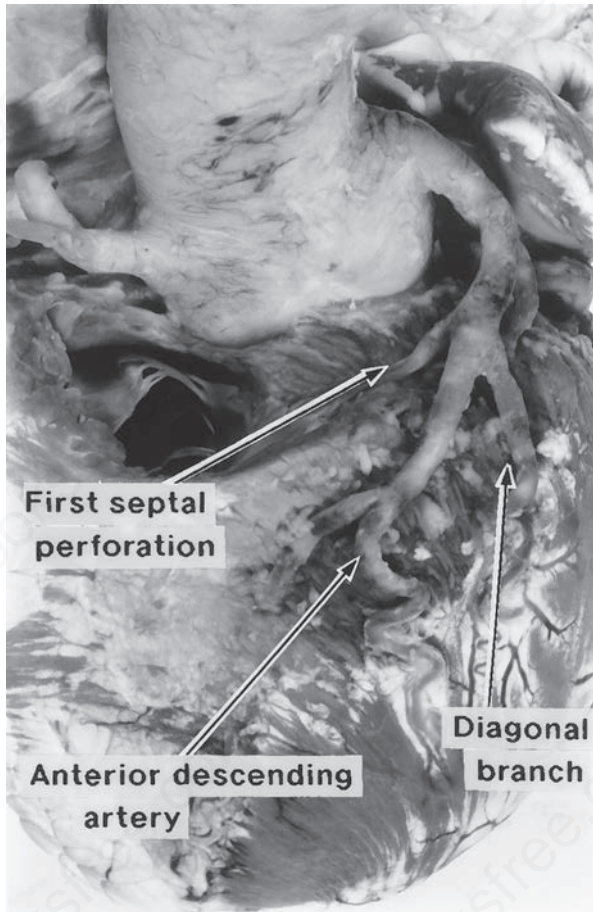

its two primary branches (1% of patients). The main stem divides into two major arteries of nearly equal diameter, the left anterior descending artery and the circumflex artery.

### Left Anterior Descending Artery

The left anterior descending (or interventricular) coronary artery continues directly from the bifurcation of the left main stem, coursing anteriorly and inferiorly in the anterior interventricular groove to the apex of the heart (Fig. 2-33). Its branches include the diagonals, the septal perforators, and the right ventricular branches. The diagonals, which may be two to six in number, course along the anterolateral wall of the left ventricle and supply this portion of the myocardium. The first diagonal generally is the largest and may arise from the bifurcation of the left main stem (formerly known as the *intermediate artery*). The septal perforators branch perpendicularly into the ventricular septum. Typically, there are three to five septal perforators; the initial one is the largest and commonly originates just beyond the take-off of the first diagonal. This perpendicular orientation is a useful marker for identification of the left anterior descending artery on coronary angiograms. The septal perforators supply blood to the anterior two-thirds of the ventricular septum. Right ventricular branches, which may not always be present, supply blood to the anterior surface of the right ventricle. In approximately 4% of hearts, the left anterior descending artery bifurcates proximally and continues as two parallel vessels of approximately equal size down the anterior interventricular groove. Occasionally, the artery

**FIGURE 2-32** The short extent of the main stem of the left coronary artery is seen before it branches into the circumflex and anterior descending arteries. Note the small right coronary artery in this heart, in which the circumflex artery was dominant (see Fig. 2-21).

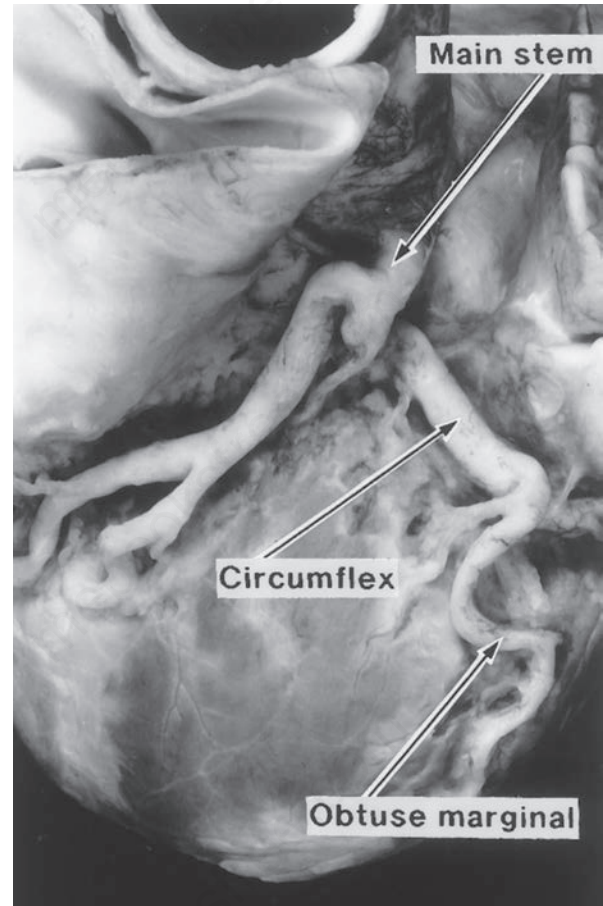

**FIGURE 2-33** The important branches of the anterior descending artery are the first septal perforating and diagonal arteries.

wraps around the apex of the left ventricle to feed the distal portion of the posterior interventricular groove. Rarely, it extends along the entire length of the posterior groove to replace the inferior interventricular artery.

### Circumflex Artery

The left circumflex coronary artery arises from the left main coronary artery roughly at a right angle to the anterior interventricular branch. It courses along the left atrioventricular groove and in 85 to 95% of patients terminates near the obtuse margin of the left ventricle (Fig. 2-34). In 10 to 15% of patients, it continues around the atrioventricular groove to the crux of the heart to give rise to the inferior interventricular artery (left dominance; see Fig. 2-21). The primary branches of the left circumflex coronary artery are the obtuse marginals. They supply blood to the lateral aspect of the left ventricular myocardium, including the posteromedial papillary muscle. Additional branches supply blood to the left atrium and, in 40 to 50% of hearts, the sinus node. When the circumflex coronary artery supplies the inferior interventricular artery, it also supplies the atrioventricular node.

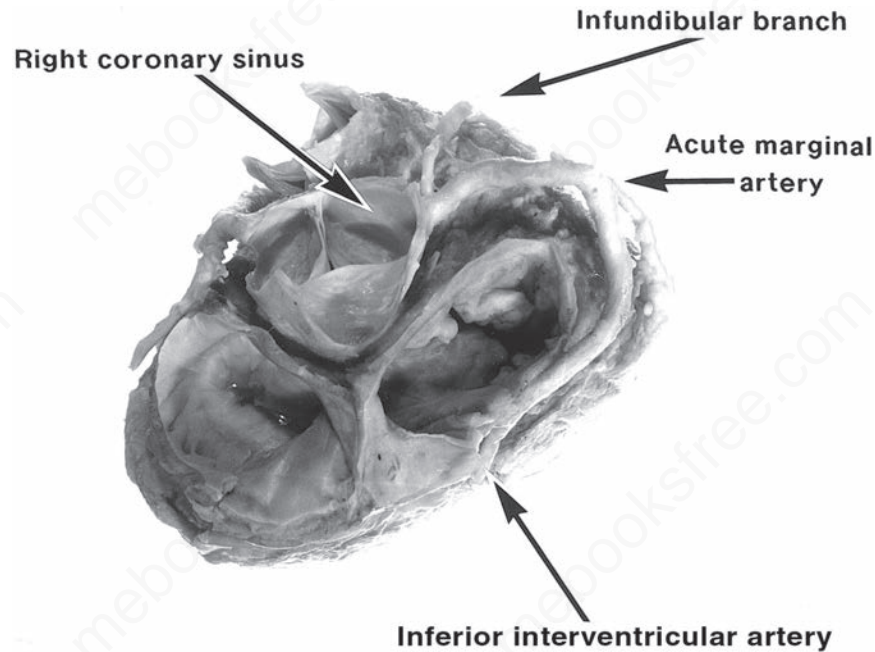

**FIGURE 2-34** The important branches of the circumflex artery, seen in anatomical orientation.

### Right Coronary Artery

The right coronary artery courses from the aorta anteriorly and laterally before descending in the right atrioventricular groove and curving posteriorly at the acute margin of the right ventricle (Fig. 2-35). In 85 to 90% of hearts, the right coronary artery crosses the crux, where it makes a characteristic U-turn before bifurcating into the inferior interventricular artery and the right posterolateral artery. In 50 to 60% of hearts, the artery to the sinus node arises from the proximal portion of the right coronary artery. The blood supply to the atrioventricular node (in patients with right-dominant circulation) arises from the midportion of the U-shaped segment. The inferior interventricular artery, usually described incorrectly as being posterior and descending, runs along the inferior interventricular groove, extending for a variable distance toward the apex of the heart. It gives off perpendicular branches, the inferior septal perforators, that course anteriorly in the ventricular septum. Typically, these perforators supply the inferior one-third of the ventricular septal myocardium.

The right posterolateral artery gives rise to a variable number of branches that supply the posterior surface of the left

**FIGURE 2-35** This dissection shows the relationships and branches of the right coronary artery.

ventricle. The circulation of the posteroinferior portion of the left ventricular myocardium is quite variable. It may consist of branches of the right coronary artery, the circumflex artery, or both. The acute marginal arteries branch from the right coronary artery along the acute margin of the heart, before its bifurcation at the crux. These marginals supply the anterior free wall of the right ventricle. In 10 to 20% of hearts, one of these acute marginal arteries courses across the diaphragmatic surface of the right ventricle to reach the distal ventricular septum. The right coronary artery supplies important collaterals to the left anterior descending artery through its septal perforators. In addition, its infundibular (or conus) branch, which arises from the proximal portion of the right coronary artery, courses anteriorly over the base of the ventricular infundibulum and may serve as a collateral to the anterior descending artery. Kugel's artery is an anastomotic vessel between the proximal right coronary and the circumflex coronary artery that also can provide a branch that runs through the base of the atrial septum to the crux of the heart, where it supplies collateral circulation to the atrioventricular node.<sup>15</sup>

## THE CORONARY VEINS<sup>14</sup>

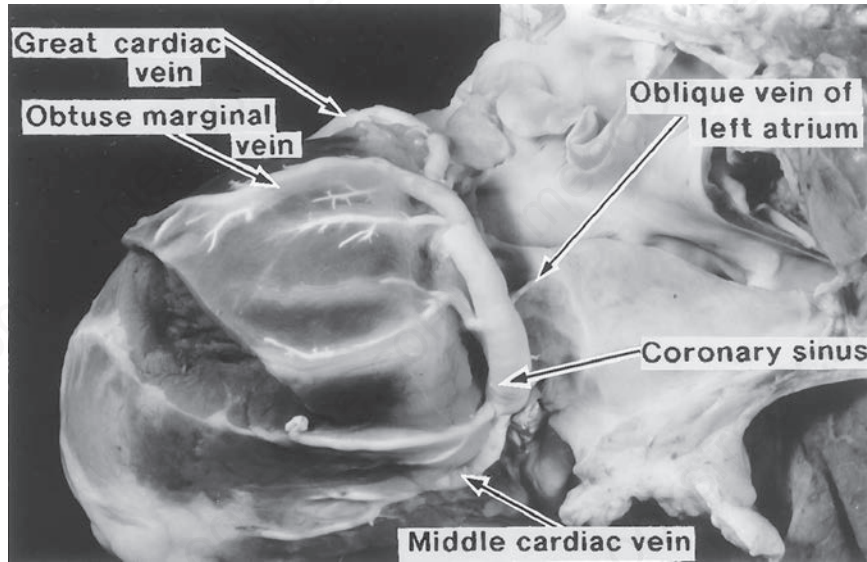

A complex network of veins drains the coronary circulation. An extensive degree of collateralization among these veins and the coronary arteries and the paucity of valves within coronary veins enable the use of retrograde coronary sinus cardioplegia for intraoperative myocardial protection. The venous circulation can be divided into three systems: the coronary sinus and its tributaries, the anterior right ventricular veins, and the thebesian veins.

## Coronary Sinus and Its Tributaries

The coronary sinus predominantly drains the left ventricle and receives approximately 85% of coronary venous blood. It lies within the posterior atrioventricular groove and empties into the right atrium at the lateral border of the triangle of Koch (Fig. 2-36). The orifice of the coronary sinus is guarded by the crescent-shaped thebesian valve. The named tributaries of the coronary sinus include the anterior interventricular vein, which courses parallel to the left anterior descending coronary artery. Adjacent to the bifurcation of the left main stem, the anterior interventricular vein courses leftward in the atrioventricular groove, where it is referred to as the *great cardiac vein*. It receives blood from the marginal and posterior left ventricular branches before becoming the coronary sinus at the origin of the oblique vein (of Marshall) at the posterior margin of the left atrium. The inferior interventricular vein, or *middle cardiac vein*, arises at the apex, courses parallel to the inferior interventricular artery, and extends proximally to the crux. Here, this vein drains directly either into the right atrium or into the coronary sinus just prior to its orifice. The *small cardiac vein* runs inferiorly through the right atrioventricular groove.

## Anterior Right Ventricular Veins

The anterior right ventricular veins travel across the right ventricular surface to the right atrioventricular groove, where they enter directly into either the right atrium or coalesce to form the small cardiac vein. As indicated, this vein travels down the right atrioventricular groove, around the acute margin,

**FIGURE 2-36** The coronary veins on the diaphragmatic surface of the heart, seen in anatomical orientation, have been emphasized by filling them with sealant. The tributaries of the coronary sinus are well demonstrated. Note that, strictly speaking, the sinus does not begin until the oblique vein enters the great cardiac vein.

and enters into the right atrium directly or joins the coronary sinus just proximal to its orifice.

### Thebesian Veins

The thebesian veins are small venous tributaries that drain directly into the cardiac chambers. They exist primarily in the right atrium and right ventricle.

# Cardiac Surgical Physiology

Edward B. Savage • Nicolas A. Brozzi

A cardiac surgical procedure is the most acute application of basic dynamic physiology that exists in medical care. Basic physiologic concepts of electromechanical activation and association, loading conditions, inotropy, etc all affect a successful outcome. Working knowledge of these fundamental concepts is imperative to maintain and return a patient to normal function. The purpose of this chapter is to present a manageable outline of cardiac physiology that can be used in daily practice, as a framework against which pathologic processes can be measured, assessed, and treated.

## CELLULAR COMPONENTS AND CELLULAR ACTIVATION

The heart beats continuously based on the unique features of its component cells. A cardiac cycle begins when spontaneous depolarization of a pacemaker cell initiates an action potential. This electrical activity is transmitted to atrial muscle cells and to the conduction system which transmits the electrical activity to the ventricle. Activation is dependent on components of the cell membrane and cell which induce and maintain the ion currents that promote and spread electrical activation.

The activity of cells in the heart is triggered by an action potential. An action potential is a cyclical activation of the cell comprised of a rapid change in the membrane potential (the electrical gradient across the cell membrane) and subsequent return to a resting membrane potential. This process is dependent on a selectively permeable cell membrane and proteins that actively and passively direct ion passage across the cell membrane. The specific components of the myocyte action potential are detailed in Figure 3-3. The myocyte action potential is characterized by a rapid initial depolarization mediated by fast channels (sodium channels), then a plateau phase mediated by slow channels (calcium channels). Further details of this process are introduced as their components are described.

### The Sarcolemma

The cardiac cell is surrounded by a membrane (plasmalemma or more specific to a muscle cell, sarcolemma). The structural

components of the sarcolemma allow for the origination and then the conduction of an electrical signal through the heart with subsequent initiation of the excitation-contraction coupling process. The sarcolemma also participates in the regulation of excitation, contraction, and intracellular metabolism in response to neuronal and chemical stimulation.

### THE PHOSPHOLIPID BILAYER

The sarcolemma is a phospholipid bilayer that provides a barrier between the extracellular compartment and the intracellular compartment or cytosol. The sarcolemma, which is only two molecules thick, consists of phospholipids and cholesterol aligned so that the lipid, or the hydrophobic, portion of the molecule is on the inside of the membrane, and the hydrophilic portion of the molecule is on the outside (Figure 3-1). The phospholipid bilayer provides a fluid barrier that is particularly *impermeable to the diffusion of ions*. Small lipid-soluble molecules such as oxygen and carbon dioxide diffuse easily through the membrane. The water molecule, although insoluble in the membrane, is small enough that it diffuses easily through the membrane (or through pores in the membrane). Other, slightly larger molecules (sodium, chloride, potassium, calcium) cannot easily diffuse through the lipid bilayer and require specialized channels for transport.<sup>1,2</sup>

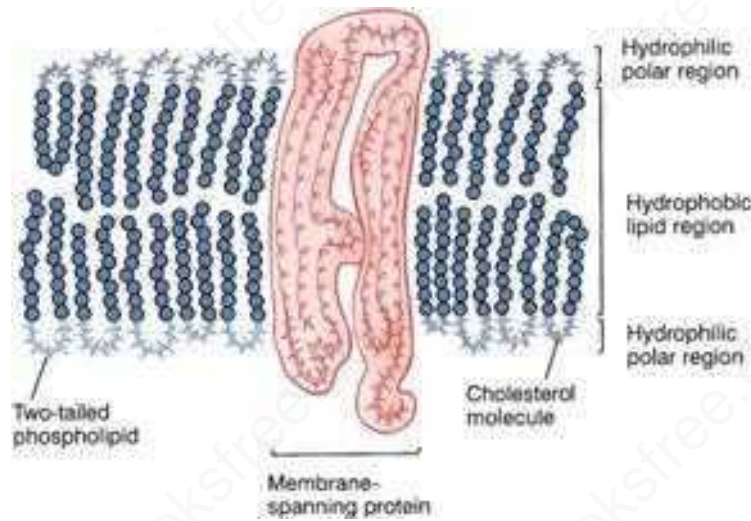

The specialized ion-transport systems within the sarcolemma consist of membrane-spanning proteins that float in and penetrate through the lipid bilayer. These proteins are associated with three different types of ion transport: (1) diffusion through transmembrane channels that can be opened or closed (gated) in response to electrical (voltage-gated) or chemical (ligand-gated) stimuli; (2) exchange of one ion for another by attachment to binding sites for transmission in response to an electrochemical gradient; and (3) active (energy-dependent) transport of ions against an electrochemical gradient.

Other proteins located in the sarcolemma serve as receptors for neuronal or chemical control of cellular processes.

### ION CHANNELS

Most of the voltage-gated channels consist of four subunits that surround the water-filled pore through which ions cross

**FIGURE 3-1** The sarcolemma is a bilayer in which phospholipid and cholesterol molecules are arranged with hydrophobic domains within the membrane and hydrophilic domains facing outward. The membrane-spanning protein shown here is similar to many ion channels, with six hydrophobic alpha-helices spanning the membrane and surrounding a central channel.

the membrane. A schematic diagram of an ion channel is shown in Figure 3-2. Each channel contains a selectivity filter that allows the passage of particular ions based upon pore size and electrical charge, and an activation gate regulated by conformational changes induced by either a voltage-sensitive or a ligand-binding region of the protein. Many channels also have an inactivation gate.<sup>1,3</sup>

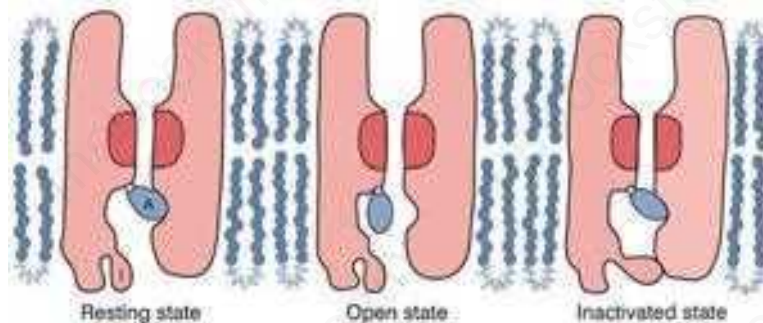

### Voltage-Gated Sodium Channels

The voltage-gated sodium channel is prominent in most electrically excitable muscle and nerve cells. Energy-dependent pumps and other ions create a large concentration gradient of positive sodium ions (142 mEq/L outside, 10 mEq/L inside) and a large electrical gradient ( $-70$  to  $-90$  millivolts (mV) from outside to inside) across the cell membrane. Both gradients favor the influx of sodium. This passive influx is termed an inward current. The inward current of sodium ions begins to depolarize (reduce the

electrical gradient) across the sarcolemma. When the membrane potential is raised to between  $-70$  and  $-50$  mV, the activation gate of the sodium channel opens. Sodium ions rapidly rush into the cell depolarizing the sarcolemmal membrane. The inactivation gate of the sodium channel begins to close at the same voltage, with a built-in time delay, so the sodium channel is open for only a few milliseconds. Because these channels open and close so quickly, they are called fast channels. The inactivation gate of the sodium channel remains closed until the cell is repolarized to the resting negative membrane potential.<sup>4,5</sup>

### Voltage-Gated Calcium Channels

There are two important calcium channels. The type T (transient)-calcium channels open as the membrane potential rises to  $-60$  to  $-50$  mV, and then close quickly. These T-calcium channels are important in early depolarization, especially in atrial pacemaker cells.

**FIGURE 3-2** A voltage-gated sodium channel is schematically depicted. The shaded region is the selectivity filter. *A* represents the activation gate, and *I* represents the inactivation gate. At rest, the inactivation gate is open and the activation gate is closed. As the transmembrane potential rises from  $-80$  to  $-60$  mV, the activation gate opens, and sodium ions pass through the channel. Within a few milliseconds, the inactivation gate closes. Once the cell repolarizes the resting ion channel returns to the resting state.

The second major calcium channel, type L (long-lasting) channel, a slow channel, leads to an inward (depolarizing) current that is slowly inactivated and therefore prolonged. These channels open at a less negative potential ( $-30$  to  $-20$  mV). Once open, the prolonged inward calcium current (Figure 3-3) sustains the action potential. This increase in cytosolic calcium begins the excitation-contraction sequence. Beta-receptor stimulation induces conformational changes in the channel, resulting in an increased influx of calcium ions and an associated increase in the strength of sarcomere contraction. This effect is attenuated by stimulation of acetylcholine and adenosine receptors.<sup>6,7</sup>

## Potassium Channels

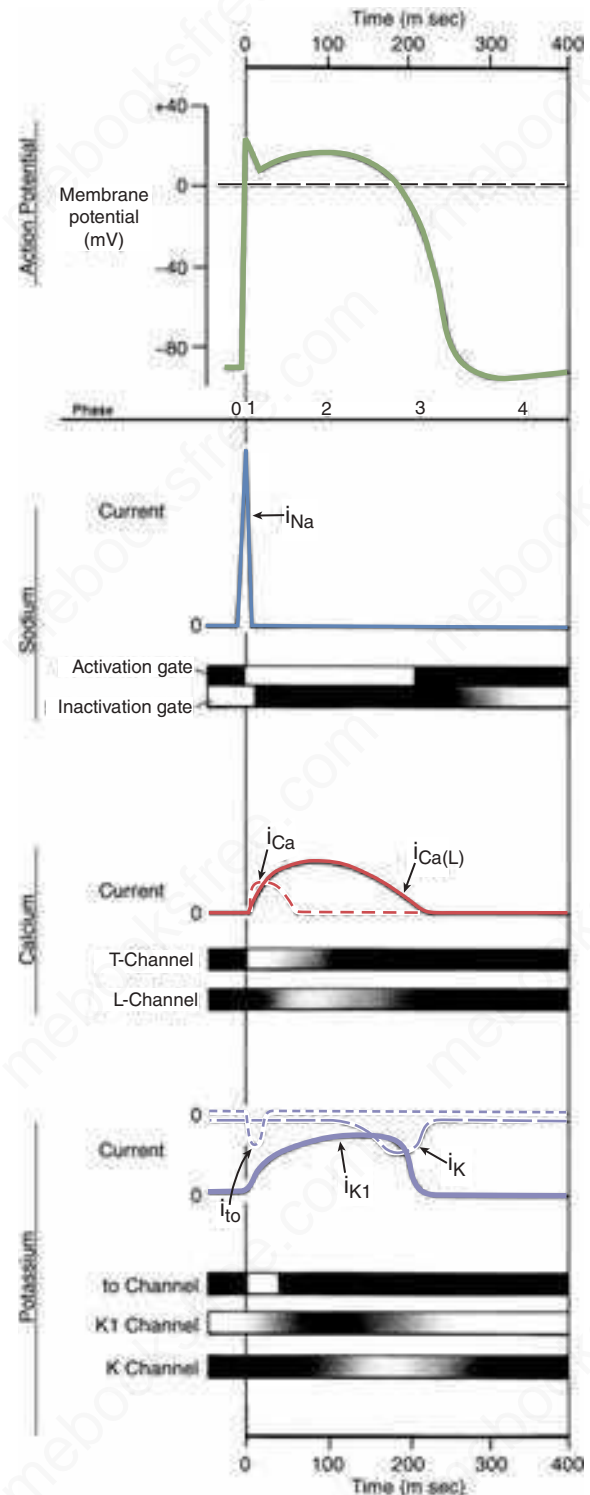

A variety of potassium channels, both voltage- and ligand-gated, are present in cardiac cells. Three voltage-gated potassium channels moderate the delayed rectifier current which repolarizes the cell membrane (Figure 3-3).<sup>8</sup>

Several ligand-gated potassium channels have been identified. Acetylcholine and adenosine-activated potassium channels are time-independent, and lead to hyperpolarization in pacemaker and nodal cells, thereby delaying spontaneous depolarization. A calcium-activated potassium channel opens in the presence of high levels of cytosolic calcium and probably enhances the delayed rectifier current, leading to early termination of the action potential. An adenosine triphosphate (ATP)-sensitive potassium channel is closed in the metabolically normal myocyte, but is opened in the metabolically starved myocyte in which ATP stores have been depleted, leading to hyperpolarization of the cell, thereby retarding depolarization and contraction.

## ENERGY-DEPENDENT ION PUMPS

**Sodium-potassium atp-dependent pump.** The sodium-potassium pump uses the energy obtained from the hydrolysis of ATP to move three  $\text{Na}^+$  ions out of the cell and two  $\text{K}^+$  ions into the cell, each against its respective concentration gradient. Since there is a net outward current (three  $\text{Na}^+$  ions for two  $\text{K}^+$  ions), the pump contributes about 10 mV to the resting membrane potential. The activity of the pump is strongly stimulated by attachment of sodium to its binding site. The  $\text{Na}^+$ - $\text{K}^+$  adenosine triphosphatase,  $\text{Na}^+$ - $\text{K}^+$  (ATPase), has a very high affinity for ATP, so that the pump continues to function even if ATP levels are reduced.

**Atp-dependent calcium pump.** The ATP-dependent calcium pump transports calcium out of the cell against a strong concentration gradient. This action represents a net outward current, but the magnitude of this current is quite small because the bulk of calcium transferred out of the cell occurs with sodium-calcium exchange (described in the following). The cytosolic protein, calmodulin, can complex with calcium and facilitate the action of the pump; thus, increased intracellular calcium levels stimulate the pump.<sup>9,10</sup>

**FIGURE 3-3** A typical ventricular myocyte action potential and the ion currents contributing to it are schematically represented. Inward (depolarizing) currents are depicted as positive, and outward (repolarizing) currents are depicted as negative. The horizontal filled bars show the state of the gate of the ion channel (white = open; black = closed; shaded = partially open). In the case of the sodium channel, both the activation and inactivation gates are shown (Ca = calcium; i = current; K = potassium; Na = sodium).

## ION EXCHANGERS

**Sodium-calcium exchanger.** Multiple proteins that traverse the membrane allow ion exchanges using the potential energy of the electrochemical gradient which favors the influx of sodium. The sodium-calcium exchanger exchanges three extracellular sodium ions for one intracellular calcium ion, leading to a net single positive charge transported into the cell with each exchange. The exchange system is sensitive to the concentration of sodium and calcium on both sides of the membrane, and to the membrane potential. If external sodium concentrations decrease, the driving force for removal of calcium from the cell is decreased, leading to an increase in cytosolic calcium (and a consequent increase in contraction). Thus, hyponatremia can increase cardiac contractility. If the intracellular sodium concentration increases, as occurs with ischemia, the gradient for sodium influx is reduced, and the pump slows down or actually reverses, extruding sodium in exchange for an influx of calcium. This mechanism may be central to the accumulation of calcium during ischemia. The sodium-calcium exchange mechanism has a maximum exchange rate that is some 30 times higher than the sarcolemmal ATP-dependent calcium pump and is the primary mechanism for removal of excess cytosolic calcium.<sup>7</sup>

**Sodium-hydrogen exchanger.** The sodium-hydrogen exchanger extrudes one intracellular hydrogen ion in exchange for one extracellular sodium ion, and is electrically neutral. This pump prevents intracellular acidification. Acidification (eg, during ischemia) increases the affinity of the pump for H<sup>+</sup> ions, promoting the removal of H<sup>+</sup> preserving intracellular pH at the expense of sodium accumulation. The accumulation of

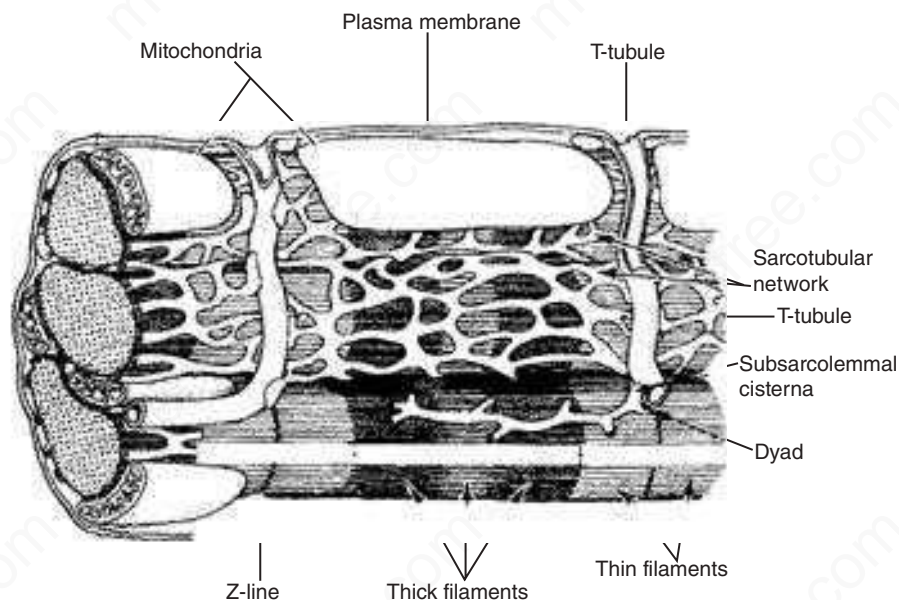

sodium ions may then trigger reversal of the sodium-calcium exchange pump to favor the accumulation of calcium within the cell. This is a possible mechanism underlying injury or cell death during ischemia-reperfusion.

## INTRACELLULAR COMMUNICATION PATHWAYS

To allow concurrent activation of all the myofibrils in the muscle cell, the electrical activation signal must be rapidly and evenly spread through all portions of the cell. This is accomplished through the t-tubules, and the subsarcolemmal cisternae and sarcotubular network of the sarcoplasmic reticulum.

**Transverse tubules (T-tubules).** The basic contractile unit in a muscle cell is the sarcomere. Sarcomeres are joined together in the myofibril at the z-lines. A system of transverse tubules (t-tubules) extends the sarcolemma into the interior of the cardiac cell (Figure 3-4). These tubules are perpendicular to the sarcomere, near the z-lines, extending the extracellular space close to the contractile proteins. The transverse tubules contain the calcium channels, which are in close relationship to the foot proteins of the subsarcolemmal cisternae.

**Sarcoplasmic reticulum.** The sarcoplasmic reticulum is a membrane network within the cytoplasm of the cell surrounding the myofibrils. The primary function of the sarcoplasmic reticulum is excitation-contraction coupling by sudden release of calcium to stimulate the contraction proteins and then rapid removal of this calcium to allow relaxation of the contractile elements. The subsarcolemmal cisternae and the

**FIGURE 3-4** Myocyte anatomy. (Reproduced with permission from Katz AM: *Physiology of the Heart*, 4th ed. Philadelphia, Lippincott Williams & Wilkins; 2006.)

sarcotubular network are the two portions of the sarcoplasmic reticulum that mediate this process.

The subsarcolemmal cisternae are near the sarcolemma and the t-tubules. Foot proteins are found in the membrane of the sarcoplasmic reticulum, with a large protein component extending into the gap between the subsarcolemmal cisternae and the sarcolemma of the t-tubule. The foot proteins respond to the release of calcium by opening a calcium channel, which allows the release of a much larger quantity of calcium from the subsarcolemmal cisternae. This is “calcium-triggered” calcium release with calcium transported across the sarcolemma, leading to calcium release from the subsarcolemmal cisternae. The magnitude of calcium release from the subsarcolemmal cisternae appears to be related to the magnitude of the trigger. The calcium channels then close and the calcium is returned to the sarcoplasmic reticulum by an ATP-dependent calcium pump located in the sarcotubular network.<sup>1,10</sup> The sarcotubular network is the portion of the sarcoplasmic reticulum that surrounds the contractile elements of the sarcomere (Figure 3-5).

Regulation of calcium transport by the cardiac sarcoplasmic reticulum occurs primarily at the site of the calcium pump. A calcium-calmodulin complex phosphorylates the pump to stimulate pump activity. Reduced ATP availability will slow

pump function. Phospholamban inhibits the basal rate of calcium transport by the calcium pump. This inhibition is reversed when phospholamban is phosphorylated by a cyclic AMP-or calcium-calmodulin-dependent protein kinase. This is a very important mechanism for beta-adrenergic regulation; cyclic AMP levels increase with activation of the beta-adrenergic receptor. As phospholamban is phosphorylated, there is accelerated calcium turnover and increased sensitivity of the calcium pump, which facilitates uptake of calcium from the cytosol and relaxation of the heart. Phosphorylation of phospholamban does not affect the sarcolemmal calcium pump, thereby tending to favor retention of calcium within the cell (increasing the calcium content of the sarcoplasmic reticulum at the expense of calcium removed from the cell through the sarcolemma). This might lead to an increased pulse of calcium within the cell, thereby favoring increased contractility.<sup>7,10</sup> Phosphorylation of phospholamban, in the presence of intracellular calcium, stimulates calcium uptake to protect the heart from calcium overload.

In this ionic milieu, the importance of intracellular pH maintenance should be stressed. Regulation of intracellular pH is complex and beyond the scope of this text, but a few simple principles are important to review. Reduced intracellular pH diminishes the amount of calcium released from

**FIGURE 3-5** Anatomy of the cardiac sarcomere.  $\text{Ca}^{2+}$  influx during excitation provokes the release of additional  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum (SR). The  $\text{Ca}^{2+}$  binds to troponin on the thin filaments triggering sarcomeric contraction (systole). The  $\text{Ca}^{2+}$  is then removed from the cytosol through uptake into the SR and extracellular extrusion allowing sarcomere relaxation (diastole). (Reproduced with permission from Kobirumaki-Shimozawa F, Inoue T, Shintani SA, et al: Cardiac thin filament regulation and the Frank-Starling mechanism, *J Physiol Sci*. 2014 Jul;64(4):221-232.)

the sarcoplasmic reticulum and reduces the responsiveness of myofilaments to calcium. Elevation of the pH will have the opposite effect. The clinical relevance of this observation cannot be overstressed.

## ELECTRICAL ACTIVATION OF THE HEART

### Normal Cardiac Rhythm

#### THE RESTING MEMBRANE POTENTIAL

The state of the cardiac cell is determined by a balance of forces based on electrical and chemical gradients. At rest (during diastole), the cardiac cell is polarized. The electrical potential across the sarcolemma is primarily determined by the concentration gradient of potassium across the membrane. This gradient is established by the sodium-potassium pump. However, once this pump shuts off, the steady state is determined by the balance of electrical and chemical forces. The sarcolemma is impermeable to some ions, permeable to others, and selectively permeable to others. Steady-state properties of a mixture of ions of variable permeabilities across a membrane are described by the Gibbs-Donnan equilibrium.<sup>11</sup> The sarcolemma prevents the diffusion of large anions (eg, proteins and organic phosphates). At rest, the sarcolemma is relatively permeable to potassium ions because of the open state of most potassium channels, but less permeable to sodium. The concentration gradient established by the sodium-potassium pump promotes the efflux of potassium ions across the sarcolemma. The outward flow of positive ions is counterbalanced by the increasing electronegativity of the interior of the cell owing to the impermeant anions. A Gibbs-Donnan equilibrium is established such that the electronegativity of the cell interior retards potassium-ion efflux to the same degree that the concentration gradient favors  $K^+$  efflux. At equilibrium, the forces balance with an intracellular potassium concentration of 135 mM and extra-cellular concentration of 4 mM and a predicted resting membrane potential of  $-94$  mV. The actual resting membrane potential is measured at about  $-90$  mV because of smaller contributions from the current of other less permeable ions (eg, sodium and calcium). However, the potassium current is the main determinant of the resting membrane potential.<sup>12</sup>

#### THE ACTION POTENTIAL

The action potential represents the triggered response to a stimulus derived either internally (slow depolarizing ionic currents) or externally (depolarization of adjacent cells). A typical fast-response action potential which occurs in atrial and ventricular myocytes and special conduction fibers is depicted in Fig. 3-3. As the transmembrane potential decreases to approximately  $-65$  mV, the "fast" sodium channels open. These channels remain open for a few milliseconds when the inactivation gate of the "fast" sodium channel closes. The large gradient of sodium ions promotes rapid influx, depolarizing the cell to a slightly positive transmembrane potential:

phase 0 of the action potential. A transient potassium current ( $i_{to}$ ) causes a very early repolarization (phase 1) of the action potential, but this fast channel closes quickly. The plateau of the action potential (phase 2) is sustained at a neutral or slightly positive level by an inward flowing calcium current, first from the transient calcium channel and second through the long-lasting calcium channel. The plateau is also sustained by a decrease in the outward potassium current ( $i_{K1}$ ). With time, the long-lasting calcium channels begin to close, and the repolarizing potassium current ( $i_K$ , the delayed rectifier current) leads to the initiation of phase 3 of the action potential. As repolarization progresses, the stronger first potassium current ( $i_{K1}$ ) dominates, leading to full repolarization of the membrane to the resting negative potential. During the bulk of the depolarized interval (phase 4) the first potassium current predominates in myocytes.

#### REFRACTORY PERIOD

The sodium channels cannot respond to a second wave of depolarization until the inactivation gates are reopened (by repolarization during phase 3). As a result, the membrane is refractory to the propagation of a second impulse during this time interval, referred to as the absolute refractory period. As the membrane is repolarized during early phase 3 of the action potential, and some of the sodium channels have been reactivated, a short interval exists during which only very strong impulses can activate the cell, which is termed the relative refractory period. A drug that acts to speed up the inactivation gate will shorten both the absolute and the relative refractory periods.<sup>1,13,14</sup>

#### SPONTANEOUS DEPOLARIZATION

The action potential of the slow response cells of the nodal tissue (sinoatrial node, or SA node, and atrioventricular node, or AV node) differs from that in the fast-response cells, as shown in Figure 3-6. The rapid upstroke of phase 0 is less prominent due to the absence of fast  $Na^+$  channels. Phase 1 is absent, as there is no rapid inward potassium current. In addition, the plateau phase (phase 2) is abbreviated because of the lack of a sustained active  $Na^+$  inward current, and the lack of sustained calcium current. The repolarization phase (phase 3) leads to a resting phase (phase 4) that begins to depolarize again, as opposed to the relatively stable resting membrane potential of myocytes. The slowly depolarizing phase 4 resting potential is called the diastolic depolarization current, or the pacemaker potential. Continued depolarization of the membrane potential ultimately reduces it to the threshold potential that stimulates another action potential. This diastolic depolarization potential is the mechanism of automaticity in cardiac pacemaker cells. Diastolic depolarization is caused by the concerted and net actions of: (1) a decrease in the outward  $K^+$  current during early diastole (phase 4); (2) persistence of the slow inward  $Ca^{2+}$  current; and (3) an increasing inward  $Na^+$  current during diastole. The inward  $Na^+$  current most likely predominates in nodal and conduction tissue. The slope of the diastolic

**FIGURE 3-6** The membrane potential of a spontaneously depolarizing cell of the sinoatrial node, and the ion currents contributing to it. Inward (depolarizing) currents are depicted as positive, and outward (repolarizing) currents are depicted as negative (Ca = calcium; i = current; K = potassium; Na = sodium).

depolarization determines the rate of action-potential generation in the pacemaker cells, and is the primary mechanism determining heart rate. Of all the cardiac cells, the fastest rate of depolarization is in the SA node, and action potentials are generated at a rate of 70 to 80 per minute. The AV node is a slower rate of depolarization, at 40 to 60 times per minute. The ventricular myocytes are the slowest, at 30 to 40 times per minute. Once a depolarization is initiated in a pacemaker cell and propagated, it will depolarize the remainder of the heart in a synchronized and sequential manner. The heart rate can be altered by changing the slope of the diastolic depolarization (eg, acetylcholine decreases the slope and heart rate; beta-adrenergic agonists increase the slope and heart rate). If the slope is unchanged, hyperpolarization (more negative resting potential) or raising the

threshold potential will increase the time to reach threshold, thus decreasing the heart rate.

### PROPAGATION OF THE ACTION POTENTIAL

Each myocyte is mechanically anchored and electrically connected to the next myocyte by an intercalated disc at the end of the cell. These discs contain gap junctions that facilitate flow of charged molecules from one cell to the next. These pores are composed of a protein, connexin. Permeability through the cardiac gap junction is increased by both ATP- and cyclic AMP-dependent kinases. This allows the gap junctions to close if ATP levels fall, thereby reducing electrical and presumably mechanical activity, which is essential in limiting cell death when one region of the heart is damaged. It also

allows conduction to increase when cyclic AMP increases in response to adrenergic stimulation.

After spontaneous depolarization occurs in the pacemaker cells of the SA node, the action potential is conducted throughout the heart. Special electrical pathways facilitate this conduction. Three internodal paths exist through the atrium between the SA node and the AV node. After traversing the AV node, the action potential is propagated rapidly through the bundle of His and into the Purkinje fibers located on the endocardium of the left and right ventricles. Rapid conduction through the atrium causes contraction of most of the atrial muscle synchronously (within 60 to 90 ms). Similarly, the rapid conduction of the signal throughout the ventricle leads to synchronous contraction of the bulk of the ventricular myocardium (within 60 ms). The delay in the propagation of the action potential through the AV node by 120 to 140 ms allows the atria to complete contraction before the ventricles contract. Slow conduction in the AV node is related to a relatively higher internal resistance because of a small number of gap junctions between cells, and slowly rising action potentials.

## Abnormal Cardiac Rhythm

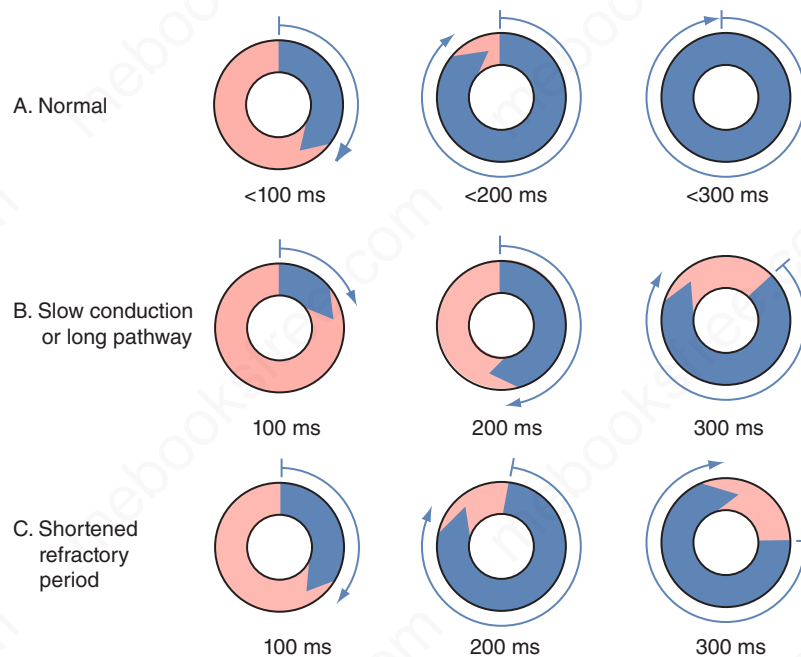

### ABERRANT PACEMAKER FOCI

Normally the SA node spontaneously depolarizes first, such that the cardiac beat originates from this primary pacemaker site. If the SA node is damaged or slowed by vagal stimulation

or drugs (eg, acetylcholine), ectopic pacemakers in the atrium, AV node, or the His-Purkinje system can take over. Occasionally, aberrant foci in the heart spontaneously depolarize, thereby leading to aberrant or “premature” contractions from the atrium or the ventricle. These contractions ordinarily do not interfere with the normal depolarization of the heart.

### REENTRY ARRHYTHMIAS

Reentry arrhythmias are perhaps the most common dangerous cardiac rhythm. Ordinarily, the action potential depolarizes the entire atrium or the entire ventricle in a short enough time interval so that all of the muscle is refractory to further stimulation at the same time. A reentry arrhythmia is caused by propagation of an action potential through the heart in a “circuit” movement. For reentry to occur there must be a unidirectional block (transient or permanent) to action potential propagation. Additionally, the effective refractory period of the reentered region must be shorter than the propagation time around the loop.<sup>12</sup> For example, if a portion of the previously depolarized myocardium has repolarized before the propagation of the action potential is completed throughout the atrium or ventricle, then that action potential can continue its propagation into this repolarized muscle. Such an event generally requires either dramatic slowing of conduction of the action potential, a long conduction pathway, or a shortened refractory period (Figure 3-7). All of these situations occur clinically. Ischemia slows the sodium-potassium pump, which decreases the resting membrane potential and slows

**FIGURE 3-7** Three conditions predisposing to reentry or “circuit” pathways for action potential propagation are shown. Muscle that is refractory to action potential propagation is shown as black. Normally, as the action potential travels through the atrium or ventricle, all the muscle is depolarized sufficiently that the action potential encounters no more nonrefractory muscle and stops (*A*). If there is slowed conduction speed or a long pathway (*B*), the action potential may find repolarized (nonrefractory) muscle and continue in a circular path. Similarly, a shortened refractory period (*C*) may lead to rapid repolarization and predispose to a reentry and continuation of the action potential.

propagation of the action potential. Hyperkalemia decreases the resting membrane potential, which increases excitability and inactivates the sodium-potassium pump, slowing propagation of the action potential. Progressive atrial dilation creates a long conduction pathway around the atrium. Adrenergic stimulation shortens the refractory period.

A special type of reentry arrhythmia occurs in Wolff-Parkinson-White syndrome in which an accessory pathway electrically connects the atrium and the ventricle. This accessory pathway can complete a circular electrical pathway between the atrium and the ventricle. Conduction is unidirectional across the AV node and the accessory pathway creates a loop that has a propagation time that is greater than the AV node refractory period, resulting in supraventricular tachycardia. In an alternative situation, because the accessory pathway does not have the inherent delay and refractory period of the AV node, rapid atrial tachycardias can be conducted in a 1:1 manner across the accessory pathway, leading to ventricular rates as fast as 300 beats per minute.

## REGULATION OF CELLULAR FUNCTION

### Types of Receptors and Second Messengers

Numerous types of receptors are involved in regulating cardiovascular function. They include G-protein (GTP-binding proteins) coupled receptors, enzyme-linked receptors, ion channel-linked receptors, and nuclear receptors. Other ligands, such as nitric oxide, bind directly to their intracellular target.<sup>15</sup> G-protein-coupled receptors are the most important. Ligand binding activates the synthesis of intracellular second messengers, protein kinases, and voltage-gated potassium channels.<sup>16</sup> The most important second messenger is cyclic AMP, which transmits the response to sympathetic stimulation. Cyclic AMP is produced from ATP by adenylyl cyclase and broken down to AMP by phosphodiesterases. Cyclic AMP production is promoted by sympathetic and inhibited by parasympathetic stimulation. Another second messenger, cyclic guanosine monophosphate (GMP) is similarly produced, in response to nitric oxide and natriuretic peptides, by guanylyl cyclase and broken down by phosphodiesterases and opposes the actions of cyclic AMP.<sup>17</sup> These and other second messengers activate signaling enzymes within the cell such as protein kinases.

### Innervation of the Heart

Sympathetic fibers originate from the fourth and fifth thoracic spinal cord regions. Parasympathetic innervation derives through the vagus nerve connecting to the SA and AV nodes, atria, and blood vessels. Stretch receptors located in the atria and ventricles provide feedback to the central nervous system. Atrial natriuretic peptide, (similar to B-type natriuretic peptide which is clinically measured) is secreted by atrial myocytes in response to stretch and promotes natriuresis, diuresis,

and smooth muscle relaxation. Stretch receptors on the posterior and inferior ventricular wall can trigger parasympathetic stimulation and inhibit sympathetic activity, leading to bradycardia and conduction block (von Bezold-Jarisch reflex).<sup>18</sup>

## PARASYMPATHETIC REGULATION

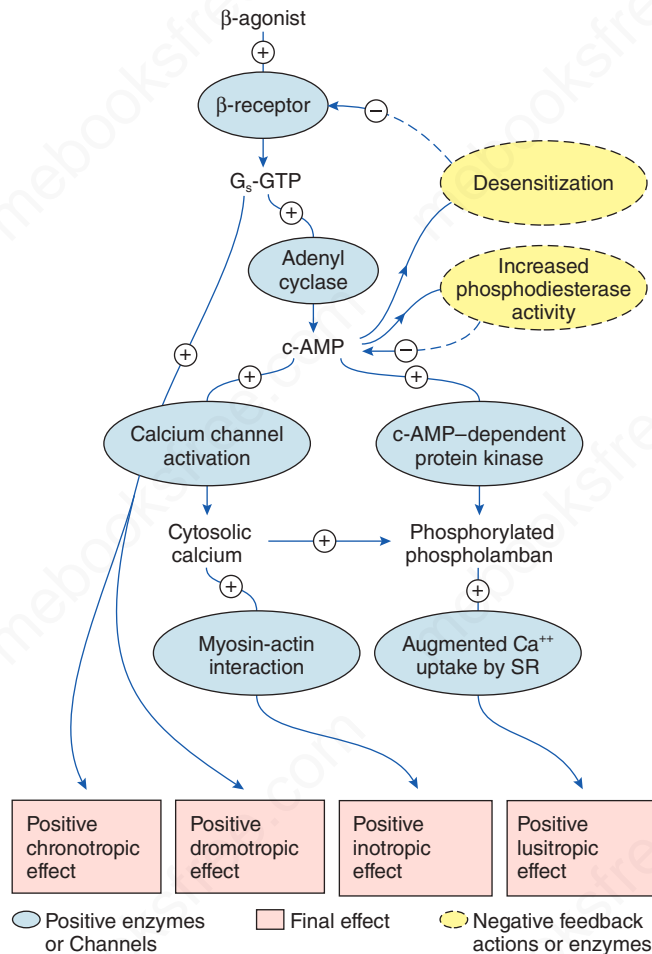

The parasympathetic nervous system is particularly important in control of the SA node. Acetylcholine released by the nerve endings of the parasympathetic system stimulates muscarinic receptors in the heart. The activated receptors produce an intracellular stimulatory G-protein that opens acetylcholine gated potassium channels. An increased outward (repolarizing) flow of potassium leads to hyperpolarization of the SA node cells. Stimulation of the muscarinic receptors also inhibits the formation of cyclic AMP, inhibiting the opening of calcium channels. A decreased inward flow of calcium, combined with an increased outward flow of potassium, leads to slowing of the spontaneous diastolic depolarization of the SA node cells (Figure 3-6). A similar effect in the AV node leads to slowing of conduction through the AV node.<sup>1</sup>

## SYMPATHETIC STIMULATION AND BLOCKADE

Sympathetic or adrenergic receptors in the heart affect heart rate, contractility, conduction velocity, and automaticity; and in the peripheral vasculature they affect smooth muscle contraction and relaxation. Alpha-adrenergic receptors cause vasoconstriction. There are two types of beta-adrenergic receptors: the beta<sub>1</sub>-adrenergic receptors, which predominate in the heart, and the beta<sub>2</sub>-adrenergic receptors, which are present in blood vessels and promote relaxation. The number of beta receptors per unit area (receptor density) of the sarcolemma can be upregulated or downregulated in response to various stimuli. Receptor sensitivity can also change depending on ambient conditions and variable stimuli.<sup>19</sup> Cardiopulmonary bypass and ischemia cause downregulation of cardiac beta receptors. Acidemia causes desensitization of beta receptors. This is important in the perioperative period when acidemia can reduce cardiac contractility, systemic vascular tone, and the response to inotropic agents.

The beta<sub>1</sub>-adrenergic receptor couples with adenylyl cyclase (Figure 3-8). When the receptor site is occupied by an adrenergic agonist, a stimulatory G-protein is formed, which combines with GTP. This activated G-protein-GTP complex then promotes the activity of adenylyl cyclase, leading to the formation of cyclic AMP from ATP. The G-protein-GTP complex and the cyclic AMP actively promote calcium channel opening. The increased tendency for calcium channels to open during beta<sub>1</sub>-receptor stimulation increases cytosolic calcium and leads to a number of physiologic effects: (1) A positive chronotropic (heart rate) effect whereby the heart rate, conduction, and contraction velocity increase and the action potential is shortened, leading to a shortening of systole; (2) a positive dromotropic (conduction velocity) effect of accelerated conduction through the AV node; and (3) a positive inotropic (contractility) effect. Increased activity of the sarcoplasmic reticulum calcium pump (more rapid calcium

**FIGURE 3-8** Adrenergic stimulation via the action of beta agonists on beta receptors leads to a cascade of events in the myocyte, some of which are shown here. Note that an increase in cyclic AMP causes the activation of two inhibitory pathways, retarding excessively sustained adrenergic stimulation (cyclic AMP = cyclic adenosine monophosphate;  $G_s$  = stimulatory G-protein; GTP = guanosine triphosphate; SR = sarcoplasmic reticulum).

uptake) leads to more rapid relaxation, which facilitates ventricular filling; (4) a positive lusitropic (relaxation) effect.<sup>20</sup>

Two negative feedback systems diminish the response to beta agonists when stimulation is repetitive or persistent (tachyphylaxis). Increased cyclic AMP leads to: (1) increased phosphorylation of beta receptors leading to downregulation; and (2) increased activity of phosphodiesterase, the enzyme that degrades cyclic AMP. Acidosis will inhibit many steps in the sympathetic activation cascade, impairing contractility.

The activity spectrum of adrenergic receptors forms the basis of many therapeutic interventions; perioperatively to support cardiac function, and chronically to reduce mortality from myocardial infarction and treat congestive heart failure. The selectivity of the agonists and antagonists allows adaptation for various clinical scenarios. Some examples are detailed in Table 3-1.

Reduction in inotropy, lusitropy, chronotropy, and dromotropy by beta blockade will reduce myocardial oxygen consumption contributing to many of its beneficial effects. As beta blockade will lead to upregulation of sarcolemmal

receptors, sudden cessation of beta blockade may cause a temporarily enhanced (and potentially dangerous) sensitivity to adrenergic stimulation.

### PHOSPHODIESTERASE INHIBITION

Cyclic AMP plays a central role in the regulation of the cardiac cell. Cytosolic levels of cyclic AMP are also increased by activation of receptors other than beta receptors (ie, for histamine, dopamine, glucagon), and are decreased by inhibitory G-proteins produced by stimulation of muscarinic receptors by acetylcholine and by stimulation of adenosine receptors. Referring to Figure 3-8, one negative feedback response to the increase in cyclic AMP is an increase in phosphodiesterase, which breaks down cyclic AMP. Phosphodiesterase inhibitors (amrinone, milrinone) inhibit the breakdown of cyclic AMP and thereby increase its level in the cytosol. Their effect is synergistic to that of beta agonists. Because they do not stimulate the production

**TABLE 3-1: Adrenergic Agonists and Antagonists Correlating Selective Activity with Clinical Usage**

	Drug	Alpha	Beta <sub>1</sub>	Beta <sub>2</sub>	Clinical Usage
Agonists	Epinephrine	Y	Y	Y	Low cardiac output, hypotension
	Norepinephrine	Y	Y		Hypotension
	Phenylephrine	Y			Hypotension
	Dobutamine		Y		Low cardiac output
	Dopamine	Y	Y		Low cardiac output, hypotension
	Isoproterenol		Y	Y	Bradycardia, low cardiac output, pulmonary hypertension
Antagonists (beta-blockers)	Metoprolol		Y		Tachycardia, hypertension, MI, angina
	Atenolol		Y		Tachycardia, hypertension, MI, angina
	Esmolol		Y		Tachycardia, hypertension, MI, angina
	Carvedilol	Y (alpha-1)	Y	Y	Congestive heart failure

of the G-protein–GTP complex, they have a lesser effect on calcium channel activation, and therefore less of the troublesome positive chronotropic and dromotropic effects of beta-adrenergic stimulation.<sup>21</sup>

### ADENOSINE RECEPTORS

There are four types of adenosine receptors. Adenosine receptors are linked to inhibitory and stimulatory G-proteins and various kinases. Activation of adenosine A<sub>1</sub> receptors leads to inhibition of cyclic AMP production, inhibition of the slow calcium channel, and opening of an adenosine-activated ATP-sensitive potassium (K<sub>ATP</sub>) channel. This leads to hyperpolarization, which delays conduction through the AV node and slows the ventricular response to atrial tachycardia.<sup>1,22</sup> Pretreatment with adenosine confers a cardioprotective effect during ischemia and can inhibit the inflammatory responses initiated by ischemia and reperfusion.<sup>22</sup>

### Other Regulators of Hemodynamic Function

Angiotensin II is a vasoconstrictor and reduces renal fluid excretion. It is the final effector of the renin-angiotensin-aldosterone system. Renin, secreted by the juxtaglomerular apparatus in the kidney, splits angiotensin I from angiotensinogen, produced by the liver. Angiotensin I is converted to angiotensin II by the angiotensin-converting enzyme (ACE or kininase II, the target of ACE inhibitors) mainly in the lungs. Angiotensin II acts by causing: (1) vasoconstriction to increase systemic vascular resistance; and (2) stimulation of the adrenal cortex to secrete aldosterone, which increases fluid volume and thus cardiac output. Through both actions, angiotensin II modifies blood pressure. Angiotensin II receptor blockers (ARBs) directly inhibit angiotensin II subtype IA receptors.

The endothelins (ETs) have multiple effects. When bound to ET-A receptors they cause vasoconstriction, increased contractility, and proliferation. When bound to ET-B receptors

they stimulate the release of nitric oxide and prostacyclin and have a vasodilatory effect.<sup>23</sup>

Bradykinins, acting through their receptors, cause vasodilation. Arginine vasopressin promotes reabsorption of water by the kidney and has a vasoconstrictor effect. Natriuretic peptides, released in response to atrial distension, promote diuresis and arteriolar dilatation.

Nitric oxide (NO) plays an essential role in cardiac excitation-contraction coupling. NO can regulate Ca<sup>2+</sup> entry into the cardiomyocyte, and the release of NO in specific subcellular compartments can influence Ca<sup>2+</sup> release from the sarcoplasmic reticulum. NO influences the contractile kinetics of the myofilaments, ensuring that Ca<sup>2+</sup> homeostasis is closely matched with the activity of the contractile machinery and allowing for dynamic adjustments during the systolic and diastolic phase. Through the stimulus of cyclic-GMP production, low amounts of NO can increase contractility but higher doses attenuate cardiomyocyte contraction.<sup>17,24,25</sup> Changes in cardiac NO production by nitric oxide synthase impact responses to heart failure, diabetes, atrial fibrillation and ischemia reperfusion states.<sup>26</sup> Inhaled NO administered at low concentrations causes pulmonary arterial dilatation, reduces chronotropy, and has a positive inotropic effect.<sup>27</sup>

## CONTRACTION OF CARDIAC MUSCLE

### Molecular Level (The Sarcomere)

The primary contractile unit of all muscle cells is the sarcomere (Figs. 3-4 and 3-5). Sarcomeres are connected end to end at the z-line to form myofibrils. The myocyte contains numerous myofibrils arranged in parallel. A portion of a sarcomere is schematically depicted in Figure 3-9. Actin polymerizes to form the thin filaments that are anchored at the z-line. Myosin polymerizes to form the thick filaments of the sarcomere. Myosin consists of a tail of two “heavy” chains

**FIGURE 3-9** The interaction of actin and myosin filaments converts chemical energy into mechanical movement. In diastole, the active sites on the actin filament are covered by tropomyosin. When calcium combines with troponin, the tropomyosin is pulled away from the actin active sites, allowing the energized myosin heads (depicted in solid black and cocked at right angles to the filament) to engage and sweep the actin filament along. The myosin heads are de-energized in this process. Myosin ATPase re-cocks (re-energizes) the head by utilizing the energy derived from the hydrolysis of ATP. In systole, a de-energizing head (C), a de-energized head (B), and a re-energizing head (A) are shown.

intertwined to form a helix, forming the rigid backbone of the thick filament. The globular head of myosin is attached to the heavy chain backbone by a mobile hinge and projects outward. Myosin connects with the z-line via an elastic fiber made of titin. Titin is like a spring impacting passive elasticity. The globular myosin head is an ATPase with a binding site for actin. Actin binds to the myosin globular head activating the myosin ATPase to hydrolyze ATP. This leads to a conformational change in the myosin that pulls the filament (Figure 3-9B).

Two proteins modulate the interaction of actin and myosin: troponin and tropomyosin. Troponin (“T” in Figure 3-9A) is composed of three units: Tn-C, the regulatory calcium binding unit; Tn-T, which binds the troponin complex to tropomyosin; and Tn-I, which facilitates interruption of actin-myosin interaction by tropomyosin. Associated with each troponin complex is tropomyosin, a filamentous protein composed of two tightly coiled chains that lie in the groove formed by the two intertwined filaments of actin. In the absence of calcium, Tn-I is tightly bound to actin so that tropomyosin blocks the binding of myosin to actin. When calcium binds to troponin C, Tn-I becomes unbound, the tropomyosin moves to expose the myosin binding site on

actin, thereby allowing cross-bridge formation between actin and myosin. Tn-C has several regulatory sites that are affected by phosphorylation in response to hormonal and other stimuli, to alter the sensitivity and degree of force generation. Acidosis will reduce contractile force through an allosteric effect because of protons binding to Tn-I, and reducing affinity of calcium binding sites.<sup>28</sup>

During diastole,  $\text{Ca}^{2+}$  is unavailable to bind troponin C and the myosin binding site on actin is blocked. Depolarization leads to an influx of calcium ions and the subsequent “calcium-triggered, calcium release” increases the intracellular  $\text{Ca}^{2+}$  levels by approximately two orders of magnitude (from  $10^{-7}$  M in diastole to  $10^{-5}$  M in systole). This provides sufficient calcium to bind to troponin C, which causes a conformational change in the troponin molecule, removing the inhibitory effect of troponin I-tropomyosin, allowing actin-myosin cross-bridge formation (Figure 3-9A). Cross-bridge formation activates the myosin ATPase and initiates the conformational change in the myosin “hinge” drawing the z-lines closer together (Figure 3-9B). Adenosine diphosphate (ADP) and  $\text{P}_i$  are released. ATP binds to the myosin head, allowing dissociation from the actin and realigning the myosin globular head, preparing it to repeat the process. This process

cycles until the end of muscular contraction is signaled by the reduction in intracellular calcium levels by sequestration into the sarcoplasmic reticulum.

The strength of the myocardial contraction is primarily mediated by the degree to which actin-binding sites are exposed. This depends on the affinity of troponin for calcium and the availability of calcium ions. The initial calcium ion influx is altered by cyclic AMP, stimulatory and inhibitory G-proteins, and acetylcholine. The magnitude of the calcium trigger determines the magnitude of the cytosolic calcium release from the sarcoplasmic reticulum. The rate of uptake of calcium from the cytosol is altered by cyclic AMP (Figure 3-8). Cyclic AMP can phosphorylate a portion of the troponin molecule, facilitating the rapid release of calcium, increasing the rate of relaxation of the actin-myosin complex.<sup>7,29</sup>

## The Cytoskeleton

Cytoskeletal elements include microfilaments composed of actin, intermediate filaments composed of desmin, and micro-tubules made of tubulin.<sup>30</sup> The cytoskeleton maintains cellular anatomy, transmits developed tension, and links adjacent myocytes. It also has a role in intracellular signaling. Cardiac myocytes are mechanically linked through the intercalated discs by the fascia adherens and desmosomes.<sup>31</sup> Sarcomere tension is transmitted through actin microfilaments to the fascia adherens of the intercalated discs. Intermediate filaments of adjacent cells are linked through desmosomes.

## Regulation of the Strength of Contraction by Initial Sarcomere Length

In cardiac muscle, the strength of contraction is related to resting sarcomere length (see also the Frank-Starling relationship in the following). Maximal contraction force occurs when the resting sarcomere length is between 2 and 2.4  $\mu\text{m}$ . At this length, there is optimal overlap of the actin and myosin maximizing the number of actin-myosin cross-bridges. Force declines at a greater sarcomere length, with decreased overlap of actin and myosin. In the heart, a decrease in contractility related to decreased overlap of the filaments does not seem to occur clinically, as the resting length of the cardiac sarcomere rarely exceeds 2.2 to 2.4  $\mu\text{m}$ . Once this length is reached, a stiff parallel elastic element prevents further dilation. If chamber dilation does occur, it appears to be primarily through slippage of fibers or myofibers rather than stretching of sarcomeres.<sup>1</sup> Stretching the myocardium increases contractility by increasing the sensitivity of troponin C to calcium. This length-dependent sensitivity to calcium is an important part of the ascending limb of the Starling curve observed in the intact ventricle. Two known factors that contribute to control of length-dependent activation are: (1) conformational changes in the lattice of titin fibers and (2) thin filament “on-off” equilibrium regulated by protein kinase A and protein kinase C.<sup>32</sup>

## THE PUMP

### Microscopic Architecture

Each myocyte is surrounded by a connective tissue framework called the endomysium. Groups of myocytes are joined within the perimysium, and the entire muscle within the epimysium. Muscle bundles are anchored in the fibrous skeleton at the base of the heart. Muscle bundles spiral around the cavity in overlapping patterns.

### Macroscopic Architecture

The geometry of each ventricle is adapted to the function required of it. The left ventricle, which must eject against high pressure, is conical in shape with inlet and outlet adjacent at the base of the cone. Cavity volume is reduced during systole by a combination of concentric contraction and wall thickening, the latter predominating. The right ventricle wraps around the left ventricle, its cavity is crescent shaped with separated points of inflow and outflow. Cavity reduction is primarily a result of concentric contraction of the right ventricular free wall against the septum.

## Mechanics

### CLINICALLY MEASUREABLE PHYSIOLOGIC PARAMETERS

Cardiac surgeons can assess the function of the heart in a number of ways. Aortic, pulmonary artery, pulmonary capillary wedge, and central venous pressures can be measured directly. Cardiac output can be estimated using thermodilution or based on oxygen saturation measurements. From these direct measurements, other parameters can be derived—although less accurate because of the cumulative error of the measured parameters inherent in the calculation—such as pulmonary and systemic vascular resistance, and ventricular stroke work. Ejection fraction—defined as stroke volume/end-diastolic volume—can be estimated by echocardiography and ventriculography, but is subject to change based on loading conditions, heart rate, and degree of contractility. Although clinically useful, these parameters do not directly measure contractility.

### THE FRANK-STARLING RELATIONSHIP

Within physiologic limits, the heart functions as a sump pump. The heart has an intrinsic ability to increase systolic force in response to a rise in ventricular filling. The more the heart is filled during diastole, the greater the quantity of blood that will be pumped out of the heart during systole. Under normal circumstances, the heart pumps all the blood that comes back to it without excessive elevation of venous pressures. In the normal heart, as ventricular filling is increased, the strength of ventricular contraction increases. The influence of sarcomere length on the force of contraction is called the Frank-Starling relationship. This relationship for the left ventricle is depicted in Figure 3-10. Also depicted

**FIGURE 3-10** Starling curves for the left ventricle. The influence of four different states of neurohumoral stimulation on global ventricular performance is shown.

in Figure 3-10 are two other states, a condition of normal adrenergic stimulation and a condition of maximal adrenergic stimulation. Force is increased for the same resting conditions by adrenergic stimulation; this is a positive inotropic effect.

### PRELOAD: DIASTOLIC DISTENSIBILITY AND COMPLIANCE

Preload is the load placed on a resting muscle that stretches it to its functional length. In the heart, preload references the volume of blood in the cavity immediately prior to contraction (at end-diastole) because volume determines the degree of stretch imposed on the resting sarcomere. As volume cannot be easily assessed clinically, pressure is used as a surrogate; thus, the concept of preload is represented as the filling pressure of a chamber. The relationship between the end-diastolic pressure and the end-diastolic volume is complex. Several different diastolic pressure-volume relationships are shown in Figure 3-12 (green line). As end-diastolic volume increases, and the heart stretches, the end-diastolic pressure also increases. The compliance, or distensibility of the ventricle, is defined as the change in volume divided by the change in pressure. Conversely, the stiffness of the ventricle is the reciprocal of compliance, or the change in pressure divided by the change in volume.

A number of factors affect the diastolic pressure-volume relationship. A fibrotic heart, a hypertrophied heart, or an aging heart becomes increasingly stiff (Figure 3-12C and Figure 3-12E). In the case of fibrosis, this increasing stiffness is related to the development of a greater collagen network. In

the case of hypertrophy, this increased stiffness is related both to stiffening of the noncontractile components of the heart and also to impaired relaxation of the heart. Relaxation is an active, energy-requiring process. This process is accelerated by catecholamine stimulation, but is impaired by ischemia, hypothyroidism, and chronic congestive heart failure. Examination of the diastolic pressure-volume curves in Figure 3-12 reveals the importance of changes in diastolic distensibility in pathologic cardiac conditions.

### AFTERLOAD: VASCULAR IMPEDANCE

The afterload of an isolated muscle is the tension against which it contracts. In simplest terms, for the heart, the afterload is determined by the pressure against which the ventricle must eject. The greater the afterload, the more mechanical energy that must be imparted to the blood mass (potential energy) to begin ejection. In addition to the potential energy imparted to the ejected blood by a change in pressure, the contracting left ventricle generates kinetic energy which overcomes the compliance of the distensible aorta and systemic arterial tree to move the blood into the arterial system. The energy necessary for this flow to occur is relatively small (potential energy  $\gg$  kinetic energy). Resistance, which equals the change in pressure divided by cardiac output, reflects the potential energy imparted to blood. To accurately describe the forces overcome to eject blood from the ventricle, the compliance of the vascular system and kinetic energy imparted must also be considered: the impedance of the vascular system (commonly, but less accurately referred to as aortic impedance). Compliance reflects the capacity of the vascular system to accept the volume of ejected blood. When the vascular system is very compliant, resistance  $\approx$  impedance. As compliance decreases (eg, with arteriosclerosis), resistance is less than impedance.<sup>33</sup> The interaction of resistance and compliance define the dicrotic notch, marking end-systole, closure of the aortic valve, on the aortic pressure tracing (Figure 3-11).

### THE CARDIAC CYCLE

Multiple parameters of the cardiac cycle are represented in Figure 3-11. By convention the cardiac cycle begins at end-diastole (ED), just prior to electrical activation of the ventricle. As the heart contracts, intracavitary pressure closes the mitral valve, then rapidly increases until the systemic diastolic pressure is reached (isovolumic contraction) and the aortic valve opens. Ejection begins and the intracavitary pressure continues to rise then fall as the ventricular volume decreases (ejection). When ejection ceases and the aortic valve closes, intracavitary pressure decreases rapidly until the mitral valve opens (isovolumic relaxation). Once the mitral valve opens, the ventricle fills rapidly, then more slowly as the intracavitary pressure slightly increases from distension prior to atrial systole (diastolic filling phase). The completion of atrial systole is the end of ventricular diastole. Atrial systole serves to increase the preload of the ventricle at a given systemic venous pressure.

**FIGURE 3-11** Temporal correlation of left atrial and ventricular, aortic, and systemic venous pressures, aortic flow, left ventricular volume, and surface electrocardiogram.

A conceptual understanding of the venous pressure changes is important in diagnosing certain pathologic processes. The right atrial pressure is easily measured and pulmonary capillary wedge pressure is reflective of left atrial pressure. The “a” wave corresponds to atrial systole as pressure increases at end-diastole to complete ventricular filling. The “c” wave reflects pressure pushing the atrioventricular (AV) valve back into the atrium as the ventricular pressure rises then falls during systole. The “x” descent results from atrial relaxation and downward displacement of the AV valve with

ventricular emptying. The “v” wave reflects the increasing atrial pressure from filling before the AV valve opens. The “y” descent is caused by rapid emptying of the atrium after the AV valve opens. Characteristic changes in these waveforms are used to diagnose and differentiate constrictive and restrictive processes, as discussed elsewhere in the text. A prominent left atrial “v” wave suggests mitral regurgitation.

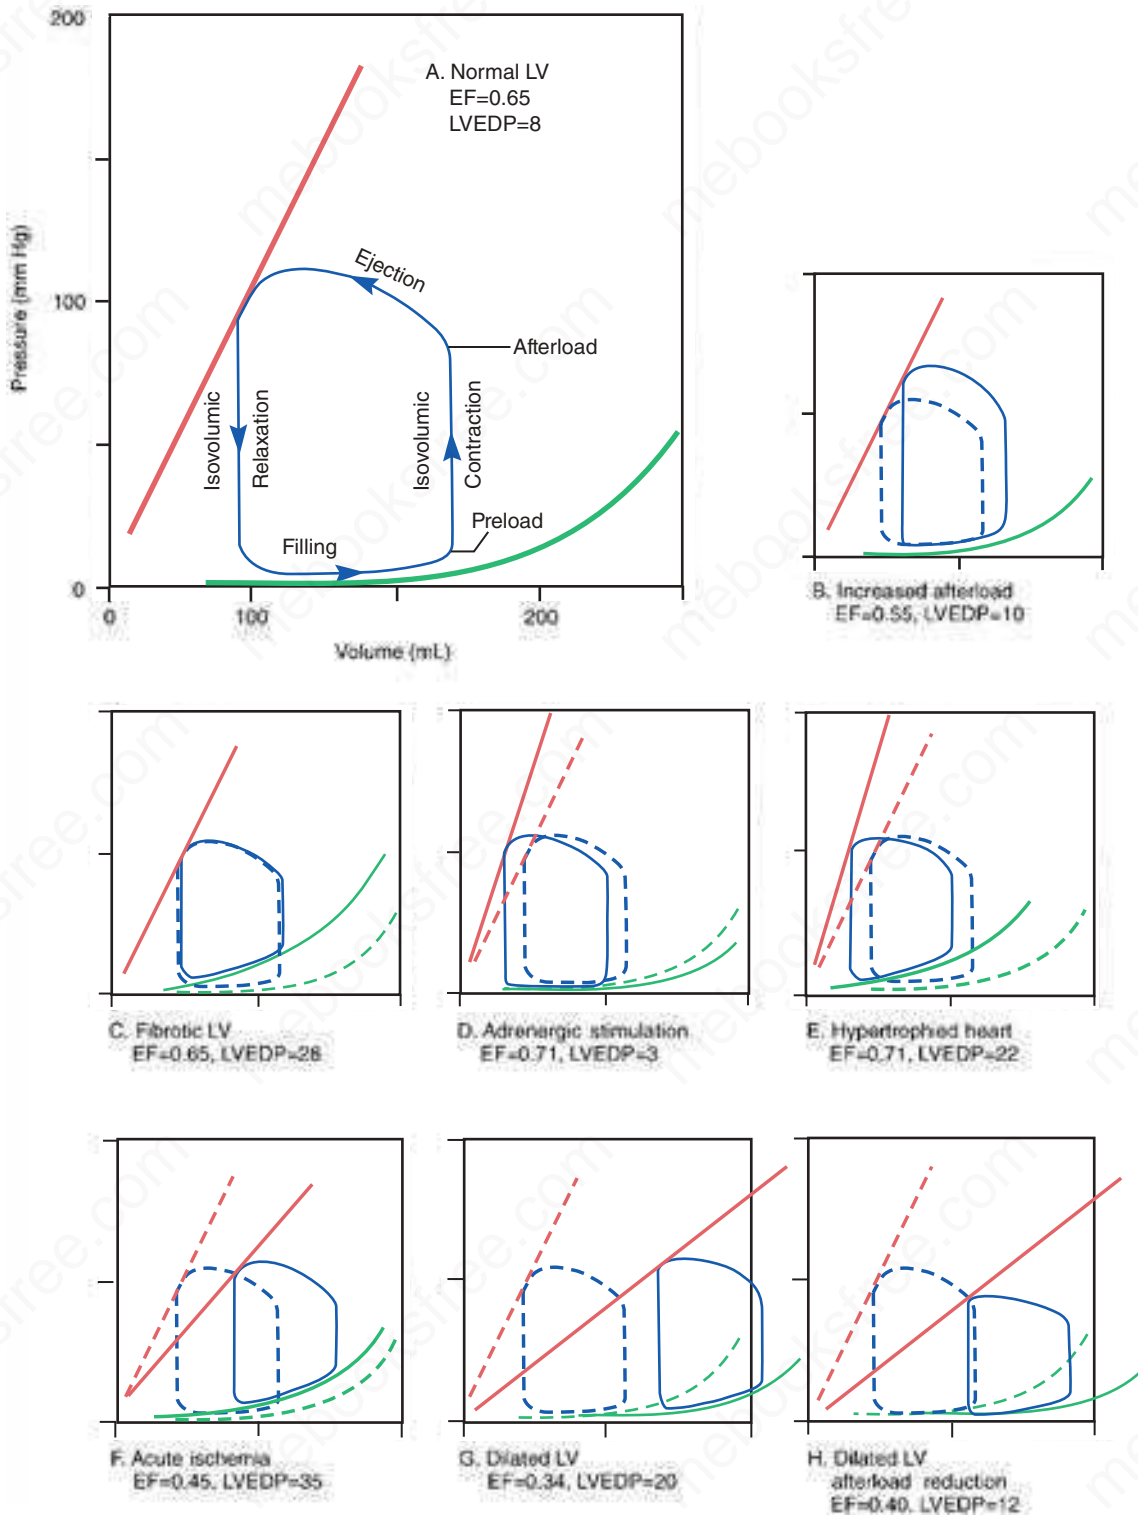

### VENTRICULAR PRESSURE-VOLUME RELATIONSHIPS

The function of the heart can be described and quantified based on the relative intraventricular pressure and volume during the cardiac cycle (Figure 3-12). Based on this relationship, various measures can be derived to assess cardiac performance. The ventricular pressure-volume relationship derives from the Frank-Starling relationship of sarcomere length and peak developed force: The force and extent of contraction (stroke volume) is a function of end-diastolic length (volume).

End-diastole (ED) is represented at the lower right corner of the loop in Figure 3-12A. The pressure-volume loop then successively tracks changes through isovolumic contraction (up to the upper right corner); ejection (left to the upper left corner, which represents end-systole [ES]); isovolumic relaxation (down to the bottom left corner); then filling (right to the lower right corner). Descriptive data to assess ventricular function are derived from the end-systolic pressure-volume point located in the upper left corner of the loop, and end-diastolic pressure-volume point located in the lower right corner of the loop. The area within the pressure-volume loop represents the internal work of the chamber.

### CONTRACTILITY

The term contractility (inotropic state) refers to the intrinsic performance of the ventricle for a given preload, afterload, and heart rate. Otherwise stated, contractility refers to all the factors that impact cardiac performance independent of the acute effects of preload, afterload, and heart rate. In the purest sense, at a level of constant contractility, increased preload will increase cardiac output and stroke volume; increased afterload will decrease cardiac output and stroke volume; and increased heart rate (assuming adequate time for complete diastolic filling) will increase cardiac output without changing stroke volume. Although the inotropic state impacts cardiac output, it is difficult to quantify in clinically useful terms. For research purposes, the pressure-volume relationship can be used to quantify contractility by deriving the end-systolic pressure-volume relationship (ESPVR): contractility is reflected in the slope ( $E_{ES}$ ) and volume axis intercept ( $V_0$ ) of the ESPVR (Figure 3-13). Holding afterload and heart rate constant, a series of pressure-volume loops are inscribed during transient preload reduction induced by temporary vena caval occlusion; the area of the loops decreases and the loops are shifted to the left. The progressive pressure-volume points at end systole are then linearized to derive the ESPVR. Within

**FIGURE 3-12** Left ventricular pressure-volume curves for various physiologic and pathologic conditions. (Detailed descriptions are in the text.) The bold curved line at the bottom of each loop series represents the diastolic pressure-volume relationship. The straight line located on the upper left side of each loop series is the end-systolic pressure-volume relationship. The stroke volume for each curve has been arbitrarily set at 75 mL. Systolic aortic pressure is 115 mm Hg in all curves except *B* (increased afterload, systolic pressure 140 mm Hg) and *H* (reduced afterload, systolic pressure 90 mm Hg) (EF = ejection fraction; LV = left ventricle; LVEDP = left ventricular end-diastolic pressure), in mm Hg.

**FIGURE 3-13** Two series of declining left ventricular pressure-volume loops generated during transient bicaval occlusion. Loops were generated in normal left ventricles (normal) and after 30 minutes of global normothermic ischemia and subsequent reperfusion (*dashed lines*). The end-systolic pressure-volume points from each series are connected by a line generated by linear regression. The end-diastolic pressure-volume relationship indicating chamber stiffness (inverse of compliance) is generated by fitting the end-diastolic point from each loop to an exponential curve. The volume axis intercept ( $V_0$ ) is shown in the inset. A negative inotropic effect (ie, ischemia-reperfusion) is characterized by a decrease in the ESPVR slope, while a positive inotropic state is characterized by an increase in ESPVR slope. Notice that the  $V_0$  for these conditions are in close proximity (*inset*). In some cases, a negative inotropic state is associated with a decrease in slope and an increase in  $V_0$ .

a clinical range of systolic pressures (80 to 120 mm Hg), the end-systolic pressure-volume line is largely linear. An increase in inotropic state of the left ventricle is expressed as an increase in  $E_{ES}$  and sometimes a decrease in  $V_0$ . Conversely, a decrease in inotropic state is expressed as a decrease in  $E_{ES}$  and sometimes an increase in  $V_0$  (Figure 3-13). As the ESPVR describes systolic function, the end-diastolic pressure volume relationship (EDPVR) (Figure 3-13) describes ventricular diastolic compliance (more specifically, the inverse of the slope of the EDPVR is compliance) a measure of lusitropy. The EDPVR is impacted by calcium uptake, ease of dissociation of contractile proteins, the cytoskeleton, ventricular wall thickness, and the pericardium.

Pressure-volume loops can be used to analyze various physiologic situations. Increased afterload (Figure 3-12B) moves the end-systolic pressure-volume point slightly upward and to the right. If stroke volume is maintained, end-diastolic volume must increase. Thus, though contractility is unchanged, ejection fraction is slightly decreased. Figure 3-12C shows the effect of a decrease in ventricular compliance (increased EDPVR) such as may result from hypertrophy, fibrosis, or cardiac tamponade. Systolic function is maintained ( $E_{ES}$  and  $V_0$  are unchanged), and stroke volume and ejection fraction can be maintained but require an increased end-diastolic pressure. The positive inotropic (increased  $E_{ES}$ ) and lusitropic (decreased EDPVR) effects

of adrenergic stimulation (Figure 3-12D), at constant stroke volume, shift the pressure-volume loop to the left, and increase the ejection fraction. In the hypertrophied heart (Figure 3-12E), in contrast to Figure 3-12C, diastolic compliance is decreased and systolic contractility is increased. A constant stroke volume leads to an increase in end-diastolic filling pressure and decreased end-diastolic volume. The pressure-volume loop shifts to the left with an increase in ejection fraction. The ability of the hypertrophied heart to increase stroke volume is limited. Acute ischemia (Figure 3-12F) decreases diastolic compliance (increases EDPVR) and contractility. The pressure-volume loop shifts to the right and up to maintain stroke volume, consistent with the clinical observation of an acute decrease in ejection fraction and increase in left ventricular filling pressure. In the dilated heart of chronic congestive heart failure (Figure 3-12G), the pressure-volume loop is shifted to the right. Note that the slope of the diastolic pressure-volume curve (EDPVR) changes little; rather the curve shifts to the right. The end-diastolic pressure is not increased because of a change in compliance; instead, to maintain stroke volume, the pressure-volume loop has moved upward on the compliance curve. Contrast this with the fibrotic process discussed in the preceding. The effect of afterload reduction on the chronically failing heart from Figure 3-12G is demonstrated in Figure 3-12H. Note that the ESPVR, EDPVR, and

**FIGURE 3-14** Plot of hypothetical measurement of preload recruitable stroke work.

stroke volume are unchanged. The pressure volume loop has moved back to the left, decreasing both the degree of chamber dilatation, end-diastolic pressure, and ejection fraction. A positive inotropic agent would shift the ESPVR line to the left (toward the dashed line), and the degree of dilatation would be reduced and both stroke volume and ejection fraction would be increased. It is important to remember that these relationships are idealized and may not completely reflect true clinical responses. For example, reduced diastolic dilatation from afterload reduction could return the ventricle to a state of improved intrinsic contractility. Despite these interactions, the pure concepts discussed here are very helpful in understanding the response of the heart to clinical interventions.

Another index of contractility, perhaps less influenced by other parameters, is the preload recruitable stroke work (PRSW) relationship. Stroke work is the area of the pressure-volume loop. For each pressure-volume loop derived by vena caval occlusion, the stroke work is plotted relative to its end-diastolic volume<sup>34</sup> (Figure 3-14). The slope of the derived linear relationship is a measure of contractility independent (within physiologic ranges) of preload and afterload. The PRSW relationship reflects overall performance of the left ventricle, combining systolic and diastolic components.<sup>35</sup>

### CLINICAL INDICES OF CONTRACTILITY

Clearly, from the preceding discussion, the degree of contractility can be assessed, but unlike blood pressure, an ideal number or range to describe it cannot be derived. Because ESPVR and PRSW are unique for each ventricle, these parameters more accurately measure changes in contractility. The greatest impediment to the clinical application of the ESPVR and PRSW is the difficulty measuring ventricular volume and inducing preload reduction to derive the pressure-volume loops. More easily measurable indices of contractility have been actively sought.

Ejection fraction is used by many clinicians as a measure of contractility. However, as noted in the discussion of Figure 3-12, ejection fraction is influenced by preload and afterload alterations without any change in contractility. Depending on loading conditions, hearts with a lower ejection fraction can produce a greater cardiac output. Although roughly indicative of cardiac reserve, ejection fraction is an inconsistent marker for overall cardiac function perioperatively but is a useful, gross measure of cardiac reserve.

### MYOCARDIAL WALL STRESS

The left ventricle is a pressurized, irregularly shaped chamber. During systole, wall stress develops to overcome afterload and eject the blood. The pressure within the chamber and the geometry of the ventricle determine the tension in the wall. A model of the ventricle as a cylinder can be used to examine the effects of chamber size and wall thickness on wall stress. In this model, circumferential stress is based on the law of Laplace:

$$\sigma = \frac{Pr}{w}$$

where  $\sigma$  is wall stress ( $\approx$  tension),  $P$  is transmural pressure,  $r$  is radius, and  $w$  is wall thickness. This relationship has several important clinical implications. Wall tension must be balanced by the energy available. The only nutrient nearly completely extracted from the blood by the heart is oxygen and wall tension is the primary determinant of oxygen consumption. In one scenario, the heart can compensate for changes in wall stress. If systolic pressure within the ventricle is chronically increased (aortic stenosis or systemic hypertension), then compensatory hypertrophy or thickening of the ventricular wall can return systolic wall stress close to normal. However, as detailed in Figure 3-12E, the price paid is that end-diastolic pressures must be higher.

In another scenario, the function of a heart that has dilated for other reasons is further compromised by the relationship between wall stress and oxygen consumption. As a result of or to compensate for systolic failure, the ventricle will dilate. The increased diastolic diameter proportionally increases wall stress and oxygen consumption. The ability of the heart to increase cardiac output in response to exercise will be limited, leading to symptoms.

### Right Ventricular Physiology

The left and right ventricles are anatomically partnered, sharing the septum, and physiologically partnered by the serial flow of blood. Changes affecting one chamber can impact the other. Many of the physiologic aspects discussed previously are easily adapted to the left ventricle because of its conical shape and axial symmetry. The right ventricular geometry is more complex since it wraps around the left ventricle and the chamber is crescent shaped in the axial plane. Though the septum contributes to right ventricular ejection most

of the decrease in chamber volume during systole is due to free wall contraction. The thinner right ventricular free wall and conus have one-sixth the muscle mass of the left ventricle. The right ventricle functions under lower pressure conditions and operates at volumes slightly greater than the left ventricle. The right ventricular end-diastolic volume is greater than that of the left ventricle. Likewise right ventricular ejection fraction is lower. The lower limit of normal for the right ventricle ranges from 40 to 45%.

The pulmonary circulation determines right ventricular afterload. The pulmonary vascular bed is a highly compliant, low-pressure, low-resistance system. Pulmonary vascular resistance is impacted by hypoxia (vasoconstriction), hypercarbia (vasoconstriction), nitric oxide (vasodilation), prostaglandins (vasodilation), and endothelins (vasoconstriction).

### Ventricular Interdependence

Functionally, the cardiac ventricles can be viewed as two hydraulic pumps in series, one coupled to a highly compliant pulmonary vasculature and the other matched to a less compliant systemic circulation. However, the ventricles have common structural elements and are contained within the non-compliant pericardium. The right ventricle, in particular, relies on the left ventricle to maintain its functional geometry. This anatomic and functional arrangement creates direct and serial interactions between the two chambers when an acute or chronic hemodynamic perturbation impacts either ventricle. Acute changes in ventricular interaction can include a shift of the septum towards one chamber in response to sudden volume overload; and enlargement of one chamber impacting diastolic filling of the other in the confined pericardial space. Clinical examples include: (1) massive right ventricular distension and reduced left ventricular filling in the setting of an acute pulmonary embolus; and (2) right ventricular dysfunction after left ventricular assist device implant due to septal shift and changes in right ventricular cavity geometry.

## ENERGETICS

### Chemical Fuels

Nearly all chemical energy used by the heart is generated by oxidative phosphorylation. Anaerobic metabolism is very limited because anaerobic enzymes are not present in sufficient concentrations. The major fuels for the myocardium are carbohydrates (glucose and lactate) and free fatty acids. When sufficient oxygen is present, these fuels are used to generate ATP. Most of the ATP used by the heart (60 to 70%) is expended in the cyclic contraction of the muscle. Ten to fifteen percent is required for maintaining the concentration gradients across the cell membrane; the rest is used in the constant uptake and release of calcium by mitochondria, the breakdown and regeneration of glycogen, and the synthesis of triglycerides.

The heart is quite flexible in the aerobic state in its use of fuels. In the fasting state, lipids may account for 70% of the fuel used by the heart. When present in adequate amounts, fatty acids will inhibit use of glucose by the heart.<sup>36</sup> After a high carbohydrate meal, blood glucose and insulin levels are high and free fatty acids are low, and glucose accounts for close to 100% of the metabolism. During exercise, elevated lactate levels inhibit the uptake of free fatty acids and carbohydrates, mostly lactate, can account for up to 70% of the metabolism.<sup>37</sup>

Whatever the fuel source, oxygen is necessary for its efficient utilization. In the absence of oxygen, there are two mechanisms to provide ATP, glycolysis and conversion of phosphate stored in creatine phosphate, since free fatty acids and the by-products of glycolysis cannot be metabolized. Glycolysis is very inefficient—for 1 mol of glucose, 2 mol of ATP are produced by anaerobic glycolysis, compared with 38 moles of ATP with aerobic metabolism. Phosphate stored in creatine phosphate can convert ADP to ATP, but this is not stored in significant amounts.

The availability of ADP is the primary determinant of the rate of oxidative phosphorylation. With ischemia and hypoxia, ATP breaks down to ADP and subsequently to AMP, adenosine, and inosine. The nucleoside building blocks of ATP, adenosine, inosine, and hypoxanthine are lost from the ischemic myocardium. If oxygen is restored, ATP levels can be partially restored rapidly by salvage pathways with inosine, hypoxanthine, or inosine monophosphate. However, *de novo* synthesis of ATP is also required and can take hours or even days to restore significant ATP levels. Glycolysis becomes the primary, albeit inefficient source of ATP with ischemia; this leads to an increase in lactate. The increase in lactate and inorganic phosphate causes acidosis. Acidosis slows glycolysis by reducing the activity of 6-phosphofructo-1-kinase, the rate-limiting enzyme in the glycolytic pathway.<sup>38</sup> The excess protons compete with calcium-binding sites, interfering with contraction and relaxation. Nevertheless, ATP generated by glycolysis maintains cell viability. Glucose, insulin, and potassium support glycolysis and may be the source of the benefit of administering this combination after an ischemic insult.<sup>39</sup>

### Determinants of Oxygen Consumption

Because nearly all the energy used by the heart is generated by oxidative metabolism, the rate of oxygen consumption ( $\dot{M}vO_2$ ) is indicative of the metabolic rate of the heart:

$$\dot{M}vO_2 = \frac{CaO_2 - CvO_2}{CBF} / \text{Mass}$$

where  $\dot{M}vO_2$  is myocardial oxygen consumption,  $CaO_2$  is arterial oxygen content in mL  $O_2$ /100mL blood,  $CvO_2$  is coronary venous oxygen content in mL  $O_2$ /100 mL blood, CBF is coronary blood flow in mL/min. Because the bulk of the energy is expended on contraction, changes in the rate

of oxygen consumption of the heart are directly related to changes in the contraction cycle and workload. Energy utilization can be increased by an increase in cardiac workload or a decrease in the efficiency of conversion of chemical to mechanical energy.

Minute work of the heart is the product of heart rate, stroke volume, and developed pressure. A change in each of these factors alters oxygen demand; however, minute work is not the direct determinant of oxygen consumption. The primary determinant of oxygen demand is the wall tension or stress developed in each cardiac cycle. Indeed, during the period of isovolumic contraction, energy is expended by the heart without the delivery of any kinetic energy to the blood.<sup>40</sup> The energetic cost of ejecting blood from the ventricular chamber is approximately 20 to 30% of that required for isovolumic contraction. To restate this simply, the principal determinant of the cardiac energy requirement is the pressure against which blood is ejected and the volume ejected at that pressure. An increase in afterload requires greater energy than an increase in volume ejected. Oxygen consumption is also increased as the heart dilates and begins ejection from a greater diastolic volume.

Cardiac efficiency relates oxygen consumption to cardiac work. Hence, cardiac efficiency =  $\text{work}/\text{M}\dot{\text{V}}\text{O}_2$ . The overall efficiency of the heart ranges from 5 to 40%, depending on the type of work (pressure versus volume versus velocity) performed.<sup>41-44</sup> The low efficiency of the heart is caused by the expenditure of a predominant portion of the oxygen consumed in generating pressure and stretching internal elastic components of the myocardium during isovolumic systole (a form of internal work). The velocity of shortening, affected in part by the inotropic state of the myocardium, also is not factored into the work equation, but contributes significantly to oxygen consumption. Dilatation of the ventricle reduces efficiency because as cavity size increases the reduction in wall stress with ejection is decreased.

Following cardiac surgery, cardiac efficiency generally decreases because of the increase in  $\text{M}\dot{\text{V}}\text{O}_2$  relative to the cardiac work performed. The additional oxygen consumed may result from an increase in basal metabolism and/or an increase in the cost of the excitation-contraction process, or inefficiencies of ATP production at the mitochondrial level.

A clear understanding of the role of wall tension and its relation to oxygen demand is essential in cardiac surgery. Excessive systemic pressure may place inordinate energy demands on a compromised ventricle. An intra-aortic balloon pump may shift the energy balance by reducing afterload and improving coronary blood flow. Ventricular distension during the weaning process after removal of the aortic cross-clamp, or with heart failure may create wall stress that outstrips the capacity to deliver oxygen to the myocardium. In the failing heart, where stroke volume is reduced, cardiac output is maintained by increasing heart rate, which increases the percentage of time that the myocardial wall stress is elevated, reduces

the time when diastolic blood flow occurs, and creates an imbalance between oxygen demand and delivery.

## FUNCTIONAL RESPONSES TO METABOLIC DEMANDS<sup>45</sup>

There are three distinct responses to altered metabolic demands. Two are responses to acute short-term alterations; the third is a response to chronic alterations in metabolic demands.

### Acute Physiologic Responses

These responses consist of intrinsic physiologic adaptations to acute changes in hemodynamics and metabolic demands. Generally, these responses are regulated by changes in end-diastolic volume mediated by changes in preload and afterload. Beat-to-beat responses to changes in end-diastolic volume are important to equalizing the output of the ventricles.

### Alterations of Biochemical Functions

Contractility (inotropy) and relaxation (lusitropy) change in response to altered metabolic demands. These are principally mediated by alterations in calcium fluxes in the myocyte.<sup>46</sup> The principal determinant of calcium concentration is the flux across the sarcoplasmic reticulum membrane. The fluxes are determined by the amount of calcium in the sarcoplasmic reticulum and the amount of calcium crossing the plasma membrane to stimulate calcium release. Reduced ATP levels inhibit calcium release and uptake. Enzymatic phosphorylation of myosin can increase the rate of cross-bridge cycling, and phosphorylation of troponin I facilitates relaxation.<sup>47</sup> Acidosis reduces contraction and relaxation by inhibiting many calcium pumps, channels, and exchangers.<sup>48</sup>

### Altered Gene Expression

Chronic changes in metabolic demands will provoke proliferative responses leading to altered gene expression. These include changes in the types of myosin and actin and changes in the number of membrane channels and pumps.

## CORONARY BLOOD FLOW

### Normal Coronary Blood Flow

Resting coronary blood flow is slightly less than 1 mL per gram of heart muscle per minute. This blood flow is delivered to the heart through large epicardial conductance vessels and then into the myocardium by penetrating arteries leading to a plexus of capillaries. The bulk of the resistance to coronary flow is in the penetrating arterioles (20 to 120  $\mu\text{m}$  in size). Because the heart is metabolically very active, there is a high density of capillaries such that there is approximately one capillary for every myocyte, with an intercapillary distance at rest of

approximately 17  $\mu\text{m}$ . Capillary density is greater in subendocardial myocardium compared with subepicardial tissue. When there is an increased myocardial oxygen demand, myocardial blood flow can increase to three or four times the normal (coronary flow reserve). This is accomplished by vasodilation of the resistance vessels and recruitment of additional capillaries (many of which are closed in the resting state). Capillary recruitment is important in decreasing the intercapillary distance and the distance that oxygen and nutrients must diffuse through the myocardium.

The blood flow pattern from a coronary artery perfusing the left ventricle, measured by flow probe, is phasic in nature, with greater blood flow occurring in diastole than in systole.<sup>49</sup> The cyclic contraction and relaxation of the left ventricle produces this phasic blood flow pattern by extravascular compression of the arteries and intramyocardial microvessels during systole. There is a gradient in these systolic extravascular compressive forces, being greater than or equal to intracavitary pressure in the subendocardial tissue, and decreasing toward the subepicardial tissue. Measurement of transmural blood flow distribution during systole shows that subepicardial vessels are preferentially perfused, whereas subendocardial vessels are significantly hypoperfused. Toward the end of systole, blood flow actually reverses in the epicardial surface vessels.<sup>50</sup> Hence, the subendocardial myocardium is perfused primarily during diastole, whereas subepicardial myocardium is perfused during both systole and diastole. A greater capillary density per square millimeter in the subendocardium compared with the subepicardial tissue facilitates the distribution of blood flow to the inner layer of myocardium.<sup>51</sup> The subendocardium is at greater risk of dysfunction, tissue injury, and necrosis during any reduction in perfusion. This is related to: (1) the greater systolic compressive forces; (2) the smaller flow reserve resulting from a greater degree of vasodilation; and (3) the greater regional oxygen demands owing to wall tension and segmental shortening. If end-diastolic pressure is elevated to 25, 30, or 35 mm Hg, then there is diastolic as well as systolic compression of the subendocardial vasculature. Flow to the subepicardium is effectively autoregulated as long as the pressure in the distal coronary artery is above approximately 40 mm Hg. Flow to the subendocardium, however, is effectively autoregulated only down to a mean distal coronary artery pressure of approximately 60 to 70 mm Hg. Below that level, local coronary flow reserve in the subendocardium is exhausted, and local blood flow decreases linearly with decreases in distal coronary artery pressure. Subendocardial perfusion is further compromised by pathologic processes that increase wall thickness and systolic and diastolic wall tension. Aortic regurgitation particularly threatens the subendocardium, because systemic diastolic arterial pressure is reduced and intraventricular systolic and diastolic pressures are elevated.<sup>49,52</sup>

In contrast to the phasic nature of blood flow in the left coronary artery, blood flow in the right coronary artery is relatively constant during the cardiac cycle. The constancy of blood flow is related to the lower intramural pressures and the near absence of extravascular compressive forces in the right ventricle compared with the left ventricle.

## Control of Coronary Blood Flow

Coronary blood flow is tightly coupled to the metabolic needs of the heart. Under normal conditions, 70% of the oxygen available in coronary arterial blood is extracted, near the physiologic maximum. Any increase in oxygen delivery comes mostly from an increase in blood flow. To maximize efficiency, local coronary blood flow is precisely controlled by a balance of vasodilator and vasoconstrictor mechanisms, including: (1) a metabolic vasodilator system; (2) aneurogenic control system; and (3) the vascular endothelium.<sup>53</sup> Blood flow is controlled by moment-to-moment adjustment of coronary tone of the resistance vessels, that is, arterioles and precapillary sphincters.

The metabolic vasodilator mechanism responds rapidly when local blood flow is insufficient to meet metabolic demand. The primary mediator is adenosine generated within the myocyte and released into the interstitial compartment. Adenosine relaxes arteriolar smooth muscle cells by activation of  $A_2$  receptors. Adenosine is formed when the oxygen supply cannot sustain the rapid rephosphorylation of ADP to ATP. Once sufficient oxygen is supplied to the myocardium, less adenosine is formed. Adenosine is therefore the coupling agent between oxygen demand and supply. Other local vasodilators that influence coronary blood flow are carbon dioxide, lactic acid, and histamine.

The sympathetic nervous system acts through alpha receptors (vasoconstriction) and beta receptors (vasodilation). There are direct innervations of the large conductance vessels and lesser direct innervations of the smaller resistance vessels. Sympathetic receptors on the smooth muscle cells of the resistance vessels respond to humoral catecholamines. Alpha receptors predominate over beta receptors such that when norepinephrine is released from the sympathetic nerve endings, vasoconstriction ordinarily occurs.

Endothelium-dependent regulation of coronary artery blood flow is a dynamic balance between vasodilating and vasoconstricting factors. Vasodilators include nitric oxide (NO) synthesized from L-arginine by endothelial nitric oxide synthase, and endothelially released adenosine. The principal vasoconstrictor is the endothelially derived constricting peptide endothelin-1. Other vasoconstrictors include angiotensin II and superoxide free radical.<sup>54</sup> NO is dominant in the local regulation of coronary arterial tone. NO is released by the coronary vascular endothelium by both soluble factors (acetylcholine, adenosine, and ATP) and mechanical signals (shear stress and pulsatile stress secondary to increased intraluminal blood flow). If the endothelium is intact, acetylcholine from the sympathetic nerves causes vasodilation through generation of NO. If the endothelium is not functionally intact, acetylcholine causes vasoconstriction by direct stimulation of the vascular smooth muscle. NO is a potent inhibitor of platelet aggregation and neutrophil function (superoxide generation, adherence, and migration), which has implications in the anti-inflammatory response to ischemia-reperfusion and cardiopulmonary bypass.

Endothelin-1 interacts principally with specific endothelin receptors,  $ET_A$ , on vascular smooth muscle, and causes smooth muscle vasoconstriction. Endothelin-1 counteracts the vasodilator effects of endogenous adenosine, NO, and prostacyclin ( $PGI_2$ ). Endothelin-1 is rapidly synthesized in the vascular endothelium, particularly during ischemia, hypoxia, and other stress conditions, where it acts in a paracrine fashion. ET-1 has a short half-life (4 to 7 minutes), which exceeds that of adenosine (8 to 12 seconds) and NO (microseconds). However, the avid binding of ET-1 to  $ET_A$  receptors prolongs its effects beyond its half-life. Human coronary arteries demonstrate abundant endothelin-1 binding sites, suggesting that ET-1 has an important role in the control of coronary blood flow in humans.<sup>55</sup> The levels of ET-1 have been observed to increase with myocardial ischemia-reperfusion and after cardiac surgery.

Under ordinary circumstances the metabolic vasodilator system is the dominant force acting on the resistance vessels. For example, the increased metabolic activity caused by sympathetic stimulation leads to vasodilation of the coronary arterioles through the metabolic system, despite a direct vasoconstriction effect of norepinephrine.<sup>56-58</sup>

Coronary artery blood flow is also determined by perfusion pressure. However, in the coronary vasculature blood flow can remain constant over a range of perfusion pressures. The control mechanisms described allow autoregulation of blood flow adjusting vascular resistance to match blood flow requirements. The autoregulatory “plateau” occurs between approximately 60 and 120 mm Hg perfusion pressure. If distal coronary artery perfusion pressure is reduced by a critical stenosis or hypotension, vasodilator capacity will be exhausted and coronary blood flow will decrease, following a linear relationship with perfusion pressure. Because the subendocardial region of the left ventricle has a lower coronary vascular reserve, maximal dilation is reached in this region before the subepicardial tissue, and a preferential hypoperfusion of the subendocardial tissue results.

## Hemodynamic Effect of Coronary Artery Stenosis

Surgically treatable atherosclerotic disease primarily affects the large conductance vessels of the heart. The hemodynamic effect of a stenosis is determined by Poiseuille’s law, which describes the resistance of a viscous fluid to laminar flow through a cylindrical tube; specifically:

$$Q = \frac{\pi(\Delta P)}{8\eta} \cdot \frac{r^4}{l}$$

where  $Q$  is the flow,  $\Delta P$  is the pressure change,  $\eta$  is the viscosity,  $r$  is the radius, and  $l$  is the length of the resistance segment. Resistance (pressure change/flow):

$$R = \frac{(\Delta P)}{Q} = \frac{8\eta}{\pi} \cdot \frac{l}{r^4}$$

is inversely proportional to the *fourth* power of the radius and directly proportional to the length of the narrowing. Therefore, a small change in diameter has a magnified effect on vascular resistance (Table 3-2). Conductance vessels are sufficiently large that a 50% reduction in the diameter of the vessel has minimal hemodynamic effect. A 60% reduction in the diameter of the vessel has only a very small hemodynamic effect. As the stenosis progresses beyond 60%, small decreases in diameter have significant effects on blood flow. For a given segment length, an 80% stenosis has a resistance that is 16 times greater a 60% stenosis. For a 90% stenosis, the resistance is 256 times greater than for a 60% stenosis.<sup>59</sup> Furthermore, for successive stenoses in the same vessel the resistance is additive. An additional factor in resistance to flow is turbulence. Stenotic lesions can cause conversion from laminar to turbulent flow.<sup>60</sup> With laminar flow the pressure drop is proportional to flow rate  $Q$ ; with turbulent flow pressure drop is

**TABLE 3-2: Effect of Degree and Length of Stenosis on Resistance to Flow Based on Poiseuille’s Law**

% Stenosis of a 1-cm-diameter vessel	Radius (in cm)	Proportional resistance for various segment lengths (cm)		
		0.25 cm	1 cm	2 cm
0	0.5	1	4	8
50	0.25	16	64	128
60	0.2	39	156	313
70	0.15	123	494	988
80	0.1	625	2500	5000
90	0.05	10000	40000	80000
Proportional increase in resistance 80% versus 60% stenosis				16
Proportional increase in resistance 90% versus 60% stenosis				256

The value for a reference vessel of length 0.25 cm with 0% stenosis (in the box) is set to 1 for comparison.

proportional to  $Q^2$ . For all of these reasons, patients who have had a small progression in the degree of coronary stenosis may experience a rapid acceleration of symptoms.

Atherosclerosis also alters normal vascular regulatory mechanisms. The endothelium is often destroyed or damaged, so vasoconstrictor mechanisms are relatively unopposed by the impaired vasodilator mechanism; constriction is exaggerated and responses to stimuli that require dilatation are blunted.<sup>61</sup>

As noted, when a stenosis is less than 60%, little change in flow is noted. This is due to compensation by the coronary flow reserve of the resistance vessels distal to the stenotic conductance vessel. As resistance to flow is additive, a decrease in distal resistance will balance an increase in proximal resistance and flow will be unchanged. As flow reserve decreases, any stimulus that increases myocardial oxygen demand (such a tachycardia, hypertension, or exercise) cannot be met by dilation of the distal vasculature, and myocardial ischemia results.<sup>53</sup>

In the human, coronary arterial vessels are end vessels with little collateral flow between major branches except in pathologic situations. With sudden coronary occlusion, although there is usually modest collateral flow through very small vessels (20 to 200  $\mu\text{m}$  in size), this flow is generally insufficient to maintain cellular viability. Collateral flow gradually begins to increase over the next 8 to 24 hours, doubling by about the third day after total occlusion. Collateral blood flow development appears to be nearly complete after 1 month, restoring normal or nearly normal resting flow to the surviving myocardium in the ischemic region. Previous ischemic events or gradually developing stenoses can lead to larger pre-existing collaterals in the human heart. The presence of these pre-existing collaterals has been shown to be important in the prevention of ischemic damage if coronary occlusion should occur.<sup>62</sup>

## Endothelial Dysfunction

As previously noted, nitric oxide, adenosine, and endothelin-1 are synthesized and released by the endothelium.<sup>63,64</sup> Ischemia-reperfusion, hypertension, diabetes, and hypercholesterolemia can impair generation of NO and vasoconstriction may predominate, mediated by the relative overexpression of endothelin-1. Reperfusion after temporary myocardial ischemia is one situation in which NO production may be impaired, leading to a vicious cycle in which the vasodilator reserve of the resistance vessels is reduced with a consequent and progressive “low-flow” or “no-flow” phenomenon. The coronary vascular NO system may also be impaired in some cases after coronary artery bypass surgery.

The endothelium helps prevent cell-cell interactions between blood-borne inflammatory cells (ie, leukocytes and platelets) that initiate a local or systemic inflammatory reaction. Inflammatory cascades occur with sepsis, ischemia-reperfusion, and cardiopulmonary bypass. Under normal conditions, the vascular endothelium resists interaction with neutrophils and platelets by tonically releasing adenosine and NO, which have potent antineutrophil and platelet inhibitory

effects. Damage to the endothelium lowers the resistance to neutrophil adhesion. Neutrophils can damage the endothelium by adhesion to its surface, and subsequent release of oxygen radicals and proteases. This amplifies the inflammatory response and decreases the tonic generation and release of adenosine and NO, which then permits further interaction with activated inflammatory cells. The products released by activated neutrophils have downstream physiologic consequences on other tissues, notably the heart, including increasing vascular permeability, creating blood flow defects (no-reflow phenomenon), and promoting the pathogenesis of necrosis and apoptosis.<sup>65</sup>

The triggers of these inflammatory reactions in the heart include cytokines (IL-1, IL-6, IL-8), complement fragments (C3a, C5a, membrane attack complex), oxygen radicals, and thrombin, which upregulate adhesion molecules expressed on both inflammatory cells (CD11a/CD18) and endothelium (P-selectin, E-selectin, and intercellular adhesion molecule-1 (ICAM-1)). The release of cytokines and complement fragments during cardiopulmonary bypass activates the vascular endothelium on a systemic basis, which contributes to the inflammatory response to cardiopulmonary bypass.<sup>66</sup> Both adenosine and NO have been used therapeutically to reduce the inflammatory responses to cardiopulmonary bypass, and to reduce ischemic-reperfusion injury and endothelial damage.<sup>67,68</sup>

## The Sequelae of Myocardial Hypoperfusion: Infarction, Myocardial Stunning, and Myocardial Hibernation

As oxygen delivery is reduced, contraction strength decreases rapidly (within 8 to 10 heart beats). This is seen acutely in response to ischemia and is rapidly reversed with reperfusion. If the extent of reduction of coronary blood flow is severe, mild-to-moderate abnormalities in cellular homeostasis occur. Reduced cellular levels of ATP lead to a loss of adenine nucleotides from the cell. If the reduction in coronary flow is sustained, progressive loss of adenine nucleotides and the elevation of intracellular and intramitochondrial calcium may lead to cellular death and subsequent necrosis. Increased intramitochondrial calcium uncouples oxidative phosphorylation, creating a vicious cycle.<sup>69</sup> If the myocyte is reperfused before subcellular organelles are irreversibly damaged, the myocyte may slowly recover. A period of days is necessary for full recovery of myocyte ATP levels as adenine nucleotides must be resynthesized. During this time contractile processes are impaired. This impairment is related to reversible damage to the contractile proteins such that their responsiveness to cytosolic levels of calcium is diminished. The magnitude of the cytosolic pulse of calcium with each heartbeat appears to be nearly normal, but the magnitude of the consequent contraction is greatly reduced. Over a period of 1 to 2 weeks this myocardium gradually recovers. This viable but dysfunctional myocardium is called stunned myocardium.<sup>70-72</sup>

With chronic hypoperfusion, oxygen delivery is at a reduced level but above the level required for cell viability. This can cause a chronic hypocontractile state known as hibernation. Hibernation appears to be associated with a decrease in the magnitude of the pulse of calcium involved in the excitation-contraction process such that the calcium levels developed within the cytosol during each heartbeat are inadequate for effective contraction to occur. Histologic examination shows islets in the subendocardium where there is a loss of contractile proteins, sarcoplasmic reticulum, and alterations of other subcellular structures.<sup>73,74</sup> With reperfusion, hibernating myocardium can very quickly resume normal and effective contraction, though complete recovery may be delayed for several months.<sup>70,75-77</sup> This is of particular importance for patients with poor ventricular function but viable heart muscle.<sup>78</sup>

Reperfusion of acutely ischemic myocardium may cause further cellular damage and necrosis rather than lead to immediate recovery. The etiology of reperfusion injury is multifactorial. Damaged endothelium in the reperfused region fails to prevent adhesion and activation of leukocytes and platelets. Oxygen-free radicals are released. Derangement of the ATP-dependent sodium-potassium pump disrupts cell volume regulation with consequent leakage of water into the cell, explosive cell swelling, and rupture of the cell membrane. Techniques applied to reduce reperfusion injury, minimize adverse sequelae, and preserve myocytes include leukocyte depletion or inactivation, prevention of endothelial activation, free radical scavenging, reperfusion with solutions low in calcium content, and reperfusion with hyperosmolar solutions.<sup>79,80</sup> Both adenosine and low-dose NO are potent cardioprotective agents that attenuate neutrophil-mediated damage, infarction, and apoptosis.<sup>81</sup>

The metabolic changes that occur with ischemia-reperfusion represent a complex system of adaptive mechanisms that allow the myocyte to survive despite a temporary reduction in oxygen delivery. These adaptive mechanisms may be triggered by a very brief coronary occlusion (as short as 5 minutes) such that the negative sequelae of a subsequent prolonged coronary occlusion are greatly minimized. This phenomenon has been called ischemic preconditioning. A coronary occlusion that might cause as much as 40% myocyte death in a region subjected to prolonged ischemia may be reduced to only 10% myocyte death if the prolonged period of ischemia is preceded by a 5-minute interval of “preconditioning” coronary occlusion.<sup>79,82,83</sup>

## PHYSIOLOGY OF HEART FAILURE

### Definition and Classification

Heart failure is the inability of the heart to deliver adequate blood to the tissues to meet end-organ metabolic needs at rest or during mild to moderate exercise. Processes that cause heart failure can impair systolic function (the ability to contract and empty) or diastolic function (the ability to relax and

fill) or both. The acute and chronic stages of a myocardial infarction involving a large area of the left ventricle cause systolic heart failure. The acute loss of contractile function compromises the ability of the ventricle to maintain a normal stroke volume (Figure 3-12F). As the infarction heals, the adaptive response of ventricular dilation reduces the heart's systolic functional reserve. Cardiomyopathies affect the myocardium globally leading to reduced systolic function. Long-standing valvular insufficiency alters ventricular geometry and muscular function leading to ventricular failure. In all these examples, the left ventricle dilates, which causes the pressure-volume relationship of the left ventricle to shift to the right (Figure 3-12G). In these situations, the diastolic portion of the pressure-volume curves is not greatly changed. However, the global systolic performance of the heart (ie, the ability to pump blood) maybe inadequate to meet even resting needs.<sup>84,85</sup>

Diastolic failure may occur without an impairment of systolic contractility if the myocardium becomes fibrotic or hypertrophied, or if there is an external constraint on filling such as with pericardial tamponade.<sup>86</sup> Increased stiffness of the left ventricular myocardium is associated with an excessive upward shift in the diastolic pressure-volume curve (Figure 3-12C and Figure 3-12E). The most common cause of increased myocardial stiffness is chronic hypertension with consequent left ventricular hypertrophy and diastolic stiffness (related both to myocyte hypertrophy and increased fibrosis of the ventricle).<sup>87,88</sup>

It should be noted from these examples that although one process may predominate, most patients with heart failure manifest both systolic and diastolic dysfunction.

### Early Cardiac and Systemic Sequelae of Heart Failure

The adaptive homeostatic reactions of the body leading to heart failure depend on the duration of the ongoing pathologic process. When cardiac function acutely deteriorates and cardiac output diminishes, neurohumoral reflexes attempt to restore both cardiac output and blood pressure. Activation of the sympathetic adrenergic system in the heart and in the peripheral vasculature causes systemic vasoconstriction and increases heart rate and contractility. A variety of mediators formed during this adaptive stage, including norepinephrine, angiotensin II, vasopressin, B-type natriuretic peptide, and endothelin, not only promote renal retention of salt and water leading to volume expansion but also cause vasoconstriction. Aldosterone output is increased, conserving sodium. The concerted responses of the adrenergic system and the renin-angiotensin system alter the primary determinants of stroke volume and cardiac output—preload, afterload, and contractility. The heart responds to loss of systolic function by progressively dilating. This dilation leads to preservation of stroke volume by Frank-Starling mechanisms but increased stroke volume is achieved at the expense of ejection fraction, as shown in Figure 3-12G, as a right shift in

the pressure-volume relationship of the left ventricle with an increase in end-diastolic volume (and pressure). In addition to a global dilation response, acute alterations in cardiac geometry may occur early after a large myocardial infarction, with thinning of the left ventricular wall in the region of the infarct as well as expansion of overall left ventricular cavity size. As volume expansion occurs, production of the cardiac atrial natriuretic peptide is increased, which tends to prevent excessive sodium retention and inhibit activation of the renin-angiotensin and aldosterone systems.<sup>89-93</sup>

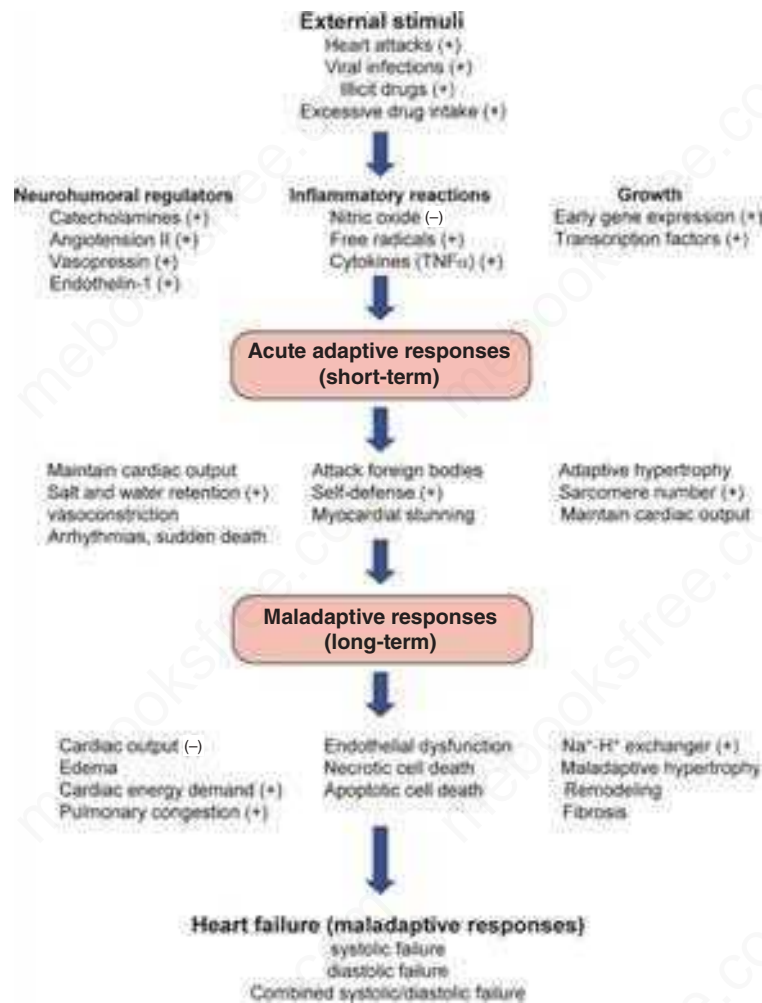

### Cardiac and Systemic Maladaptive Consequences of Chronic Heart Failure

The acute phase response is initially beneficial but becomes maladaptive and contributes to long-term problems in patients with heart failure (Figure 3-15). In the latter stages of heart failure, the kidneys tend to retain sodium and

become hyporesponsive to atrial natriuretic peptide and B-type natriuretic peptide.<sup>90</sup> Desensitization of beta-adrenergic receptors is a consequence of sustained stimulation with a reduced response to elevated circulating catecholamine levels.<sup>19</sup>

Left ventricular dilation is caused by hypertrophy of the myocytes as well as lengthening of the myocytes as sarcomeres are added. However, there is significant slippage of myofibrils leading to dilation without an increase in the number of myocytes. Progressive dilation of the heart leads to an increase in oxygen consumption during systole. Ventricular remodeling leads to progressive fibrosis.

Angiotensin and aldosterone stimulate collagen formulation and proliferation of fibroblasts in the heart, leading to an increase in the ratio of interstitial tissue to myocardial tissue in the noninfarcted regions of the heart.<sup>94</sup> The impact of aldosterone has been documented by the effectiveness of aldosterone receptor antagonists in improving the morbidity and mortality of patients with heart failure.<sup>95</sup>

**FIGURE 3-15** Pathophysiology of heart failure from stimulus (etiology) to acute adaptive and chronic maladaptive responses. (+) Indicates positive stimulation; (-) indicates negative factors that tend to reduce stimulation of heart failure.

The progressive fibrosis leads to increased diastolic stiffness which limits diastolic filling and increase end-diastolic pressure. Fibrosis and increased ventricular size predispose to reentry ventricular arrhythmias that are a common cause of death in the late stages of heart failure.<sup>96</sup> Hence, heart failure progresses as a result of a vicious cycle of left ventricular dilatation and remodeling, responses that decrease cardiac performance further.

Evidence has accumulated over the past decade that suggests endothelial dysfunction, release of cytokines, and apoptotic cell death may participate in the development of heart failure as a maladaptive reaction (Figure 3-15). Reduced availability of nitric oxide and increased production of vasoconstrictor agents such as endothelin and angiotensin II has been reported in failing hearts.<sup>97</sup> Heart failure is often accompanied by changes in the endogenous antioxidant defense mechanisms of the heart as well as evidence of oxidative injury to the myocardium. Cytokines, released from systemic and local inflammatory responses in the failing heart, directly activate inflammatory cells to release superoxide radicals and cause endothelial dysfunction by augmenting inflammatory cell-endothelial cell interactions. Cytokines may also directly induce necrotic and apoptotic myocyte cell death.<sup>98</sup>

Cardiac secretion of B-type natriuretic peptide (BNP) has been shown to be increased with heart failure. BNP is a cardiac neurohormone released as proBNP that is enzymatically cleaved to N-terminal-proBNP and BNP upon ventricular myocyte stretch. The physiologic effects of BNP include natriuresis, vasodilation and neurohumoral changes. Measurement of plasma BNP is a useful and cost-effective marker for heart failure.<sup>99</sup> Other factors rather than stretch may stimulate BNP release including fibrosis, arrhythmias, ischemia, endothelial dysfunction, and cardiac hypertrophy.

## ACKNOWLEDGMENTS

The authors would like to acknowledge the work of the authors of this chapter in the 2nd edition, Jakob Vinten-Johansen, Zhi-Qing Zhao, and Robert A. Guyton. The current revision was based on the solid foundation they had prepared.

# Cardiac Surgical Pharmacology

Jerrold H. Levy • Jacob N. Schroder • James G. Ramsay

Clinical pharmacology associated with cardiac surgery is an important part of patient management. Patients in the perioperative period receive multiple therapeutic agents that affect cardiovascular and pulmonary functions. This chapter summarizes the pharmacology of the agents commonly used for treating the primary physiologic disturbances associated with cardiac surgery, hemodynamic instability, respiratory insufficiency, and alterations of hemostasis. For cardiovascular drugs, the common theme is that pharmacologic effects are produced by intracellular ion fluxes.

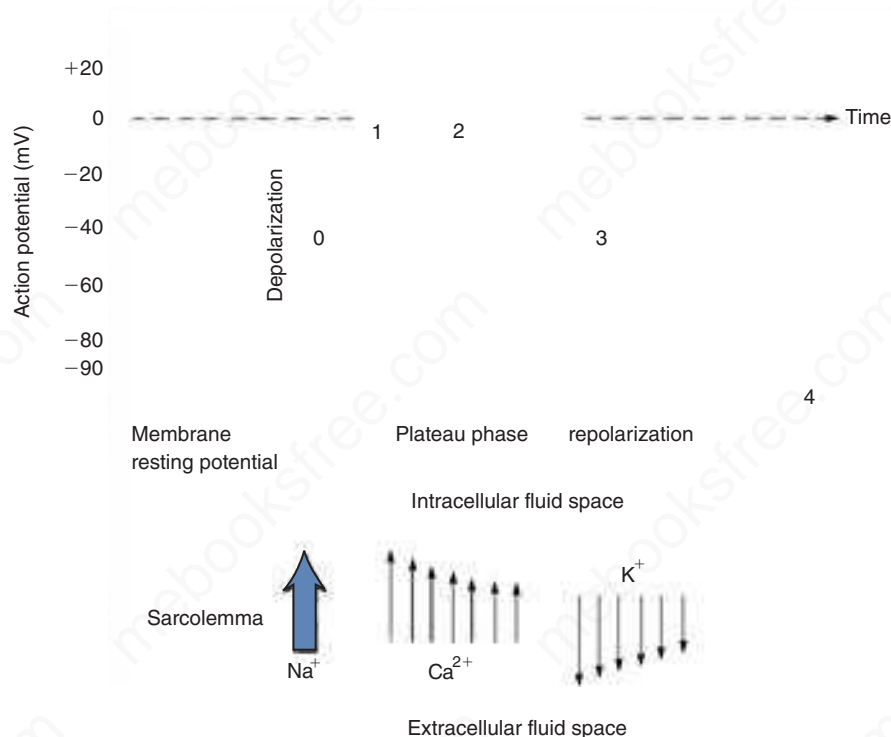

Several basic subcellular/molecular pathways are important in cardiovascular pharmacology, as shown in Fig. 4-1. The action potential in myocardial cells is a reflection of ion fluxes across the cell membrane, especially  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Ca}^{2+}$ .<sup>1,2</sup> Numerous drugs used to control heart rate and rhythm act by altering  $\text{Na}^+$  (eg, lidocaine and procainamide),  $\text{K}^+$  (eg, amiodarone, ibutilide, and sotalol), or  $\text{Ca}^{2+}$  (eg, diltiazem) currents. Calcium also has a dominant effect on the inotropic state but by highly specialized intracellular mechanisms.<sup>3,4</sup>

Myocardial contractility is a manifestation of the interaction of actin and myosin, with conversion of chemical energy from adenosine triphosphate (ATP) hydrolysis into mechanical energy. The interaction of actin and myosin in myocytes is inhibited by the associated protein tropomyosin. This inhibition is “disinhibited” by intracellular calcium. A similar situation occurs in vascular smooth muscle, where the interaction of actin and myosin (leading to vasoconstriction) is modulated by the protein calmodulin, which requires calcium as a cofactor. Thus intracellular calcium has a “tonic” effect in both the myocardium and vascular smooth muscle.

Numerous drugs used perioperatively alter intracellular calcium.<sup>3,4</sup>

Catecholamines (eg, norepinephrine, epinephrine, and dobutamine) with beta 1 agonist activity regulate intramyocyte calcium levels via the nucleotide cyclic adenosine monophosphate (cyclic AMP) (Fig. 4-2). Beta agonists bind to receptors on the cell surface that are coupled to the intracellular enzyme adenylate cyclase via the stimulatory transmembrane GTP-binding protein. This leads to increased cyclic AMP synthesis, and cyclic AMP, in turn, acts as a second messenger

for a series of intracellular reactions resulting in higher levels of intracellular calcium during systole. Less well known is that drugs with only alpha-adrenergic agonist activity also may increase intracellular  $\text{Ca}^{2+}$  levels, although by a different mechanism.<sup>5,6</sup> Although under investigation, the probable basis for the inotropic effect of alpha-adrenergic drugs is the stimulation of phospholipase C, which catalyzes hydrolysis of phosphatidyl inositol to diacylglycerol and inositol triphosphate (see Fig. 4-2). Both of these compounds increase the sensitivity of the myofilament to calcium, whereas inositol triphosphate stimulates the release of calcium from its intracellular storage site, the sarcoplasmic reticulum. There is still some debate about the mechanism for the inotropic effect of alpha-adrenergic agonists and its significance for the acute pharmacologic manipulation of contractility, but there is little debate about the importance of this mechanism in vascular smooth muscle, where the increase in intracellular calcium stimulated by alpha-adrenergic agonists can increase smooth muscle tone significantly. However, intracellular calcium in vascular smooth muscle is also controlled by cyclic nucleotides.<sup>7,8</sup> In contrast to the myocyte, in vascular smooth muscle, cyclic AMP has a primary effect of stimulating the uptake of calcium into intracellular storage sites, decreasing its availability (Fig. 4-3). Thus drugs that stimulate cyclic AMP production (beta agonists) or inhibit its breakdown (phosphodiesterase inhibitors) will cause vasodilation. In addition, cyclic guanosine monophosphate (cyclic GMP) also increases intracellular calcium storage (see Fig. 4-3), decreasing its availability for modulating the interaction of actin and myosin. Several commonly used pharmacologic agents act via cyclic GMP. For example, nitric oxide stimulates the enzyme guanylate cyclase, increasing cyclic GMP levels. Drugs such as nitroglycerin and sodium nitroprusside achieve their effect by producing nitric oxide as a metabolic product. Vasodilation is also produced by “cross-talk” between  $\text{K}^+$  and  $\text{Ca}^{2+}$  fluxes. Decreased levels of ATP, acidosis, and elevated tissue lactate levels increase the permeability of the ATP-sensitive  $\text{K}^+$  channel. This increased permeability results in hyperpolarization of the cell membrane that inhibits the entry of  $\text{Ca}^{2+}$  into the cell. This results in decreased vascular tone.

**FIGURE 4-1** Cardiac ion fluxes and the action potential. The resting membrane potential is largely a reflection of the intercellular/intracellular potassium gradient. Depolarization of the membrane during phase 4 triggers an initial fast sodium channel with overshoot (phase 0) followed by recovery (phase 1) to a plateau (phase 2) maintained by an inward calcium flux and then repolarization owing to an outward potassium flux (phase 3).

The simplistic overview of pathways of cardiac pharmacology as summarized in Figs. 4-1 through 4-3 also suggests the primary cause of difficulty in the clinical use of the drugs discussed in this chapter. The mechanisms of action for control of heart rate and rhythm, contractility, and vascular tone are interrelated. For example, beta-adrenergic agonists not only increase intracellular calcium to increase contractility, but they also alter  $K^+$  currents, leading to tachycardia. Catecholamines not only have beta-adrenergic agonist activity, with inotropic and chronotropic effects, but they also possess alpha-agonist activity, leading to increased intracellular calcium in vascular smooth muscle and vasoconstriction. Phosphodiesterase (PDE) inhibitors like milrinone not only increase contractility by increasing cyclic AMP in the myocyte, but they also cause vasodilation by increasing cyclic AMP in the vasculature. The interplay of the various mechanisms means the clinical art of cardiac surgical pharmacology lies as much in selecting drugs for their side effects as for their primary therapeutic effects.

## ANTIARRHYTHMICS

Arrhythmias are common in the cardiac surgical period. A stable cardiac rhythm requires depolarization and repolarization in a spatially and temporally coordinated manner, and dysrhythmias may occur when this coordination is disturbed. The mechanisms for arrhythmias can be divided into abnormal impulse initiation, abnormal impulse conduction, and

combinations of both.<sup>9,10</sup> Abnormal impulse initiation occurs as a result of increased automaticity (spontaneous depolarization of tissue that does not normally have pacemaking activity) or as a result of triggered activity from abnormal conduction after depolarizations during phase 3 or 4 of the action potential. Abnormal conduction often involves reentry phenomena, with recurrent depolarization around a circuit owing to unilateral conduction block in ischemic or damaged myocardium and retrograde activation by an alternate pathway through normal tissue. In this simplistic view, it is logical that dysrhythmias could be suppressed by slowing the conduction velocity of ectopic foci, allowing normal pacemaker cells to control heart rate, or by prolonging the action potential duration (and hence refractory period) to block conduction into a limb of a reentry circuit.

A scheme proposed originally by Vaughan Williams and modified subsequently<sup>11,12</sup> is used often to classify antidysrhythmic agents, and although alternative schemes describing specific channel-blocking characteristics have been proposed and may be more logical,<sup>13</sup> this discussion is organized using the Vaughan Williams system of four major drug categories. In this scheme, class I agents are those with local anesthetic properties that block  $Na^+$  channels, class II drugs are beta-blocking agents, class III drugs prolong action potential duration, and class IV drugs are calcium entry blockers. Amiodarone is discussed in detail owing to its expanding role in treating both supraventricular and ventricular arrhythmias and because its use has replaced

**FIGURE 4-2** Mediators of cardiac contractility. Myocardial contractility is a manifestation of the interaction of actin and myosin, which is facilitated by the binding of calcium to troponin C (TnC). Intercellular calcium levels are controlled by direct flux across the membrane, by cyclic AMP, and by inositol triphosphate (IP<sub>3</sub>) and diacylglycerol (DAG) produced by the action of phospholipase C (PLC). The synthesis of cyclic AMP is catalyzed by adenylate cyclase (AC), which is activated by binding of agonist to the beta-adrenergic receptor, and its breakdown is catalyzed by phosphodiesterase (PDE), which is inhibited by amrinone and milrinone. The action of PLC is activated by binding of agonist to the alpha-adrenergic receptor.

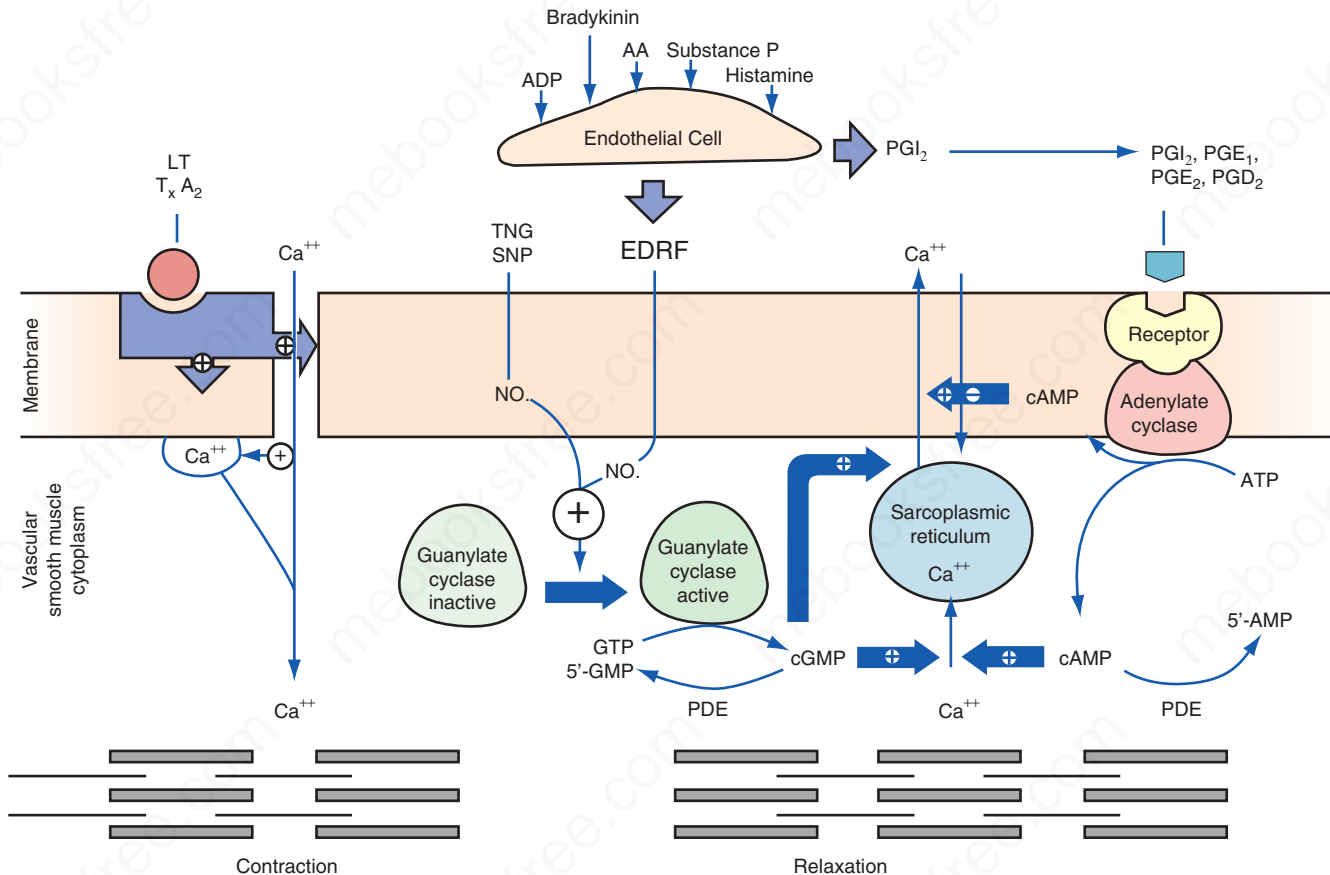

many of the previously used agents. Because of the efficacy of intravenous amiodarone and its recommendations in Advanced Cardiac Life Support (ACLS) guidelines, many of the older drugs used in cardiac surgery have a historical perspective and are considered briefly.

## Class I Agents

Although each of the class I agents blocks Na<sup>+</sup> channels, they may be subclassified based on electrophysiologic differences. These differences can be explained, to some extent, by consideration of the kinetics of the interaction of the drug and the Na<sup>+</sup> channel.<sup>14,15</sup> Class I drugs bind most avidly to open (phase 0 of the action potential; see Fig. 4-1) or inactivated (phase 2) Na<sup>+</sup> channels. Dissociation from the channel occurs during the resting (phase 4) state. If the time constant for dissociation is long in comparison with the diastolic interval

(corresponding to phase 4), the drug will accumulate in the channel to reach a steady state, slowing conduction in normal tissue. This occurs with class Ia (eg, procainamide, quinidine, and disopyramide) and class Ic (eg, encainide, flecainide, and propafenone) drugs. In contrast, for the class Ib drugs (eg, lidocaine and mexiletine), the time constant for dissociation from the Na<sup>+</sup> channel is short, the drug does not accumulate in the channel, and conduction velocity is affected minimally. However, in ischemic tissue, the depolarized state is more persistent, leading to greater accumulation of agent in the Na<sup>+</sup> channel and slowing of conduction in the damaged myocardium.

Procainamide is a class Ia drug that has various electrophysiologic effects.<sup>16</sup> Administration may be limited by the side effects of hypotension and decreased cardiac output.<sup>17,18</sup> The loading dose is 20 to 30 mg/min, up to 17 mg/kg, and should be followed by an intravenous infusion of 20 to

**FIGURE 4-3** Mediators of vascular tone. Cyclic AMP and cyclic GMP increase the uptake of calcium into cellular storage sites in vascular smooth muscle, leading to vasodilation. The synthesis of cyclic GMP is catalyzed by guanylate cyclase, which is activated by nitric oxide (NO), which, in turn, is produced by nitroglycerin (NTG) and sodium nitroprusside (SNP). Excessive vasodilation often is a reflection of other endogenous mediators such as prostaglandins ( $\text{PGI}_2$ ,  $\text{PGE}_1$ ,  $\text{PGE}_2$ , and  $\text{PGD}_2$ ) and thromboxane  $\text{A}_2$  ( $\text{TxA}_2$ ). Several mediators, such as arachidonic acid (AA), bradykinin, histamine, and substance P, stimulate the release of endothelium-derived relaxing factor (EDRF), which is identified with NO. (Reproduced with permission from Levy JH: *Anaphylactic Reactions in Anesthesia and Intensive Care*, 2nd ed. Boston, Butterworth-Heinemann, 1992.)

80 mg/kg per minute. Because procainamide prolongs action potential duration, widening of the QRS complex often heralds a potential overdose. The elimination of procainamide involves hepatic metabolism, acetylation to a metabolite with antiarrhythmic and toxic side effects, and renal elimination of this metabolite. Thus the infusion rate for patients with significant hepatic or renal disease should be at the lower end of this range.

Class Ib drugs include what is probably the best-known antiarrhythmic agent, lidocaine. As noted, lidocaine is a  $\text{Na}^+$  channel blocker that has little effect on conduction velocity in normal tissue but slows conduction in ischemic myocardium.<sup>14,15</sup> Other electrophysiologic effects include a decrease in action potential duration but a small increase in the ratio of effective refractory period to action potential duration. The exact role of these electrophysiologic effects on arrhythmia suppression is unclear. Lidocaine has no significant effects on atrial tissue, and it is not recommended for therapy in shock-resistant ventricular tachycardia/fibrillation (VT/VF) in the recent *Guidelines for Emergency Cardiovascular Care*.<sup>19</sup> After an initial bolus dose of 1 to 1.5 mg/kg of

lidocaine, plasma levels decrease rapidly owing to redistribution to muscle, fat, etc. Effective plasma concentrations are maintained only by following the bolus dose with an infusion of 20 to 50 mg/kg per minute.<sup>20</sup> Elimination occurs via hepatic metabolism to active metabolites that are cleared by the kidneys. Consequently, the dose should be reduced by approximately 50% in patients with liver or kidney disease. The primary toxic effects are associated with the central nervous system (CNS), and a lidocaine overdose may cause drowsiness, depressed level of consciousness, or seizures in very high doses. Negative inotropic or hypotensive effects are less pronounced than with most other antiarrhythmics. The other class Ib drugs likely to be encountered in the perioperative period are the oral agents tocainide and mexiletine, which have effects similar to lidocaine.<sup>15</sup>

The class Ic agents, including flecainide, encainide, and propafenone, markedly decrease conduction velocity.<sup>20,21</sup> The Cardiac Arrhythmia Suppression Trial (CAST) study<sup>20,21</sup> of moricizine found that although ventricular arrhythmias were suppressed, the incidence of sudden death was greater than with placebo with encainide and flecainide, and these drugs

are not in wide use. Propafenone is available for oral use in the United States, but IV form is available in Europe. The usual adult dose is 150 to 300 mg orally every 8 hours. It has beta-blocking (with resulting negative inotropic effects) as well as Na<sup>+</sup> channel-blocking activity; lengthens the PR, QRS, and QT duration; and may be used to treat both atrial and ventricular dysrhythmias.<sup>15</sup>

## Class II Agents

Beta-receptor-blocking agents are another important group of antiarrhythmic (denoted class II in the Vaughan Williams scheme). However, because of their use as antihypertensive as well as antiarrhythmic agents, they are discussed elsewhere in this chapter, and we will move on to consider bretylium, amiodarone, and sotalol, the class III agents in the Vaughan Williams scheme. These drugs have a number of complex ion channel-blocking effects, but possibly the most important activity is K<sup>+</sup> channel blockade.<sup>22</sup> Because the flux of K<sup>+</sup> out of the myocyte is responsible for repolarization, an important electrophysiologic effect of class III drugs is prolongation of the action potential.<sup>23</sup>

## Class III Agents

Ibutilide, dofetilide, sotalol, and bretylium are class III agents. Intravenous ibutilide and oral dofetilide are approved for the treatment of atrial fibrillation (AF) but carry the risk of torsades de pointes.<sup>24,25</sup> Sotalol is a nonselective beta-blocker that also has K<sup>+</sup> channel-blocking activity.<sup>26</sup> In the United States, it is now available for IV and previously for oral administration. The approved indication is for treating life-threatening ventricular arrhythmias, although it is effective against atrial arrhythmias as well. Bretylium is no longer available or recommended in the most recent American Heart Association (AHA) *Guidelines for Emergency Cardiovascular Care*.<sup>19</sup>

## Class IV Agents

Calcium entry blockers (class IV in the Vaughan Williams scheme), including verapamil and diltiazem, are antiarrhythmics. In sinoatrial (SA) and atrioventricular (AV) nodal tissues, Ca<sup>2+</sup> channels contribute significantly to phase 0 depolarization, and the AV nodal refractory period is prolonged by Ca<sup>2+</sup> entry blockade.<sup>27,28</sup>

This explains the effectiveness of verapamil and diltiazem in treating supraventricular arrhythmias. It is also clear why these drugs are negative inotropes. Both verapamil and diltiazem are effective in slowing the ventricular response to AF, flutter, and paroxysmal supraventricular tachycardia (SVT) and in converting to sinus rhythm.<sup>29-31</sup> Verapamil has greater negative inotrope effects than diltiazem; therefore, it is used rarely for supraventricular arrhythmias. The intravenous dose of diltiazem is 0.25 mg/kg, with a second dose of 0.35 mg/kg if the response is inadequate after 15 minutes. The loading dose should be followed by an infusion of 5 to 15 mg/h. Intravenous diltiazem, although useful for rate control, has

been replaced by intravenous amiodarone in clinical therapy of SVT and prophylaxis (see Amiodarone).

## Other Drugs

One of the difficulties of classifying antiarrhythmics by the Vaughan Williams classification is that not all drugs can be incorporated into this scheme. Three examples are digoxin, adenosine, and magnesium, each of which has important uses in the perioperative period.

Digoxin inhibits the Na<sup>+</sup>, K<sup>+</sup>-ATPase pump, leading to decreased intracellular K<sup>+</sup>, a less negative resting membrane potential, increased slope of phase 4 depolarization, and decreased conduction velocity. These direct effects, however, usually are dominated by indirect effects, including inhibition of reflex responses to congestive heart failure (HF) and a vagotonic effect.<sup>10,32</sup> The net effect is greatest at the AV node, where conduction is slowed and the refractory period is increased, explaining the effectiveness of digoxin in slowing the ventricular response to AF. The major disadvantages of digoxin are the relatively slow onset of action and many side effects, including proarrhythmia effects, and it is now used rarely for rate control in acute AF because of the advent of IV amiodarone and diltiazem.

Adenosine is an endogenous nucleoside that has an electrophysiologic effect similar to that of acetylcholine. Adenosine decreases AV node conductivity, and its primary antiarrhythmic effect is to break AV nodal reentrant tachycardia.<sup>33</sup> An intravenous dose of 100 to 200 μg/kg is the treatment of choice for paroxysmal SVT. Adverse effects, such as bronchospasm, are short-lived because its plasma half-life is so short (1 to 2 seconds). This short half-life makes it ideal for treating reentry dysrhythmia, in which transient interruption can fully suppress the dysrhythmia.

Appropriate acid-base status and electrolyte balance are important because electrolyte imbalance can perturb the membrane potential, leading to arrhythmia generation, as can altered acid-base status, by effects on K<sup>+</sup> concentrations and sympathetic tone. Therapy for dysrhythmia should include correction of acid-base and electrolyte imbalances. Magnesium supplementation should be considered.<sup>34</sup> Magnesium deficiency is common in the perioperative period, and magnesium administration has been shown to decrease the incidence of postoperative dysrhythmia.<sup>35</sup>

## Amiodarone

Intravenous amiodarone has become one of the most administered intravenous antiarrhythmics used in cardiac surgery because of its broad spectrum of efficacy. Amiodarone was developed originally as an antianginal agent because of its vasodilating effects, including coronary vasodilation.<sup>36</sup> It has various ion channel-blocking activities.<sup>10,29,36</sup> The resulting electrophysiologic effects are complex, and there are differences in acute intravenous and chronic oral administration. Acute intravenous administration can produce decreases in heart rate and blood pressure, but there are minimal changes

in QRS duration or QT interval. After chronic use, there may be significant bradycardia and increases in action potential duration in AV nodal and ventricular tissue, with increased QRS duration and QT interval.<sup>37-39</sup>

## Pharmacokinetics

Amiodarone is a complex highly lipophilic drug that undergoes variable absorption (35 to 65%) after oral administration and is taken up extensively by multiple tissues with interindividual variation and complex pharmacokinetics.<sup>38-40</sup> The short initial context-sensitive half-life after intravenous administration represents drug redistribution. The true elimination half-life for amiodarone is extremely long, up to 40 to 60 days. Because of the huge volume of distribution (~60 L/kg) and a long duration of action, an active metabolite loading period of several months may be required before reaching steady-state tissue concentrations. Further, in life-threatening arrhythmias, intravenous loading often is starting to establish initial plasma levels. Measuring amiodarone plasma concentrations is not useful owing to the complex pharmacokinetics and the metabolites of the parent drug. Plasma concentrations greater than 2.5 mg/L have been associated with an increased risk of toxicity. The optimal dose of amiodarone has not been well characterized and may vary depending on the specific arrhythmias treated. Further, there may be differences in dose requirements for therapy of supraventricular and ventricular arrhythmias.<sup>37-40</sup>

Because of these distinctive pharmacokinetic properties, steady-state plasma levels are achieved slowly. Oral administration for a typical adult consists of a loading regimen of 80 to 1600 mg/d (in two or three doses) for 10 days, 600 to 800 mg/d for 4 to 6 weeks, and then maintenance doses of 200 to 600 mg/d. For intravenous loading, specific studies will be reviewed, but the recommended dosing is 150 mg given over 10 minutes for acute therapy in an adult, followed first by a secondary loading infusion of 60 mg/h for 6 hours and then by a maintenance infusion of 30 mg/h to achieve a 1000 mg/d dosing.<sup>37-40</sup>

## Electrophysiology

The electrophysiologic actions of amiodarone are complex and incompletely understood. Amiodarone produces all four effects according to the Vaughan Williams classification. It also has been shown to have use-dependent class I activity, inhibition of the inward sodium currents, and class II activity.<sup>10</sup> The antiadrenergic effect of amiodarone, however, is different from that of beta-blocker drugs because it is noncompetitive and additive to the effect of beta-blockers. Amiodarone depresses SA node automaticity, which slows the heart rate and conduction and increases refractoriness of the AV node, properties useful in managing supraventricular arrhythmia. Its class III activity results in increases in atrial and ventricular refractoriness and prolongation of the QTc interval. The effects of oral amiodarone on SA and AV nodal function are maximal within 2 weeks, whereas the effects on

ventricular tachycardia (VT) and ventricular refractoriness emerge more gradually during oral therapy, becoming maximal after 10 weeks or more.

## Indications

The primary indication for amiodarone is VT or fibrillation.<sup>40-48</sup> It is also effective for the treatment of atrial dysrhythmias and in treating AF (see Atrial Fibrillation).

## Side Effects

Although there are numerous adverse reactions to amiodarone, they occur with long-term oral administration and are rarely associated with acute intravenous administration. The most serious is pulmonary toxicity, which has not been reported with acute administration in a perioperative setting. Some case series have reported an increased risk of marked bradycardia and hypotension immediately after cardiac surgery in patients already on amiodarone at the time of surgery.<sup>49,50</sup> Other case-control studies, however, have not reproduced this finding.<sup>51</sup> None of the placebo-controlled trials of prophylactic amiodarone for perioperative atrial fibrillation prevention report adverse cardiovascular effects, although bradycardia and hypotension are known side effects.<sup>52-56</sup> Case reports and case series of postoperative acute pulmonary toxicity are similarly lacking in the rigor of randomized, controlled methodology.

## PHARMACOLOGIC THERAPY OF SPECIFIC ARRHYTHMIAS

### Ventricular Tachyarrhythmias

Intravenous amiodarone is approved for rapid control of recurrent VT or VF. Three randomized controlled trials of patients with recurrent in-hospital, hemodynamically unstable VT or VF with two or more episodes within the past 24 hours who failed to respond to or were intolerant of lidocaine, procainamide, and (in two of the trials) bretylium have been reported.<sup>42,44,46</sup> Patients were critically ill with ischemic cardiovascular disease, 25% were on a mechanical ventilator or intraaortic balloon pump before enrollment, and 10% were undergoing cardiopulmonary resuscitation at the time of enrollment. One study compared three doses of IV amiodarone: 525, 1050, and 2100 mg/d.<sup>44</sup> Because of the use of investigator-initiated intermittent open-label amiodarone boluses for recurrent VT, the actual mean amiodarone doses received by the three groups were 742, 1175, and 1921 mg/d. There was no statistically significant difference in the number of patients without VT/VF recurrence during the 1-day study period: 32 of 86 (41%), 36 of 92 (45%), and 42 of 92 (53%) for the low-, medium-, and high-dose groups, respectively. The number of supplemental 150-mg bolus infusions of amiodarone given by blinded investigators was statistically significantly less in those randomized to higher doses of amiodarone.

A wider range of amiodarone doses (125, 500, and 1000 mg/d) was evaluated by Sheinman and colleagues, including a low dose that was expected to be subtherapeutic.<sup>46</sup> This stronger study design, however, also was confounded by open-label bolus amiodarone injections given by study investigators. There was, however, a trend toward a relationship between intended amiodarone dose and VT/VF recurrence rate ( $p = .067$ ). After adjustment for baseline imbalances, the median 24-hour recurrence rates of VT/VF, from lowest to highest doses, were 1.68, 0.96, and 0.48 events per 24 hours.

The third study compared two intravenous amiodarone doses (125 and 1000 mg/d) with bretylium (2500 mg/d).<sup>42</sup> Once again, the target amiodarone dose ratio of 8:1 was compressed to 1.8:1 because of open-label boluses. There was no significant difference in the primary outcome, which was median VT/VF recurrence rate over 24 hours. For low-dose amiodarone, high-dose amiodarone, and bretylium, these rates were 1.68, 0.48, and 0.96 events per 24 hours, respectively ( $p = .237$ ). There was no difference between high-dose amiodarone and bretylium; however, more than 50% of patients had crossed over from bretylium to amiodarone by 16 hours.

The failure of these studies to provide clear evidence of amiodarone efficacy may be related to the “active-control study design” used, a lack of adequate statistical power, high rates of supplemental amiodarone boluses, and high crossover rates. Nonetheless, these studies provide some evidence that IV amiodarone (1 g/d) is moderately effective during a 24-hour period against VT and VF.

### Sustained Monomorphic Ventricular Tachycardia and Wide QRS Tachycardia

Although the most effective and rapid treatment of any hemodynamically unstable sustained ventricular tachyarrhythmia is electrical cardioversion or defibrillation, intravenous antiarrhythmic drugs can be used for arrhythmia termination if the VT is hemodynamically stable. The *Guidelines for Emergency Cardiovascular Care*<sup>19</sup> has removed the former recommendation of lidocaine and adenosine use in stable wide QRS tachycardia, now labeled as “acceptable” but not primarily recommended (lidocaine) or not recommended (adenosine). Intravenous procainamide and sotalol are effective, based on randomized but small studies;<sup>10</sup> amiodarone is also considered acceptable.<sup>19</sup>

### Shock-Resistant Ventricular Fibrillation

The *Guidelines for Emergency Cardiovascular Care* recommends at least three shocks and epinephrine or vasopressin before any antiarrhythmic drug is administered.<sup>10,19</sup> No large-scale controlled, randomized studies have demonstrated efficacy for lidocaine, bretylium, or procainamide in shock-resistant VF,<sup>10,19</sup> and lidocaine and bretylium are no longer recommended in this setting.<sup>19</sup> Two pivotal studies have been reported recently studying the efficacy of agents in acute shock-resistant cardiac arrest.

The Amiodarone in the Out-of-Hospital Resuscitation of Refractory Sustained Ventricular Tachycardia (ARREST) study was randomized, double blind, and placebo controlled. The ARREST study in 504 patients showed that amiodarone 300 mg administered in a single intravenous bolus significantly improves survival to hospital admission in cardiac arrest still in VT or VF after three direct-current shocks (44% vs 34%;  $p < .03$ ).<sup>43</sup> Although the highest survival rate to hospital admission (79%) was achieved when the amiodarone was given within 4 to 16 minutes of dispatch, there was no significant difference in the proportional improvement in the amiodarone group compared with the placebo group when drug administration was delayed (up to 55 minutes). Amiodarone also had the highest efficacy in patients (21% of all study patients) who had a return of spontaneous circulation before drug administration (survival to hospital admission increased to 64% from 41% in the placebo group). Among patients with no return of spontaneous circulation, amiodarone only slightly improved outcome (38% vs 33%).

Dorian performed a randomized trial comparing intravenous lidocaine with intravenous amiodarone as an adjunct to defibrillation in victims of out-of-hospital cardiac arrest.<sup>48</sup> Patients were enrolled if they had out-of-hospital ventricular fibrillation resistant to three shocks, intravenous epinephrine, and a further shock or if they had recurrent ventricular fibrillation after initially successful defibrillation. They were randomly assigned in a double-blind manner to receive intravenous amiodarone plus lidocaine placebo or intravenous lidocaine plus amiodarone placebo. The primary end point was the proportion of patients who survived to be admitted to the hospital. In total, 347 patients (mean age  $67 \pm 14$  years) were enrolled. The mean interval between the time at which paramedics were dispatched to the scene of the cardiac arrest and the time of their arrival was  $7 \pm 3$  minutes, and the mean interval from dispatch to drug administration was  $25 \pm 8$  minutes. After treatment with amiodarone, 22.8% of 180 patients survived to hospital admission compared with 12.0% of 167 patients treated with lidocaine ( $p = .009$ ). Among patients for whom the time from dispatch to the administration of the drug was equal to or less than the median time (24 minutes), 27.7% of those given amiodarone and 15.3% of those given lidocaine survived to hospital admission ( $p = .05$ ). The authors concluded that compared with lidocaine, amiodarone leads to substantially higher rates of survival to hospital admission in patients with shock-resistant out-of-hospital ventricular fibrillation.

### Supraventricular Arrhythmias

A supraventricular arrhythmia is any tachyarrhythmia that requires atrial or AV junctional tissue for initiation and maintenance. It may arise from reentry caused by unidirectional conduction block in one region of the heart and slow conduction in another, from enhanced automaticity akin to that seen in normal pacemaker cells of the sinus node and in latent pacemaker cells elsewhere in the heart, or from triggered activity, a novel type of abnormally enhanced impulse

initiation caused by membrane currents that can be activated and inactivated by premature stimulation or rapid pacing.<sup>56-58</sup> Pharmacologic approaches to treating supraventricular arrhythmias, including AF, atrial flutter, atrial tachycardia, AV reentrant tachycardia, and AV nodal reentrant tachycardia, continue to evolve.<sup>56-60</sup> Because AF is perhaps the most common arrhythmia after cardiac surgery, this condition is emphasized in detail.

## Atrial Fibrillation

Atrial fibrillation is a common complication of cardiac surgery that increases the length of stay in the hospital with resulting increases in health-care resource utilization.<sup>56-61</sup> Advanced age, previous AF, and valvular heart operations are the most consistently identified risk factors for this arrhythmia. Because efforts to terminate AF after its initiation are problematic, current interests are directed at therapies to prevent postoperative AF. Most studies suggest that prophylaxis with antiarrhythmic compounds can decrease the incidence of AF, length of hospital stay, and cost significantly. Class III antiarrhythmic drugs (eg, sotalol and ibutilide) also may be effective but potentially pose the risk of drug-induced polymorphic VT (torsades de pointes). Newer intravenous agents including vernakalant were investigated but in the current Food and Drug Administration (FDA) era of drug safety concerns, antiarrhythmic agents are difficult to get approved. Defining which subpopulations benefit most from such therapy is important as older and more critically ill patients undergo surgery. Intravenous sotalol is currently available in the United States.

Amiodarone is also an effective approach for prophylactic therapy of AF. Intravenous amiodarone is an important consideration because loading with oral therapy is often not feasible in part owing to the time required. There also may be added benefits of prophylactic therapies in high-risk patients, especially those prone to ventricular arrhythmias (ie, patients with preexisting HF).

Two studies deserve mention regarding prophylaxis with amiodarone. To determine if IV amiodarone would prevent AF and decrease hospital stay after cardiac surgery, Daoud and colleagues assessed preoperative prophylaxis in 124 patients who were given either oral amiodarone (64 patients) or placebo (60 patients) for a minimum of 7 days before elective cardiac surgery.<sup>62</sup> Therapy consisted of 600 mg amiodarone per day for 7 days and then 200 mg/d until the day of discharge from the hospital. The preoperative total dose of amiodarone was  $4.8 \pm 0.96$  g over  $13 \pm 7$  days. Postoperative AF occurred in 16 of the 64 patients in the amiodarone group (25%) and 32 of the 60 patients in the placebo group (53%). Patients in the amiodarone group were hospitalized for significantly fewer days than were patients in the placebo group ( $6.5 \pm 2.6$  vs  $7.9 \pm 4.3$  days;  $p = .04$ ). Total hospitalization costs were significantly less for the amiodarone group than those for the placebo group ( $\$18,375 \pm \$13,863$  vs  $\$26,491 \pm \$23,837$ ;  $p = .03$ ). Guarneri and colleagues evaluated 300 patients randomized in

a double-blind fashion to IV amiodarone (1 g/d for 2 days) versus placebo immediately after open-heart surgery.<sup>54</sup> The primary end points of the trial were incidence of AF and length of hospital stay. AF occurred in 67 of 142 (47%) patients on placebo versus 56 of 158 (35%) on amiodarone ( $p = .01$ ). Length of hospital stay for the placebo group was  $8.2 \pm 6.2$  days, and  $7.6 \pm 5.9$  days for the amiodarone group. Low-dose IV amiodarone was safe and effective in reducing the incidence of AF after heart surgery but did not significantly alter length of hospital stay.

In summary, AF is a frequent complication of cardiac surgery. Many cases can be prevented with appropriate prophylactic therapy. Beta-adrenergic blockers should be administered to most patients without contraindication. Prophylactic amiodarone should be considered in patients at high risk for postoperative AF. The lack of data on cost-benefits and cost-efficiency in some studies may reflect the lack of higher-risk patients in the study. Patients who are poor candidates for beta-blockade may not tolerate sotalol, whereas amiodarone does not have this limitation. Additional studies also need to be performed to better assess the role of prophylactic therapy in off-pump cardiac surgery.

## INOTROPIC AGENTS

Some depression of myocardial function is common after cardiac surgery.<sup>63-65</sup> The etiology is multifactorial—preexisting disease, incomplete repair or revascularization, myocardial edema, postischemic dysfunction, reperfusion injury, etc—and usually is reversible. Adequate cardiac output usually can be maintained by exploiting the Starling curve with higher preload, but often the cardiac function curve is flattened, and it is necessary to use inotropic agents to maintain adequate organ perfusion.

The molecular basis for the contractile property of the heart is the interaction of the proteins actin and myosin, in which chemical energy (in the form of ATP) is converted into mechanical energy. In the relaxed state (diastole), the interaction of actin and myosin is inhibited by tropomyosin, a protein associated with the actin-myosin complex. With the onset of systole,  $Ca^{2+}$  enters the myocyte (during phase 1 of the action potential). This influx of  $Ca^{2+}$  triggers the release of much larger amounts of  $Ca^{2+}$  from the sarcoplasmic reticulum. The binding of  $Ca^{2+}$  to the C subunit of the protein troponin interrupts inhibition of the actin-myosin interaction by tropomyosin, facilitating the hydrolysis of ATP with the generation of a mechanical force. With repolarization of the myocyte and completion of systole,  $Ca^{2+}$  is taken back up into the sarcoplasmic reticulum, allowing tropomyosin to again inhibit the interaction of actin and myosin with consequent relaxation of contractile force. Thus inotropic action is mediated by intracellular  $Ca^{2+}$ .<sup>66</sup> A novel drug, levosimendan, currently under clinical development in the United States but approved in several countries, increases the sensitivity of the contractile apparatus to  $Ca^{2+}$ ,<sup>67</sup> whereas the positive inotropic agents available for clinical use achieve their end by increasing intracellular  $Ca^{2+}$  levels.

The first drug to be considered is simply  $\text{Ca}^{2+}$  itself. In general, administration of calcium will increase the inotropic state of the myocardium when measured by load-independent methods, but it also will increase vascular tone (afterload) and impair diastolic function. In addition, the effects of calcium on myocardial performance depend on the plasma  $\text{Ca}^{2+}$  concentration.  $\text{Ca}^{2+}$  plays important roles in cellular function, and the intracellular  $\text{Ca}^{2+}$  concentration is highly regulated by membrane ion channels and intracellular organelles.<sup>68,69</sup> If the extracellular  $\text{Ca}^{2+}$  concentration is normal, administration of  $\text{Ca}^{2+}$  will have little effect on the intracellular level and less pronounced hemodynamic effects. On the other hand, if the ionized plasma calcium concentration is low, exogenous calcium administration may increase cardiac output and blood pressure.<sup>70</sup> It also should be realized that even with normal plasma  $\text{Ca}^{2+}$  concentrations, administration of  $\text{Ca}^{2+}$  may increase vascular tone, leading to increased blood pressure but no change in cardiac output. This increased afterload, as well as the deleterious effects on diastolic function, may be the basis of the observation that  $\text{Ca}^{2+}$  administration can blunt the response to epinephrine.<sup>71</sup> Routine use of  $\text{Ca}^{2+}$  at the end of bypass should be tempered by the realization that  $\text{Ca}^{2+}$  may have little effect on cardiac output while increasing systemic vascular resistance, although this in itself may be of importance. If there is evidence of myocardial ischemia,  $\text{Ca}^{2+}$  administration may be deleterious because it may exacerbate both coronary spasm and the pathways, leading to cellular injury.<sup>72,73</sup>

Digoxin, although not effective as acute therapy for low-cardiac-output syndrome in the perioperative period, nevertheless well illustrates the role of intracellular  $\text{Ca}^{2+}$ . Digoxin functions by inhibiting  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase, which is responsible for the exchange of intracellular  $\text{Na}^+$  with extracellular  $\text{K}^+$ .<sup>3,4</sup> It is thus responsible for maintaining the intracellular/extracellular  $\text{K}^+$  and  $\text{Na}^+$  gradients. When it is inhibited, intracellular  $\text{Na}^+$  levels increase. The increased intracellular  $\text{Na}^+$  is an increased chemical potential for driving the  $\text{Ca}^{2+}/\text{Na}^+$  exchanger, an ion exchange mechanism in which intracellular  $\text{Na}^+$  is removed from the cell in exchange for  $\text{Ca}^{2+}$ . The net effect is an increase in intracellular  $\text{Ca}^{2+}$  with an enhancement of the inotropic state.

The most commonly used positive inotropic agents are the beta-adrenergic agonists. The  $\beta_1$  receptor is part of a complex consisting of the receptor on the outer surface of the cell membrane and membrane-spanning G proteins (so named because they bind GTP), which in turn stimulate adenylate cyclase on the inner surface of the membrane, catalyzing the formation cyclic adenosine monophosphate (cyclic AMP). The inotropic state is modulated by cyclic AMP via its catalysis of phosphorylation reactions by protein kinase A. These phosphorylation reactions "open"  $\text{Ca}^{2+}$  channels on the cell membrane and lead to greater release and uptake of  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum.<sup>3,4</sup>

There are many drugs that stimulate  $\beta_1$  receptors and have a positive inotropic effect, including epinephrine, norepinephrine, dopamine, isoproterenol, and dobutamine, the most commonly used catecholamines in the perioperative

period. Although there are differences in their binding at the  $\beta_1$  receptor, the most important differences between the various catecholamines are their relative effects on alpha- and  $\beta_2$  adrenergic receptors. In general, alpha receptor stimulation on the peripheral vasculature causes vasoconstriction, whereas  $\beta_2$  receptor stimulation leads to vasodilation (see the discussion elsewhere in this chapter). For some time it was believed that  $\beta_2$  and alpha receptors were found only in the peripheral vasculature, as well as in a few other organs, but not in the myocardium. However, alpha receptors are also found in the myocardium and mediate a positive inotropic effect.<sup>5,6</sup> The mechanism for this positive inotropic effect is probably the stimulation of phospholipase C, leading to hydrolysis of phosphatidyl inositol to diacylglycerol and inositol triphosphate, compounds that increase  $\text{Ca}^{2+}$  release from the sarcoplasmic reticulum and increase myofilament sensitivity to  $\text{Ca}^{2+}$ . It is also possible that alpha-adrenergic agents increase intracellular  $\text{Ca}^{2+}$  by prolonging action potential duration by inhibition of outward  $\text{K}^+$  currents during repolarization or by activating the  $\text{Na}^+/\text{H}^+$  exchange mechanism, increasing intracellular pH and increasing myofilament sensitivity to  $\text{Ca}^{2+}$ . Just as the exact mechanism is uncertain, the exact role of alpha-adrenergic stimulation in control of the inotropic state is unclear, although it is apparent that onset of the effect is slower than that of  $\beta_1$  stimulation.

Besides the discovery of alpha receptors in the myocardium,  $\beta_2$  receptors are present in the myocardium.<sup>74</sup> The fraction of  $\beta_2$  receptors (compared with  $\beta_1$  receptors) is increased in chronic HF, possibly explaining the efficacy of drugs with  $\beta_2$  activity in this setting. This phenomenon is part of the general observation of  $\beta_1$  receptor down-regulation (decrease in receptor density) and desensitization (uncoupling of effect from receptor binding) that is observed in chronic HF.<sup>75</sup> Interestingly, it has been demonstrated in a dog model that this same phenomenon occurs with cardiopulmonary bypass (CPB).<sup>76</sup> In this situation, a newer class of drugs, the phosphodiesterase inhibitors, may be of benefit. These drugs, typified by the agents available in the United States, amrinone and milrinone, increase cyclic AMP levels independently of the beta receptor by selectively inhibiting the myocardial enzyme responsible for the breakdown of cyclic AMP.<sup>3,4</sup>

In clinical use, selection of a particular inotropic agent usually is based more on its side effects than its direct inotropic properties. Of the commonly used catecholamines, norepinephrine has alpha and  $\beta_1$  but little  $\beta_2$  activity and is both an inotrope and a vasopressor. Epinephrine and dopamine are mixed agonists with alpha,  $\beta_1$ , and  $\beta_2$  activities. At lower doses, they are primarily inotropes and not vasopressors, although vasopressor effects become more pronounced at higher doses. This is especially true for dopamine, which achieves effects at higher doses by stimulating the release of norepinephrine.<sup>77</sup> Dobutamine is a more selective  $\beta_1$  agonist, in contrast to isoproterenol, which is a mixed beta agonist. Selection of a drug depends on the particular hemodynamic problem at hand. For example, a patient with depressed myocardial function in the presence of

profound vasodilation may require a drug with both positive inotropic and vasopressor effects, whereas a patient who is vasoconstricted may benefit from some other choice. Recent studies report that in patients with myocardial infarction (MI) who develop cardiogenic shock, dopamine increases mortality compared to norepinephrine.<sup>78,79</sup> On the basis of multiple considerations, we recommend an empiric approach to selecting inotropic agents with careful monitoring of the response to the drug and selection of the agent that achieves the desired effect.

Clinical experience suggests that phosphodiesterase inhibitors are effective when catecholamines do not produce an acceptable cardiac output. Milrinone is the phosphodiesterase most used, and amrinone is no longer available. Enoximone, a similar agent with different pharmacokinetic properties, was used in Europe but not available in the United States. All agents increase contractility with minimal effect on heart rate, and both are vasodilators. There is significant venodilation, as well as pulmonary and systemic vasodilation, and maintaining adequate preload is important in avoiding hypotension.<sup>80-82</sup> Administering the loading dose over 15 to 30 minutes may also attenuate possible hypotension, or alternately starting an infusion alone without loading is an alternative method. Plasma levels drop rapidly after a loading dose because of redistribution, and the loading dose should be followed immediately by a continuous infusion.<sup>82-84</sup> Because of their longer half-lives, it is rather more difficult to readily titrate plasma levels than with catecholamines (which have plasma half-lives of a few minutes).

Phosphodiesterase inhibitors, specifically milrinone, facilitate separation from CPB with biventricular dysfunction and are used for treating low-cardiac-output syndrome after cardiac surgery.<sup>82-86</sup> Doolan and colleagues also demonstrated that milrinone, in comparison with placebo, significantly facilitated separation of high-risk patients from CPB.<sup>87</sup> Despite the extensive use of pharmacologic therapy, there are no convincing data to support a distinct inotropic or vasodilator drug-based therapy as a superior solution to treat biventricular dysfunction and/or potentially reduce mortality in hemodynamically unstable patients with cardiogenic shock or low cardiac output, especially complicating an acute MI.<sup>88</sup>

## Levosimendan

Levosimendan is a class of drugs known as *calcium sensitizers*. The molecule is a pyridazinone-dinitrile derivative with additional action on ATP-sensitive potassium channels.<sup>67,89,90</sup> Levosimendan is used intravenously for treating decompensated HF because it increases contractility and produces anti-stunning effects without increasing myocardial intracellular calcium concentrations or prolonging myocardial relaxation. Levosimendan also causes coronary and systemic vasodilation. In patients with HF, IV levosimendan reduced worsening HF or death significantly. IV levosimendan significantly also increased cardiac output and decreased filling pressure in decompensated HF in large, double-blind, randomized trials and after cardiac surgery in smaller trials. Levosimendan

is well tolerated without arrhythmogenicity. In addition to sensitizing troponin to intracellular calcium, levosimendan inhibits phosphodiesterase III and open ATP-sensitive potassium channels ( $K_{ATP}$ ), which may produce vasodilation. Unlike currently available intravenous inotropes, levosimendan does not increase myocardial oxygen use and has been used effectively in beta-blocked patients. Levosimendan does not impair ventricular relaxation. Clinical studies have demonstrated short-term hemodynamic benefits of levosimendan over both placebo and dobutamine. Although large-scale, long-term morbidity and mortality data are scarce, the Levosimendan Infusion versus Dobutamine in Severe Low-Output Heart Failure (LIDO) study suggested a mortality benefit of levosimendan over dobutamine. Clinical studies comparing levosimendan with other positive inotropes, namely, milrinone, are lacking. Currently, this agent is being evaluated in a clinical trial in North America for patients with left ventricular dysfunction undergoing CPB (<https://clinicaltrials.gov/ct2/show/NCT02025621?term=levosimendan&rank=14>).

## Clinical Trials

Despite their common use after cardiac surgery, there have been relatively few comparative studies of inotropic agents in the perioperative period. In 1978, Steen reported the hemodynamic effects of epinephrine, dobutamine, and epinephrine immediately after separation from CPB.<sup>91</sup> The largest mean increase in cardiac index was achieved with dopamine at 15 mcg/kg per minute. However, it should be noted that the only epinephrine dose studied was 0.04 mcg/kg per minute. In a later comparison of dopamine and dobutamine, Salomon concluded that dobutamine produced more consistent increases in cardiac index, although the hemodynamic differences were small, and all patients had good cardiac indices at the onset of the study.<sup>92</sup> Fowler also found insignificant differences in the hemodynamic effects of dobutamine and dopamine, although they reported that coronary flow increased more in proportion to myocardial oxygen consumption with dobutamine.<sup>93</sup> Although neither of these groups reported significant increases in heart rate for either dopamine or dobutamine, clinical experience has been otherwise. This is supported by a study by Sethna, who found that the increase in cardiac index with dobutamine occurs simply because of increased heart rate, although they found that myocardial oxygen was maintained.<sup>94</sup> Butterworth subsequently demonstrated that the older and much cheaper agent, epinephrine, effectively increased stroke volume without as great an increase in heart rate as dobutamine.<sup>95</sup> More recently, Feneck compared dobutamine and milrinone and found them to be equally effective in treating low-cardiac-output syndrome after cardiac surgery.<sup>96</sup> This study was a comparison of two drugs, and the investigators emphasized that the most efficacious therapy is probably a combination of drugs. In particular, phosphodiesterase inhibitors require the synthesis of cyclic AMP to be effective, and thus use of a combination of a  $\beta_1$ -adrenergic agonist and a phosphodiesterase inhibitor would be predicted to be more effective than either agent alone.

Finally, while global hemodynamic goals (ie, heart rate, blood pressure, filling pressures, and cardiac output) may be achieved with inotropic agents, this does not guarantee adequate regional perfusion, in particular renal and mesenteric perfusion. So far there have been few investigations of regional perfusion after cardiac surgery. There has been more interest in regional (especially mesenteric) perfusion in the critical care medicine literature, and some of the studies may be relevant to postoperative care of the cardiac surgical patient. Two studies have indicated that epinephrine may impair splanchnic perfusion, especially in comparison with combining norepinephrine and dobutamine.<sup>97,98</sup> Norepinephrine alone has variable effects on splanchnic blood flow in septic shock,<sup>99</sup> although adding dobutamine can improve splanchnic perfusion significantly when blood pressure is supported with norepinephrine.<sup>98</sup> Low-dose dopamine improves splanchnic blood flow,<sup>100</sup> but there is evidence that dopamine in higher doses impairs gastric perfusion.<sup>101</sup> The relevance of these studies of septic patients for the cardiac surgical patient is unclear, although there are similarities between the inflammatory responses to CPB and to sepsis.

## VASOPRESSORS

CPB often is characterized by derangements of vascular tone. Sometimes CPB induces elevations in endogenous catecholamines, as well as other mediators, such as serotonin and arginine vasopressin (AVP), leading to vasoconstriction. However, more often CPB is characterized by a systemic inflammatory response, with a cascade of cytokine and inflammatory mediator release and profound vasodilation. The pathophysiology has a striking resemblance to that of sepsis or an anaphylactic reaction. Further, vasodilation after cardiac surgery may be exacerbated by the preoperative use of angiotensin-converting enzyme (ACE) inhibitors and post-CPB use of milrinone.

The mechanisms of vasodilatory shock have been reviewed previously.<sup>102</sup> Vascular tone is modulated by intracellular  $\text{Ca}^{2+}$ , which binds calmodulin. The  $\text{Ca}^{2+}$ -calmodulin complex activates myosin light-chain kinase, which catalyzes the phosphorylation of myosin to facilitate the interaction with actin. Conversely, intracellular cyclic GMP activates myosin phosphatase (also via a kinase-mediated phosphorylation of myosin phosphatase), which dephosphorylates myosin and inhibits the interaction of actin and myosin. A primary mediator of vasodilatory shock is nitric oxide (NO), which is induced by cytokine cascades. NO activates guanylate cyclase, with resulting loss of vascular tone. Another mechanism of vasodilation that may be particularly relevant to prolonged CPB is activation of ATP-sensitive potassium ( $\text{K}_{\text{ATP}}$ ) channels. These channels are activated by decreases in cellular ATP or increases in hydrogen ion or lactate. All these could result from the abnormal perfusion associated with CPB and/or hypothermia. Increases in potassium channel conductance result in hyperpolarization of the vascular smooth muscle membrane, which decreases  $\text{Ca}^{2+}$  flux into the cell, leading to decreased vascular tone. A third mechanism of vasodilatory shock that also may be particularly relevant to cardiac surgery

is deficiency of vasopressin. As noted earlier, CPB often induces the release of vasopressin, and this may contribute to the excessive vasoconstriction sometimes seen after CPB. However, it has been observed in several experimental models of shock that the initially high levels of vasopressin decrease as shock persists, leading some investigators to suggest that vasopressin stores are limited and are depleted by the initial response to hypotension.

Excessive vasodilation during shock usually is treated with catecholamines, most typically phenylephrine, dopamine, epinephrine, or norepinephrine.<sup>103</sup> Although catecholamines produce both alpha- and beta-adrenergic effects, alpha-adrenergic receptor stimulation produces vasoconstriction. As noted, stimulation of these receptors activates membrane phospholipase C, which in turn hydrolyzes phosphatidylinositol 4,5-diphosphate.<sup>7</sup> This leads to the subsequent generation of two second messengers, including diacyl glycerol and inositol triphosphate. Both these second messengers increase cytosolic  $\text{Ca}^{2+}$  by different mechanisms, which include facilitating release of calcium from the sarcoplasmic reticulum and potentially increasing the calcium sensitivity of the contractile proteins in vascular smooth muscle.

Mediator-induced vasodilation often is poorly responsive to catecholamines,<sup>103</sup> and the most potent pressor among catecholamines, norepinephrine, is required frequently. Some clinicians are concerned about renal, hepatic, and mesenteric function during norepinephrine administration. However, in septic patients, norepinephrine can improve renal function,<sup>102-107</sup> and there is evidence that it may improve mesenteric perfusion as well.<sup>108</sup> Given the hemodynamic similarities between septic patients and some patients at the end of CPB, these results often are extrapolated to the cardiac surgical patient but have not been confirmed by a systematic study. In some cases of profound vasodilatory shock, even norepinephrine is inadequate to restore systemic blood pressure. In this situation, low doses of vasopressin may be useful. Argenziano<sup>109</sup> studied 40 patients with vasodilatory shock (defined as a mean arterial blood pressure of less than 70 mm Hg with a cardiac index greater than 2.5 L/m<sup>2</sup> per minute) after cardiac surgery. AVP levels were inappropriately low in this group of patients, and low-dose vasopressin infusion ( $\leq 0.1$  U/min) effectively restored blood pressure and reduced norepinephrine requirements without significantly changing cardiac index. These observations were similar to an earlier report of the use of vasopressin in vasodilatory septic shock.<sup>110</sup> Vasopressin also has been reported to be useful in treating milrinone-induced hypotension.<sup>111</sup> In this latter report, vasopressin was reported to increase urine output, presumably via glomerular efferent arteriole constriction. However, the overall effects on renal function are unclear. In addition, there are still important unanswered questions about vasopressin and mesenteric perfusion. Although vasopressin effectively may restore blood pressure in vasodilatory shock, it must be remembered that in physiologic concentrations it is a mesenteric vasoconstrictor, and mesenteric hypoperfusion may be a factor in developing sepsis and multiorgan dysfunction syndrome.

## VASODILATORS

Different pharmacologic approaches are available to produce vasodilation (Table 4-1). Potential therapeutic approaches include (1) blockade of  $\alpha_1$ -adrenergic receptors, ganglionic transmission, and calcium channel receptors; (2) stimulation of central  $\alpha_2$ -adrenergic receptors or vascular guanylate cyclase and adenylate cyclase; and (3) inhibition of phosphodiesterase enzymes and ACEs.<sup>112</sup> Adenosine in low concentrations is also a potent vasodilator with a short half-life, but it is used, as noted earlier, for its ability to inhibit AV conduction. Losartan, a novel angiotensin II (AII) antagonist, has just been released for treating hypertension but is not available for intravenous use.

### Stimulation of Adenylate Cyclase (Cyclic AMP)

Prostacyclin, prostaglandin  $E_1$ , and isoproterenol increase cyclic nucleotide formation (eg, adenosine-3',5'-monophosphate and cyclic AMP) in vascular smooth muscle to produce calcium mobilization out of vascular smooth muscle. Inhibiting the breakdown of cyclic AMP by phosphodiesterase also will increase cyclic AMP.<sup>112</sup> Increasing cyclic AMP in vascular smooth muscle facilitates calcium uptake by intracellular storage sites, thus decreasing calcium available for contraction. The net effect of increasing calcium uptake is to produce vascular smooth muscle relaxation and hence vasodilation. However, most catecholamines with  $\beta_2$ -adrenergic activity (eg, isoproterenol) and phosphodiesterase inhibitors have positive inotropic and other side effects that include tachycardia, glycogenolysis, and kaluresis.<sup>113</sup> Prostaglandins (ie, prostacyclin and prostaglandin  $E_1$ ) are potent inhibitors of platelet aggregation and activation. Catecholamines with  $\beta_2$ -adrenergic activity, phosphodiesterase inhibitors, and prostaglandin  $E_1$  and prostacyclin have been used to vasodilate the pulmonary circulation in patients with pulmonary hypertension and right ventricular failure (see Table 4-1).<sup>113</sup>

**TABLE 4-1: Vasodilators Used in the Treatment of Hypertension, Pulmonary Hypertension, and Heart Failure**

Angiotensin-converting enzyme inhibitors
Angiotensin II antagonists
Alpha <sub>1</sub> -adrenergic antagonists (prazosin)
Alpha <sub>2</sub> -adrenergic agonists (clonidine)
Endothelin antagonists
Nitrates
Nitric oxide
Hydralazine
Phosphodiesterase inhibitors (milrinone, sildenafil)
Prostacyclin, PGE <sub>1</sub>
Calcium channel blockers
Dihydropyridine agents (clevidipine, nicardipine, amlodipine)

### Nitrates, Nitrovasodilators, and Stimulation of Guanylyl Cyclase (Cyclic GMP)

The vascular endothelium modulates vascular relaxation by releasing both nitric oxide and prostacyclin.<sup>114-116</sup> Inflammatory mediators also can stimulate the vascular endothelium to release excessive amounts of endothelium-derived relaxing factor (EDRF, or nitric oxide), which activates guanylyl cyclase to generate cyclic GMP.<sup>89,90</sup> Nitrates and sodium nitroprusside, however, generate nitric oxide directly, independent of vascular endothelium.<sup>115,116</sup> The active form of any nitrovasodilator is nitric oxide (NO), in which the nitrogen is in a +2 oxidation state. For any nitrovasodilator to be active, it first must be converted to NO. For nitroprusside, this is easily accomplished because nitrogen is in a +3 oxidation state, with the nitric oxide molecule bound to the charged iron molecule in an unstable manner, allowing nitroprusside to readily donate its nitric oxide moiety. For nitroglycerin, nitrogen molecules exist in a +5 oxidation state, and thus they must undergo significant metabolic transformations before they are converted to an active molecule. Nitroglycerin is a selective coronary vasodilator and does not produce coronary steal compared with nitroprusside because the small intracoronary resistance vessels, those less than 100  $\mu\text{m}$  thick, lack whatever metabolic transformation pathway is required to convert nitroglycerin into its active form of nitric oxide.<sup>115,116</sup> Chronic nitrate therapy can produce tolerance through different mechanisms.<sup>114-118</sup> Sodium nitroprusside and nitroglycerin are effective vasodilators that produce venodilation that contributes significantly to the labile hemodynamic state.<sup>114</sup> Intravenous volume administration often is required with nitroprusside owing to the relative intravascular hypovolemia.

### Dihydropyridine Calcium Channel Blockers

Dihydropyridine calcium channel blockers are direct arterial vasodilators.<sup>119</sup> Nifedipine was the first dihydropyridine calcium channel blocker, and intravenous forms studied in cardiac surgery include clevidipine, isradipine, and nicardipine. These agents are selective arterial vasodilators that have no effects on the vascular capacitance bed, AV nodal conduction, or negative inotropic effects.<sup>120-125</sup> Clevidipine and nicardipine are available in the United States and offer novel and important therapeutic options to treat perioperative hypertension following cardiac surgery. Also, intravenous dihydropyridines can be used to treat acute hypertension that occurs during the perioperative period (ie, intubation, extubation, CPB-induced hypertension, and aortic cross-clamping) and postoperative hypertension.

### Phosphodiesterase Inhibitors

Two major classes of phosphodiesterase inhibitors are currently available for use. Milrinone is a prototypic type III inhibitor that is cyclic AMP specific, as previously described, and

produces both positive inotropic effects and vasodilation.<sup>126</sup> When administered to patients with ventricular dysfunction, milrinone increases cardiac output, venodilates, vasodilates, and is a pulmonary vasodilator. Sildenafil is a type V-specific inhibitor that is cyclic GMP specific and is a pulmonary and systemic vasodilator without a primary inotropic response, although isotypes for phosphodiesterases exist. Because of their unique mechanisms of vasodilation, these agents are especially useful for patients with acute pulmonary vasoconstriction and right ventricular dysfunction. Multiple forms of the drug are available including bipyridines (eg, amrinone and milrinone), imidazolones (eg, enoximone), and methylxanthines (eg, aminophylline), and sildenafil. Papaverine, a benzyl isoquinolinium derivative isolated from opium, is a nonspecific phosphodiesterase inhibitor and vasodilator used by cardiac surgeons for its ability to dilate the internal mammary artery.<sup>126</sup>

### Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors have growing use in managing HF, and more patients are receiving these drugs. The ACE inhibitors prevent the conversion of angiotensin I to angiotensin II by inhibiting an enzyme called *kininase* in the pulmonary and systemic vascular endothelium. This enzyme is also important for the metabolism of bradykinin, a potent endogenous vasodilator, and for release of EDRF. Although there are little data in the literature regarding the preoperative management of patients receiving these drugs, withholding them on the day of surgery has been our clinical practice based on their potential to produce excessive vasodilation during CPB. Although Tuman was unable to find any difference in blood pressure during CPB in patients receiving ACE inhibitors, contact activation during CPB has the ability to generate bradykinin and thus amplify the potential for vasodilation. The vasoconstrictor requirements were increased after bypass in his study.

### Angiotensin II-Receptor Blockers

ACE inhibitors may not be tolerated in some patients owing to cough (common) and angioedema (rare). Inhibition of kininase II by ACE inhibitors leads to bradykinin accumulation in the lungs and vasculature, causing cough and vasodilation. Alternative treatment with angiotensin II-receptor blockers (ARBs) may be associated less frequently with these side effects because ARBs do not affect kinin metabolism. Six ARBs are currently available for antihypertensive therapy in the United States: losartan (Cozaar), valsartan (Diovan), irbesartan (Avapro), candesartan (Atacand), eprosartan (Teveten), and telmisartan (Micardis). Mortality in chronic HF is related to activation of the autonomic nervous and renin-angiotensin systems, and ACE inhibitor therapy seems to attenuate progression of myocardial dysfunction and remodeling. ACE inhibitors do not completely block angiotensin II (A-II) production,<sup>127</sup> and may even increase circulating A-II levels in patients with HF. It was thought initially that ARBs might

offer advantages over ACE inhibitors for heart failure therapy in terms of tolerability and more complete A-II blockade. Although ARBs were better tolerated, all-cause mortality and the number of sudden deaths or resuscitated cardiac arrests were not different when losartan (Cozaar) and captopril (Capoten) were compared in patients (>60 years of age, New York Heart Association (NYHA) classes II to IV, left-ventricular ejection fraction (LVEF) <40%).<sup>128</sup> Perioperative hypotension may be encountered in ARB-treated patients as well as ACE inhibitor-treated patients, and increased inotropic support may be required.

## BETA-ADRENERGIC RECEPTOR BLOCKERS

Not surprisingly, most of the effects observed after administration of a beta-adrenergic receptor blocker reflect the reduced responsiveness of tissues containing beta-adrenergic receptors to catecholamines present in the vicinity of those receptors. Hence the intensity of the effects of beta-blockers depends on both the dose of the blocker and the receptor concentrations of catecholamines, primarily epinephrine and norepinephrine. In fact, a purely competitive interaction of beta-blockers and catecholamines can be demonstrated in normal human volunteers as well as in isolated tissues studied in the laboratory. The presence of disease and other types of drugs modifies the responses to beta-blockers observed in patients, but the underlying competitive interaction is still operative. The key to successful use of beta-adrenergic receptor blockers is to titrate the dose to the desired degree of effect and to remember that excessive effects from larger than necessary doses of beta-adrenergic receptor blockers can be overcome by (1) administering a catecholamine to compete at the blocked receptors; and/or (2) administering other types of drugs to reduce the activity of counterbalancing autonomic mechanisms that are unopposed in the presence of beta-receptor blockade. An example of the latter is propranolol-induced bradycardia, which reflects the increased dominance of the vagal cholinergic mechanism on cardiac nodal tissue. Excessive bradycardia may be relieved by administering atropine to block the cholinergic receptors, which are also located in the SA and AV nodes (see Table 4-2).

Knowledge of the type, location, and action of beta receptor is fundamental to understanding and predicting effects of beta-adrenergic receptor-blocking drugs<sup>129</sup> (see Table 4-2). Beta-adrenergic receptor blockers are competitive inhibitors; hence, the intensity of blockade depends on both the dose of the drug and the receptor concentrations of catecholamines, primarily epinephrine and norepinephrine.

Beta-adrenergic receptor antagonists (blockers) include many drugs (Table 4-3) that typically are classified by their relative selectivity for beta<sub>1</sub> and beta<sub>2</sub> receptors (ie, cardioselective or nonselective), the presence or absence of agonistic activity, membrane-stabilizing properties, alpha-receptor-blocking efficacy, and various pharmacokinetic features (eg, lipid solubility, oral bioavailability, and elimination half-time).<sup>129</sup> The

**TABLE 4-2: Location and Actions of Beta-Adrenergic Receptors**

Tissue	Receptor	Action	Opposing Actions
Heart			
Sinus and AV nodes	1	↑ Automaticity	Cholinergic receptors

Gallbladder	2	Relaxation	Cholinergic receptors
Urinary bladder detrussor muscle	2	Relaxation	Cholinergic receptors
Uterus	2	Relaxation	Oxytocin
Platelets	2	↓ Aggregation	Alpha <sub>2</sub> -adrenergic receptors (aggregation)

practitioner must realize that the selectivity of individual drugs for beta<sub>1</sub> and beta<sub>2</sub> receptors is relative, not absolute. For example, the risk of inducing bronchospasm with a beta<sub>1</sub>-adrenergic (cardioselective) blocker (eg, esmolol or metoprolol) may be relatively less than that with a nonselective blockers (eg, propranolol); however, the risk is still present.

### Acute Myocardial Infarction

Earlier clinical trials of intravenous beta-adrenergic blockers in the early phases of acute myocardial infarction suggest they decrease mortality. Following myocardial infarction, chronic oral beta-blocking agents reduce the incidence of recurrent myocardial infarction (see Table 4-3).<sup>130</sup>

### Supraventricular Tachycardias and Ventricular Dysrhythmias

Beta-adrenergic blocking agents are Vaughan Williams class II antidysrhythmics that primarily block cardiac responses to catecholamines. Metoprolol and esmolol are used commonly for this indication. Beta-blocking agents decrease spontaneous depolarization in the SA and AV nodes, decrease automaticity in Purkinje fibers, increase AV nodal refractoriness, increase threshold for fibrillation (but not for depolarization), and decrease ventricular slow responses that depend on catecholamines. Amiodarone, a class III agent, also exerts non-competitive alpha- and beta-adrenergic blockade, which may contribute its antidysrhythmic and antihypertensive actions. Sotalol is another class III antidysrhythmic with nonselective

beta-blocking action. Beta-adrenergic blocking agents also decrease intramyocardial conduction in ischemic tissue and reduce the risks of dysrhythmias to the extent that they decrease myocardial ischemia.

**TABLE 4-3: Beta-Adrenergic Receptors Blockers**

Generic Name	Trade Name	Dosage Forms	Beta <sub>1</sub> -Selective
Acebutolol	Sectral	PO	Yes
Atenolol	Tenormin	IV, PO	Yes

Sotalol	Betapace	PO	No
Timolol	Blocadren	PO	No

\*Alpha<sub>1</sub>: beta-adrenergic blocking ratio; carvedilol 1:10, labetalol 1:3 (oral)/1:7 (IV).

## Hypertension

Hypertension, if not treated, is a major risk factor for myocardial infarction, stroke, renal failure and death, and patients often present for cardiac surgery with poorly controlled blood pressure (BP) management. The recently published recommendations of Eighth Joint National Committee (JNC 8) provide an evidence-based approach to recommend treatment thresholds, goals and specific therapy for management of hypertension, and have been liberalized since the last report.<sup>131</sup> They recommend treating patients aged >60 years with <150/90 mm Hg whereas younger patients 30 to 59 years to a diastolic goal of <90 mm Hg, and in younger patients a BP of <140/90 mm Hg, whether or not they have diabetes or chronic kidney disease (CKD). They suggest initiating therapy with an ACE inhibitor, angiotensin receptor blocker, calcium channel blocker, or thiazide-type diuretic in the nonblack hypertensive population, including those with diabetes. In the black hypertensive population, a calcium channel blocker or thiazide-type diuretic is recommended as initial therapy. There is moderate evidence to support initial or add-on antihypertensive therapy with an ACE inhibitor or angiotensin receptor blocker in persons with CKD to improve kidney outcomes. Of note, they emphasize the importance of clinical judgment as a critical component.<sup>131,132</sup>

## Hypertensive Emergencies and Urgencies

Hypertensive emergencies/crises include multiple clinical presentations where uncontrolled hypertension leads to progressive or impending end-organ dysfunction requiring BP to be lowered aggressively over minutes to hours. Neurologic end-organ dysfunction due to uncontrolled hypertension includes encephalopathy, cerebral vascular infarction, subarachnoid hemorrhage, and/or intracranial hemorrhage. Cardiovascular end-organ injury includes myocardial ischemia and/or infarction, acute HF, pulmonary edema, and/or aortic dissection. Other organ systems may also be affected by uncontrolled hypertension, which may lead to acute renal failure/insufficiency, eclampsia, or coagulopathy. In hypertensive emergencies, intravenous therapy with specific BP titration is the cornerstone of therapy.

Hypertensive urgencies are seen in a clinical setting where patients present asymptotically with high blood pressures that should be treated but with oral therapies, restarting on their medications or therapy initiated with care to avoid overshoot and hypotension. Hypertensive urgencies are common in cardiac surgery where BP is maintained at specific arbitrary levels based on concerns about bleeding and/or suture line disruption.

## Acute Dissecting Aortic Aneurysm

The primary goal in managing dissecting aneurysms is to reduce stress on the dissected aortic wall by reducing the systolic acceleration of blood flow. Beta-blockers reduce cardiac

inotropy and ventricular ejection fraction. They also may limit reflex sympathetic responses to vasodilators used to control systemic arterial pressure.

## Pheochromocytoma

The presence of catecholamine-secreting tissue is tantamount to the continuous or intermittent infusion of a varying mixture of norepinephrine and epinephrine. It is absolutely essential that virtually complete alpha-adrenergic receptor blockade be established prior to administering the beta-blocker to prevent exacerbation of hypertensive episodes by unopposed alpha-adrenergic receptor activity in vascular smooth muscle.

## Chronic Heart Failure

It is now understood that activation of the autonomic nervous system (ANS) and renin-angiotensin system (RAS) as compensatory mechanisms for the failing heart actually may contribute to deterioration of myocardial function. Mortality in chronic HF seems related to activation of ANS and RAS. Progression of myocardial dysfunction and remodeling may be attenuated by the use of beta-blocking agents and ACE inhibitors. Carvedilol (Coreg) is a beta-blocker approved by the FDA to treat patients with HF. It has an alpha<sub>1</sub>- and nonselective beta-blocking activity (alpha:beta = 1:10). It is contraindicated in severe decompensated HF and asthma. In patients with AF and left-sided HF treated with carvedilol, improved ejection fraction, and a trend toward a decreased incidence of death and chronic HF hospitalization were observed in a retrospective analysis of a US carvedilol study. There are several ongoing clinical trials with carvedilol, metoprolol (Toprol), and bisoprolol (Zebeta). The results of these studies may provide answers as to which beta-blocking agent would be most successful in the treatment of specific patient populations.

## Other Indications

The other clinical applications of beta-adrenergic receptor blockers listed in Table 4-4 are based on largely symptomatic treatment or empirical trials of beta-adrenergic antagonists.

## Side Effects and Toxicity

The most obvious and immediate signs of a toxic overdose of a beta-adrenergic receptor blocker are hypotension, bradycardia, congestive HF, decreased AV conduction, and a widened QRS complex on the electrocardiogram. Treatment is aimed at blocking the cholinergic receptor responses to vagal nerve activity (eg, atropine) and administering a sympathomimetic to compete with the beta-blockers at adrenergic receptors. In patients with asthma and chronic obstructive pulmonary disease (COPD), beta-blockers may cause bronchospasm. Beta-blockers may increase levels of plasma triglycerides and reduce levels of high-density lipoprotein (HDL) cholesterol. Rarely, beta-blockers may mask the symptoms of hypoglycemia in

**TABLE 4-4: Clinical Applications of Beta-Adrenergic Receptor Blockers**

Angina pectoris
Acute myocardial infarction (prophylaxis)
Supraventricular tachycardia
Ventricular dysrhythmias
Hypertension (usually in combination with other drugs)
Pheochromocytoma (after alpha-receptor blockade is established)
Acute dissecting aortic aneurysm
Hyperthyroidism
Hypertrophic obstructive cardiomyopathy (IHSS)
Dilated cardiomyopathy (selected patients)
Migraine prophylaxis
Acute panic attack
Alcohol withdrawal syndrome
Glaucoma (topically)

diabetic patients. Other side effects include mental depression, physical fatigue, altered sleep patterns, sexual dysfunction, and gastrointestinal symptoms, including indigestion, constipation, and diarrhea (see Table 4-4).

## Drug Interactions

Pharmacokinetic drug interactions include reduced gastrointestinal absorption of the beta-blocker (eg, aluminum-containing antacids and cholestyramine), increased biotransformation of the beta-blocker (eg, phenytoin, phenobarbital, rifampin, and smoking), and increased bioavailability owing to decreased biotransformation (eg, cimetidine and hydralazine). Pharmacodynamic interactions include an additive effect with calcium channel blockers to decrease conduction in the heart and a reduced antihypertensive effect of beta-blockers when administered with some of the nonsteroidal anti-inflammatory drugs (NSAIDs).

## DIURETICS

Diuretics are drugs that act directly on the kidneys to increase urine volume and produce a net loss of solute (principally sodium and other electrolytes) and water. Diuretics and beta-blockers are initial drugs of choice for uncomplicated hypertension in patients younger than 65 years.<sup>132</sup> The currently available diuretic drugs have a number of other uses in medicine (eg, glaucoma and increased intracranial pressure). The principal indications for the use of diuretics by intravenous administration in the perioperative period are to: (1) increase urine flow in oliguria; (2) reduce intravascular volume in patients at risk for acute HF from excessive fluid administration or acute HF; and (3) mobilize edema.

Renal function depends on adequate renal perfusion to maintain the integrity of renal cells and provide the

hydrostatic pressure that produces glomerular filtration. There are no drugs that act directly on the renal glomerulus to affect glomerular filtration rate (GFR). In the normal adult human of average size, GFR averages 125 mL/min and urine production approximates 1 mL/min. In other words, 99% of the glomerular filtrate is reabsorbed. Diuretics act primarily on specific segments of the renal tubule to alter reabsorption of electrolytes, principally sodium, and water.

There are two basic mechanisms behind the renal tubular reabsorption of sodium. First, sodium is extruded from the tubular cell into peritubular fluid primarily by active transport of the sodium ion, which reflects the action of the Na<sup>+</sup>, K<sup>+</sup> ATPase pump, as well as the bicarbonate reabsorption mechanism (see the following). This extrusion of sodium creates an electrochemical gradient that causes diffusion of sodium from the tubular lumen into the tubular cell. Second, sodium moves from the glomerular filtrate in the tubular fluid into the peritubular fluid by several different mechanisms. The most important quantitatively is the sodium electrochemical gradient created by the active extrusion of sodium from the tubular cell into the peritubular fluid. In addition, sodium is coupled with organic solutes and phosphate ions, exchanged for hydrogen ions diffusing from the tubular cell into the tubular lumen, and coupled to the transfer of a chloride ion or a combination of potassium and two chloride ions (Na<sup>+</sup>-K<sup>+</sup>-2Cl<sup>-</sup> cotransport) from the tubular fluid into the tubular cell. Diuretics are classified by their principal site of action in the nephron and by the primary mechanism of their natriuretic effect (Table 4-5).

## Osmotic Diuretics

Mannitol is the principal example of this type of diuretic, which is used for two primary indications: (1) prophylaxis and early treatment of acute renal failure that is characterized by a decrease in GFR leading to a decreased urine volume and an increase in the concentration of toxic substances in the renal tubular fluid; and (2) enhancing the actions of other diuretics by retaining water and solutes in the tubular lumen, thereby providing the substrate for the action of other types of diuretics. Normally, 80% of the glomerular filtrate is reabsorbed isosmotically in the proximal tubules. By its osmotic effect, mannitol limits the reabsorption of water and dilutes the proximal tubular fluid. This reduces the electrochemical gradient for sodium and limits its reabsorption so that more is delivered to the distal portions of the nephron. Mannitol produces a prostaglandin-mediated increase in renal blood flow that partially washes out the medullary hypertonicity, which is essential for the countercurrent mechanism promoting the reabsorption of water in the late distal tubules and collecting system under the influence of antidiuretic hormone (ADH). Mannitol is used often (25 to 50 g) as part of the priming solution of CPB for the above-mentioned indications. The principal toxicity of mannitol is acute expansion of the extracellular fluid volume leading to HF in the patient with compromised cardiac function (see Table 4-5).

**TABLE 4-5: Classification of Diuretics**

Site of Action	Mechanism	
Osmotic	Proximal convoluted and late proximal for Na <sup>+</sup> diffusion from tubular fluid into tubular cell Late proximal tubule	↓ Electrochemical gradient  ↓ Gradient for Cl <sup>-</sup> (accompanying Na <sup>+</sup> diffusion)
Carbonic Thiazides	Thick ascending loop of Henle Proximal convoluted tubule anhydrase inhibitors	↓ Na <sup>+</sup> -K <sup>+</sup> -2Cl <sup>-</sup> cotransport
High-ceiling loop diuretics	Distal convoluted tubule	↓ Na <sup>+</sup> -H <sup>+</sup> exchange
Potassium-sparing diuretics	Thick ascending loop of Henle	↓ Na <sup>+</sup> -Cl <sup>-</sup> cotransport
	Late distal tubule and collecting duct	↓ Na <sup>+</sup> -K <sup>+</sup> -2Cl <sup>-</sup> cotransport ↓ Electrogenic Na <sup>+</sup> entry into cells (driving force for K <sup>+</sup> secretion)

### High-Ceiling (Loop) Diuretics

Furosemide (Lasix), bumetanide (Bumex), and ethacrynic acid (Edecrin) are three chemically dissimilar compounds that have the same primary diuretic mechanism of action. They act on the tubular epithelial cell in the thick ascending loop of Henle to inhibit the Na<sup>+</sup>-K<sup>+</sup>-2Cl<sup>-</sup> cotransport mechanism. Their peak diuretic effect is far greater than that of the other diuretics currently available. Administered intravenously, they have a rapid onset and relatively short duration of action, the latter reflecting both the pharmacokinetics of the drugs and the body's compensatory mechanisms to the consequences of diuresis.

These three diuretics increase renal blood flow without increasing GFR and redistribute blood flow from the medulla to the cortex and within the renal cortex. These changes in renal blood flow are also short-lived, reflecting the reduced extracellular fluid volume resulting from diuresis. Minor actions, including carbonic anhydrase inhibition by furosemide and bumetanide and actions on the proximal tubule and on sites distal to the ascending limb, remain controversial. All three of the loop diuretics increase the release of renin and prostaglandin, and indomethacin blunts the release as well as the augmentation in renal blood flow and natriuresis. All three of the loop diuretics produce an acute increase in venous capacitance for a brief period of time after the first intravenous dose is administered, and this effect is also blocked by indomethacin.

Potassium, magnesium, and calcium excretion is increased in proportion to the increase in sodium excretion. In addition, there is augmentation of titratable acid and ammonia excretion by the distal tubules leading to metabolic alkalosis, which is also produced by contraction of the extracellular volume. Hyperuricemia can occur but usually is of little physiologic significance. The nephrotoxicity of cephaloridine, and possibly other cephalosporins, is increased. A rare but serious side effect of the loop diuretics is deafness, which may reflect electrolyte changes in the endolymph.

Because of their high degree of efficacy, prompt onset, and relatively short duration of action, the high-ceiling or

loop diuretics are favored for intravenous administration in the perioperative period to treat the three principal problems cited earlier. Dosage requirements vary considerably among patients. Some may only require furosemide 3 to 5 mg (IV) to produce a good diuresis. And for some patients, the less potent benzothiazides may be sufficient.

### Benzothiazides

Hydrochlorothiazide (HCTZ) is the prototype of more than a dozen currently available diuretics in this class. Although the drugs differ in potency, they all act by the same mechanism of action and have the same maximum efficacy. All are actively secreted into the tubular lumen by tubular cells and act in the early distal tubules to decrease the electroneutral Na<sup>+</sup>-Cl<sup>-</sup> cotransport reabsorption of sodium. Their moderate efficacy probably reflects the fact that more than 90% of the filtrated sodium is reabsorbed before reaching the distal tubules. Their action is enhanced by their combined administration with an osmotic diuretic such as mannitol. The benzothiazides increase urine volume and the excretion of sodium, chloride, and potassium. The decreased reabsorption of potassium reflects the higher rate of urine flow through the distal tubule (diminished reabsorption time).

This class of diuretics produces the least disturbance of extracellular fluid composition, reflecting their moderate efficacy as diuretics and perhaps suggesting their usefulness when a moderate degree of diuretic effect is indicated. Their principal side effects include hyperuricemia, decreased calcium excretion, and enhanced magnesium loss. Hyperglycemia can occur and reflects multiple variables. With prolonged use and development of a contracted extracellular fluid volume, urine formation decreases (ie, tolerance develops to their diuretic actions). These agents also have a direct action on the renal vasculature to decrease GFR.

### Carbonic Anhydrase Inhibitors

Acetazolamide (Diamox) is the only diuretic of this class available for intravenous administration. Its use is directed

primarily toward alkalization of urine in the presence of metabolic alkalosis, which is a common consequence of prolonged diuretic therapy. It acts in the proximal convoluted tubule to inhibit carbonic anhydrase in the brush border of the tubular epithelium, thereby reducing the destruction of bicarbonate ions (ie, conversion to  $\text{CO}_2$  that diffuses into the tubular cell). The carbonic anhydrase enzyme in the cytoplasm of the tubular cell is also inhibited, and as a consequence, conversion of  $\text{CO}_2$  to carbonic acid is reduced markedly, as is the availability of hydrogen ions for the Na-H exchange mechanism. Hence the reabsorption of both sodium and bicarbonate in the proximal tubules is diminished. However, more than half the bicarbonate is reabsorbed in more distal segments of the nephron, thereby limiting the overall efficacy of this class of diuretics.

### Potassium-Sparing Diuretics

Spironolactone (Aldactone) is a competitive antagonist of aldosterone. Spironolactone binds to the cytoplasmic aldosterone receptor and prevents its conformational change to the active form, thereby aborting the synthesis of active transport proteins in the late distal tubules and collecting system in which the reabsorption of sodium and secretion of potassium are reduced.

Triamterene (Dyrenium) and amiloride (Midamor) are potassium-sparing diuretics with a mechanism of action independent of the mineralocorticoids. They have a moderate natriuretic effect leading to an increased excretion of sodium and chloride with little change or a slight increase in potassium excretion when the latter is low. When potassium secretion is high, they produce a sharp reduction in the electrogenic entry of sodium ions into the distal tubular cells and thereby reduce the electrical potential that is the driving force for potassium secretion.

Both types of potassium-sparing diuretics are used primarily in combination with other diuretics to reduce potassium loss. Their principal side effect is hyperkalemia. It is appropriate to limit the intake of potassium when using this type of diuretic. It is also appropriate to use this type of diuretic cautiously in patients taking ACE inhibitors, which decrease aldosterone formation and consequently increase serum potassium concentrations.

### Other Measures to Enhance Urine Output and Mobilization of Edema Fluid

The infusion of albumin (5–25% solutions) or other plasma volume expanders (eg, hetastarch) is often employed in an attempt to draw water and its accompanying electrolytes (ie, edema fluid) osmotically from the tissues into the circulating blood and thereby enhance their delivery to the kidneys for excretion. In the presence of a reduced circulating blood volume, this approach seems to be a logical method to increase the circulating blood volume and renal perfusion. The limiting feature of this approach to enhancing diuresis

relates to the fact that the osmotic effect of albumin and plasma expanders is transient because they can diffuse (at a rate slower than water) from blood through capillary membranes into tissue. The albumin or plasma expander then tends to hold water and its accompanying electrolytes in tissue (ie, rebound edema). The same limiting feature applies to osmotic diuretics such as mannitol, which may transiently draw water and its accompanying electrolytes from tissues into the circulating blood for delivery to the kidneys, where the mannitol passes through the glomerulus and delays the reabsorption of water and its accompanying electrolytes from the proximal tubular fluid. Although this mechanism may enhance the actions of other diuretics, it is a transient effect that is limited by the diffusion of mannitol from blood into tissues with the production of rebound edema.

Dopamine, at doses from 1 to 3  $\mu\text{g}/\text{kg}$  per minute, has been used conventionally to support mesenteric and renal perfusion as “renal dose dopamine.” Vasodilation at low doses is mediated via vascular dopamine 1 ( $\text{D}_1$ ) receptors in coronary, mesenteric, and renal vascular beds. By activating adenylyl cyclase and raising intracellular concentrations of cyclic AMP,  $\text{D}_1$ -receptor agonists cause vasodilatation. There are also dopamine 2 ( $\text{D}_2$ ) receptors that antagonize  $\text{D}_1$ -receptor stimulation. Fenoldopam (Corlopan), a parenteral  $\text{D}_1$ -receptor-specific agonist, is also available as a therapy. However, there are no data supporting its use to improve renal function other than by increasing cardiac output, and it also increases the risk of postoperative AF.<sup>133</sup> Infusion of fenoldopam (0.1 to 0.3  $\mu\text{g}/\text{kg}$  per minute) causes an increase in GFR, renal blood flow, and  $\text{Na}^+$  excretion.

Clinical trials of dopamine failed to show improvement in renal function, which probably is a result of the nonspecificity of dopamine. As a catecholamine and a precursor in the metabolic synthesis of norepinephrine and epinephrine, dopamine has inotropic and chronotropic effects on the heart. The inotropic effect is mediated by  $\beta_1$ -adrenergic receptors and usually requires infusion rates higher than those able to produce enhanced renal perfusion and diuresis. However, there are varied pharmacokinetic responses to dopamine infusion even in healthy subjects; therefore, the use of a “renal dose” dopamine regimen may not always result in the desirable effects. Stimulation of catecholamine receptors and  $\text{D}_2$  receptors antagonizes the effects of  $\text{D}_1$ -receptor stimulation. Current data do not consistently demonstrate improved renal outcomes with use of the  $\text{D}_1$ -receptor-specific agonist fenoldopam.

## HERBAL MEDICINE

A large number of Americans take herbal remedies for their health. Most of these herbal therapies are not supported by clear scientific evidence and are not under rigorous control by the FDA.<sup>134-136</sup> Patients who take alternative remedies may not necessarily disclose this information to their physicians.<sup>135</sup> There are increasing concerns regarding serious drug interactions between herbal therapy and prescribed medication.

**TABLE 4-6: Commonly Used Herbal Remedies**

Name	Common Uses	Side Effects/Drug Interactions
Cayenne (paprika)	Muscle spasm, GI disorders	Skin ulcers/blistering Hypothermia
Echinacea	Common cold, antitussive, urinary tract infections	May cause hepatotoxicity
Ephedra (Mahuang)	Antitussive, bacteriostatic	May decrease effects of steroids and cyclosporine Enhanced sympathomimetic effects with guanethidine or monoamine oxidase inhibitor (MAOI) Arrhythmias with halothane or digoxin Hypertension with oxytocin
Feverfew	Migraine, antipyretic	Platelet inhibition, rebound headache, aphthous ulcers, GI irritation
Garlic	Lipid-lowering, antihypertensive antithrombotic	May potentiate warfarin
Ginger	Antinauseant, antispasmodic	May potentiate aspirin and warfarin
Ginkgo	Improve circulation	May potentiate aspirin and warfarin
Ginseng	Adaptogenic, enhance energy level, antioxidant	Ginseng abuse syndrome: sleepiness, hypertonia, edema May cause mania in patients on phenelzine May decrease effects of warfarin Postmenopausal bleeding Mastalgia
Goldenseal	Diuretic, anti-inflammatory, laxative, hemostatic	Overdose may cause paralysis; aquaretic (no sodium excretion); may worsen edema/hypertension
Kava-kava	Anxiolytic	Potentiates barbiturates and benzodiazepines Potentiates ethanol May increase suicide risk in depression
Licorice	Antitussive, gastric ulcers	High blood pressure, hypokalemia, and edema
Saw palmetto	Benign prostatic hypertrophy, antiandrogenic	Additive effects with other hormone replacement therapy (eg, HRT)
St. John's wort	Antidepressant, anxiolytic	Possible interaction with MAOIs Decreases metabolism of fentanyl and ondansetron
Valerian	Mild sedative, anxiolytic	Potentiates barbiturates and benzodiazepines

Some of the most common herbal remedies and drug interactions are summarized in Table 4-6.

## AIRWAY MANAGEMENT

Airway management in cardiovascular surgical patients is important because patients often present with coexisting conditions that may complicate endotracheal intubation. For example, a patient with morbid obesity and sleep apnea may require awake intubation with a fiberoptic bronchoscope, or a history of smoking and COPD may make the patient susceptible to rapid desaturation and/or bronchospasm. Airway management in the perioperative period is a primary responsibility of the anesthesiologist, but the surgeon becomes involved in the absence of the anesthesiologist or in assisting the anesthesiologist in difficult situations. Airway management involves instrumentation and mechanics (not discussed here) and employs pharmacologic approaches to overcome

pathophysiologic problems contributing to airway obstruction and to facilitate manipulation and instrumentation of the airway. Pharmacologic agents are considered at the end of this section.

Five major challenges may be encountered in airway management. Each of these is described succinctly below to facilitate understanding of the roles that drugs play in meeting the challenges. The five challenges are (1) overcoming airway obstruction, (2) preventing pulmonary aspiration, (3) performing endotracheal intubation, (4) maintaining intermittent positive-pressure ventilation (IPPV), and (5) reestablishing spontaneous ventilation and airway protective reflexes.

### Airway Obstruction

Obstruction to gas flow can occur from the entry of a foreign object (including food) into the airway and as a result

of pathophysiologic processes involving airway structures (eg, trauma and edema). In the anesthetized or comatose patient, the loss of muscle tone can allow otherwise normal tissues (eg, tongue and epiglottis) to collapse into the airway and cause obstruction. The first measure in relieving such obstructions involves manipulation of the head and jaw, insertion of an artificial nasal or oral airway device, and evacuation of obstructing objects and substances (eg, blood, secretions, or food particles). Except for drugs used to facilitate endotracheal intubation (see the following), the only drug useful to improve gas flow through a narrowed airway is a mixture of helium and oxygen (Heliox), which has a much reduced viscosity resulting in reduced resistance to gas flow.

## Aspiration

The upper airway (above the larynx/epiglottis) is a shared porthole to the lungs (gas exchange) and gastrointestinal tract (fluids and nutrition). Passive regurgitation or active vomiting resulting in accumulation of gastric contents in the pharynx places the patient at risk of pulmonary aspiration, especially under circumstances in which airway reflexes (eg, glottic closure and coughing) and voluntary avoidance maneuvers are suppressed (eg, anesthesia or coma). Particulate matter can obstruct the tracheobronchial tree, and acidic fluid (pH < 2.5) can injure the lung parenchyma. The resulting pneumonitis can cause significant morbidity (eg, acute respiratory distress syndrome) and has a high mortality rate. Preoperative restriction of fluids and food (NPO status) does not guarantee the absence of aspiration risks. Similarly, the advance placement of a nasogastric or orogastric tube may serve to reduce intragastric pressure but does not guarantee complete removal of gastric contents. Nevertheless, both NPO orders and the insertion of a nasogastric or orogastric tube under some circumstances are worthwhile measures to reduce the risks of pulmonary aspiration. In some circumstances, the deliberate induction of vomiting in a conscious patient may be indicated, but this is done rarely and almost never involves the use of an emetic drug. In fact, more often antiemetic drugs are employed to reduce the risks of vomiting during airway manipulation and induction of anesthesia.

Drug therapy to reduce the risks of pulmonary aspiration is focused on decreasing the quantity and acidity of gastric contents and on facilitating endotracheal intubation (see the following). Nonparticulate antacids (eg, sodium citrate [Bicitra]) are used to neutralize the acidity of gastric fluids. Drugs to reduce gastric acid production include H<sub>2</sub>-receptor blockers (eg, cimetidine [Tagamet], ranitidine [Zantac], famotidine [Pepcid]), and inhibitors of gastric parietal cell hydrogen-potassium ATPase (proton pump inhibitors, eg, omeprazole [Prilosec], lansoprazole [Prevacid], and esomeprazole [Nexium]). Metoclopramide [Reglan] enhances gastric emptying and increases gastroesophageal sphincter tone. Cisapride [Propulsid] also increases gastrointestinal motility via the release of acetylcholine at the myenteric plexus.

Antiemetic drugs are used more commonly in the postoperative period and include several different drug classes: anticholinergics (eg, scopolamine [Transderm Scop]), antihistamines (eg, hydroxyzine [Vistaril] and promethazine [Phenergan]), and antidopaminergics (eg, droperidol [Inapsine] and prochlorperazine [Compazine]). Antidopaminergic agents may cause extrapyramidal side effects in elderly patients. More costly but effective alternatives include the use of antiserotonergics (eg, ondansetron [Zofran] and dolasetron [Anzemet]).

## Endotracheal Intubation

Drugs are employed for three purposes in facilitating endotracheal intubation: (1) to improve visualization of the larynx during laryngoscopy; (2) to prevent closure of the larynx; and (3) to facilitate manipulation of the head and jaw.

For bronchoscopy, laryngoscopy, or fiberoptic endotracheal intubation, the reflex responses to airway manipulation can be suppressed by several different methods alone or in combination. Topical anesthesia (2 or 4% lidocaine spray) can be used to anesthetize the mucosal surfaces of the nose, oral cavity, pharynx, and epiglottis. Atomized local anesthetic can be inhaled to anesthetize the mucosa below the vocal cords. The subglottic mucosa also can be anesthetized topically by injecting local anesthetic into the tracheal lumen through the cricothyroid membrane. A bilateral superior laryngeal nerve block eliminates sensory input from mechanical contact or irritation of the larynx above the vocal cords. It must be remembered that anesthesia of the mucosal surfaces to obtund airway reflexes compromises the reflex-protective mechanisms of the airway and increases the patient's vulnerability to aspiration of substances from the pharynx. Improvement of visualization of the larynx includes decreasing salivation and tracheal bronchial secretions by administration of an anticholinergic drug (eg, glycopyrrolate), reducing mucosal swelling by topical administration of a vasoconstrictor (eg, phenylephrine), and minimizing bleeding owing to mucosal erosion by instrumentation, which also is minimized by topical vasoconstrictors. The use of steroids in minimizing acute inflammatory responses in the airway may have some delayed benefit, but steroids usually are not indicated just before intubation.

Systemic drugs, usually administered intravenously, can be used to obtund the cough reflex. Intravenous lidocaine (1 to 2 mg/kg) transiently obtunds the cough reflex without affecting spontaneous ventilation to any significant degree. The risks of CNS stimulation and seizure-like activity have to be kept in mind and can be reduced by the prior administration of an intravenous barbiturate or benzodiazepine in small doses. Intravenous opioids are effective in suppressing cough reflexes, but the doses required impair spontaneous ventilation to the point of apnea. A combination of an intravenous opioid and a major tranquilizer (eg, neuroleptic analgesia) allows the patient to tolerate an endotracheal tube with much smaller doses of the opioid and less embarrassment of spontaneous ventilation. Small doses of opioids are also useful in

obtunding airway reflexes during general anesthesia provided by either intravenous (eg, thiopental) or inhaled anesthetics (eg, isoflurane). Not only do the opioids obtund the cough reflex that results in closure of the larynx, but they also are useful in limiting the autonomic sympathetic response to endotracheal intubation that typically leads to hypertension and tachycardia.

Skeletal muscle relaxants are used most commonly in conjunction with a general anesthetic to allow manipulation of the head and jaw and prevent reflex closure of the larynx. Of course, they also render the patient apneic, and two procedures are used commonly to maintain oxygenation of the patient's blood. First, the patient breathes 100% oxygen by mask while still awake to eliminate nitrogen from the lungs, and then a rapid-sequence administration of an intravenous anesthetic (eg, thiopental) is followed immediately by a rapid-acting neuromuscular blocker (eg, succinylcholine or rocuronium), and cricoid pressure is applied (Sellick maneuver). As soon as the muscle relaxation is apparent (30 to 90 seconds), laryngoscopy is performed, an endotracheal tube is inserted, the tracheal tube cuff is inflated, and the position of the tube in the trachea is verified. Second, when there is minimal risk of pulmonary aspiration (eg, presumed empty stomach), the patient is anesthetized and paralyzed while ventilation is supported by intermittent positive pressure delivered via a face mask. At the appropriate time, laryngoscopy is performed and the endotracheal tube is inserted.

### Normalizing Pulmonary Function during Positive-Pressure Ventilation

Once an endotracheal tube is in place, it is common practice in the operating room to maintain general anesthesia and partial muscular paralysis in order to facilitate positive-pressure ventilation and continued toleration of the endotracheal tube by the patient. Postoperatively, in the post-anesthesia care unit (PACU) and intensive care unit (ICU), general anesthesia and partial muscular paralysis may be continued if prolonged positive-pressure ventilation is anticipated, or sedatives may be administered by intravenous infusion to allow toleration of the endotracheal tube in anticipation of recovery of spontaneous ventilation and tracheal extubation.

Three other problems are encountered in the patient whose ventilation is supported mechanically by an endotracheal tube: (1) poor ventilatory compliance; (2) bronchoconstriction; and (3) impaired gas exchange. Poor ventilatory compliance can reflect limited compliance of the chest wall and diaphragm, limited compliance of the lungs per se, or both. Deepening general anesthesia and administration of a skeletal muscle relaxant can be used to reduce intercostal and diaphragmatic muscle tone, but they obviously cannot improve the chest cavity compliance that is fixed by disease (eg, scoliosis or emphysema).

Poor lung compliance may reflect pulmonary interstitial edema, consolidation, bronchial obstruction (eg, mucus plugs), bronchoconstriction, or compression of the lung by

intrathoracic substances (eg, pneumothorax, hemothorax, or tumor mass). Treatment of these involves drug therapy of HF and infection and procedures such as bronchoscopy and thoracentesis.

Bronchoconstriction may exist chronically (eg, asthma or reactive airways disease), and these conditions can be exacerbated by the collection of tracheobronchial secretions in the presence of an endotracheal tube, which reduces the effectiveness of coughing in clearing the airway. Occasionally bronchoconstriction can be induced by mechanical stimulation of the airway by an endotracheal tube or other object in an otherwise normal patient. Drug treatment is focused on reducing bronchial smooth muscle tone (eg, beta<sub>2</sub> sympathomimetic or anticholinergic agents), minimizing tracheal secretions, and decreasing sensory input from the tracheal bronchial tree (eg, topical anesthetic, deeper general anesthesia, intravenous lidocaine, or an opioid). Acute treatment of bronchoconstriction may involve any combination of the following: (1) an aerosolized beta<sub>2</sub> sympathomimetic and/or anticholinergic agent; and (2) systemic intravenous administration of a beta<sub>2</sub> sympathomimetic agent, a phosphodiesterase inhibitor (eg, theophylline salts [aminophylline]), and/or an anticholinergic agent.

Intravenous steroids are indicated in severe bronchoconstriction, especially in asthmatic patients, for whom they have been effective in the past. With the administration of 100% oxygen, blood oxygenation usually is not the main problem in patients with bronchoconstriction; the progressive development of hypercarbia and the trapping of air in lung parenchyma reduce ventilatory compliance and increase intrathoracic pressure. These, in turn, reduce venous return and may cause a tamponade-like impairment of cardiac function.

Impaired alveolar-capillary membrane gas exchange can result from alveolar pulmonary edema (treated by diuretics, inotropes, and vasodilators), decreased pulmonary perfusion (treated by inotropes and vasodilators), and lung consolidation (antibiotic therapy for infection).

### Restoration of Spontaneous Ventilation and Airway Protective Mechanisms

The anesthesiologist attempts to tailor the anesthetic plan according to postoperative expectations for the patient. In the relatively healthy patient for whom tracheal extubation can be anticipated in the operating room, the goal is to have the patient breathing spontaneously with airway reflexes intact and the patient arousable to command immediately on completion of the operation. The challenge for the anesthesiologist is to maintain satisfactory general anesthesia through the entire course of the operation and yet have the patient sufficiently recovered from anesthetic drugs, including hypnotics and opioids, shortly after conclusion of the operation. If this is not possible, then the patient is transferred to the PACU to allow additional time for elimination of drugs that depress spontaneous ventilation and cough reflexes. Another possibility is to administer antagonists to opioids (eg, naloxone) and benzodiazepines

(eg, flumazenil), but this approach risks sudden awakening, pain, and uncontrolled autonomic sympathetic activity leading to undesirable hemodynamic changes. And there is the risk of recurrent ventilatory depression because it is difficult to match the doses of the antagonists to the residual amounts of anesthetic drugs. On the other hand, it is fairly routine for the effects of neuromuscular blockers to be antagonized by administration of an anticholinesterase (eg, neostigmine) in combination with an anticholinergic agent (eg, atropine) to limit the autonomic cholinergic side effects of the anticholinesterase.

When the expectation is for maintenance of mechanical ventilation for some time in the postoperative period, then the patient's tolerance of the endotracheal tube is facilitated by the persistent effect of residual anesthetic drugs subsequently supplemented by administration of intravenous hypnotics (eg, propofol) and opioids (eg, fentanyl or morphine). These agents can be associated with side effects, including respiratory depression, especially when they are used concurrently. Dexmedetomidine (Precedex), an  $\alpha_2$ -adrenergic agonist, may offer advantages for sedation during weaning from mechanical ventilation because it provides sedation, pain relief, anxiety reduction, stable respiratory rates, and predictable cardiovascular responses. Dexmedetomidine facilitates patient comfort, compliance, and comprehension by offering sedation with the ability to rouse patients. This "arousability" allows patients to remain sedated yet communicate with health-care workers.

When the appropriate time comes to have the patient take over his or her own ventilation completely, these sedative and analgesic drugs are weaned to a level allowing satisfactory maintenance of blood oxygenation and carbon dioxide removal, easy arousal of the patient, and at least partial restoration of airway reflex mechanisms.

## Pharmacology Related to Airway and Lung Management

Cardiac surgical patients are usually kept intubated and ventilated at the end of surgery, and ventilator support is withdrawn in the ICU. Sedative drugs are required to facilitate this transfer from operating room to intensive care, and while the patient is ventilated. Some patients require continued ventilation because of primary pulmonary disease, underlying cardiac disease and/or perioperative complications. Others may require medications to treat bronchospasm or airway obstruction, or to facilitate reintubation if they develop respiratory failure once extubated.

## Sedative Medications to Facilitate Mechanical Ventilation

### PROPOFOL

The medications used in cardiac surgery patients are the same as those used in other mechanically ventilated patients. A common approach is to use propofol, an intravenous anesthetic/sedative agent that is rapidly eliminated by the liver

and therefore facilitates rapid awakening. This drug is not water soluble so is supplied in a lipid emulsion; for short-term infusions (less than a day or two) lipid accumulation is not an issue, but triglyceride levels should be measured if the drug is given in high doses, especially at the same time as intravenous feeding. The hemodynamic effects of propofol are mostly a result of vasodilation, both arterial and venous, as well as the usual "withdrawal of sympathetic tone," which occurs when anxious, stressed patients are sedated. In addition there is a mild bradycardia and blunted heart rate response to hypotension, and a mild negative inotropic effect usually not relevant at clinical doses. The clinical dose range for sedation is 25 to 75  $\mu\text{g}/\text{kg}$  per minute but must be titrated.

## Benzodiazepines

Benzodiazepines are also used to facilitate mechanical ventilation, commonly midazolam (Versed) or lorazepam (Ativan). These drugs do not have the vasodilating effects of propofol, are good amnestic agents, but have a major disadvantage in that awakening is less predictable and more often prolonged, especially with lorazepam. In addition, these drugs appear to be more associated with postoperative delirium than other sedative drugs. Despite these problems, benzodiazepines are useful in the sedation of severely hypotensive patients requiring vasoconstrictor support. They have minimal, if any, direct cardiovascular effects, but withdrawal of sympathetic tone can lead to hypotension. Midazolam is usually administered as a continuous infusion of 1 to 4 mg/h, while lorazepam is most often given by intermittent dosing of 1 to 2 mg every 4 to 6 hours.

## Dexmedetomidine

A relatively new addition to the sedative drug family is dexmedetomidine (Precedex), a centrally acting  $\alpha_2$  agonist. This drug is the same class as clonidine, but has a much greater affinity for the alpha receptor. Not surprisingly, the most common hemodynamic effect, which sometimes limits its use, is bradycardia and hypotension. This drug can be used as a single agent to facilitate transfer from the operating room (OR) to the ICU and the period of ventilator weaning and extubation. The major advantage of dexmedetomidine is that it does not affect ventilatory drive and patients can usually be aroused while receiving the drug. It also has a significant analgesic component, different from propofol or the benzodiazepines. The usual infusion rate of dexmedetomidine is 0.2 to 0.7  $\mu\text{g}/\text{kg}$  per hour, preceded by a loading dose of 1  $\mu\text{g}/\text{kg}$  over 20 to 30 minutes. The loading dose can be reduced or not given if hemodynamics warrant.

## Opioids

The main reason patients need sedation during mechanical ventilation is to tolerate the presence of a transoral tracheal tube. In addition to general discomfort, there is continuous

airway stimulation by the foreign object. To blunt airway reflexes as well as to treat postoperative pain, it is useful to add an opioid drug to whichever sedative agent the patient is receiving. For early postoperative awakening (ie, in the first hours), this is less of an issue as there is usually residual opioid effect from drugs given intraoperatively; however, patients will need additional opioid as they awaken and experience pain. For patients ventilated overnight or longer, use of opioid drugs will have these same benefits and likely result in a reduced need for the sedative drug. Fentanyl is a commonly used drug in this setting, partly because it has a rapid onset of action and relatively rapid recovery if dosing is not prolonged. Infusions of 1 to 4  $\mu\text{g}/\text{kg}$  per hour are used. Alternatively intermittent dosing with 1 to 4 mg morphine or 0.5 to 1 mg hydromorphone (Dilaudid) every 1 to 4 hours may be employed.

### Medications Used to Facilitate Urgent Tracheal Intubation

Patients in extremis (eg, during cardiac or respiratory arrest) rarely require medications to facilitate intubation. In decompensating patients who are fully or partially conscious, challenges may include agitation, resistance to opening the mouth, and/or closed vocal cords when intubation is attempted. In some patients small doses of sedative/opioid medications with a rapid onset such as midazolam and fentanyl, respectively, are adequate; in others an anesthetic induction agent such as propofol or etomidate can be used, with or without a paralytic drug. The disadvantage to propofol is hypotension caused by vasodilation, as referred to in the preceding. This drug should be used in incremental doses, 10 to 20 mg at time, until a dose of 1 to 2 mg/kg has been given. Etomidate has no direct cardiovascular effects and is usually given in a dose of 0.15 to 0.3 mg/kg. This drug has an unusual side effect of impairing steroid synthesis and has been associated with adrenal insufficiency in critically ill patients when given by infusion. In addition, many patients experience unusual movements as this drug is administered. In general, the use of paralytic drugs is discouraged unless there is an anesthesiology provider or someone skilled in the use of these drugs and airway management present.

Succinylcholine is the most rapidly acting paralytic agent with an onset of 30 to 60 seconds and is given in a dose of 1 mg/kg. This depolarizing agent causes potassium release and must be avoided in hyperkalemic patients. It causes stimulation of muscarinic and nicotinic receptors, an increase in serum catecholamines, and many different, usually mild, dysrhythmias have been reported. Alternatively, rocuronium in a dose of 0.5 mg/kg can be given, but 60 to 90 seconds are required for adequate paralysis. Rocuronium in this dose has no cardiovascular effect. If an anesthetic induction agent and/or a neuromuscular blocking agent are being considered, an important issue is the possibility of aspiration of stomach contents. In an urgent situation the risk of this is reduced if the drugs are administered in rapid sequence with an assistant

providing cricoid pressure (to occlude the esophagus), and manual ventilation is minimized until the tube is in place.

### Drugs to Treat Airway Pathology: Stridor/Edema, Bronchospasm, Secretions

Fluid overload, prolonged positioning with the head dependent, or superior vena cava obstruction may all lead to edema of the upper airway. Alternatively, trauma from intubation or other devices in the oropharynx (eg, transesophageal echocardiography [TEE] probe) may cause glottis edema. There may be edema below the cords resulting from presence of the endotracheal tube/cuff. The common treatments for airway narrowing resulting from edema are: (1) use of a mixture of helium/oxygen; (2) inhaled racemic epinephrine; (3) diuretics and head-up position; and (4) a brief course of dexamethasone (IV).

**Helium/Oxygen.** Helium with oxygen (Heliox) is supplied as an 80:20 mix. Helium is less dense than nitrogen, facilitating laminar rather than turbulent flow through a narrowed airway. If a patient cannot tolerate the relatively low concentration of oxygen (20%), then additional oxygen will need to be administered. Although the greatest benefit is provided by 80% helium, concentrations of 40 to 50% provide some benefit.

**Racemic Epinephrine.** Racemic epinephrine is supplied as 1% solution and administered through an aerosol mask in a dose of 2.5 mL to cause vasoconstriction and reduced airway edema. Absorption of epinephrine can cause tachycardia and hypertension.

**Diuretics and Dexamethasone.** Specific diuretic drugs are discussed in the preceding; when a rapid effect is desired, then usually a loop diuretic such as furosemide is employed. Although this may not specifically treat airway edema, the combination of elevated head and diuresis will reduce edema in the upper body. Dexamethasone is used as part of the "steroids for anything that swells" philosophy. There is little evidence of efficacy of corticosteroids in this setting; dexamethasone is used to avoid the mineralocorticoid effect of other potent intravenous steroid preparations. The usual dose is 8 mg followed by 4 mg every 6 hours for four to eight doses.

**Bronchodilators and Mucolytics.** A summary of bronchodilator and mucolytic drugs is given in Table 4-7. In the cardiac surgical patient, wheezing is more likely because of fluid overload or left ventricular failure than primary bronchospastic disease, but inhaled bronchodilators may give some relief while treatment of the primary disorder is being instituted (eg, diuresis or administration of an inotropic drug). In order of preference, inhaled beta agonists, anticholinergic agents, and intravenous steroids are used.<sup>137</sup> All three

**TABLE 4-7: Inhaled Bronchodilators and Mucolytics**

	Drug	Mechanism	Dosage	Frequency
Bronchodilators	Albuterol	Beta <sub>2</sub> agonist	2.5 mg/3 mL	Q 4-6 h*
	Levalbuterol	Beta <sub>2</sub> agonist	0.63-1.25 mg/3 mL	Q 6 h
	Ipratropium	Anticholinergic	0.5 mg/3 mL	Q 4-6 h
Mucolytic	Dornase alpha	Cleaves DNA	2.5 mg/3 cc	Q 12 h

\*May be given more frequently.

may be indicated. Beta agonists relax smooth muscle in the airways and usually have the most rapid therapeutic effect. In the acute setting aerosolized drug via a facemask is more effective than metered-dose inhalers. It should be noted that management of chronic asthma focuses on inhaled anti-inflammatory agents, but these drugs are not helpful in the acute setting, such as postoperatively. The presence of tenacious secretions should prompt consideration of an inhaled mucolytic such as dornase/DNAse (Pulmozyme). *N*-acetylcysteine (Mucomyst) is another mucolytic but may cause airway irritation so should not be given in the setting of acute bronchospasm. See the table for dosages of these drugs (see Table 4-7).

# Cardiovascular Pathology

Frederick J. Schoen • Robert F. Padera

Cardiovascular pathology defines the morphology and mechanisms of cardiovascular disease in individual patients and patient cohorts, both along the natural history of a disease and following surgery and interventions. The data derived through cardiovascular pathology thereby facilitate evidence-based choices among surgical or catheter-based interventional options and optimize short- and long-term patient management. Beyond implicit clinical benefit for individual patients, the discipline of cardiovascular pathology is a cornerstone of modern cardiovascular research and the preclinical development and clinical implementation of innovative drugs, devices, and other therapeutic options.

This chapter summarizes pathologic anatomy, clinicopathologic correlations, and pathophysiologic mechanisms in the various forms of structural heart disease most relevant to surgery and catheter-based interventions used to diagnose and treat the major forms of acquired structural cardiovascular disease. In view of space limitations, several important areas (eg, aortic disease) are necessarily omitted from discussion and others (eg, cardiac assist and replacement devices) are focused on details not covered elsewhere in this book. Moreover, although we have not included the key considerations herein, we are mindful that the number of adults with congenital heart disease is increasing rapidly and that they have unique and important clinical and pathologic concerns.<sup>1,2</sup>

## MYOCARDIAL RESPONSE TO INCREASED WORK AND MYOCARDIAL DISEASE

### Myocardial Hypertrophy

*Hypertrophy* is the compensatory response of the cardiac muscle (the *myocardium*), to increased work (Fig. 5-1).<sup>3</sup> This structural and functional adaptation accompanies nearly all forms of heart disease, and its consequences often dominate the clinical picture. Hypertrophy induces an increase in the overall mass and size of the heart that reflects an increased size of individual myocytes largely through addition of contractile elements (the *sarcomeres*) and associated cell and

tissue elements. Substantial and functionally beneficial augmentation of myocyte number (*hyperplasia*) in response to stress or injury has not been demonstrated in the adult heart.

The pattern of hypertrophy reflects the nature of the stimulus (see Fig. 5-1B). Pressure overload (eg, in systemic hypertension or aortic stenosis) induces an increased ventricular mass, increased wall thickness, and increased ratio of wall thickness to cavity radius without dilation. In contrast, volume overload (eg, in aortic or mitral regurgitation, myocardial infarction, or dilated cardiomyopathy) promotes hypertrophy accompanied by chamber dilation, in which both ventricular radius and total mass are increased. The chamber wall is affected globally by the increased chamber pressure of hypertension, the pressure or volume overload of valvular heart disease, and in dilated cardiomyopathy. In contrast, the ischemic myocyte necrosis and loss of contractile tissue myocardial infarction induce hypertrophy only in non-infarcted regions of myocardium. The terms *concentric*, *eccentric*, and *compensatory* have previously been used to describe pressure, volume, and ischemic injury-related hypertrophy, respectively.

The constellation of changes that occur regionally following myocardial infarction, or more globally in pressure and volume overload, is called *ventricular remodeling*.<sup>4</sup> At a cell level, pressure overload promotes augmentation of cell width via parallel addition of sarcomeres; in contrast, volume overload and/or dilation stimulate augmentation of both cell width and length via both parallel and series addition of sarcomeres.

Hypertrophic changes initially increase the efficiency of the heart, enhance function, and are thereby adaptive. However, when these changes are excessive and prolonged, they may ultimately become deleterious and contribute to cardiac failure via several mechanisms. Because the vasculature does not proliferate and blood flow is not augmented commensurate with increased cardiac mass, hypertrophied myocardium is vulnerable to ischemic damage. Moreover, myocardial fibrous tissue is often increased. Also important are the molecular changes that accompany and likely mediate enhanced function in hypertrophied hearts, and which may subsequently

**FIGURE 5-1** Summary of the gross and microscopic changes in cardiac hypertrophy. (A) Gross photo of heart with hypertrophy caused by aortic stenosis. The wall of the left ventricle is thick and the chamber is not dilated. The left ventricle is on the lower right in this apical four-chamber view of the heart. (B) Altered cardiac configuration in left ventricular hypertrophy without and with dilation, viewed in transverse heart sections. Compared with a normal heart (*center of this panel*), a pressure overloaded heart, caused for example by aortic valve stenosis (*left*), has increased mass and a thick left ventricular wall, whereas a volume overloaded heart, caused for example by mitral valve regurgitation, is both hypertrophied and dilated (*right*), having increased mass with a near normal or diminished wall thickness. (C) Photomicrograph of normal myocardium. (D) Photomicrograph of hypertrophied myocardium at same magnification as (C), showing large cells with enlarged nuclei. (B) Reproduced with permission from Allen HD, Gutgesell HP, Clark EB, et al: *Moss and Adams' Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adults*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2001. [C and D] Reproduced with permission from Kumar V, Fausto N, Abbas A, et al: *Robbins/Cotran Pathologic Basis of Disease*, 8th ed. Philadelphia, WB Saunders, 2010.)

promote development of heart failure. For example, hypertrophy induces a gene expression profile in cardiac myocytes that is similar to that of proliferating cells generally and particularly that of fetal cardiac myocytes during development. Differentially expressed proteins may be less functional and/or more or less abundant than normal. Hypertrophied and/or failing myocardium also may have a mechanical disadvantage engendered by altered chamber configuration, impaired energetics, reduced adrenergic responsiveness, decreased calcium availability, impaired mitochondrial function, microcirculatory spasm, and apoptosis of cardiac myocytes.

Novel therapeutic strategies for heart failure treatment based on molecular mechanisms are under investigation.<sup>5</sup>

Owing to the totality of the changes described above, cardiac hypertrophy comprises a tenuous balance. The adaptive changes may be overwhelmed by potentially deleterious quantitative or qualitative alterations in structure, function, and biochemistry/gene expression, including cardiac configuration, metabolic requirements of an enlarged muscle mass, protein synthesis, decreased capillary/myocyte ratio, fibrosis, microvascular spasm, cell loss, and impaired contractile mechanisms. Hypertrophy also decreases

**FIGURE 5-2** Cardiac failure necessitating heart transplantation. (A) Ischemic heart disease, with a large anteroapical-septal myocardial infarct (with mural thrombus) noted to the left of center of the photo (arrow). (B) Four years following mitral valve replacement with a porcine bioprosthesis for congenital deformity causing mitral regurgitation. ([A] Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989.)

myocardial compliance and may thereby hinder diastolic filling. In addition, hypertrophy is an independent risk factor for cardiac mortality and morbidity, especially sudden death.<sup>6</sup>

Heart failure can occur with pressure or volume overload of many causes, owing to both regional and global lesions (Fig. 5-2). Although left ventricular hypertrophy (as measured by left ventricular size and mass) regresses in many cases following removal of the stimulus, the extent of resolution in an individual is unpredictable, and the processes by which recovery of the hypertrophied or failing heart (often termed reverse remodeling occur) are uncertain.<sup>7</sup> Moreover, progressive cardiac failure may ensue following cardiac surgery and despite revascularization or hemodynamic adjustment, by structural repair (see Fig. 5-2B). In addition, the markedly increased cardiac muscle mass in a hypertrophied heart may compromise intraoperative myocardial preservation.

## Cardiomyopathies

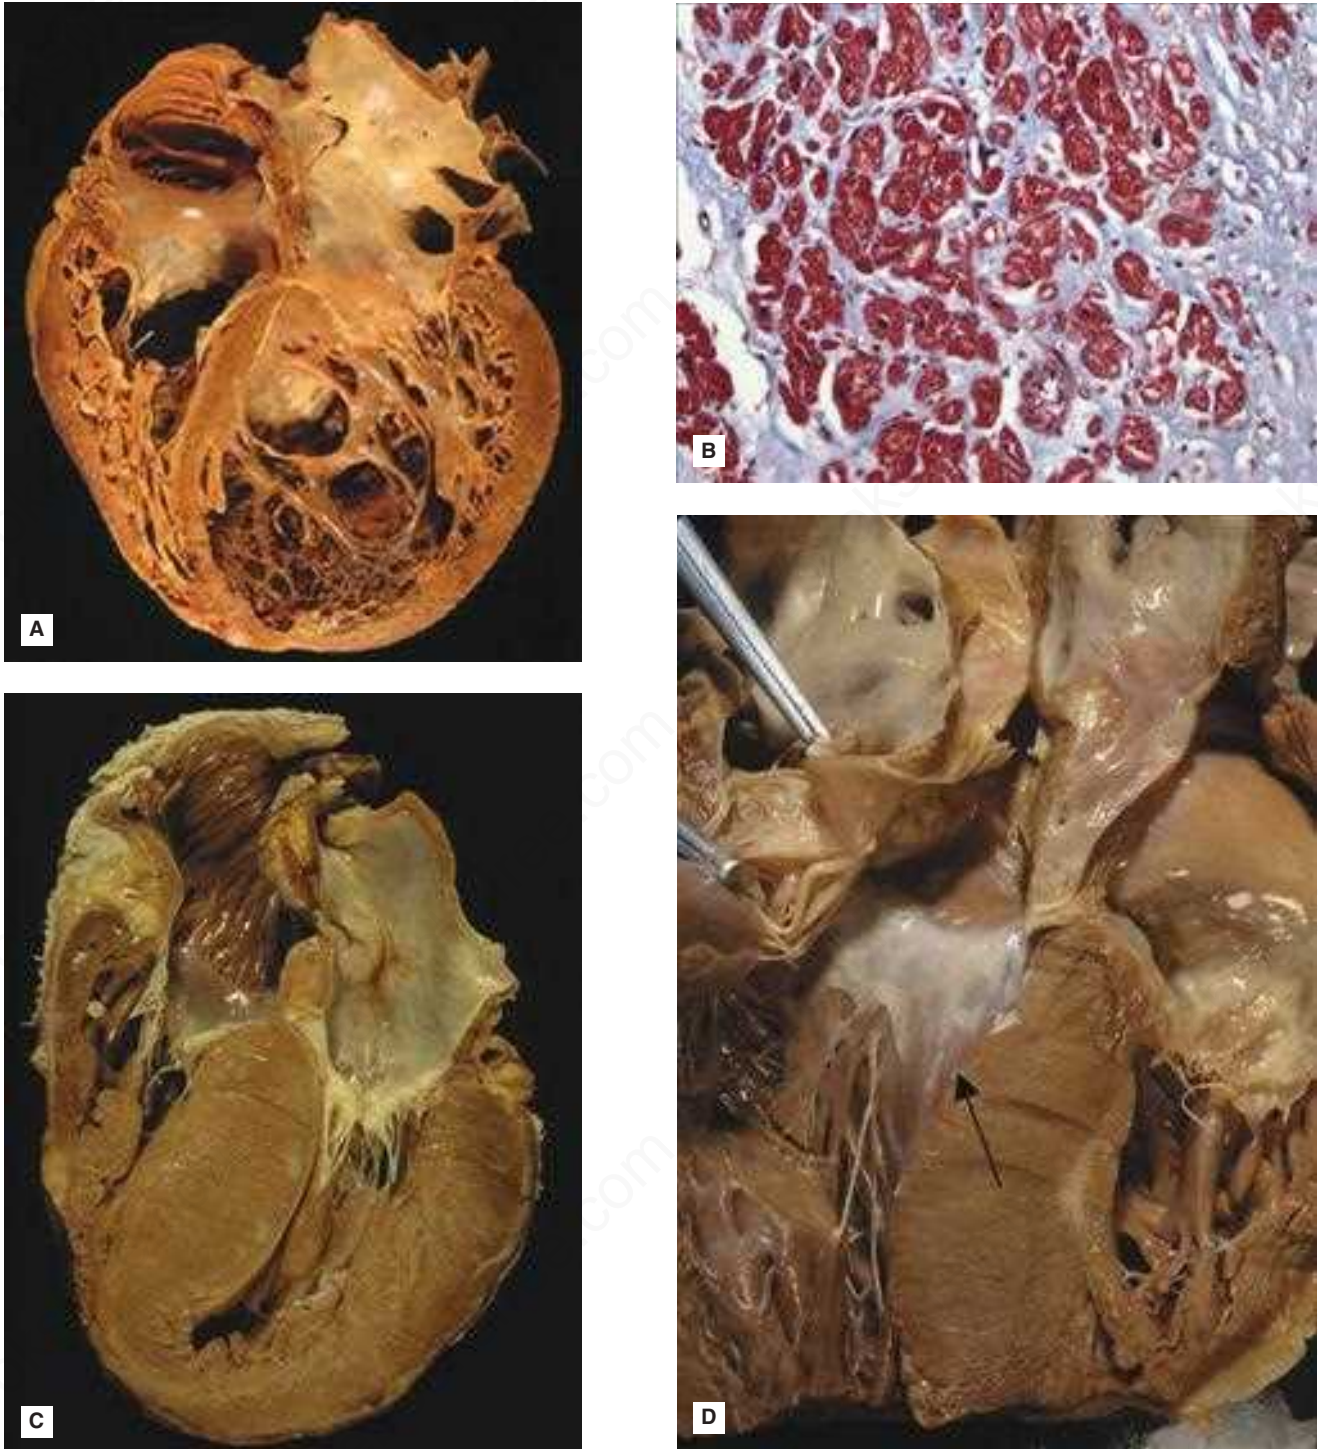

Cardiomyopathies are diseases in which the primary cardiovascular abnormality is in the myocardium. A *primary cardiomyopathy* comprises a condition solely or predominantly confined to heart muscle, whereas a *secondary cardiomyopathy* (often called *specific heart muscle disease*) implies myocardial involvement as a feature of a generalized systemic or multisystem disorder, such as amyloidosis and hemochromatosis, other infiltrative and storage diseases, drug and other toxic reactions, sarcoidosis, various autoimmune and collagen vascular diseases, or neuromuscular/neurologic disorders (eg, Duchenne-Becker muscular dystrophy). Genetic causes of primary cardiomyopathy include hypertrophic cardiomyopathy (HCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), left ventricular noncompaction, the ion channel disorders (eg, long QT and Brugada syndromes), and some cases of dilated cardiomyopathy.<sup>8</sup> Acquired causes include myocarditis (inflammatory cardiomyopathy), and stress-provoked (takotsubo), tachycardia-induced, and peripartum cardiomyopathy. Although ischemic heart disease, valvular heart disease, and hypertensive heart disease can lead to a clinical practice resembling dilated cardiomyopathy, the terms *ischemic cardiomyopathy*, *valvular cardiomyopathy*, and *hypertensive cardiomyopathy* are discouraged because these conditions more likely reflect compensatory and remodeling changes induced by another cardiovascular abnormality. In contrast to the atherosclerotic coronary arterial disease that underlies most cases of ischemic heart disease, the epicardial coronary arteries are usually free of significant obstructions in patients with a cardiomyopathy.

In some cases (eg, myocarditis, sarcoidosis, amyloidosis, and hemochromatosis) the cause of a cardiomyopathy may be revealed by light and/or electron microscopic examination of a sample of myocardium obtained by endomyocardial biopsy, and other conditions such as ARVC and HCM have characteristic gross and microscopic features demonstrated at the time of transplantation or autopsy (but not generally by endomyocardial biopsy). In endomyocardial biopsy, also used in the management of the ongoing surveillance of cardiac transplant recipients,<sup>9</sup> a biptome is inserted into either the right internal jugular or femoral vein and advanced under fluoroscopic or echocardiographic guidance through the tricuspid valve, to the apical aspect of the right side of the ventricular septum, yielding 1- to 3-mm fragments of myocardium.

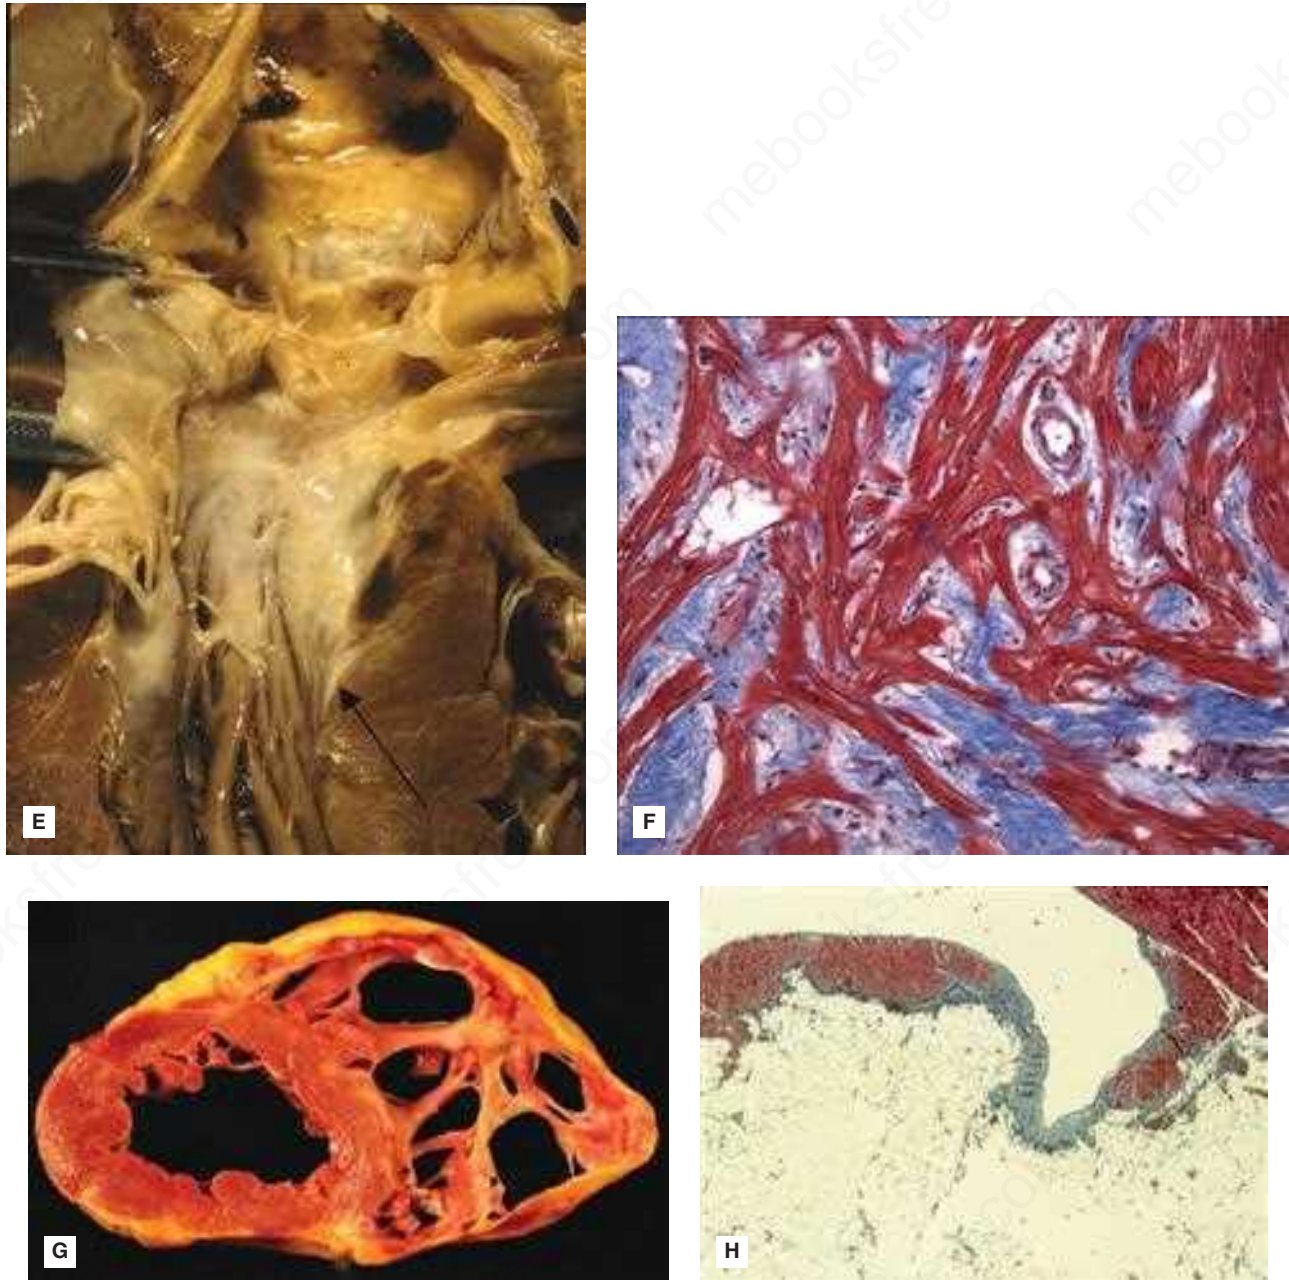

The common variants of cardiomyopathy are illustrated in Fig. 5-3.

## Dilated Cardiomyopathy

Dilated cardiomyopathy is characterized by cardiomegaly usually two to three times of normal weight, and four-chamber dilation (see Fig. 5-3A). The primary functional abnormality in dilated cardiomyopathy is impairment of left ventricular systolic function. Mural thrombi are sometimes

**FIGURE 5-3** Cardiomyopathies. (A and B) Dilated cardiomyopathy. (A) Gross photo showing four-chamber dilation and hypertrophy. (B) Photomicrograph of myocardium in dilated cardiomyopathy, demonstrating irregular hypertrophy and interstitial fibrosis. (C-F) Hypertrophic cardiomyopathy. (C) Gross photo, showing septal muscle bulging into the left ventricular outflow tract. In the gross photo shown in (D) the anterior mitral leaflet has been moved away from the septum to reveal a fibrous endocardial plaque, caused by systolic anterior motion (see text). In (A) and (C), the LV is on the right side of the photo; in (D) the LV is on the left. (E) Gross photo of left ventricular outflow tract of patient with extensive fibrosis owing to remote surgical septal myotomy/myectomy. (F) Photomicrograph of myocardium in hypertrophic cardiomyopathy demonstrating myofiber disarray, with marked hypertrophy, abnormal branching of myocytes, and interstitial fibrosis. (G and H) Arrhythmogenic right ventricular cardiomyopathy. (G) Gross photograph, showing dilation of the right ventricle (on the right) and near transmural replacement of the right ventricular free-wall myocardium by fat and fibrosis. (H) Photomicrograph of the right ventricular free wall in arrhythmogenic right ventricular cardiomyopathy, demonstrating focal transmural replacement of myocardium by fibrosis and fat. Fibrosis (collagen) is blue in the Masson trichrome stain in parts (B), (F), and (H).

**FIGURE 5-3** (Continued)

present predominantly in the left ventricle, and are a potential source of thromboemboli. The histologic changes in dilated cardiomyopathy, comprising myocyte hypertrophy and interstitial fibrosis, are nonspecific and indistinguishable from those in failing muscle in ischemic or valvular heart disease (see Fig. 5-3B). Moreover, the severity of the morphologic changes does not necessarily correlate with the severity of dysfunction or the patient's prognosis.

Dilated cardiomyopathy has a genetic and often familial basis in approximately 25 to 50% of cases, and our knowledge of the relevant molecular biology is increasing rapidly.<sup>10</sup>

Mutations most commonly involve genes encoding proteins of the cardiac myocyte cytoskeleton and sarcomere. Alcoholism, pregnancy-associated nutritional deficiency, and myocarditis can yield a dilated phenotype.<sup>11</sup>

### Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is characterized macroscopically by massive myocardial hypertrophy, usually without dilation (see Fig. 5-3C), and often with disproportionate thickening of the ventricular septum relative to the free wall

of the left ventricle (ratio > 1.3) (termed *asymmetric septal hypertrophy*). In some patients, the basal septum is markedly thickened at the level of the mitral valve, and the outflow of the left ventricle may be narrowed during systole, yielding dynamic left ventricular outflow tract obstruction. In such cases, contact between the left ventricular outflow tract and the anterior mitral leaflet during ventricular systole (observed by echocardiography as *systolic anterior motion* of the mitral valve) results in outflow tract endocardial thickening, in a configuration that mirrors the anterior leaflet of the mitral valve (see Fig. 5-3D). The most important microscopic features in HCM include (1) disorganized myocytes and contractile elements within cells (*myofiber disarray*); (2) extreme myocyte hypertrophy, with myocyte diameters frequently more than 40  $\mu\text{m}$  (normal approximately 15 to 20  $\mu\text{m}$ ); and (3) interstitial and replacement fibrosis (see Fig. 5-3F).

Hypertrophic cardiomyopathy usually has a genetic basis.<sup>12</sup> In many patients the disease is familial; remaining cases are sporadic. Over 1500 mutations have been identified in at least 11 genes; almost all occur in genes for sarcomeric proteins, most commonly  $\beta$ -myosin heavy chain and myosin-binding protein C. Occasional cases mimicking HCM are a result of deposition (eg, Fabry's disease).

The clinical course of HCM is variable. Complications include atrial fibrillation with potential mural thrombus formation and embolization, infective endocarditis of the mitral valve, intractable cardiac failure, and sudden death. End-stage heart failure can be accompanied by cardiac dilation. Sudden death is common, with risk related to the degree of hypertrophy and specific gene mutations. Reduced stroke volume results from decreased diastolic filling of the massively hypertrophied left ventricle. Patients with left ventricular obstruction may benefit from septal reduction by surgical myotomy/myectomy or chemical ablation.<sup>13</sup>

## Restrictive Cardiomyopathy

Restrictive cardiomyopathy comprises a pathophysiologically heterogeneous spectrum of conditions characterized by heart failure with preserved ejection fraction and previously called *diastolic dysfunction*; many of the potential causes are functional and are potentiated by aging, obesity, and hypertension.<sup>14</sup> Biatrial dilation may be prominent. Structural disorders that interfere with ventricular filling can cause restrictive cardiomyopathy physiology (eg, eosinophilic endomyocardial disease, amyloidosis, storage diseases such as Fabry's disease, or postirradiation fibrosis, constrictive pericarditis, and HCM). Distinct morphologic patterns may be revealed by endomyocardial biopsy.

## Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy is characterized by a dilated right ventricular chamber and severely thinned right ventricular wall, with extensive fatty infiltration,

loss of myocytes with compensatory myocyte hypertrophy, and interstitial fibrosis (see Fig. 5-3G-H).<sup>15</sup> Clinical features include right-sided heart failure and arrhythmias. Arrhythmias are often brought on by exertion, and this condition is associated with sudden death in athletes. ARVC may be associated with mutations in several genes involved in cell-cell adhesion and in intracellular signaling.

## CORONARY ARTERY AND ISCHEMIC HEART DISEASE

*Myocardial ischemia* occurs when perfusion via coronary flow is inadequate to meet metabolic needs, thus interfering with both the cellular delivery of oxygen and nutrients to cardiac myocytes, and the removal of waste products. Myocardial ischemia most often results from obstruction or narrowing of a coronary artery secondary to atherosclerosis. Nonatherosclerotic epicardial coronary artery obstructions can also occur in autoimmune diseases (eg, systemic lupus erythematosus and rheumatoid arthritis), progressive systemic sclerosis (scleroderma), vasculitis (eg, Buerger disease and Kawasaki disease), fibromuscular dysplasia, and as a result of dissection, spasm, embolism, or some drugs such as cocaine. Obstruction of small intramural coronary arteries occurs in diabetes, Fabry's disease, and amyloidosis, and in cardiac allografts (see later). Decreased coronary flow leading to global hypoperfusion and myocardial ischemia can occur during cardiopulmonary bypass. Ischemia can also result from increased cardiac demand secondary to exercise, tachycardia, hyperthyroidism, or ventricular hypertrophy and/or dilation. Moreover, the effects of ischemia are potentiated when oxygen supply is decreased secondary to anemia, hypoxia, or cardiac failure.

## Atherosclerosis

Atherosclerosis is a chronic, progressive, multifocal disease of the vessel wall, beginning in the intima, whose characteristic lesion is the atheroma or plaque that forms through intimal thickening (mediated predominantly by smooth muscle cell proliferation and matrix production) and lipid accumulation (mediated primarily by insudation of lipid into the arterial wall).<sup>16</sup> Atherosclerosis primarily affects the large elastic arteries and large- and medium-sized muscular arteries of the systemic circulation, particularly near branches, sharp curvatures, and bifurcations. Coronary arterial atherosclerosis involves especially the epicardial branches of the left anterior descending (LAD) and circumflex arteries, and the right coronary diffusely, but generally not their intramural branches. Most atheromas in the coronary arteries are segmental and eccentric, with plaque-free segments longitudinally and circumferentially. In early lesions, the plaque bulges outward at the expense of the media with the arterial lumen remaining circular in cross-section at essentially the same original diameter (ie, the vessel wall outer diameter enlarges, a process termed *vascular remodeling*).<sup>17</sup>

Although veins are usually spared from atherosclerosis, venous grafts interposed within branches of the arterial system (such as aorto-coronary bypass grafts created from saphenous vein) frequently develop intimal thickening and ultimately atherosclerosis, with obstructions or aneurysms. Paradoxically, some arteries used as arterial grafts, including the internal mammary artery (IMA), are largely spared.

## Pathogenesis

The prevailing theory of lesion formation in atherosclerosis centers on interactions among arterial wall endothelial and vascular smooth muscle cells, circulating monocytes, platelets, and plasma lipoproteins. A key contributor to atherosclerosis is endothelial cell injury induced by chronic hypercholesterolemia, homocystinemia, chemicals in cigarette smoke, viruses, localized hemodynamic forces, systemic hypertension, hyperglycemia, or the local effects of cytokines. These factors cause phenotypic and hence functional changes in endothelial cells, called *endothelial dysfunction*.<sup>18</sup> Endothelial dysfunction causes (1) vasoconstriction owing to decreased production of the vasodilator nitric oxide; (2) increased permeability to lipoproteins; (3) expression of tissue factor leading to thrombosis; and (4) expression of certain injury-induced adhesion molecules leading to adherence of platelets and inflammatory cells.

Progression from an early, subendothelial lesion (called a *fatty streak*) to a complex atheromatous plaque involves the following processes: (1) monocytes adhere to endothelial cells, migrate into the subendothelial space, and transform into tissue macrophages; (2) smooth muscle cells migrate from the media into the intima, proliferate, and secrete collagen and other extracellular matrix (ECM) constituents; (3) lipids accumulate via phagocytosis in macrophages (forming foam cells) and smooth muscle cells, as well as extracellularly; (4) lipoproteins are oxidized in the vessel wall leading to generation of potent biologic stimuli such as chemoattractants and cytotoxins; (5) persistent chronic inflammation; (6) cellular necrosis with release of intracellular lipids (mostly cholesterol esters); and often (7) calcification. Mature atherosclerotic plaques consist of a central core of lipid, cholesterol crystals, macrophages, smooth muscle cells, foam cells, and lymphocytes along with necrotic debris, separated from the lumen by a fibrous cap rich in collagen.

Clinical manifestations of advanced coronary arterial atherosclerosis occur through encroachment of the lumen leading to progressive stenosis, or to acute plaque disruption with thrombosis (see the following). In the absence of significant coronary blockages, myocardial perfusion is adequate at rest, and compensatory vasodilation provides flow reserve that is more than sufficient to accommodate increased metabolic demand during vigorous exertion. When the coronary luminal cross-sectional area is decreased by approximately 75%, blood flow becomes limited during exertion; with 90% reduction, coronary flow may be inadequate at rest. However, occlusions that develop slowly may stimulate the formation of collateral vessels that protect against distal myocardial ischemia. Aneurysms may form secondary to atherosclerosis as a result

**FIGURE 5-4** Acute plaque rupture with superimposed thrombus complicating coronary arterial atherosclerosis and triggering fatal myocardial infarction. (A) Gross photo. (B) Photomicrograph. (The arrow demonstrates the site of plaque rupture.) ([B] Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989.)

of destruction of the media beneath a plaque, a process most common in the aorta and other large vessels (where plaque does not easily cause obstruction). The natural history, morphologic features, key pathogenetic events, and clinical complications of atherosclerosis are summarized in Figs. 5-4 and 5-5.

## Role of Acute Plaque Change

The onset and prognosis of ischemic heart disease are not well predicted by the angiographically determined extent and severity of luminal obstructions.<sup>19</sup> The conversion of chronic stable angina or an asymptomatic state to an *acute coronary syndrome* (ie, myocardial infarction, unstable angina, and sudden coronary death) is dependent on dynamic vascular

**FIGURE 5-5** Schematic diagram summarizing the morphology, pathogenesis, and complications of atherosclerosis. Plaques usually develop slowly and insidiously over many years, beginning in childhood or shortly thereafter and exerting clinical effect in middle age or later. As described in the text, lesions may progress from a fatty streak to a fibrous plaque and then to plaque complications that lead to disease. ECM = extracellular matrix; SMC = smooth muscle cell. (Reproduced with permission from Kumar V, Fausto N, Abbas A, et al: *Robbins/Cotran Pathologic Basis of Disease*, 8th ed. Philadelphia, WB Saunders, 2010.)

changes, such as fracture or rupture of the fibrous cap, exposing deep plaque constituents, and subsequent thrombus, with or without occlusive, or partial, sometimes with emboli. Less commonly, the change is erosion and/or ulceration of the fibrous cap, setting the stage for platelet aggregation and mural or total thrombosis.

Plaques having a high propensity to rupture are known as *vulnerable plaques*. Such lesions (1) have a thin collagenous fibrous cap and few smooth muscle cells (the cells that produce collagenous matrix); (2) contain many macrophages producing matrix metalloproteinases (MMP) (enzymes that degrade the collagen that ordinarily lends strength to the fibrous cap); and (3) contain large areas of foam cells, extracellular lipid and necrotic debris. Inflammation may contribute to coronary thrombosis by altering the balance between prothrombotic and fibrinolytic properties of the endothelium. There is evidence that lipid lowering by diet or drugs such as statins (HMG CoA reductase inhibitors) reduces accumulation of macrophages expressing matrix-degrading enzymes and thereby stabilizes plaque by increasing the thickness and strength of the fibrous cap.<sup>20</sup>

Vulnerable plaques without significant obstruction can be clinically important. Indeed, pathologic and clinical studies show that plaques that rupture and lead to coronary occlusion often produced only mild to moderate luminal stenosis (and often no symptoms) prior to acute plaque change. Thus, there is great interest in identifying vulnerable plaques in individuals at a potentially therapeutic stage. Calcification of the coronary arteries detected noninvasively by electron beam computed tomography predicts the extent

of atherosclerotic disease overall but does not predict plaque instability. The most relevant features of plaque structure can be evaluated using intravascular ultrasound, optical coherence tomography (OCT), and potentially noninvasive molecular imaging.<sup>21</sup>

The events that trigger abrupt changes in plaque configuration and superimposed thrombosis and the efficacy and safety of interventional therapies depend on influences both intrinsic (eg, structure and composition, as described above) and extrinsic (eg, blood pressure, vasospasm, and platelet reactivity) to the plaque.<sup>22,23</sup> Potential outcomes for ruptured plaques include progression to thrombotic occlusion, non-occlusive thrombosis, healing at the site of plaque erosion, atheroembolization or thromboembolization, organization of mural thrombus causing (plaque progression), and organization of the occlusive mass with recanalization.

The clinical manifestations of ischemic heart disease most frequently reflect the downstream effects of a complex and dynamic interaction among fixed atherosclerotic narrowing of the epicardial coronary arteries, plaque vulnerability, intraluminal thrombosis overlying a ruptured or fissured atherosclerotic plaque, platelet aggregation, vasospasm, and the responses of the myocardium to ischemia.

## Progression of Ischemic Myocardial Injury

The changes in the myocardium following the onset of myocardial ischemia are sequential and the cellular consequences are primarily determined by the severity and duration of

**TABLE 5-1: Approximate Time of Onset and Recognition of Key Features of Ischemic Myocardial Injury**

Event/process	Time of onset
Onset of anerobic metabolism	Within seconds
Loss of contractility	<2 min
ATP* reduced	
to 50% of normal	10 min
to 10% of normal	40 min
Irreversible cell injury	20-40 min
Microvascular injury	>1 h
Pathologic feature	Time of recognition
Ultrastructural features of reversible injury	5-10 min
Ultrastructural features of irreversible damage	20-40 min
Wavy fibers	1-3 h
Staining defect with tetrazolium dye	2-3 h
Classic histologic features of necrosis	6-12 h
Gross alterations	12-24 h

\*ATP = adenosine triphosphate.

flow deprivation (Table 5-1). Within seconds of onset, ischemia induces a transition from aerobic metabolism to anaerobic glycolysis in cardiac myocytes, leading to inadequate production of high-energy phosphates such as ATP, and the accumulation of metabolites such as lactic acid, causing intracellular acidosis. Myocardial function is exquisitely sensitive to these biochemical consequences, with total loss of contraction within 2 minutes in severe ischemia. Nevertheless, ischemic changes in an individual cell are not immediately lethal, and short duration injury is potentially reversible. Irreversible injury of cardiac myocytes marked

by cell membrane structural defects occurs only after 20 to 40 minutes within the most severely ischemic area (Fig. 5-6). Lethal injury to clusters of cells owing to severe prolonged ischemia causes *myocardial infarction*.

Within the region of myocardium vulnerable to die if ischemia is not relieved in a timely manner (termed the *area at risk*), loss of perfusion is not uniform and not all cells in the area at risk are equally affected. The most severely affected myocytes, and therefore the first to become necrotic, reside in the subendocardium and in the papillary muscles furthest from lateral regions of noncompromised circulation and adequate perfusion. Thus, if uninterrupted ischemia progresses, there is a *wavefront* of cell death outward from the mid-subendocardial region, eventually encompassing the lateral borders and less severely ischemic subepicardial and peripheral regions of the area at risk. In myocardial infarction, approximately 50% of the area at risk becomes necrotic in approximately 3 to 4 hours. The final transmural extent of an infarct is generally established within 6 to 12 hours. The key principle is that if perfusion is restored prior to the onset of irreversible changes, cell death can be prevented. Thus, restoration of flow to a severely ischemic area via therapeutic intervention (such as percutaneous coronary intervention [PCI] with stent placement) can alter the outcome, depending on the interval between the onset of ischemia and restoration of blood flow (*reperfusion*).<sup>24</sup>

Necrosis existing less than 6 or more hours before patient death is not visible by routine gross or microscopic pathologic analysis of a cardiac specimen at autopsy. However, in a patient who died at least 2 to 3 hours following the onset of gross infarction, the presence of a necrotic region may be detected as a staining defect with triphenyl tetrazolium chloride (TTC), a dye that turns viable myocardium a brick-red color on reaction of the dye with intact myocardial dehydrogenases.<sup>25</sup> The earliest observable microscopic features of infarction are intense eosinophilia, nuclear pyknosis, and loss of myocytes in clusters; some may be stretched and wavy. Short-term ischemia

**FIGURE 5-6** Temporal sequence of early biochemical findings and progression of necrosis after onset of severe myocardial ischemia. *Left panel:* Early changes include loss of ATP and accumulation of lactate. *Right panel:* Myocardial injury is potentially reversible for approximately 20 minutes after the onset of even the most severe ischemia. Thereafter, progressive loss of viability occurs, which is complete by 6 to 12 hours. The benefits of reperfusion are greatest when it is achieved early; progressively smaller benefit is accrued when reperfusion is delayed.

without necrosis cannot be reliably demonstrated by pathologic examination.

**Tissue repair following myocardial infarction.** The inflammation and repair sequence in response to myocardial cell death follows a largely stereotyped sequence similar to tissue repair following injury at extracardiac sites. The inflammatory reaction is characterized by early exudation of polymorphonuclear leukocytes, seen after 6 to 12 hours and maximal within 1 to 3 days. Subsequently (3 to 5 days), the infiltrate consists predominantly of macrophages that remove the necrotic tissue. Collagen production accompanied by neovascularization begins approximately 7 to 10 days at the margins of preserved tissue. The gross appearance reflects the progressive microscopic changes described above (Fig. 5-7). Ultimately, the infarcted tissue is replaced by dense collagenous scar, which is fully mature by about 6 to 8 weeks. Healing of myocardial infarction may be altered by reperfusion (see the following), mechanical stress, sex, and neurohumoral and other factors such as immunosuppressive drugs.<sup>26</sup>

Although cardiac myocytes are traditionally thought incapable of regeneration, a growing body of evidence suggests

that regeneration of cardiac myocytes can occur under certain circumstances, including at the viable borders of myocardial infarcts.<sup>27</sup> Whether this capacity for renewal can be harnessed to therapeutic advantage is not yet known (discussed later in this chapter).

## Effects of Reperfusion

Reperfusion of an ischemic zone occurring before the onset of irreversible injury (recall, approximately 20 to 30 minutes) prevents infarction. Reperfusion later (ie, following some cell death) may limit infarct size through salvage of myocytes located outside the leading edge of the “wavefront,” provided that these myocytes are only reversibly injured at the time reperfusion occurs.<sup>28</sup> Thus, the potential for recovery of viable tissue decreases with increasing severity and duration of ischemia (see Fig. 5-6). Owing to the typical progression of ischemic injury, reperfusion 3 to 4 hours following onset of ischemia is considered the practical limit for significant myocardial salvage, and 90 minutes (“door to balloon time”) is the present clinical goal in PCI.<sup>29</sup>

Reperfused previously ischemic myocardium often has hemorrhage (owing to microvascular damage; see the following) and necrotic myocytes with transverse eosinophilic lines (called *contraction bands*) that represent hypercontracted sarcomeres (Fig. 5-8) caused by ischemic cell membrane damage followed by a massive cellular influx of calcium derived from the restored blood flow. Microvascular occlusions (resulting from endothelial or interstitial edema and/or plugging by platelet or neutrophil aggregates) may inhibit the reperfusion of damaged regions (*no-reflow phenomenon*).<sup>30</sup> Moreover, reperfusion itself may damage some of the ischemic but still viable myocytes that were not irreversibly injured (called *reperfusion injury*), and arrhythmias may occur.<sup>31</sup> In reperfusion after severe global ischemia (eg, during cardiac surgery), the left ventricle may undergo a massive tetanic contraction (*stone heart syndrome*).<sup>32</sup>

## MYOCARDIAL STUNNING, HIBERNATION, AND PRECONDITIONING

Although reperfusion may salvage ischemic but not necrotic myocardium, metabolic and functional recovery is usually not instantaneous; indeed, reversible postischemic myocardial dysfunction (called *myocardial stunning*) may persist for hours to days following brief periods of ischemia.<sup>33</sup> Myocardial stunning may also occur in the setting of PCI, cardiopulmonary bypass, or ischemia related to unstable angina or stress.

Regions of viable myocardium with chronically reduced coronary blood flow may have impaired function (termed *hibernating myocardium*).<sup>34,35</sup> Myocardial hibernation is characterized by (1) persistent wall motion abnormality, (2) low myocardial blood flow, and (3) evidence of viability in at least some of the affected areas. Contractile function of hibernating myocardium can improve if blood flow returns toward normal or if oxygen demand is reduced. Correction of this abnormality is likely responsible for the reversal of long-standing defects in ventricular wall motion observed following coronary bypass graft surgery or PCI. Morphologically,

**FIGURE 5-7** Gross photos of healing myocardial infarcts (A) approximately 3 to 4 days, (B) approximately 2 weeks. Asterisk highlights area of damage in each case.

**FIGURE 5-8** Reperfusion following severe myocardial ischemia. (A) Large, densely hemorrhagic anteroseptal acute myocardial infarct from patient treated by intracoronary thrombolysis for left anterior descending (LAD) artery thrombus, approximately 4 hours following onset. (B) Subendocardial circumferential hemorrhagic acute myocardial necrosis occurring perioperatively in cardiac valve replacement. (C) Photomicrograph of hemorrhagic myocardial necrosis. (D) High-power photomicrograph demonstrating contraction bands (*arrow*). Hematoxylin and eosin 375 $\times$ .

sublethal chronic ischemic injury often manifests as myocyte vacuolization, particularly in the subendocardium.<sup>36</sup>

Adaptation to short-term transient ischemia (ie, duration insufficient to cause cell death) may induce tolerance against subsequent, more severe ischemic insults (*ischemic preconditioning*).<sup>37</sup> Thus, short (eg, 5-minute) periods of cardiac ischemia followed by reperfusion can protect myocardium against injury during a prolonged period of subsequent ischemia. Understanding the yet uncertain mechanisms of this protection could lead to targets for “preemptive” pharmacologic stimulation of these pathways.

### Myocardial Infarction and Its Complications

Coronary atherosclerosis with acute plaque rupture and superimposed thrombosis often results in a *transmural* (Q-wave)

myocardial infarct, in which ischemic necrosis involves at least half and usually a nearly full thickness of the ventricular wall in the distribution of the involved artery. In contrast, a *subendocardial* (nontransmural, non-Q-wave) infarct constitutes an area of ischemic necrosis that is limited to the inner third to half of the ventricular wall, which can occur in the setting of episodic hypotension, global ischemia, or hypoxemia, or from interruption by reperfusion of the evolution of a transmural infarct. Subendocardial infarction associated with diffuse stenosing coronary atherosclerosis can be multifocal, extending laterally beyond the perfusion territory of a single coronary artery.

The short-term in-hospital mortality rate from acute myocardial infarction has declined from nearly 30% in the 1950s and 1960s to 7% or less today, especially for patients who receive aggressive reperfusion/revascularization and pharmacologic therapy.<sup>38</sup> However, half of all deaths from myocardial infarction occur within the first hour after the onset of

symptoms, potentially before a victim can reach the hospital. Poor prognostic factors include advanced age, female sex, diabetes mellitus, and a previous myocardial infarction. Left ventricular function and the extent of obstructive lesions in vessels perfusing viable myocardium are the most important prognostic factors.

Important complications of myocardial infarction include ventricular dysfunction, cardiogenic shock, arrhythmias,

cardiac rupture, infarct extension and expansion, papillary muscle dysfunction, right ventricular involvement, ventricular aneurysm, pericarditis, and systemic arterial embolism; the cardiac rupture syndromes and ventricular aneurysm are illustrated in Fig. 5-9. Outcome after myocardial infarction depends on infarct size, location, and transmuralty. Patients with transmural anterior infarcts are at greatest risk for regional dilation and mural thrombi and have a worse clinical

**FIGURE 5-9** Cardiac rupture syndromes and ventricular aneurysm following myocardial infarction. (A) Anterior myocardial rupture (*arrow*). (B) Rupture of the ventricular septum (*arrow*). (C) Rupture of a necrotic papillary muscle (*arrow*). (D) Large left ventricular aneurysm, with thin fibrotic wall (*arrow*) and mural thrombus.

course than those with inferior-posterior infarcts. In contrast, inferior-posterior infarcts are more likely to have serious conduction blocks and right ventricular involvement.

Myocardial infarcts produce functional abnormalities approximately proportional to their size. Large infarcts have a higher probability of cardiogenic shock and congestive heart failure. Nonfunctional scar tissue resulting from previous infarcts and areas of stunned or hibernating myocardium may also contribute to overall ventricular dysfunction. Cardiogenic shock following myocardial infarction generally indicates a large infarct (often > 40% of the left ventricle). The high mortality of myocardial dysfunction and cardiogenic shock has been alleviated somewhat by the use of ventricular assist devices (VADs) to bridge patients through phases of prolonged reversible ischemic dysfunction.

Although many patients have cardiac rhythm abnormalities following myocardial infarction, the conduction system is involved by necrosis or inflammation only in a minority, and heart block following myocardial infarction usually is transient. Tachyarrhythmias usually originate owing to electrically unstable ischemic or necrotic myocardium, often at the edge of an infarct. However, autopsy studies of sudden death victims and clinical studies of resuscitated survivors of cardiac arrest show that only a minority of patients with ischemia-induced malignant ventricular arrhythmias develop a full-blown acute myocardial infarction.

Cardiac rupture syndromes comprise three entities (see Fig. 5-9A-C): (1) rupture of the ventricular free wall (most common), usually with hemopericardium and cardiac tamponade; (2) rupture of the ventricular septum (less common), leading to an acquired ventricular septal defect with a left-to-right shunt; and (3) papillary muscle rupture (least common), resulting in the acute onset of severe mitral regurgitation. Ruptures tend to occur relatively early following infarction with as many as 25% presenting within 24 hours (mean interval 4 to 5 days), most commonly through the lateral free wall. Acute free wall ruptures usually are rapidly fatal; repair is rarely possible.<sup>39</sup> Rarely, a rupture is contained as a hematoma communicating with the ventricular cavity (*false aneurysm*); this is an unstable situation and the false aneurysm may eventually rupture.

Postinfarction septal ruptures with acute ventricular septal defect are of two types: (1) single or multiple sharply localized, jagged, linear passageways that connect the ventricular chambers (simple type), usually involving the anteroapical aspect of the septum; and (2) defects that tunnel serpigiously through the septum to a somewhat distant opening on the right side (complex type), usually involving the basal inferoseptal wall.<sup>40</sup> In complex lesions, the tract may extend into regions remote from the site of the infarct, such as the right ventricular free wall. Without surgery, the prognosis is poor for patients with infarct-related ventricular septal defects.

Papillary muscles are particularly vulnerable to ischemic injury and rupture, particularly the posterior medial papillary muscle, and rupture can occur later than other rupture syndromes (as late as 1 month after myocardial infarction). Because tendinous cords arise from the heads of the papillary

muscles and cords from each are distributed to both valve leaflets, interference with the structure or function of either papillary muscle can result in dysfunction of both mitral valve leaflets and resultant mitral regurgitation (see later).

Isolated right ventricular infarction and involvement of the right ventricle by extension of a posteroseptal infarct can have important functional consequences, including right ventricular failure with or without tricuspid regurgitation and arrhythmias.

Infarct *extension* is characterized by incremental new or recurrent necrosis in the same distribution as a completed recent infarct. Extension most often occurs along the lateral and subepicardial borders of a recent infarct, and histologically appears younger than the previously necrotic myocardium. In contrast, infarct *expansion* is a disproportionate thinning and dilation of the infarcted region which does not lead to additional necrotic myocardium per se, but may promote both further ischemia and intracardiac mural thrombus formation. The increase in ventricular volume caused by regional dilation increases the wall stress and thereby the workload of noninfarcted myocardium. Infarct expansion is often the substrate for late aneurysm formation and increases morbidity and mortality.

Ventricular aneurysms are large scars that paradoxically bulge during ventricular systole and often result from healing of a large transmural infarct that undergoes expansion (see Fig. 5-9D).<sup>41</sup> Although frequently as thin as 1 mm, ventricular aneurysms rarely rupture owing to their walls of tough fibrous or fibrocalcific tissue. Hypertrophied myocardial remnants as well as necrotic but inadequately healed myocardium often are present in aneurysm walls and mural thrombus is common.

*Ventricular remodeling* comprises the collective structural changes that occur in both the necrotic zone and uninvolved areas of the heart, including left ventricular dilation, wall thinning by infarct expansion, compensatory hypertrophy of noninfarcted myocardium, and potentially late aneurysm formation.<sup>42</sup> Congestive heart failure secondary to coronary artery disease (CAD) occurs when the overall function of viable myocardium can no longer maintain an adequate cardiac output or regions of hyperfunctioning residual myocardium suffer additional ischemic episodes.

## Revascularization

Revascularization early after acute myocardial infarction is rationalized as follows: (1) prolonged thrombotic occlusion of a coronary artery causes transmural infarction; (2) the extent of necrosis during an evolving myocardial infarction progresses as a wavefront and becomes complete only 6 to 12 hours or more following coronary occlusion (see Fig. 5-6); (3) both early- and long-term mortality following acute myocardial infarction correlate strongly with the amount of residual functioning myocardium; and (4) early reperfusion rescues some jeopardized myocardium.<sup>43</sup> Thus, the benefits of revascularization depend on and are assessed by the amount of myocardium salvaged, recovery of left ventricular function, and resultant reduction in mortality. These clinical end points are largely determined by the time interval between onset of symptoms and successful reflow, and the degree of residual

stenosis of the infarct vessel. Spontaneous recanalization via endogenous thrombolysis can be beneficial to left ventricular function but occurs in only a small percentage of patients within the critical interval.

## Percutaneous Coronary Intervention

Percutaneous coronary intervention can restore blood flow through a diseased portion of the coronary circulation obstructed by atherosclerotic plaque and/or thrombotic deposits, and in obstructions in saphenous vein grafts, IMA grafts, and occasionally, coronary arteries in transplanted hearts.

### PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY

In percutaneous transluminal coronary angioplasty (PTCA), the plaque splits at its weakest point and enlargement of the lumen occurs by plaque fracture (the predominant mechanism); and by embolization, compression, redistribution of the plaque contents, and overall mechanical expansion of the vessel wall can also occur.<sup>44</sup> The split extends to the intimal-medial border and often into the media, is accompanied by variable circumferential and longitudinal medial dissection, and can induce a flap that impinges on the lumen. These changes can result in local flow abnormalities and generation of new, thrombogenic blood-contacting surfaces (to some extent similar to what is observed with spontaneously disrupted plaque) and contribute to the propensity for acute thrombotic closure.

The long-term success of PTCA is limited by the development of progressive restenosis, which occurs in 30 to 50% of patients, most frequently within the first 4 to 6 months.<sup>45</sup> Although vessel wall recoil and organization of thrombus likely contribute, the major process leading to restenosis is excessive medial smooth muscle migration to the intima, proliferation, and secretion of abundant ECM as a response to angioplasty-induced injury.

Although not widely used today, coronary atherectomy of primary or restenosis lesions mechanically can remove obstructive tissue by excision.<sup>46</sup> Deep arterial resection, including medial and even adventitial elements, occurs frequently but has not been associated with acute symptomatic complications. The morphology of arterial vessel healing after directional or rotational atherectomy is similar to that following angioplasty.

### STENTS

Stents are expandable tubes of metallic or polymeric mesh that are used to split open the vessel wall at the site of balloon angioplasty and thereby mitigate the negative sequelae of PTCA.<sup>47</sup> Stents preserve luminal patency and provide a larger and more regular lumen by acting as a scaffold to support the disrupted vascular wall and minimize flow disruption and thrombus formation. Placement of a stent yields outcomes superior to angioplasty alone in vessels greater than 3 mm in diameter, chronic total occlusions, stenotic vein grafts, restenotic lesions after angioplasty alone, and in patients with myocardial infarction.<sup>48</sup>

Stent technology has undergone a rapid evolution, including sequentially: (1) bare-metal stents (BMS); and (2) drug-eluting stents (DES), both used extensively in clinical interventional cardiology; and more recently (3) completely resorbable/biodegradable stents (RBS). Bare-metal stents for coronary implantation are short tubular segments of metal mesh composed of balloon-expandable 316L stainless steel or nickel-titanium alloy (Nitinol) that range from approximately 2.5 to 3.5 mm in diameter and approximately 1 to 3 cm in length. Development has focused on permitting stents to become more flexible and more easily delivered and deployed, allowing the treatment of a greater number and variety of lesions.

Key stent complications are thrombosis, usually occurring early, and late proliferative restenosis (Fig. 5-10). Thrombotic occlusion, occurring in 1 to 3% of patients within 7 to 10 days of the procedure (see Fig. 5-10A), has largely been overcome by aggressive multidrug treatment with antiplatelet agents such as clopidogrel, aspirin, and glycoprotein IIb/IIIa inhibitors. The major long-term complication of bare-metal stenting is in-stent restenosis, which occurs in 50% of patients within 6 months.<sup>49</sup> The causes of stent thrombosis and restenosis are complex and are largely owing to stent-tissue interactions, damage to the endothelial lining, and stretching of the vessel wall, which stimulate inflammation and adherence and accumulation of platelets and fibrin.<sup>50</sup> Stent wires may eventually become completely embedded in an endothelium-lined intimal fibrosis layer composed of smooth muscle cells in a collagen matrix (see Fig. 5-10B). This tissue may thicken secondary to the release of growth factors, chemotactic factors, and inflammatory mediators from platelets and other inflammatory cells that result in proliferation of smooth muscle cells and increased production of ECM molecules, narrowing the lumen and resulting in restenosis.

Drug-eluting stents, which impart the controlled release of drugs from durable polymers to the vessel wall, effectively inhibit in-stent restenosis.<sup>51,52</sup> The drugs used most widely are rapamycin (sirolimus)<sup>53</sup> and paclitaxel<sup>54</sup> in the Cypher (Cordis) and Taxus (Boston Scientific) stents, respectively. Rapamycin, a drug used for immunosuppression in solid organ transplant recipients, inhibits proliferation, migration, and growth of smooth muscle cells and ECM synthesis. Paclitaxel, a drug used in the chemotherapeutic regimens for several types of cancer, also has similar anti-smooth muscle cell activities. These drugs are embedded in a polymer matrix (such as a copolymer of poly-*n*-butyl methacrylate and polyethylene-vinyl acetate or a gelatin-chondroitin sulfate coacervate film) that is coated onto the stent. However, stent thrombosis emerged as a major safety concern with DES early after their adoption in clinical practice, requiring prolonged dual antiplatelet therapy.<sup>55</sup> Pathological examination of clinical specimens and animal studies have suggested that these DES were associated with DES-induced inhibition of stent endothelialization and delayed arterial healing and polymer hypersensitivity reactions resulting in chronic inflammation that contributed to stent thrombosis. Recently, DES have

**FIGURE 5-10** Stent pathology. (A) Thrombosis. H&E stain. (B) Thickened proliferative neointima separating the stent wires (*black structure*) from the lumen, with bare metal coronary artery stent implanted long term. Movat stain. been developed to overcome these issues with improved stent designs and construction and the use of biocompatible polymers.<sup>56</sup>

In contrast to the permanent presence of a foreign body in BMS and DES, RBS provide a scaffold and then ultimately disappear by resorption of foreign scaffold material that may potentiate a thrombotic event, permit more versatility in subsequent therapies, and not interfere with the diagnostic evaluation by noninvasive imaging such as cardiac magnetic resonance and CT.<sup>57,58</sup> Several RBS are in development or in clinical trials. The key challenge is to balance biomechanics (strength, deliverability, and lesion crossing), potential for side-branch occlusion (owing to thicker struts), durability

and biocompatibility, and to control the kinetics of stent degradation at a rate appropriate to maintain mechanical strength to limit recoil.

### Coronary Artery Bypass Graft Surgery

Coronary artery bypass graft (CABG) surgery improves survival in patients with significant left main CAD, three-vessel (and possibly two-vessel) disease, or reduced ventricular function, and prolongs and improves the quality of life in patients with left main equivalent disease (proximal LAD and proximal left circumflex), but does not protect them from the risk of subsequent myocardial infarction.<sup>59</sup> The principal mechanism for these benefits is thought to be the restoration of blood flow to hibernating myocardium.

The hospital mortality rate for CABG surgery is approximately 1% in low-risk patients, with fewer than 3% of patients suffering perioperative myocardial infarction. The most consistent predictors of mortality after CABG are urgency of operation, age, prior cardiac surgery, female sex, low left ventricular ejection fraction, degree of left main stenosis, and number of vessels with significant stenoses. The most common mode of early death after CABG is acute cardiac failure leading to low output or arrhythmias, owing to myocardial necrosis (often with features of reperfusion described in the preceding), postischemic dysfunction of viable myocardium, or a metabolic cause, such as hypokalemia.

Early thrombotic occlusion of the graft vessel may occur, usually potentiated by inadequate distal run-off from extremely small and/or atherosclerotic distal native coronaries. Additional factors may include atherosclerosis, arterial branching or dissection of blood into the graft or native vessel at the anastomotic site, or distortion of a graft that is too short or too long for the intended bypass. In some cases, thrombosis occurring early postoperatively involves only the distal portion of the graft, suggesting that early graft thrombosis was initiated at the distal anastomosis. Most patients who die early after CABG have patent grafts.

The patency of saphenous vein grafts is reported as 60% at 10 years; occlusion results from (with increasing postoperative interval) thrombosis, progressive intimal thickening, and/or obstructive atherosclerosis.<sup>60</sup> Between 1 month and approximately 1 year, graft stenosis is usually caused by intimal hyperplasia with excessive smooth muscle proliferation and ECM production (similar to that seen in restenosis following angioplasty and stenting). Atherosclerosis becomes the predominant mechanism in graft occlusion beyond 1 to 3 years after CABG, and earliest in those patients with the most significant atherosclerotic risk factors. Plaques in grafts often have poorly developed fibrous caps with large necrotic cores and can develop secondary dystrophic calcific deposits that extend to the lumen (Fig. 5-11); thus, the potential for disruption, aneurysmal dilation, and embolization of atherosclerotic lesions in vein grafts exceeds that for native coronary atherosclerotic lesions, and balloon angioplasty, stenting or intraoperative manipulation of grafts may potentiate atheroembolism.

**FIGURE 5-11** Atherosclerosis of saphenous vein bypass graft. (A) Fibrous cap (*between arrows*) is attenuated over the necrotic core (*large asterisk*). Lumen is at upper right. **FIGURE 5-12** Internal mammary artery as coronary artery bypass graft removed 13 years following surgery, demonstrating near-normal morphology, including an intact internal elastic lamina (*arrow*) Verhoff von Giesen stain (for elastin, *black*) 60 $\times$ . (Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989.)

In contrast to saphenous vein grafts, IMA grafts have greater than 90% patency at 10 years (Fig. 5-12).<sup>61</sup> Multiple factors likely contribute to the remarkably higher long-term patency of IMA grafts compared with vein grafts. Although free saphenous vein grafts sustain disruption of their vasa vasora and nerves, endothelial damage, medial ischemia, and acutely increased internal pressure, an IMA graft generally has minimal preexisting atherosclerosis and requires minimal surgical manipulation, maintains its nutrient blood supply, is adapted to arterial pressures, needs no proximal anastomosis, and has an artery-to-artery distal anastomosis. Graft and recipient vessel have comparable sizes with the IMA but are disparate (graft substantially larger) with saphenous vein. The advent of off-pump and minimally invasive coronary artery bypass grafting has stimulated efforts to facilitate sutureless anastomosis of the graft to the aorta.<sup>62</sup>

Although advances in medical therapy and PCI have contributed to fewer CABGs performed each year, challenges remain and new technologies are under consideration to make the procedure safer and more efficacious.<sup>63</sup>

For example, patients needing revascularization have a much more complicated combination of disease processes and many of the patients have extensive CAD with prior attempts at revascularization. The future of coronary artery bypass grafting may benefit from smaller incisions and potentially robotic endoscopic CABG, facilitated by novel anastomotic devices and intraoperative determination of graft patency. Hybrid surgical/catheterization suites that allow for simultaneous staged CABG and PCI are currently under development.

## VALVULAR HEART DISEASE

Normal valve function requires structural integrity and coordinated interactions among multiple anatomical components. For the atrioventricular valves (mitral and tricuspid), these elements include leaflets, commissures, annulus, tendinous cords (chordae tendineae), papillary muscles, and the atrial and ventricular myocardium. For the semilunar valves (aortic and pulmonary), the key structures are the cusps, commissures, and their respective supporting structures in the aortic and pulmonary roots.

The anatomy of the mitral and aortic valves is illustrated in Fig. 5-13.

### Mitral Valve

The mitral valve (see Fig. 5-13A) has two leaflets: the anterior (also called septal, or aortic) leaflet, roughly triangular and deep, with the base inserting on approximately one-third of the annulus, and the posterior (also called mural or ventricular) leaflet, more shallow than the anterior and attached to about two-thirds of the annulus. The posterior leaflet typically has distinct scallops that are designated P1, P2, and P3, respectively, beginning from the anterolateral toward the posteromedial commissure. The mitral leaflets have a combined area approximately twice that of the annulus; apposition during systole occurs over approximately 50% of the depth of the posterior leaflet and 30% that of the anterior leaflet. Each leaflet receives tendinous cords from both anterior and posterior papillary muscles. The mitral valve orifice is D-shaped, with the flat anteromedial portion comprising the subaortic attachment of the anterior mitral leaflet. This part of the annulus is fibrous and noncontractile; in contrast, the posterolateral portion of the annulus is muscular and contracts during systole to asymmetrically reduce the area of the orifice. The edges of the mitral leaflets are held in or below the plane of the orifice by the tendinous cords, which themselves are pulled from below by the contracting papillary muscles during systole. This serves to draw the leaflets to closure and maintain competence. The posterior leaflet, with its more delicate structure and shorter annulus-to-free-edge dimension than the anterior, is more prone to postinflammatory fibrous retraction and deformation owing to myxomatous degeneration. The orifice of the tricuspid valve is larger and less distinct than that of the mitral; its three leaflets (anterior,

posterior, and septal) are larger and thinner than those of the mitral valve.

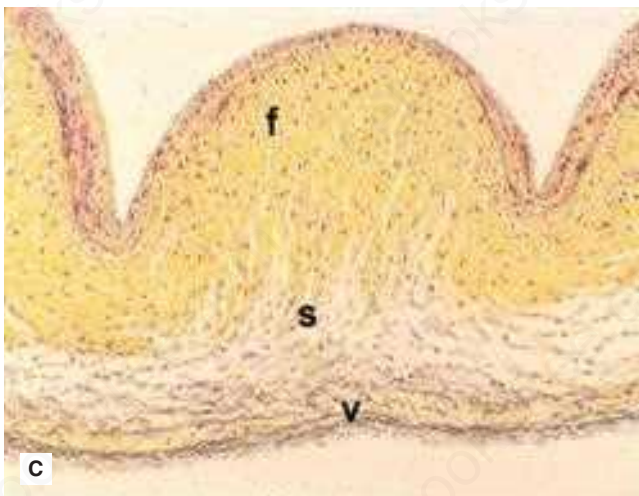

### Aortic Valve

The aortic valve has structural complexity at several levels.<sup>64</sup> The three aortic valve cusps (left, right, and noncoronary) attach to the aortic wall in a semilunar fashion, ascending to the commissures and descending to the base of each cusp (see Fig. 5-13B). Commissures are spaced approximately 120 degrees apart and occupy the three points of the annular crown, representing the sites of separation between adjacent cusps. Behind the valve cusps are dilated pockets of aortic root, called the sinuses of Valsalva. The right and left coronary arteries arise from orifices behind the right and left cusps, respectively. At the midpoint of the free edge of each cusp is a fibrous nodule called the nodule of Arantius. A thin, crescent-shaped portion of the cusp on either side of the nodule, termed the lunula, defines the surfaces of apposition of the cusps when the valve is closed (approximately 40% of the separating area). The lunular tissue does not contribute to separate aortic from ventricular blood during diastole. Thus, fenestrations (holes) near the free edges commonly occur as a small (<2 mm in diameter), developmental, or degenerative abnormality and have no functional significance. In contrast, defects in the portion of the cusp below the lunula are associated with functional incompetence; such holes also suggest previous or active infection. When the aortic valve is closed during diastole, there is a back pressure on the cusps of approximately 80 mm Hg. The pulmonary valve cusps and surrounding tissues have architectural similarity to but are more delicate than those of the corresponding aortic components, and lack coronary arterial origins.

All four cardiac valves have a similar microscopically inhomogeneous architecture, consisting of well-defined tissue layers in the plane of the cusp. Using the aortic valve as the paradigm (see Fig. 5-13C), beneath the valvular endothelium, on the inflow side the *ventricularis* faces the left ventricular chamber and is enriched in radially aligned elastic fibers, which enable the cusps to have minimal surface area when the valve is open but stretch during diastole to form a large coaptation area. The *spongiosa* is centrally located and is composed of loosely arranged collagen and abundant proteoglycans. This layer has negligible structural strength, but accommodates relative movement between layers during the cardiac cycle and absorbs shock during closure. The *fibrosa* provides structural integrity and mechanical stability through a dense aggregate of circumferentially aligned, densely packed collagen fibers, largely arranged parallel to the cuspal free edge. Normal human aortic and pulmonary valve cusps have few blood vessels; they are sufficiently thin to be perfused from the surrounding blood. In contrast, the mitral and tricuspid leaflets contain a few capillaries in their most basal thirds.

Best developed in aortic valve, key specializations facilitating valve function include crimp of collagen fibers along

**FIGURE 5-13** Normal mitral and aortic valves. In (A), opened left ventricle of the normal heart, demonstrating mitral valve and components of the mitral apparatus. (B) Aortic valve viewed from distal aspect in open (*bottom*) and closed (*top*) phases. (C) Normal aortic valve histology, demonstrating layered structure, including the fibrosa (f), spongiosa (s), and ventricularis (v) layers. The inflow surface is at bottom. Verhoeff van Gieson (stain for elastin, *black*) 150 $\times$ . ([A] Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989. [B and C] Reproduced with permission from Silver MD, Gotlieb AI, Schoen FJ: *Cardiovascular Pathology*, 3rd ed. New York: Churchill Livingstone/Elsevier; 2001.)

their length, bundles of collagen in the fibrous layer oriented toward the commissures, and grossly visible corrugations; these allow cusps to be extremely soft and pliable when unloaded in systole, but taut and stiff when stretched in diastole. Moreover, the orientation of connective tissue and other architectural elements is nonrandom in the plane of the cusp, yielding greater compliance in the radial than circumferential direction. The fibrous network within the cusps effectively transfers the stresses of the closed phase to the annulus and aortic wall. This minimizes sagging of the cusp centers, preserves maximum coaptation, and prevents regurgitation. Additionally, for the mitral valve, the subvalvular apparatus including tendinous cords and papillary muscles is a critical mechanism of valve competency.

### Valvular Cell Biology

Recent studies have fostered an emerging picture of how valves form embryologically, mature in the fetus, and function, adapt, maintain homeostasis, and change throughout life. These essential relationships facilitate an understanding of valve pathology and mechanisms of disease, foster the development of improved tissue heart valve substitutes, and inform innovative approaches to heart valve repair and regeneration.<sup>65</sup>

During normal development of the heart, the heart tube undergoes looping, following which the valve cusps/leaflets originate from mesenchymal outgrowths known as endocardial cushions.<sup>66</sup> A subset of endothelial cells in the cushion-forming area, driven by a complex array of signals from the underlying myocardium, changes their phenotype to mesenchymal cells and migrates into the acellular ECM called cardiac jelly. Likely regulated by TGF- $\beta$  and vascular endothelial growth factor (VEGF), the transformation of endocardial cells to mesenchymal cells is termed transdifferentiation or *endothelial-to-mesenchymal transformation* (EMT). Changes in cell phenotype and ECM remodeling continue throughout human fetal and postnatal development, and throughout life, leading to ongoing changes in properties, as evidenced by increasing valve stiffness with increasing age.<sup>67,68</sup>

Two types of cells are present in the aortic valve: endothelial cells located superficially and interstitial cells located deep to the surface. Aortic valve endothelial cells (VECs) have a different phenotype than endothelial cells in the adjacent aorta and elsewhere,<sup>69,70</sup> but the implications of these differences are not yet known. The second cell type comprises the valvular interstitial cells (VICs), which have variable properties of fibroblasts, smooth muscle cells, and myofibroblasts. VICs maintain the valvular ECM, the key determinant of valve durability. To maintain integrity and pliability throughout life, the valve cusps and leaflets must undergo ongoing physiologic remodeling that entails synthesis, degradation, and reorganization of its ECM, which depends on matrix-degrading enzymes such as MMP. Although VICs are predominantly fibroblast-like in normal valves, they can become activated when exposed to environmental (ie, mechanical and

chemical) stimulation and assume a myofibroblast-like phenotype that mediates connective tissue remodeling.

### Pathologic Anatomy of Valvular Heart Disease

Cardiac valve operations utilizing replacement or repair usually are undertaken for dysfunction caused by calcification, fibrosis, fusion, retraction, perforation, rupture, stretching, infection, dilation, or congenital malformations of the valve leaflets/cusps or associated structures. Valvular stenosis, defined as inhibition of forward flow secondary to obstruction caused by failure of a valve to open completely, is almost always caused by a cuspal abnormality that induces a chronic disease process. In contrast, valvular insufficiency, defined as reverse flow caused by failure of a valve to close completely, may result from intrinsic disease of the cusps/leaflets and/or damage to or distortion of the supporting structures (eg, the aorta, mitral annulus, chordae tendineae, papillary muscles, and ventricular free wall). Thus, regurgitation can appear either precipitously, as with cordal rupture, or gradually, as with leaflet scarring and retraction. Both stenosis and insufficiency can coexist in a single valve. The most commonly encountered types of valvular heart disease are illustrated in Figs. 5-14 and 5-15.

### Calcific Aortic Valve Stenosis

Aortic stenosis (AS) is the most common valvular heart disease in Western countries and has serious consequences.<sup>71</sup> The prevalence of AS increases with age, reaching about 3% after the age of 75 in the United States. Thus, the global burden of AS is expected to double within the next 50 years as life expectancy lengthens. The limited available understanding of AS mechanisms and pathobiology has precluded development of effective noninvasive medical treatments.<sup>72</sup> Symptomatic severe AS not treated promptly by corrective surgery has a high mortality as well as high and accelerating symptom burden.

Calcific AS, the most frequent valvular abnormality requiring surgery, is usually the consequence of calcium phosphate deposition in either an anatomically normal aortic valve or in a congenitally bicuspid valve (see Fig. 5-14A,B).<sup>73</sup> Stenotic, previously normal tricuspid valves present primarily with calcific aortic valve disease in the seventh to ninth decades of life, while congenitally bicuspid valves with superimposed calcification generally become symptomatic earlier (usually sixth to seventh decades).<sup>74</sup>

Calcific AS is characterized by heaped-up, calcified masses initiated in the cuspal fibrosa at the points of maximal cusp flexion (the margins of attachment); they protrude distally from the aortic aspect into the sinuses of Valsalva, inhibiting cuspal opening. However, the ventricular surfaces of the cusps usually remain smooth (see Fig. 5-14C). The calcification process generally does not involve the free cuspal edges, appreciable commissural fusion is absent, and the mitral valve generally is uninvolved. Calcified material resembling bone is

**FIGURE 5-14** Calcific aortic valve stenosis. (A) Calcific aortic valve disease causing aortic stenosis in an elderly patient, characterized by mineral deposits at basal aspect of cusps. (B) Calcification of congenitally bicuspid aortic valve, having two unequal cusps, the larger with a central raphe (*arrow*). (C and D) Photomicrographs of calcific deposits in calcific aortic valve disease. Hematoxylin and eosin 15 $\times$ . Calcific aortic valve stenosis. (C) Nearly transmural deposits with only thin uninvolvement cusp on inflow surface (at bottom). (D) Bone formation (osseous metaplasia).

often present (see Fig. 5-14D). Aortic valve *sclerosis* comprises a common, earlier, and hemodynamically less significant stage of the calcification process. Nevertheless, aortic sclerosis is associated with an approximately 50% increase in the risk of death from cardiovascular causes, even in the absence of hemodynamically significant obstruction of left ventricular outflow.<sup>75</sup>

Aortic stenosis induces a pressure gradient across the valve, which may reach 75 to 100 mg Hg in severe cases,

necessitating a left ventricular pressure of 200 mg Hg or more to expel blood. Consequently, cardiac output is maintained by the development of pressure-overload left ventricular hypertrophy. The onset of symptoms such as angina, syncope, or heart failure in AS heralds the exhaustion of compensatory cardiac hyperfunction and carries a poor prognosis if not treated by aortic valve replacement (AVR).<sup>76</sup> Other complications of calcific AS include embolization that may occur spontaneously or during interventional procedures,

**FIGURE 5-15** Etiologies of mitral valvular disease. (A and B) Rheumatic valve disease. (A) Atrial view and (B) subvalvular aspect of valve from patient with rheumatic mitral stenosis. The valvular changes are severe, including diffuse leaflet fibrosis and commissural fusion and ulceration of the free edges of the valve, as well as prominent subvalvular involvement with distortion (*arrow* in [B]). (C and D) Myxomatous degeneration of the mitral valve. In (C) there is prolapse into the left atrium of a redundant posterior leaflet (*arrow*). (D) Surgically resected, markedly redundant myxomatous valve. ([A and B] Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989.)

hemolysis, infective endocarditis, and extension of the calcific deposits into the ventricular septum causing conduction abnormalities.

Aortic valve calcification has been traditionally considered a wholly degenerative, dystrophic, and passive process. However, recent studies suggest active regulation of calcification in aortic valves, with mechanisms that include inflammation, lipid infiltration, and phenotypic modulation of VIC to an osteoblastic phenotype,<sup>77</sup> and risk factors overlapping with those of arterial atherosclerosis. Similarities to atherosclerosis have stimulated interest in the possibility that statin drugs may decrease the rate of AS progression; however, benefit of statins for AS has not been supported by clinical studies.<sup>78</sup>

### Congenitally Bicuspid Aortic Valve

Bicuspid aortic valve (BAV) typically has two cusps of unequal size, with the larger (conjoined) cusp having a midline raphe, representing an incomplete separation or congenital fusion of two cusps. Less frequently, the cusps are of equal size (see Fig. 5-14B). Neither stenotic nor symptomatic at birth or throughout early life, BAV are predisposed to accelerated calcification; ultimately, almost all become stenotic. Aortic pathology, including dilation and/or dissection, commonly accompanies BAV. Despite a prevalence of approximately 1%,<sup>79</sup> BAV and other congenital valve abnormalities underlie over two-thirds of AS in children and almost 50% in adults. Infrequently, BAV become purely incompetent, or complicated by infective endocarditis, even when the valve is hemodynamically normal. Only rarely is an uncomplicated BAV encountered incidentally at autopsy.

Recent studies have confirmed previous reports of familial clustering of BAV and left ventricular outflow tract obstruction malformations, and their association with other cardiovascular malformations.<sup>80</sup> For example, mutations in the signaling and transcriptional regulator NOTCH1 caused a spectrum of developmental aortic valve abnormalities and severe calcification in two families with nonsyndromic familial aortic valve disease.<sup>81</sup>

### Mitral Annular Calcification

Calcific deposits also can develop in the ring (annulus) of the mitral valve of elderly individuals, especially women. Although generally asymptomatic, the calcific nodules may lead to regurgitation by interference with systolic contraction of the mitral valve ring or, very rarely, stenosis by impairing mobility of the mitral leaflets during opening. Occasionally, the calcium deposits may penetrate sufficiently deeply to impinge on the atrioventricular conduction system to produce arrhythmias (and rarely sudden death). Patients with mitral annular calcification have an increased risk of stroke, and the calcific nodules, especially if ulcerated, can be

the nidus for thrombotic deposits or infective endocarditis. Mitral annular calcification can also mimic a left ventricular neoplasm.

### Rheumatic Heart Disease

Rheumatic fever is an acute, often recurrent, inflammatory disease that generally follows a pharyngeal infection with group A beta-hemolytic streptococci, principally in children. In the past several decades, rheumatic fever and rheumatic heart disease have declined markedly but not disappeared in the United States and other developed countries. Evidence strongly suggests that rheumatic fever is the result of an immune response to streptococcal antigens, inciting either a cross-reaction to tissue antigens or a streptococcal-induced autoimmune reaction to normal tissue antigens.<sup>82</sup>

Chronic rheumatic heart disease most frequently affects the mitral and to a lesser extent the aortic and/or the tricuspid valves. Usually dominated by mitral stenosis,<sup>83</sup> chronic rheumatic valve disease is characterized by fibrous or fibrocalcific thickening of leaflets and tendinous cords, and commissural and chordal fusion (see Fig. 5-15A and B). Stenosis results from leaflet and chordal fibrous thickening and commissural fusion, with or without secondary calcification. Regurgitation usually results from postinflammatory scarring-induced retraction of cords and leaflets. Combinations of lesions may yield valves that are both stenotic and regurgitant. Although considered the pathognomonic inflammatory myocardial lesions in acute rheumatic fever, Aschoff nodules are found infrequently in myocardium sampled at autopsy or at valve replacement surgery, most likely reflecting the extended interval from acute disease to critical functional impairment.

### Degeneration of the Mitral Valve (Mitral Valve Prolapse)

Degenerative mitral valve disease (mitral valve prolapse) causes chronic, pure, isolated mitral regurgitation by leaflet stretching and prolapse into the left atrium and occasionally cordal rupture.<sup>84</sup> Owing to improved imaging technology and large community studies, a prevalence of mitral valve prolapse (MVP) of approximately 2% has been established. Potentially serious complications include progressive congestive heart failure, infective endocarditis, stroke, or other manifestation of thromboembolism, sudden death, or atrial fibrillation. Mitral valve prolapse is the most common indication for mitral valve repair or replacement.

In MVP, one or both mitral leaflets are enlarged, redundant, or floppy and will prolapse or balloon back into the left atrium during ventricular systole (see Fig. 5-15C). The three characteristic anatomic changes in MVP are: (1) intercordal ballooning (hooding) of the mitral leaflets or portions thereof (most frequently involving the posterior leaflet), sometimes accompanied by elongated, thinned, or ruptured cords;

(2) rubbery diffuse leaflet thickening that hinders adequate coaptation and interdigitation of leaflet tissue during valve closure; and (3) annular dilation, with diameters and circumferences that may exceed 3.5 and 11.0 cm, respectively (see Fig. 5-15D). Pathologic mitral annular enlargement predominates in and may be confined to the posterior leaflet, because the anterior leaflet is firmly anchored by the fibrous tissue at the aortic valve and is far less distensible. The key microscopic change is myxomatous degeneration with attenuation or focal disruption of the fibrous layer of the valve, weakening the leaflet. Focal or diffuse thickening of the spongy layer by proteoglycan deposition gives the tissue an edematous, blue appearance on microscopy (called *myxomatous* by pathologists).<sup>85</sup> Concomitant involvement of the tricuspid valve is present in some cases, and the aortic and pulmonary valves are rarely affected.

Secondary changes may occur, including (1) fibrous thickening along both surfaces of the valve leaflets; (2) linear thickening of the subjacent mural endocardium of the left ventricle as a consequence of friction-induced injury by cordal hamstringing of the prolapsing leaflets; (3) thrombi on the atrial surfaces of the leaflets, particularly in the recesses behind the ballooned leaflet segments; (4) calcification along the base of the posterior mitral leaflet; and (5) cordal thickening and fusion that can resemble post-rheumatic disease.

Although the pathogenesis of mitral valve degeneration is uncertain, this valvular abnormality is a common feature of Marfan's syndrome and occasionally other hereditary connective tissue disorders such as Ehlers-Danlos syndrome, suggesting an analogous connective tissue defect. In heritable disorders of connective tissue, including Marfan's syndrome, MVP is usually associated with mutations in fibrillin-1 (FBN-1); recent evidence also has implicated abnormal TGF- $\beta$  signaling (similar to the aortic abnormalities in the pathogenesis of Marfan's syndrome and related disorders).<sup>86</sup> Although it is unlikely that more than 1 to 2% of patients with MVP have an identifiable connective tissue disorder, studies utilizing genetic linkage analysis have mapped families with autosomal dominant MVP to specific chromosomal abnormalities, several of which involve genes that could be involved in valvular tissue remodeling.

## Ischemic Mitral Regurgitation

In ischemic mitral regurgitation (IMR), also called functional mitral regurgitation, myocardial structure and function are altered by ischemic injury; in contrast to degenerative valve disease, the leaflets are intrinsically normal.<sup>87</sup> Present in many patients with CAD, IMR worsens prognosis following myocardial infarction, with reduced survival directly related to the severity of the regurgitation. Mechanisms of IMR include an ischemic papillary muscle that fails to tighten the cords during systole, and fibrotic, shortened papillary muscle that fixes the chordae deeply within the ventricle. Nevertheless, papillary muscle dysfunction alone is generally insufficient

to produce IMR, and regional dysfunction and dilation with an increasing spherical shape of the left ventricle, which pulls the papillary muscles down and away from the center of the chamber, usually contributes. Although there is substantial interest in developing surgical and/or percutaneous approaches to the repair of IMR,<sup>88,89</sup> the degree to which correcting IMR improves survival and/or symptoms remains uncertain.<sup>90,91</sup>

## Carcinoid and Drug-Induced Valve Disease

Patients with the carcinoid syndrome often develop plaque-like intimal thickenings of the endocardium of the tricuspid valve, right ventricular outflow tract, and pulmonary valve superimposed on otherwise unaltered endocardium.<sup>92</sup> The left side of the heart is usually unaffected. These lesions are related to elaboration by carcinoid tumors (most often primary in the gut) of bioactive products, including serotonin, which cause valvular endothelial cell proliferation but are inactivated by passage through the lung.

Left-sided but similar valve lesions have been reported to complicate the administration of fenfluramine and phentermine (fen-phen), appetite suppressants used for the treatment of obesity, which may affect systemic serotonin metabolism (see Fig. 5-15E).<sup>93</sup> Typical diet drug-associated plaques have proliferation of myofibroblast-like cells in a myxoid stroma. Similar left-sided plaques may be found in patients who receive methysergide or ergotamine therapy for migraine headaches; these serotonin analogs are metabolized to serotonin as they pass through the pulmonary vasculature. Moreover, drug-related valve disease has been reported in patients taking pergolide mesylate, an ergot-derived dopamine receptor agonist used to treat Parkinson's disease and restless leg syndrome.<sup>94</sup>

## Infective Endocarditis

Infective endocarditis is characterized by colonization or invasion of the heart valves, mural endocardium, aorta, aneurysmal sacs, or other blood vessels, by a microbiologic agent, leading to the formation of friable vegetations laden with organisms, fibrin, and inflammatory cells (Fig. 5-16).<sup>95</sup> Although virtually any type of microbiologic agent can cause infective endocarditis, most cases are bacterial.

The clinical classification into acute and subacute forms is based on the severity and tempo of the disease, virulence of the infecting microorganism, and presence of underlying cardiac disease. *Acute endocarditis* is a destructive infection by a highly virulent organism, often involving a previously normal heart valve, and leading to death within days to weeks in more than 50% of patients if left untreated. In contrast, in a more indolent lesion, called *subacute endocarditis*, organisms of low virulence cause infection on previously deformed valves; in this situation, the infection may pursue a protracted

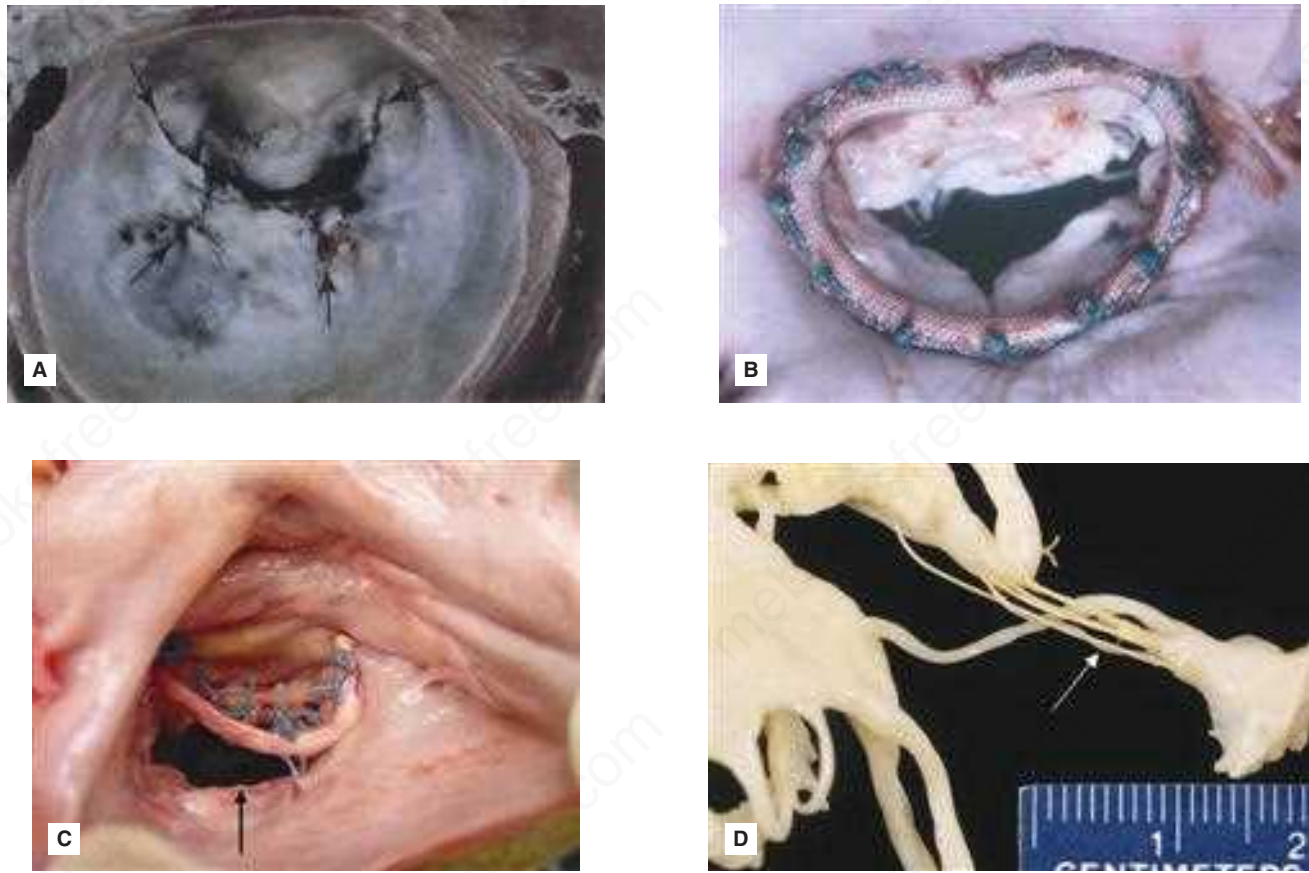

**FIGURE 5-16** Infective (bacterial) endocarditis. (A) Endocarditis of mitral valve with damage to the anterior mitral leaflet. (B) Acute endocarditis of congenitally bicuspid aortic valve (caused by *Staphylococcus aureus*), with large vegetation, causing extensive cuspal destruction and ring abscess (arrow). (C) Photomicrograph of vegetation, showing extensive acute inflammatory cells and fibrin. Bacterial organisms were demonstrated by tissue Gram stain. (D) Healed endocarditis, demonstrating aortic valvular destruction but no active vegetations on a congenitally bicuspid aortic valve. ([B] Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989. [C] Reproduced with permission from Schoen FJ. Surgical pathology of removed natural and prosthetic heart valves, *Hum Pathol*. 1987 Jun;18(6):558-567.)

course of weeks to months during which the infection may be undetected and untreated.

*Staphylococcus aureus* is the leading cause of acute endocarditis and produces necrotizing, ulcerative, invasive, and highly destructive valvular infections. The subacute form is usually caused by *Streptococcus viridans*. Cardiac abnormalities, such as chronic rheumatic heart disease, congenital heart disease (particularly anomalies that have small shunts or tight stenoses creating high-velocity jet streams), degenerative mitral valves, BAVs, and artificial valves and their sewing rings predispose to endocarditis. In intravenous drug abusers, left-sided lesions predominate, but right-sided valves are commonly affected. In about 5 to 20% of all cases of endocarditis, no organism can be isolated from the blood (*culture-negative endocarditis*), often because of prior antibiotic therapy or organisms difficult to culture.<sup>96</sup>

The modified Duke criteria provide a standardized assessment of patients with suspected infective endocarditis that integrates factors predisposing patients to the development of infective endocarditis, blood-culture evidence of infection, echocardiographic findings, and clinical and laboratory information.<sup>97</sup> The previously important clinical findings of petechiae, subungual hemorrhages, Janeway's lesions, Osler's nodes, and Roth's spots in the eyes (secondary to retinal microemboli) have now become uncommon owing to the shortened clinical course of the disease as a result of antibiotic therapy.

The complications of endocarditis include valvular insufficiency (rarely stenosis), abscess of the valve annulus (*ring abscess*), suppurative pericarditis, and embolization. With appropriate antibiotic therapy, vegetations may undergo healing, with progressive sterilization, organization, fibrosis, and

**FIGURE 5-17** Open surgical reconstructive procedures for mitral valve disease. (A) Mitral commissurotomy in mitral stenosis; incised commissures are indicated by arrows. (B) Mitral valve repair with annuloplasty ring. (C) Dehiscence of mitral annuloplasty ring (*arrow*). (D) ePTFE suture replacement (*arrow*) of ruptured cord in myxomatous mitral valve. ([A] Reproduced with permission from Schoen FJ. Surgical pathology of removed natural and prosthetic heart valves, *Hum Pathol*. 1987 Jun;18(6):558-67. [C] Used with permission from William A. Muller, MD, PhD, Northwestern University School of Medicine, Chicago.)

occasionally calcification. Cusp or leaflet perforation, chordal rupture, or fistula formation from a ring abscess into an adjacent cardiac chamber or great vessel can cause regurgitation. Ring abscesses are generally associated with virulent organisms, and a relatively high mortality rate.

### Valve Reconstruction and Repair

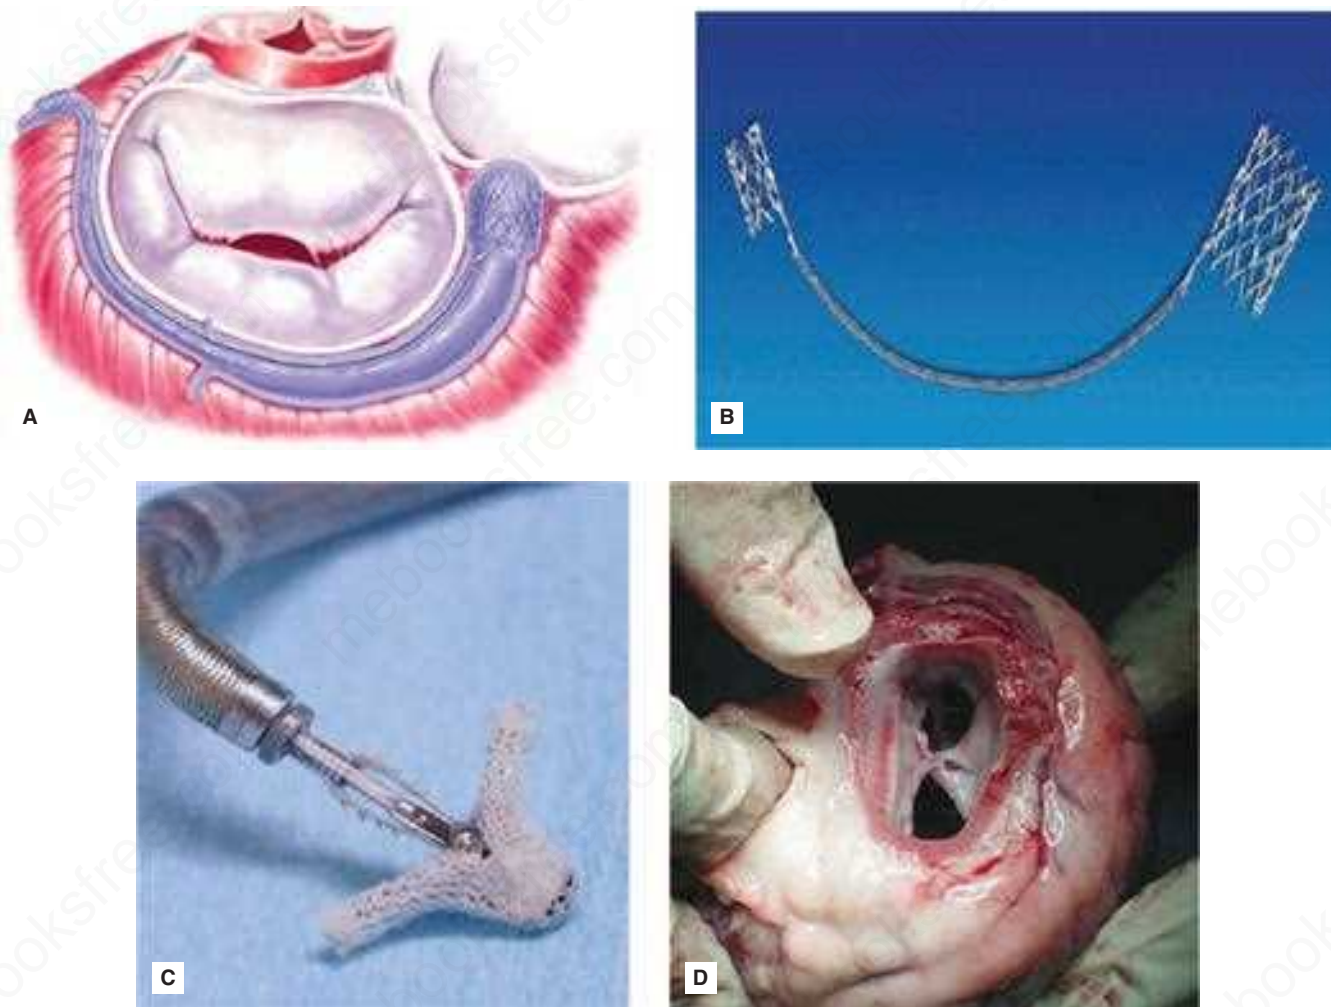

Reconstructive procedures to repair mitral insufficiency of various etiologies and to minimize the severity of rheumatic mitral stenosis are now highly effective and commonplace.<sup>98</sup> Reconstructive therapy of selected patients with aortic insufficiency (AI) and aortic dilation may also be done in some cases,<sup>99</sup> but repair of AS has been notably more challenging. The major advantage of repair over replacement relates to the elimination of both prosthesis-related complications and the need for chronic anticoagulation therapy. Other reported advantages include a lower hospital mortality, better long-term function owing to the ability to maintain the continuity of the mitral apparatus, and a lower rate

of postoperative endocarditis. Figures 5-17 and 5-18 illustrate the pathologic anatomy of various open and catheter-based mitral valve reconstruction procedures. Figure 5-19 illustrates a key difficulty of surgical repairs for AS, in that the cuspal calcification extends nearly to the inflow surface (recall Fig.14-C).

### Mitral Stenosis

Commissurotomy may be employed in the operative repair of some stenotic mitral valves in which fibrosis and shortening of both cords and leaflets have markedly decreased leaflet mobility and area. Factors that compromise the late functional results of or technically prevent mitral commissurotomy and thereby necessitate valve replacement include (1) left ventricular dysfunction; (2) pulmonary venous hypertension and right-sided cardiac factors, including right ventricular failure, tricuspid regurgitation, or a combination of these; (3) systemic embolization; (4) coexistent cardiac disorders, such as coronary artery or aortic valve diseases;

**FIGURE 5-18** Percutaneous correction of mitral regurgitation. (A) Schematic approach utilizing the proximity of the coronary sinus to the posterior mitral annulus to effect a simulated annuloplasty. Diagram showing the relationship of the coronary sinus and the posterior leaflet of the mitral valve. A remodeling device is seen within the coronary sinus. (B) The Monarc device consists of two anchoring stents with a bridge connector that shortens approximately 25% over the space of weeks with the intention of reducing the dimensions of the mitral annulus. Percutaneous correction of mitral regurgitation. (C and D) Edge-to-edge approximation of the anterior and posterior leaflets of the mitral valve is achieved by deployment of clip (Evalve mitral clip device) that is analogous to an Alfieri stitch, thereby creating a double orifice with improved leaflet coaptation. (Reproduced with permission from McManus BM, Braunwald E: *Atlas of Cardiovascular Pathology for the Clinician*. Philadelphia: Current Medicine; 2008.)

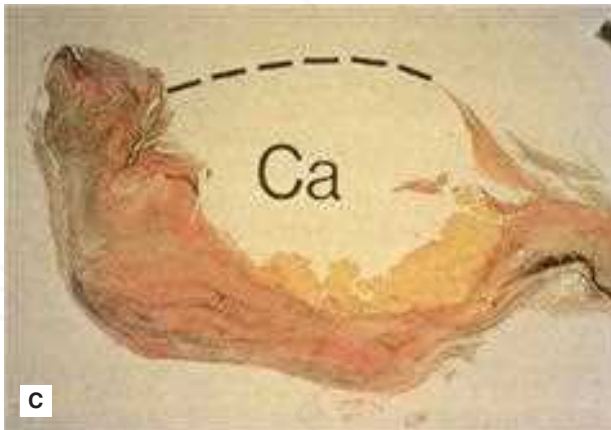

(5) residual or progressive mitral valve disease, including valve restenosis, residual (unrelieved) stenosis, or regurgitation induced at operation; (6) advanced leaflet (especially commissural) calcification; (7) subvalvar (predominantly chordal) fibrotic changes; and (8) significant regurgitation owing to retraction.

Percutaneous balloon mitral valvuloplasty has been used to treat mitral stenosis for over two decades, with excellent success in patients with suitable valvular and subvalvular morphology.<sup>100</sup> However, because balloon valvuloplasty largely involves separation of the fused leaflets at the commissures, this procedure is also unlikely to provide significant benefit to patients with the valve features summarized in the preceding that obviate surgical commissurotomy.

## Mitral Regurgitation

Reconstructive techniques are widely used to repair mitral valves with nonrheumatic mitral regurgitation.<sup>101-103</sup> Structural defects responsible for chronic mitral regurgitation include (1) dilation of the mitral annulus; (2) leaflet prolapse into the left atrium with or without elongation or rupture of chordae tendineae; (3) redundancy and deformity of leaflets; (4) leaflet perforations or defects; and (5) restricted leaflet motion as a result of commissural fusion in an opened position, and leaflet retraction, or chordal shortening or thickening.

Following surgical resection of excess anterior or posterior leaflet tissue in valves with redundancy, annuloplasty with or without a prosthetic ring is used to reduce the annulus

**FIGURE 5-19** Reconstructive procedures for aortic stenosis. (A) Aortic valve balloon valvuloplasty for degenerative calcific aortic stenosis, demonstrating fractures of nodular deposits of calcifications highlighted by tapes. [B and C] Operative decalcification of the aortic valve. (B) Aortic valve after operative mechanical decalcification demonstrating perforated cusp. ([A] Reproduced with permission from Silver MD, Gotlieb AI, Schoen FJ: *Cardiovascular Pathology*, 3rd ed. New York: Churchill Livingstone/Elsevier; 2001. [B and C] Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989.)

dimension to correspond to the amount of leaflet tissue available. Edge-to-edge (Alfieri stitch) mitral valve repair has also been used.<sup>104</sup> Tissue substitutes such as glutaraldehyde-pretreated xenograft or autologous pericardium can be used to repair or enlarge leaflets. Ruptured or elongated cords may be repaired by shortening or replacement with pericardial tissue or thick suture material.

Percutaneous approaches currently being evaluated for mitral regurgitation attempt to emulate one or more of the components of surgical mitral valve repair, including annular reduction and edge-to-edge mitral leaflet apposition.<sup>105-107</sup> However, leaflet resection and cordal modification cannot be easily done via catheter, and there is considerable anatomical variability of the coronary sinus.<sup>108</sup> Percutaneous approaches considered include implantation of a device in the coronary sinus, left atrium (or both), or by device placement behind the posterolateral leaflet of the mitral valve (see Fig. 5-18A and B). The goal is to plicate or straighten the posterior mitral annulus. Additional annuloplasty approaches, presently in preclinical testing, include a suture annuloplasty from the

ventricular side of the mitral annulus, thermal modification of the annulus to obtain shrinkage, and a percutaneous ventricular restraint system that attempts to reshape the left ventricle. Another catheter-based approach uses an edge-to-edge clip prosthesis simulating the edge-to-edge surgical (Alfieri stitch) repair in which the midportions of the anterior and posterior mitral leaflets are clipped together (see Fig. 5-18C and D).<sup>109,110</sup>

## Aortic Stenosis

In balloon dilation of calcific AS, individual functional responses vary considerably and data suggest a modest early incremental benefit, high early mortality, and high early restenosis rate owing to recoil of stretched tissue. Improvement derives from commissural separation, fracture of calcific deposits, and stretching of the valve cusps (see Fig. 5-19A). The major complications include cerebrovascular accident secondary to embolism, massive regurgitation owing to valve trauma, and cardiac perforation with tamponade. Fractured calcific

nodules can themselves prove dangerous.<sup>111</sup> In pediatric cases in which the cusps are generally pliable, cuspal stretching, tearing, or avulsion may also occur.

In calcific AS, the calcific deposits arise deep in the valve fibrous layer (see Fig. 5-14C). Their removal by sharp dissection or ultrasonic debridement generally removes a considerable fraction of the valve substance, resulting in severe compromise of mechanical integrity (see Fig. 5-19B and C).<sup>112</sup>

## Valve Replacement

Severe symptomatic valvular heart disease other than pure mitral stenosis or incompetence is most frequently treated by excision of the diseased valve(s) and replacement by a functional substitute. Five key factors determine the results of valve replacement in an individual patient: (1) technical aspects of the procedure; (2) intraoperative myocardial ischemic injury; (3) irreversible and chronic structural alterations in the heart and lungs secondary to the valvular abnormality; (4) coexistent obstructive CAD; and (5) valve prosthesis reliability and host-tissue interactions.

Cardiac valvular substitutes are of two types, mechanical and biologic tissue (Fig. 5-20 and Table 5-2).<sup>113,114</sup> Prostheses function passively, responding to pressure and flow changes within the heart. Mechanical valves are composed of nonphysiologic biomaterials and employ a rigid, mobile occluder (composed of pyrolytic carbon in contemporary valves), in a metallic cage (cobalt-chrome or titanium alloy) as in the Bjork-Shiley, Hall-Medtronic, or Omniscience valves, or two carbon hemidisks in a carbon housing (as in the St. Jude Medical, CarboMedics CPHV, and On-X prostheses). Pyrolytic carbon has high strength and fatigue and wear resistance and good thromboresistance. Tissue valves resemble natural semilunar valves, with pseudoanatomical central flow and biological material. In the past decade, innovations in tissue valve technologies and design have expanded indications for their use. Contemporary utilization of bioprosthetic tissue valves is estimated to be about 80% of all aortic and 69% of all mitral substitute heart valves.<sup>115,116</sup> Most tissue valves are bioprosthetic xenografts fabricated from porcine aortic valve or bovine pericardium, which have been preserved in a dilute glutaraldehyde solution, and a small percentage are cryopreserved allografts.

In a recent compilation of risk models of isolated valve surgery by the Society for Thoracic Surgeons, the overall mortality was 3.4% (3.2% aortic and 5.7% mitral) and varied strongly with case mix.<sup>117</sup> The majority of early deaths are caused by hemorrhage, pulmonary failure, low cardiac output, and sudden death with or without myocardial necrosis or documented arrhythmias. Potential complications related to mitral valve insertion include hemorrhagic disruption and dissection of the atrioventricular groove, perforation or entrapment of the left circumflex coronary artery by a suture, and pseudoaneurysm or rupture of the left ventricular free wall.

Improvement in late outcome has occurred predominantly from earlier referral of patients for valve replacement, decreased intraoperative myocardial damage, improved surgical technique, and improved valve prostheses. Following valve

replacement with currently used devices, the probability of 5-year survival is about 80% and of 10-year survival about 70%, depending on overall functional state, preoperative left ventricular function, left ventricular and left atrial size, and extent and severity of CAD.

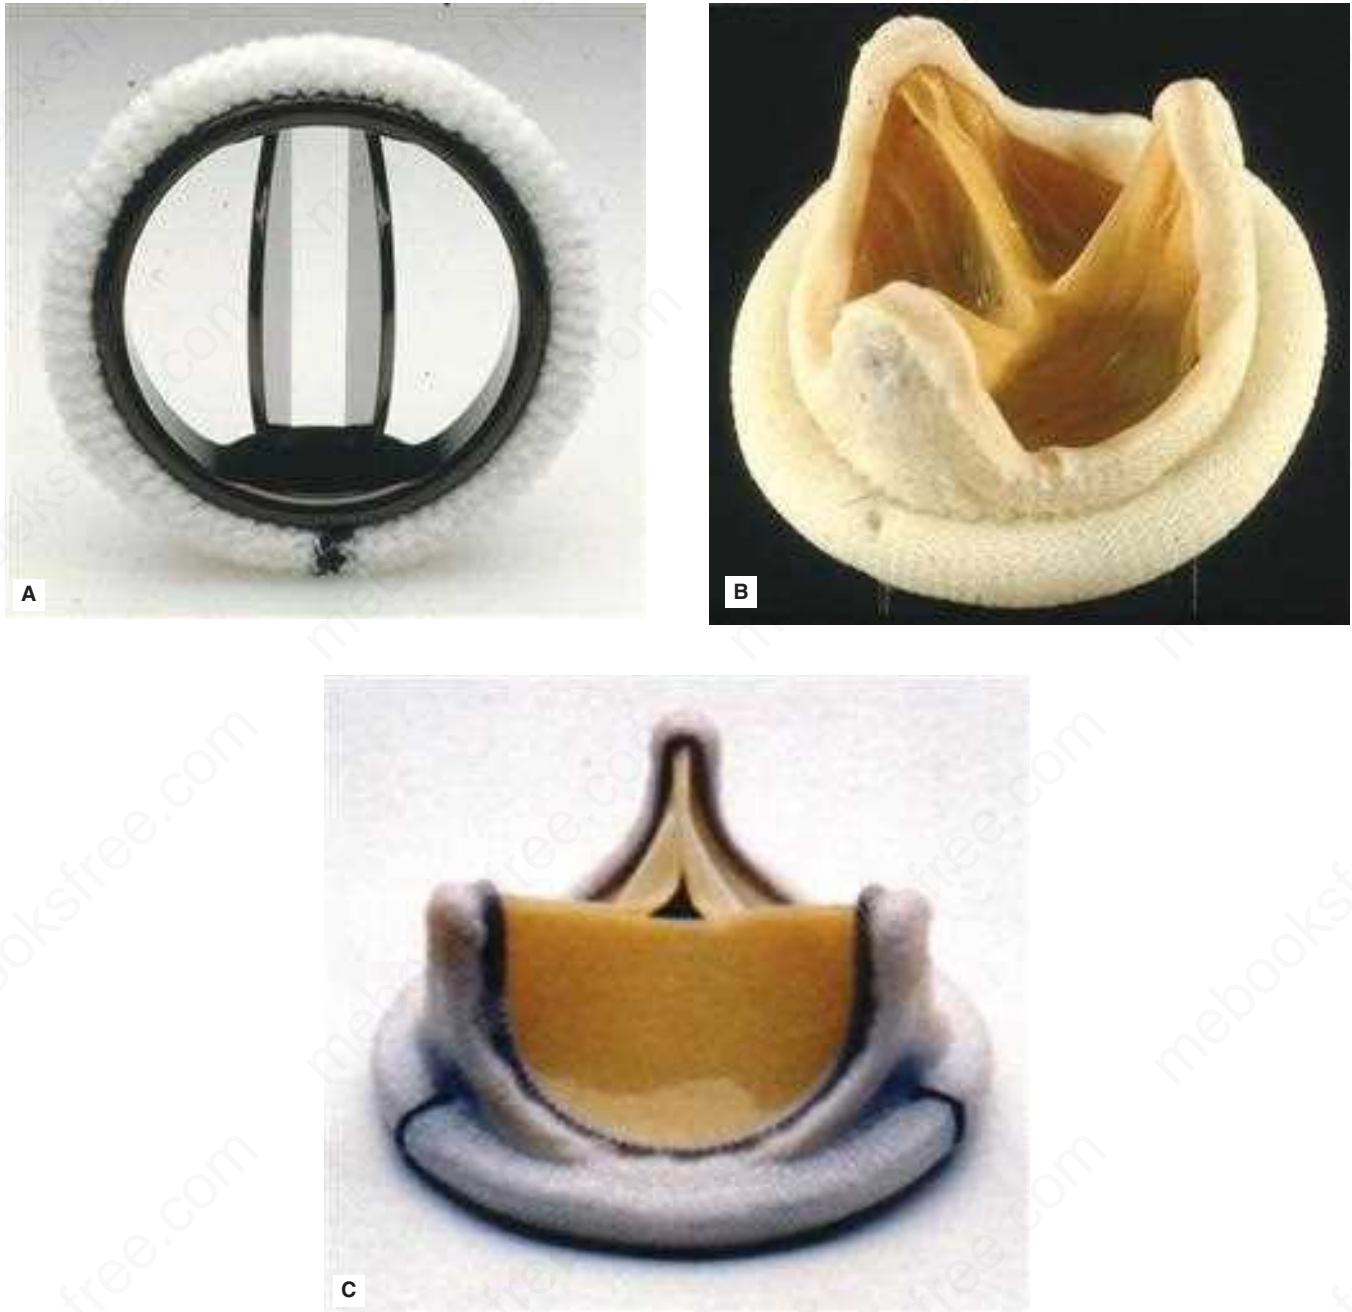

## Substitute Valve-Related Complications

Although early prosthetic valve-associated complications are unusual, prosthetic valve-associated pathology becomes an important consideration beyond the early postoperative period. Late death following valve replacement results predominantly from either cardiovascular pathology unrelated to the substitute valve or prosthesis-associated complications. In the few randomized studies comparing mechanical prosthetic and bioprosthetic valves several decades ago (comprising Bjork-Shiley mechanical and porcine aortic bioprosthetic valves), approximately 60% or more patients had an important device-related complication within 10 years postoperatively. Moreover, long-term survival was better among patients with a mechanical valve, but with an increased risk of bleeding.<sup>118,119</sup> Valve-related complications frequently necessitate reoperation, now accounting for approximately 10 to 15% of all valve procedures, and they may cause death. Four categories of valve-related complications are most important: thromboembolism and related problems, infection, structural dysfunction (ie, failure or degeneration of the biomaterials comprising a prosthesis), and nonstructural dysfunction (ie, miscellaneous complications and modes of failure not encompassed in the previous groups) (Table 5-3).<sup>120</sup>

### THROMBOSIS AND THROMBOEMBOLISM

*Thromboembolic complications* are the major valve-related cause of mortality and morbidity after replacement with mechanical valves, and patients receiving them require lifetime chronic therapeutic anticoagulation with warfarin derivatives.<sup>121,122</sup> Thrombotic deposits on a prosthetic valve can immobilize the occluder(s) or cusps, or shed emboli (Fig. 5-21). Owing to biologic material and central flow, tissue valves are less thrombogenic than mechanical valves; their recipients generally do not require long-term anticoagulation in the absence of another specific indication, such as atrial fibrillation. Nevertheless, the rate of thromboembolism in patients with mechanical valves on anticoagulation is not widely different from that in patients with bioprosthetic valves without anticoagulation (2 to 4% per year). Chronic oral anticoagulation also carries a risk of hemorrhage. Anticoagulation is particularly difficult to manage in pregnant women.<sup>123</sup> The risk of thromboembolism is potentiated by preoperative or postoperative cardiac functional impairment.

“Virchow’s triad” of factors promoting thrombosis (surface thrombogenicity, hypercoagulability, and locally static blood flow) largely predicts the relative propensity toward and locations of thrombotic deposits.<sup>124</sup> For example, with caged-ball prostheses, thrombi form distal to the poppet at the cage apex. Tilting disk prostheses are particularly susceptible to

**FIGURE 5-20** Photographs of the widely used types of heart valve substitutes. (A) Bileaflet tilting disk mechanical heart valve (St. Jude Medical, St. Jude Medical Inc., St. Paul, MN). (B) Porcine aortic valve bioprosthesis (Hancock, Medtronic Heart Valves, Santa Ana, CA). (C) Bovine pericardial bioprosthesis (Carpentier-Edwards, Edwards Life Sciences, Santa Ana, CA). total thrombotic occlusion or shedding emboli from small thrombi, with the thrombotic deposits generally initiated in a flow stagnation zone in the minor orifice of the outflow region of the prosthesis. In contrast, bileaflet tilting disk valves are most vulnerable to thrombus formation near the hinges where the leaflets insert into the housing (see Fig. 5-21A). Late thrombosis of a bioprosthetic valve is marked by large

thrombotic deposits in one or more of the prosthetic sinuses of Valsalva (see Fig. 5-21B), and no causal underlying cuspal pathology can usually be demonstrated by pathologic studies. Some valve thromboemboli, especially early postoperatively with any valve type, are thought to be initiated at the valve sewing cuff before it is healed, thus providing a rationale for early antithrombotic therapy for all types.

**TABLE 5-2: Types and Characteristics of Representative Types of Substitute Heart Valves\***

Valve type	Model(s)	Hemodynamics	Freedom from thrombosis/ thromboembolism	Durability
<b>Mechanical</b>

Although platelet deposition dominates initial blood-surface interaction, and prosthetic valve thromboembolism correlates strongly with altered platelet function, antiplatelet therapy alone is generally considered insufficient to adequately prevent thromboembolism. The lack of vascular tissue adjacent to thrombi that form on bioprosthetic or mechanical valves retards their histologic organization and may prolong the susceptibility to embolization as well as render the age of such thrombi difficult to determine microscopically. Nevertheless, this feature has permitted thrombolytic therapy to be an option in some cases.<sup>125</sup>

### PROSTHETIC VALVE ENDOCARDITIS

*Prosthetic valve infective endocarditis* (Fig. 5-22) occurs in 3 to 6% of recipients of substitute valves.<sup>126</sup> Infection can occur early or late. The microbial etiology of early prosthetic valve endocarditis (<60 days postoperative) is dominated by *Staphylococcus epidermidis* and *S. aureus*, even though prophylactic regimens used today target these microorganisms. The clinical course of early prosthetic valve endocarditis tends to be fulminant. In the generally less virulent late endocarditis, a source of infection and/or bacteremia can often be found; the most frequent initiators are dental procedures, urologic infections and interventions, and indwelling catheters. The most common organisms in these late infections are *S. epidermidis*, *S. aureus*, *S. viridans*, and enterococci. Rates of infection of bioprostheses and mechanical valves are similar, and

**FIGURE 5-21** Thrombotic occlusion of substitute heart valves. previous endocarditis on a natural or substitute valve markedly increases the risk.

Infections associated with mechanical prosthetic valves and some with bioprosthetic valves are localized to the prosthesis-tissue junction at the sewing ring, and accompanied by tissue destruction around the prosthesis (see Fig. 5-22A). This comprises a ring abscess, with potential paraprosthetic leak, dehiscence, fistula formation, or heart block caused by

**FIGURE 5-22** Prosthetic valve endocarditis. (A) Endocarditis with large ring abscess (*arrow*) observed from ventricular surface of aortic Bjork-Shiley tilting disk prosthesis in patient who died suddenly. Ring abscess impinged on proximal atrioventricular conduction system. (B and C) Bioprosthesis valve endocarditis viewed from inflow (B) and outflow (C) aspects. (Reproduced with permission from Schoen FJ: Cardiac valve prostheses: pathological and bioengineering considerations, *J Card Surg*. 1987 Mar;2(1):65-108.)

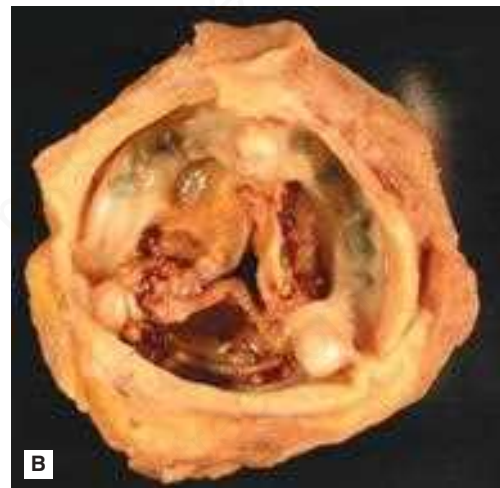

conduction system damage. Bioprosthetic valve infections may also involve, and are occasionally limited to, the cuspal tissue, sometimes causing secondary cuspal tearing or perforation with valve incompetence or obstruction (see Fig. 5-22 B and C). Surgical reintervention usually is indicated for large highly mobile vegetations or cerebral thromboembolic episodes, or persistent ring abscess.

### STRUCTURAL VALVE DYSFUNCTION

*Prosthetic valve dysfunction* owing to materials degradation can necessitate reoperation or cause prosthesis-associated death

(Fig. 5-23). Durability considerations vary widely for mechanical valves and bioprostheses, specific types of each, different models of a particular prosthesis (utilizing different materials or having different design features), and even for the same model prosthesis placed in the aortic rather than the mitral site. Mechanical valve structural failure is often catastrophic and may be life threatening; in contrast, bioprosthetic valve failure generally causes progressive symptomatic deterioration.

Fractures of metallic carbon components (disks or housing) are unusual in most contemporary bileaflet tilting disk mechanical valves<sup>127</sup> (see Fig. 5-23A). Historically, however,

**FIGURE 5-23** Structural valve dysfunction. (A) Disk fracture and escape in a Hemex-Duramedics heart valve prosthesis. (B and C) Porcine valve primary tissue failure owing to calcification with severe stenosis. (B) Gross photograph. (C) Photomicrograph demonstrating predominant site of calcification in cells of the residual porcine valve matrix (*arrows*). ([A] Reproduced with permission from Schoen FJ, Levy RJ, Piehler HR: Pathological considerations in replacement cardiac valves, *Cardiovasc Pathol.* 1992 Jan-Mar;1(1):29-52. [B] Reproduced with permission from Schoen FJ, et al: Long-term failure rate and morphologic correlations in porcine bioprosthetic heart valves, *Am J Cardiol.* 1983 Mar 15;51(6):957-964. [C] Reproduced with permission from Silver MD, Gotlieb AI, Schoen FJ: *Cardiovascular Pathology*, 3rd ed. New York: Churchill Livingstone/Elsevier; 2001.)

durability failures of mechanical valves were not uncommon. For example, of approximately 86,000 Bjork-Shiley 60- and 70-degree convexo-concave heart valves implanted, a cluster of more than 500 cases has been reported in which the two attachment points of the welded outlet strut fractured because of metal fatigue, leading to disk escape and often death.<sup>128</sup>

In contrast, structural dysfunction of tissue valves continues to be the major cause of failure of the most widely used bioprostheses (flexible-stent-mounted, glutaraldehyde-preserved porcine aortic valves, and bovine pericardial valves) (see Fig. 5-23B-D).<sup>129</sup> Long-term data on the first several decades of bioprosthetic valves (1970s through almost 2000) indicate that 50% of bioprosthetic mitral or AVRs require replacement within 15 to 20 years following implantation, because of structural dysfunction manifested as primary tissue failure. Cuspal mineralization is the key mechanism, causing stenosis, and secondary tears can cause regurgitation. Noncalcific structural damage owing to collagen fiber disruption (independent of calcification) also contributes to bioprosthetic heart valve failure.<sup>130</sup> Calcific deposits are usually localized to cuspal tissue (*intrinsic calcification*), but calcific deposits extrinsic to the cusps may occur in thrombi or endocarditic vegetations. Calcification is markedly accelerated in younger patients, with children and adolescents having an especially accelerated course. Bovine pericardial valves can also suffer calcification and tearing, with abrasion of the pericardial tissue an important contributing factor in some designs.<sup>131</sup>

The morphology and determinants of calcification of bioprosthetic valve tissue have been widely studied. The process is initiated primarily within residual membranes and organelles of the nonviable connective tissue cells that have been devitalized by glutaraldehyde pretreatment procedures, and involves reaction of calcium-containing extracellular fluid with membrane-associated phosphorus. The pathologic changes in bioprosthetic valves that occur following implantation are largely rationalized on the basis of changes induced by the preservation and manufacture of a bioprosthesis, including (1) denudation of surface cells, including endothelial cells in porcine aortic valves, and mesothelial cells in bovine pericardium; (2) loss of viability of the interstitial cells; and (3) locking of the cuspal microstructure in a static geometry.<sup>129</sup>

## NONSTRUCTURAL DYSFUNCTION

Nonstructural dysfunction of substitute heart valves are illustrated in Fig. 5-24. Paravalvular defects may be clinically inconsequential may aggravate hemolysis or may cause heart failure through regurgitation. Early paravalvular leaks may be related to suture knot failure, inadequate suture placement, or separation of sutures from a pathologic annulus in endocarditis with ring abscess, myxomatous valvular degeneration, or calcified valvular annulus as in calcific AS or mitral annular calcification. Late small paravalvular leaks usually are caused by tissue retraction from the sewing ring between sutures during healing. Small paravalvular defects are difficult to locate by surgical or pathologic examination (see Fig. 5-24A).

Extrinsic factors can mediate late prosthetic valve stenosis or regurgitation, including a large mitral annular calcific

nodule, septal hypertrophy, exuberant overgrowth of fibrous tissue (see Fig. 5-24B and C), interference by retained valve remnants (such as a retained posterior mitral leaflet or components of the submitral apparatus; see Fig. 5-24D), or unraveled, long, or looped sutures or knots (see Fig. 5-24E). With bioprosthetic valves, cuspal motion can be restricted by sutures looped around stents, and suture ends cut too long may erode into or perforate a bioprosthetic valve cusp.

## Valvular Allografts/Homografts

Aortic or pulmonary valves (with or without associated vascular conduits) transplanted from one individual to another have exceptionally good hemodynamic profiles, a low incidence of thromboembolic complications without chronic anticoagulation, and a low reinfection rate following valve replacement for endocarditis.<sup>132</sup> Contemporary cryopreserved allografts, in which freezing is performed with protection from crystallization by dimethyl-sulfoxide and storage until use at  $-196^{\circ}\text{C}$  in liquid nitrogen, have demonstrated freedom from degeneration and durability equal to or better than those of conventional porcine bioprosthetic valves.

Morphologic changes are summarized in Fig. 5-25. Cryopreserved human allograft heart valves/conduits show gross changes of conduit calcification and cuspal stretching (see Fig. 5-25A and B). Microscopically, there is progressive loss of normal structural demarcations and cells beginning in days. Long-term explants are devoid of both surface endothelium and deep connective tissue cells; they have minimal inflammatory cellularity (Fig. 5-25C).<sup>133</sup> Despite the widely discussed hypothesis that human allograft valve failure can be attributed to an immunological process, the available evidence supports purely degenerative mechanisms.

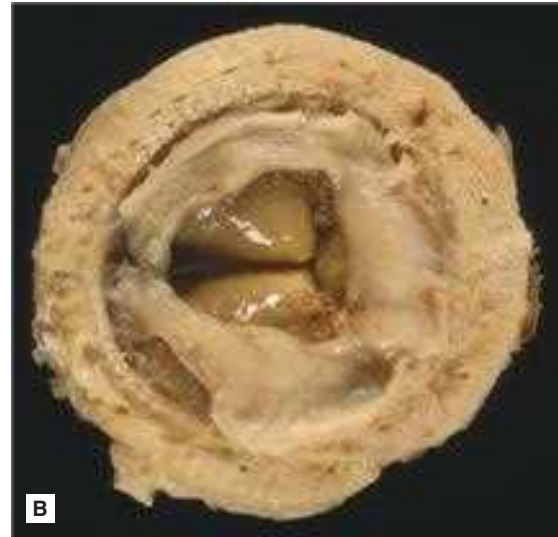

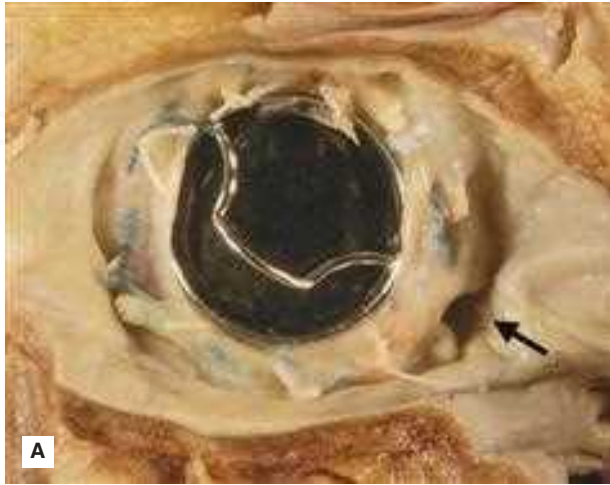

## Pulmonary Valvular Autografts

Often called the *Ross operation* in recognition of its originator, Sir Donald Ross, pulmonary autograft replacement of the aortic valve yields excellent hemodynamic performance, avoids anticoagulation, and carries a low risk of thromboembolism.<sup>134</sup> Explanted pulmonary autograft cusps show (1) near-normal trilaminar structure; (2) near-normal collagen architecture; (3) viable endothelium and interstitial cells; (4) usual outflow surface corrugations; (5) sparse inflammatory cells; and (6) absence of calcification and thrombus (see Fig. 5-25C).<sup>135</sup> However, the arterial walls show considerable transmural damage (probably perioperative ischemic injury caused by disruption of vasa vasorum) with scarring and loss of medial smooth muscle cells and elastin. The early necrosis and healing with probable resultant loss of strength/elasticity of the aortic wall may potentiate late aortic root dilation.<sup>136,137</sup>

## Stentless Porcine Aortic Valve Bioprostheses

*Nonstented (stentless) porcine aortic valve bioprostheses* consist of glutaraldehyde-pretreated pig aortic root and valve cusps that have no supporting stent.<sup>138</sup> The most widely used models,

**FIGURE 5-24** Nonstructural dysfunction of prosthetic heart valves. (A) Paravalvular leak adjacent to mitral valve prosthesis (*arrow*). (B) Tissue overgrowth compromising inflow orifice of porcine bioprosthesis. (C) Tissue overgrowth incorporating and resultant retraction and obliteration of bioprosthesis valve cusps. (D) Immobility of tilting disk leaflet by impingement of retained component of submitral apparatus (*arrow*) that had moved through orifice late following mitral valve replacement surgery. **FIGURE 5-25** Morphology of valve allografts (homografts) valve and pulmonary valve autografts. (A) Gross photograph of pulmonary valve allograft removed following 7 years for conduit stenosis in a child. The pulmonary arterial wall is heavily calcified but the cusps are not. (B) Gross appearance of cryopreserved aortic valve allograft removed at 3 years for aortic insufficiency. (C) Comparative morphologic features of autografts and homografts obtained from the same patients. Autograft valves had near-normal structure and cellular population (a, c, e), in contrast, homografts from the same patients (b, d, f) had a progressive collagen hyalinization and loss of cellularity. Bar = 200  $\mu\text{m}$   $\times$ 400. (Reproduced with permission from Rabkin-Aikawa E, Aikawa M, Farber M, et al: Clinical pulmonary autograft valves: pathological evidence of adaptive remodeling in the aortic site, *J Thorac Cardiovasc Surg.* 2004 Oct;128(4):552-561.)

St. Jude Medical Toronto SPV (St. Jude Medical Inc., St. Paul, MN), Medtronic Freestyle (Medtronic Heart Valves, Santa Ana, CA), and Edwards Prima (Edwards Life Sciences, Irvine, CA), bioprostheses differ slightly in overall configuration, details of glutaraldehyde fixation conditions, and anticalcification pretreatment. The principal advantage of a stentless porcine aortic valve is that it generally allows for the implantation of a larger bioprosthesis (than stented) in any given aortic root, which is hypothesized to enhance hemodynamics and thereby regression of hypertrophy and patient survival.<sup>139</sup>

The available evidence suggests that the durability of stentless bioprostheses is comparable with that of contemporary stented bioprostheses. However, nonstented porcine aortic valves have greater portions of aortic wall exposed to blood than in currently used stented valves, and calcification of the aortic wall and inflammation at the junction of aortic wall within the recipient's tissue, are potentially deleterious, owing to the large area of this interface. Calcification of the wall portion of a stentless valve could stiffen the root, cause nodular calcific obstruction potentiate wall rupture, or provide a nidus for emboli. Analyses of explanted nonstented valves show pannus and tissue degeneration, manifest as tears and cuspal calcification, but not substantial aortic wall calcification.<sup>140,141</sup>

## Catheter-Based Valve Implantation

New catheter techniques for inserting foldable prosthetic valves within stenotic aortic and pulmonary valves, and for emulating surgical repair of regurgitant mitral valves are in various stages of preclinical development and clinical use.<sup>142,143</sup> Presently, catheter-based, percutaneous or transapical valve replacement is most widely used in patients with severe AS disease deemed otherwise inoperable as a bridge to valve replacement in patients in whom surgery needs to be delayed or has excessive risk, in repair of failed bioprosthetic valves, and in congenital heart disease, in which percutaneous pulmonary valve replacement may find a distinct niche to obviate the morbidity of reoperation to replace malfunctioning pulmonary conduits.

Catheter-based valve implantation uses a device that has two components: (1) an outer stentlike structure and (2) leaflets; these two components together constitute a functioning valvular prosthesis. Representative designs are illustrated in Fig. 5-26. The stent holds open a valve annulus or segment of a prosthetic conduit, resists recoil, provides the means for seating of the prosthesis in the annulus or vessel, and supports the valve leaflets.

Valves designed for catheter-based implantation generally consist of biologic tissue such as bovine, equine, or porcine pericardium (for aortic valve implantation) and bovine jugular venous valves (for pulmonary conduit implantation) mounted within a collapsible stent. The stents can be made from self-expandable or shape-memory materials such as nickel-titanium alloys (eg, Nitinol), or from balloon-expandable materials such as stainless steel, platinum-iridium, or other alloys. For a balloon-expandable device the delivery strategy involves collapsing the device over a balloon and placing it within a catheter-based sheath. The catheter containing the device can be inserted into the femoral artery (or vein) for right-sided valves.

The Medtronic Melody transcatheter pulmonary valve is composed of a balloon expandable platinum-iridium alloy stent that houses a segment of bovine jugular vein containing its native venous valve. The Melody was designed to be used in children or young adults with congenital heart disease who have received surgically implanted right ventricular outflow tract conduits that are failing because of either stenosis or regurgitation.

Catheter-based stent-mounted prosthetic valves present novel challenges. Valved stents are significantly larger than most existing percutaneous cardiac catheters and devices, and are presently on the order of 22 to 24 Fr. In the aortic position, there is the potential to impede coronary flow, or interfere with anterior mitral leaflet mobility or the conduction system or the native diseased leaflets. Stent architecture may also preclude future catheter access to the coronaries for possible interventions. Secure seating without paravalvular leaks within the aortic annulus or a pulmonary conduit and long-term durability of both the stent and the valve tissue are also major considerations.

## Transcatheter Aortic Valve Implantation

Transcatheter aortic valve implantation (TAVI), first performed in humans in 2002, is accomplished through peripheral arterial access, is a less invasive alternative to conventional AVR, and extends the opportunity for effective mechanical correction to a potentially large population of otherwise untreatable individuals.<sup>144,145</sup> Approximately 65,000 AVRs are done in the United States each year. It is estimated that at least 30% of patients with severe symptomatic AS are inoperable.<sup>146</sup> Previously, incumbent surgical valve manufacturers offered no effective surgical intervention suitable for these patients.

Clinical experience with TAVI is growing rapidly, with an estimated 200,000+ TAVI procedures performed worldwide to date. Randomized and observational clinical trials comparing TAVI to classical open surgical AVR suggest that survival following TAVI in high-risk patients is equivalent to or better than that of AVR at 1 to 2 years.<sup>147-149</sup> TAVI has rapidly become the new standard of care for many patients with symptomatic AS who would otherwise be deemed inoperable or have high risk for surgery.

For repair of AS, the device is passed from the femoral artery retrograde up the aorta to the aortic valve and deployed between the cusps of the calcified aortic valve, pushing the diseased cusps out of the way. Alternatively, in patients with significant atherosclerotic disease of the femoral artery and/or aorta, the device can be deployed in an antegrade fashion through a minimally invasive surgical approach exposing the apex of the left ventricle (transapical implantation). The valve is inserted within the diseased native aortic valve, unlike surgical AVR that removes the native valve, and without the use of cardiopulmonary bypass. Access is obtained either through a peripheral artery (femoral or subclavian) or directly through the aorta or left ventricular apex. Once located at the level of the aortic valve, the device requires balloon dilatation or self-expands (if fabricated from a shape memory alloy such as Nitinol). The patient's native aortic valve is not removed (as in AVR) but rather is pushed aside to the periphery of

**FIGURE 5-26** Transcatheter valves. (A) The Cribier-Edwards/Sapien valve consists of three equine pericardial leaflets fixed to a balloon-expandable steel stent. It is hand crimped over a delivery balloon prior to deployment. (B) The CoreValve system is constructed of porcine pericardium attached to a self-expanding nickel-titanium alloy (nitinol) stent. The ventricular portion has a high radial force to compress the native valve. The midportion is tapered to avoid interference with the coronary arteries. The aortic portion is flared to provide additional fixation against the wall of the ascending aorta. (C) The Melody pulmonary valve is constructed from a bovine jugular venous valve attached with sutures to a platinum-iridium alloy stent. Its use is primarily in failed surgically constructed right ventricular to pulmonary artery conduits in the pediatric population. (D) Postmortem photograph from a patient who died following percutaneous valve implantation. The valve prosthesis can be seen to be fully expanded within the left ventricular outflow tract with good leaflet coaptation. The interventricular septum can be seen to the left and the anterior leaflet of the mitral valve to the right. (E) Specimen from a patient who had a valve-in-valve procedure. (Reproduced with permission from McManus BM, Braunwald E: *Atlas of Cardiovascular Pathology for the Clinician*. Philadelphia: Current Medicine; 2008.)

the annulus, and compressed against the aortic root. During TAVI, delivery, positioning, and permanent fixation in the optimal location are guided by fluoroscopy and echocardiography are critical to procedural success. These devices may also play a role in the treatment of surgically implanted bioprosthetic valves that are failing because of stenosis or regurgitation in a so-called “valve-in-valve” application, in which a new valve is placed via catheter into the lumen of the existing valve (see Fig. 5-26E).

The design of the devices used in TAVI is necessarily different than that of conventional substitute heart valves. Valves used in TAVI generally consist of a bioprosthetic tissue valve, typically fabricated from bovine pericardium, mounted on a compressible metallic stent (Fig. 5-26). Complications have been observed in approximately one-third of patients and may include vascular injury, paravalvular leak, and stroke.<sup>150</sup>

Several devices are currently in various stages of development and clinical use in the aortic and pulmonary position. The two transcatheter aortic valves with the largest clinical experience are the Edwards SAPIEN device (Fig. 5-26A) and the CoreValve system (Fig. 5-26B).<sup>151,152</sup> The SAPIEN device is composed of a balloon expandable stainless steel stent that houses a bovine pericardial valve. The stent has a low profile and is designed to be placed in the subcoronary position. There is a polymer skirt circumferentially attached to the stent to reduce paravalvular leaks. The CoreValve device is composed of a self-expandable Nitinol stent that houses a porcine pericardial trileaflet valve. The CoreValve stent is longer and is meant to be placed in the left ventricular outflow tract extending into the aortic root. These devices have been approved by the US Food and Drug Administration (FDA) and other regulatory bodies abroad.

There have been a number of clinical trials from different countries, including randomized trials comparing transcatheter aortic valve replacement to classical AVR. The consensus of these studies is that TAVI is not inferior to classical AVR in terms of procedure “success” and short-term morbidity and mortality. Long-term survival is primarily limited by comorbidities in this elderly group of patients—death is often due to severe renal, pulmonary, or nonvalvular heart disease.

Aortic insufficiency, while uncommon after classical AVR, is common after TAVI, and is usually due to paravalvular leaks. Repositionable valves may be beneficial in lowering procedural complications. Vascular events are the most common complications of the procedure and contribute to procedural mortality. The resulting vascular injury may lead to significant bleeding requiring transfusion and even death. As smaller, lower-profile systems are developed, vascular injuries leading to significant blood loss are expected to occur less frequently. A rise in creatinine following TAVR has been reported in 5 to 28% of cases. However, renal function often improves with the increase in cardiac output. Elderly patients that are candidates for TAVI generally have some degree of atherosclerotic CAD. The presence of severe CAD increases procedural risks and must be dealt with before the procedure. The coronary ostia can be blocked by the device. The risk is dependent on the site of placement of the device and anatomic factors, such as unusually heavy calcification of the

aortic valve or aortic root, or low coronary ostia. The conduction system passes through the interventricular septum immediately below the aortic valve. Hence, injury to this region during valve placement may cause partial or complete heart block. New-onset bundle branch block following TAVI has been reported in up to 45% of patients, according to early reports. TAVI is commonly associated with some myocardial injury, as assessed by CK-MB and cTnT release. Myocardial injury, judged by elevated cardiac biomarkers, is inversely correlated to improvement in ejection fraction and directly proportional to postprocedural cardiac mortality. Stroke during or after TAVI may occur from thromboemboli, aortic injury (eg, dissection or atheroemboli), hypotension, hemorrhage, or dislodgement of calcific fragments during valvuloplasty. Given that TAVI is intended for individuals who are poor surgical candidates, it is not surprising that many have comorbidities that increase the risk of thrombosis and stroke. Not surprisingly, individuals most at risk include those with a history of atrial fibrillation, severe diastolic dysfunction, and/or left atrial or ventricular hypertrophy.

Transcatheter heart valves (THVs) are susceptible to failure modes typical to those of surgical bioprostheses and unique to their specific design.<sup>153</sup> A recent review found 87 published cases of TAVI failure. Similar to surgical bioprosthetic heart valve failure, prosthetic valve endocarditis, structural valve failure due to leaflet calcification thrombosis were the most frequent complications. THV embolization and THV compression occurred in multiple cases following cardiopulmonary resuscitation (CPR).

## CARDIAC REPLACEMENT AND MECHANICAL ASSIST

### Cardiac Transplantation

Cardiac transplantation provides long-term survival and improved quality of life for many individuals with end-stage cardiac failure that is refractory to optimal medical management.<sup>154</sup> The current 1-year survival is approximately 90% and 5-year survival is about 70%.<sup>155</sup> The most common indications for cardiac transplantation, accounting for 90% of the adult recipients, are idiopathic cardiomyopathy and end-stage ischemic heart disease; other recipients have congenital, other myocardial, or valvular heart disease. Retransplantation is a viable option for patients with failing allografts, and rates of retransplantation have been rising recently.

Hearts explanted at the time of transplantation may also have previously undiagnosed conditions and unexpected findings.<sup>156</sup> Some of these findings are important for patient management, as certain diseases responsible for failure of the native heart such as amyloidosis, sarcoidosis, giant cell myocarditis, and Chagas disease may recur in the transplanted heart. Making a specific diagnosis of a genetic condition such as HCM or ARVC at the time of explant has important implications for the family members. The most frequent unexpected finding in the explanted heart is eosinophilic or hypersensitivity myocarditis, seen in 7 to 20% of explants and characterized by a focal or diffuse mixed inflammatory

infiltrate, rich in eosinophils, and generally associated with minimal myocyte necrosis. In virtually all cases, the hypersensitivity is a response to one or more of the many heart failure medications taken by transplant candidates, including dobutamine. Recipients of heart transplants undergo surveillance endomyocardial biopsies on an institution-specific schedule, which typically evolves from weekly during the early postoperative period, to biweekly until 3 to 6 months, and then approximately one to four times annually, or at any time when there is a change in clinical state. Histologic findings of rejection frequently precede clinical signs and symptoms of acute rejection. Optimal biopsy interpretation requires four or more pieces of myocardial tissue; descriptions of technical details and potential tissue artifacts are available.<sup>157</sup>

The major sources of mortality and morbidity in the first few post transplant years are perioperative ischemic injury/graft failure, infection, and multisystem organ failure, while malignancy, graft vasculopathy, and renal failure dominate after 3 to 5 years posttransplant. Because of the success of surveillance endomyocardial biopsies and current effective immunosuppressive therapies, acute cellular rejection is an uncommon cause of death in the modern era.<sup>155</sup>

### Early Ischemic Injury

Ischemic injury can originate from the ischemia that accompanies procurement and implantation of the donor heart. Several time intervals are potentially important: (1) the donor interval between brain death and heart removal, perhaps partially related to terminal administration of pressor agents or the release of norepinephrine and cytokines associated with brain death; (2) the interval of warm ischemia between donor cardiectomy to cold storage; (3) the interval during cold transport; and (4) the interval during rewarming, trimming, and implantation. Hypertrophy and coronary obstructions in the donor heart tend to promote ischemia, whereas decreased tissue temperature and cardioplegic arrest mitigate against ischemic injury. As in other situations of transient myocardial ischemia, frank necrosis, or prolonged

ischemic dysfunction of viable myocardium or both may be present. Myocardial injury can cause low cardiac output in the perioperative period.

Perioperative myocardial ischemic injury may be detectable in endomyocardial biopsies. Owing to the anti-inflammatory effects of immunosuppressive therapy, the histologic progression of healing of myocardial necrosis in transplanted hearts may be delayed (Fig. 5-27). Therefore, the repair phase of perioperative myocardial necrosis frequently confounds the diagnosis of rejection in the first postoperative month, and in some cases, for as long as 6 weeks. Late ischemic necrosis suggests occlusive graft vasculopathy (see the following).

### Rejection

Improved immunosuppressive regimens in heart transplant patients have substantially decreased the incidence and severity of rejection episodes. Hyperacute rejection occurs rarely, most often when a major blood group incompatibility exists between donor and recipient, and acute rejection is unusual earlier than 2 to 4 weeks postoperatively. Although acute rejection episodes occur largely in the first several months after transplantation, rejection can occur years postoperatively, rationalizing the practice of many transplant centers to continue late surveillance biopsies at late but widely spaced intervals.

Acute cellular rejection is characterized histologically by an inflammatory cell infiltrate, with or without damage to cardiac myocytes; in late stages, vascular injury may become prominent (Fig. 5-28). The current International Society for Heart and Lung Transplantation (ISHLT) grading system for acute cellular rejection, revised (denoted by “R”) in 2004 from the 1990 version, is: Grade 0R—no rejection (no change from 1990), Grade 1R—mild rejection (1990 grades 1A, 1B, and 2), Grade 2R—moderate rejection (1990 grade 3A), and Grade 3R—severe rejection (1990 grades 3B and 4).<sup>158</sup> The 1990 and 2004 formulations are compared in Table 5-4. The past decade has seen tremendous progress in the recognition, understanding, and diagnosis of acute antibody-mediated rejection (AMR). AMR was originally recognized as a

**FIGURE 5-27** Perioperative ischemic myocardial injury demonstrated on endomyocardial biopsy. (A) Coagulative myocyte necrosis (arrows). (B) Healing perioperative ischemic injury with predominantly interstitial inflammatory response (arrows), not encroaching on and clearly separated from adjacent viable myocytes. The infiltrate consists of a mixture of polymorphonuclear leukocytes, macrophages, lymphocytes, and plasma cells. Hematoxylin and eosin, 200 $\times$ .

**FIGURE 5-28** Histologic features of cardiac transplant rejection, designated as International Society for Heart and Lung Transplantation (ISHLT), 2004 Formulation, grades of rejection. (A-C) Grade 1R (mild). Focal perivascular lymphocytic and diffuse interstitial lymphocytic infiltrate without damage to adjacent myocytes, and up to one focus of dense lymphocytic infiltrate with associated myocyte damage, respectively. (D) Grade 2R (moderate). Multiple foci of dense lymphocytic infiltrates with associated myocyte damage and intervening areas of uninvolved myocardium. (E and F) Grade 3R (severe). Diffuse infiltrate with associated myocyte damage and polymorphous infiltrate with extensive myocyte damage, edema, and hemorrhage, respectively. (H&E stain). (Reproduced with permission from Silver MD, Gotlieb AI, Schoen FJ: *Cardiovascular Pathology*, 3rd ed. New York: Churchill Livingstone/Elsevier; 2001.)

clinicopathologic entity characterized by (1) cardiac dysfunction in the absence of cellular rejection or ischemic injury; (2) histologic features of interstitial edema, endothelial cell swelling, and intravascular macrophages on endomyocardial biopsy; (3) positive immunoperoxidase staining for C4d; and (4) the presence of circulating antidonor antibodies. Recently, the ISHLT has recommended pathologic grading of AMR in the following manner: pAMR0—no histologic changes of AMR and negative immunopathologic (eg, C4d) staining, pAMR1 (H+)—histologic changes consistent with AMR but immunopathologic studies are negative, pAMR1

(I+)—no histologic changes of AMR but immunopathologic studies are positive, pAMR2—pathologic AMR with histologic changes and positive immunopathologic studies, pAMR3—severe pathologic AMR with histologic changes, positive immunopathologic studies and marked edema, interstitial hemorrhage, capillary fragmentation, endothelial cell damage, and mixed interstitial inflammation.<sup>159</sup> AMR most often is diagnosed in sensitized patients (including those with previous transplantation, transfusion or pregnancy, and previous ventricular assist device use) and is associated with worse graft survival. Evidence is mounting that

**TABLE 5-4: ISHLT Standardized Cardiac Biopsy Grading of Acute Cellular Rejection: Clinicopathologic Comparison of 1990 and 2004 Formulations**

Rejection level	Histologic findings	Rejection grade 1990	Rejection grade 2004	Clinical response
None	Normal	0	0R	No change
Mild	Lymphocytic inflammation ± one focus of myocyte damage	1A, 1B, 2	1R	No/minimal change to chronic immunosuppressive regimen
Moderate	Lymphocytic inflammation + multiple foci of myocyte damage	3A	2R	Steroid bolus ± change in chronic immunosuppressive regimen
Severe	Lymphocytic inflammation + diffuse myocyte damage ± vascular injury	3B, 4	3R	Aggressive therapy (eg, steroids ± monoclonal antibodies [OKT3])

ISHLT = International Society for Heart and Lung Transplantation.

episodes of AMR predispose to the earlier development of allograft coronary disease. Although the optimal therapeutic strategy is still under debate, most transplant centers will use plasmapheresis to treat AMR with impaired cardiac function. Findings in surveillance endomyocardial biopsies that must be distinguished from rejection include lymphoid infiltrates either confined to the endocardium or extending into the underlying myocardium and often accompanied by myocyte damage (so-called Quilty lesions, which have no known clinical significance), old biopsy sites, and healing ischemic injury either in the perioperative period or resulting from graft vasculopathy. Lymphoproliferative disorders and infections also may be seen in biopsies.

## Infection

The immunosuppressive therapy required in all heart transplant recipients confers an increased risk of infection with bacterial, fungal, protozoan, and viral pathogens, with cytomegalovirus (CMV) and *Toxoplasma gondii* remaining common opportunistic infections in this setting. Prophylaxis is typically given to patients at high risk of primary CMV infection (donor seropositive, recipient seronegative). Viral and parasitic infections can present a challenge in endomyocardial biopsies as the multifocal lymphocytic infiltrates with occasional necrosis seen with these infections can mimic rejection.

## Graft Vasculopathy (Graft Coronary Disease)

Graft vasculopathy is the major limitation to long-term graft and recipient survival following heart transplantation.<sup>160</sup> Up to 50% of recipients have angiographically evident disease 5 years after transplantation, whereas intravascular ultrasound identifies graft vasculopathy in 75% of patients at 3 years posttransplant. However, graft vasculopathy may become significant at any time and can progress at variable rates. We have encountered graft coronary disease in several patients as early as 6 to 12 months postoperatively at the Brigham and Women's Hospital.

Graft vasculopathy (Fig. 5-29) occurs diffusely and ultimately involves both intramyocardial and epicardial allograft vessels, potentially leading to myocardial infarction, arrhythmias, congestive heart failure, or sudden death. Although this process has been called “accelerated atherosclerosis,” the morphology of the obstructive lesion of graft vasculopathy is distinct from that of typical atherosclerosis (Table 5-5).

The vessels involved have concentric occlusions characterized by marked intimal proliferation of myofibroblasts and smooth muscle cells with deposition of collagen, ECM, and lipid (see Fig. 5-29A and B). Lymphocytic infiltration varies from almost none to quite prominent. The internal elastic lamina often is almost completely intact, with only focal fragmentation. The resulting myocardial pathology includes subendocardial myocyte vacuolization (indicative of sublethal ischemic injury) and myocardial coagulation necrosis (indicative of infarction).

Evidence suggests that chronic allogeneic immune response to the transplant and nonimmunologic factors mediate the vascular injury.<sup>161</sup> Conventional risk factors of atherosclerosis (eg, hyperlipidemia, diabetes, advanced age), pre- or peritransplant injuries, infection, innate immunity, T-cell-mediated immunity, and B-cell-mediated immunity via production of donor specific antibodies have been associated with increased and accelerated graft vasculopathy, likely acting in concert with each other. There is no apparent difference in the frequency with which graft vasculopathy develops in patients who were transplanted for end-stage CAD versus idiopathic cardiomyopathy.

Early diagnosis of graft vasculopathy is limited by the lack of clinical symptoms of ischemia in the denervated allograft, by the relative insensitivity of coronary angiography, which frequently underestimates the extent and severity of this diffuse disease, and by the exclusive or predominant involvement of small intramyocardial vessels. Histologic changes of chronic ischemia such as subendothelial myocyte vacuolization can be seen on surveillance biopsies as evidence of myocardial ischemia and may suggest graft vasculopathy (see Fig. 5-29C and D). Obstructive vascular lesions are not usually amenable to PCI or coronary artery bypass grafting

**FIGURE 5-29** Gross and microscopic features of graft coronary disease and graft arteriosclerosis–induced myocardial pathology in heart transplant recipients. (A) Gross photograph of transverse cross-section of heart from patient who died of graft arteriosclerosis. Severe concentric stenosis of an epicardial coronary is apparent with only a pinhole lumen (*arrow*). (B) Histologic appearance of graft arteriosclerosis as low-power photomicrograph of vessel cross-section, demonstrating severe, near-complete, and predominantly concentric intimal proliferation with nearly intact internal elastic lamina (*arrow*). Verhoeff-van Gieson stain (for elastin) 60 $\times$ . Gross and microscopic features of graft coronary disease and graft arteriosclerosis–induced myocardial pathology in heart transplant recipients. (C) Myocardial microinfarct indicative of disease of small intramural arteries (*outlined by arrows*) Hematoxylin and eosin and (D) subendocardial myocyte vacuolization indicative of severe chronic ischemia. Trichrome stain, 375 $\times$ . ([B] Reproduced with permission from Salomon RN, Hughes CWH, Schoen FJ, et al: Human coronary transplantation-associated arteriosclerosis: evidence for a chronic immune reaction to activated graft endothelial cells, *Am J Pathol.* 1991 Apr;138(4):791-798.)

because of their diffuse distribution. Retransplantation is the only effective therapy for most cases of established graft atherosclerosis.

### Posttransplant Lymphoproliferative Disorders

Posttransplant lymphoproliferative disorders (PTLDs) are a well-recognized and serious complication of the high-intensity long-term immunosuppressive therapy required to prevent rejection in cardiac allografts. PTLD occurs in approximately

2% of cardiac allograft recipients. Several factors increase the risk of PTLD, including pretransplant Epstein-Barr virus (EBV) seronegativity (10- to 75-fold increase), young recipient age, and CMV infection or mismatching (donor-positive, recipient-negative).<sup>162</sup>

Posttransplant lymphoproliferative disorders can present as an infectious mononucleosis-like illness or with localized solid tumor masses, especially in extranodal sites (eg, heart, lungs, gastrointestinal tract). The vast majority (>90%) of PTLDs derive from the B-cell lineage and are associated with EBV infection, although T- or NK-cell origin and late-arising

**TABLE 5-5: Characteristics of Graft Arteriosclerosis versus Typical Atherosclerosis**

Graft arteriosclerosis	Typical atherosclerosis
Rapid onset (months to years)	Slow onset (many years)
Risk factors uncertain	Hypertension, lipids, smoking, etc
Usually silent/congestive heart failure, sudden death	Chest pain, etc
Diffuse	Focal
Epicardial/intramural	Epicardial
Concentric	Eccentric
Lesions rarely locally complicated	Lesions often locally complicated
Smooth muscle cells, macrophages, lymphocytes	Smooth muscle cells, macrophages, foam cells
Primary immunologic mechanism(s)	Complicated stimuli
Difficult to treat; retransplant usually only option	Revascularization by angioplasty, stents, aortocoronary bypass

Reproduced with permission from Schoen FJ, Libby P: Cardiac transplant graft arteriosclerosis, *Trends Cardiovasc Med.* 1991 Jul-Aug;1(5):216-223.

EBV-negative lymphoid malignancies have been described. There is strong evidence that the lesions progress from polyclonal B-cell hyperplasias (early lesions) to lymphomas (monomorphic PTLDs) in a short period of time, in association with the appearance of cytogenetic abnormalities. Therapy centers on a stepwise approach of antiviral treatment and reduction in immunosuppression, and then progression to lymphoma chemotherapy.

## Cardiac Assist Devices and Total Artificial Hearts

Continuing and increasing discrepancy between the number of available donor hearts and therefore transplants performed (2500 annually in the United States) and the number of patients in the terminal phase of heart failure and refractory to medical management (estimated at 250,000 to 500,000 in the United States, and rising) has prompted efforts in the development of VADs, total artificial hearts, and other therapies.

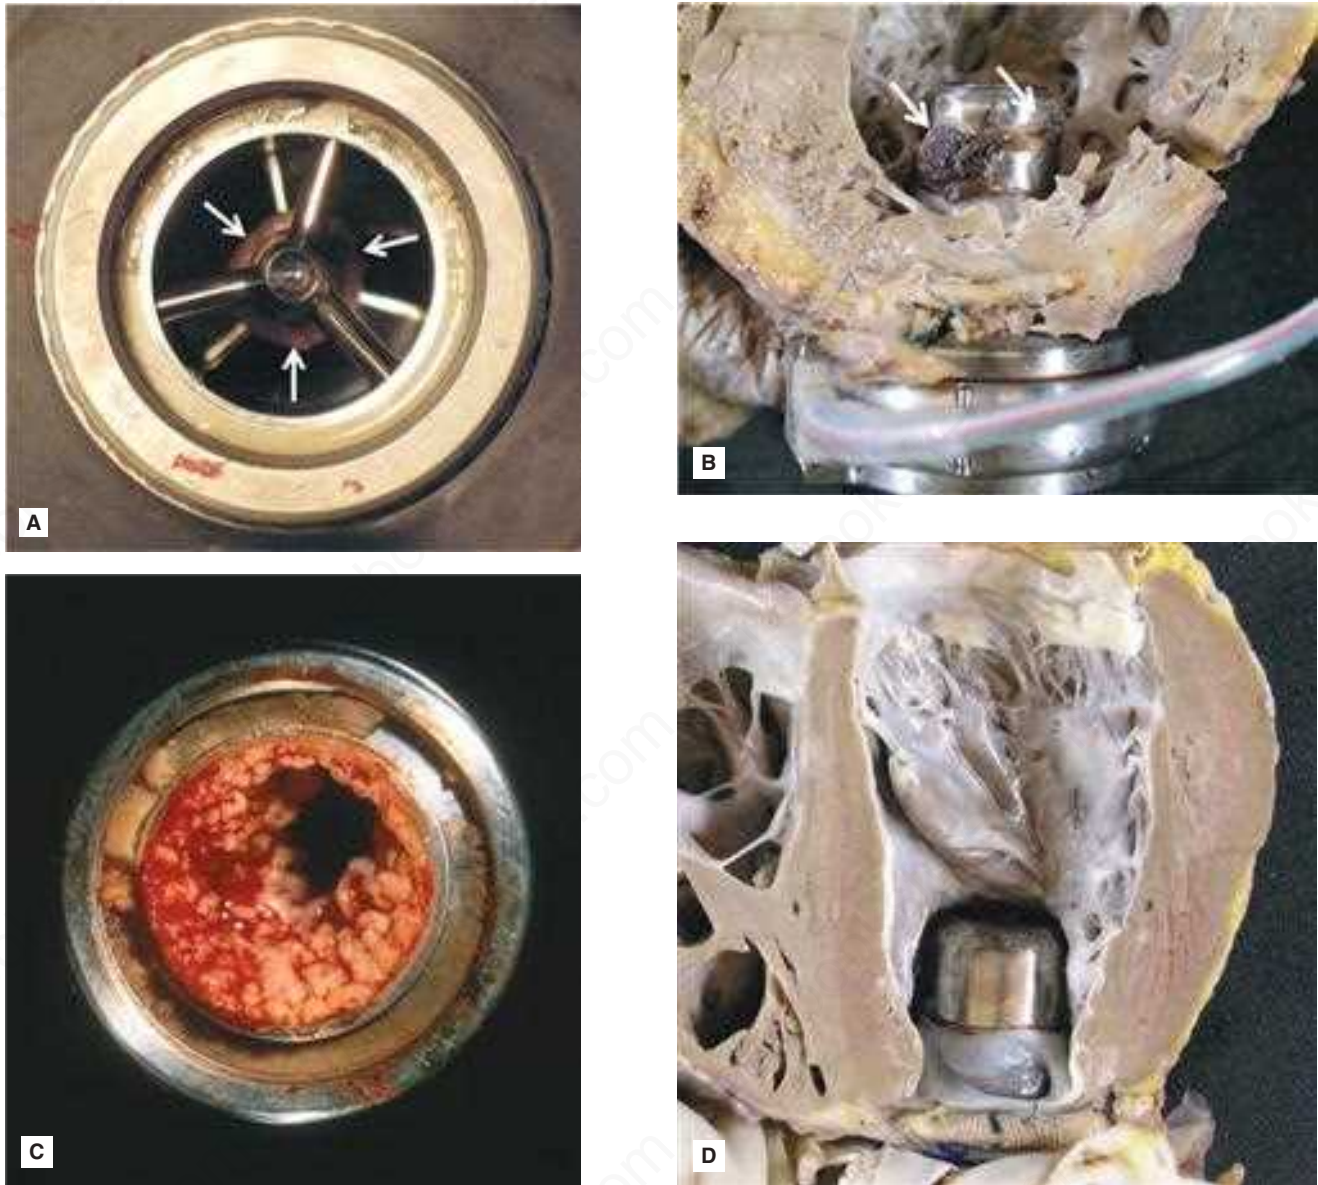

Mechanical cardiac assist devices and artificial hearts have traditionally been used in two settings: for ventricular augmentation sufficient to permit a patient to survive postcardiotomy or postinfarction cardiogenic shock while ventricular recovery is occurring, and as a bridge to transplantation when ventricular recovery is not expected and the goal is hemodynamic support until a suitable donor organ is located. More recently, left ventricular assist devices (LVADs) have been shown to provide long-term cardiac support with survival and quality-of-life improvement over optimal medical therapy in patients with end-stage congestive heart failure who are not candidates for transplantation. LVADs are also being investigated as a “bridge-to-recovery” in patients with congestive

heart failure to induce reverse ventricular remodeling leading to an improvement in cardiac function that would eventually allow device removal. Many types of pumps are currently under development or in clinical use as ventricular assist devices.<sup>163</sup> Mechanical devices that entirely replace the native heart are currently in use or under development as bridge to transplant (SynCardia Total Artificial Heart)<sup>164</sup> or as destination therapy (Abiomed AbioCor).<sup>165</sup>

The major complications of cardiac assist devices are hemorrhage, thrombosis/thromboembolism, infection, and interactions with host tissue (Fig. 5-30).<sup>166</sup> Hemorrhage continues to be a problem in device recipients, although the risk of major hemorrhage has been decreasing with improved devices, therapies, patient selection, and surgical methods. Many factors predispose to perioperative hemorrhage, including (1) coagulopathy secondary to hepatic dysfunction, poor nutritional status, and antibiotic therapy; (2) platelet dysfunction and thrombocytopenia secondary to cardiopulmonary bypass; and (3) the extensive nature of the required surgery.

Nonthrombogenic blood-contacting surfaces are essential for a clinically useful cardiac assist device or artificial heart. Indeed, thromboembolism occurred in most patients having long-term implantation of the Jarvik-7 artificial heart and is a major design consideration for current devices. The current generation of continuous flow LVADs is carefully designed to minimize thrombosis, but oral anticoagulation is still required. The incidence of pump thrombosis in the continuous axial flow HeartMate II LVAD (see Fig 5-30A) appears to have been increasing,<sup>167</sup> and is currently the subject of intense debate and research. Thrombi also may form outside the LVAD, often in association with crevices and voids, and in areas of disturbed blood flow such as near connections of conduits and other components to the native heart (see Fig. 5-30B).<sup>168</sup> Accounting for significant morbidity and mortality following the prolonged use of cardiac assist devices, infection can occur either within the device or associated with percutaneous drive lines (see Fig. 5-30C). Susceptibility to infection is potentiated by not only the usual prosthesis-associated factors (see later), but also by the multisystem organ damage from the underlying disease, the periprosthetic culture medium provided by postoperative hemorrhage, and by prolonged hospitalization with the associated risk of nosocomial infections. Assist device-associated infections are often resistant to antibiotic therapy and host defenses, but are generally considered not an absolute contraindication to subsequent cardiac transplantation. Novel device designs, including alternative sites for driveline placement and the elimination of the driveline altogether with transcutaneous energy transmission technology, may play a role in further decreasing infection.

Left ventricular assist device implantation can allow for reverse remodeling (see below), resulting in a decrease of the size of the left ventricular chamber. Therefore, an LVAD inflow cannula may end up contacting cardiac structures in the now-smaller left ventricular chamber that it was nowhere near at the time of implantation into a dilated ventricle. This can lead to inflow obstruction (see Fig. 5-30D), acquired

**FIGURE 5-30** Complications of left ventricular assist devices (LVADs). (A) Circumferential thrombus (*arrows*) on the inflow bearing of the impeller of a Thoratec HeartMate II LVAD. (B) Thrombus (*arrows*) on the outer aspect of the inflow cannula of a HeartWare HVAD within the left ventricular cavity. (C) Fungal infection in LVAD outflow graft. (D) Inflow cannula of a HeartWare HVAD impinging on the posterior left ventricular wall resulting in obstruction. (Reproduced with permission from Silver MD, Gotlieb AI, Schoen FJ: *Cardiovascular Pathology*, 3rd ed. New York: Churchill Livingstone/Elsevier; 2001.)

ventricular septal defect, myocardial hemorrhage, and potential arrhythmias. Other complications include hemolysis, pannus formation around anastomotic sites, calcification, and device malfunction. There is evidence that patients on LVADs are more likely to develop allosensitization, which can pose a significant risk to posttransplantation outcome in the bridge-to-transplant patients.<sup>169</sup> These complications not only have significant morbidity and can be fatal, but they may make a previously suitable patient ineligible for future transplantation.

Long-term LVADs are primarily used as a bridge to transplantation because cardiac transplantation currently offers a better long-term outlook for most patients. In a subset of patients, support by LVAD results in improved cardiac function, with heart transplantation no longer necessary even after removal of the LVAD (bridge to recovery). Left ventricular assist device support is now recognized to offer potential for myocardial recovery, a favorable outcome that is further enhanced by combination with pharmacologic therapy. LVADs lead to lowered cardiac pressure and volume overload

in the myocardium followed by decreased ventricular wall tension, reduced cardiomyocyte hypertrophy, improved coronary perfusion, and decreased chronic ischemia.

To what extent recovery of myocardial function can occur during VAD implantation is uncertain. Many pathophysiologic changes occur during the progression to end-stage heart failure, ranging from the subcellular (eg, abnormal mitochondrial function and calcium metabolism) to the organ and system level (eg, ventricular dilation, decreased ejection fraction, and neurohormonal changes), leading to the signs and symptoms of congestive failure. Implantation of an LVAD can reverse many of these changes (*reverse remodeling*), leading to increased cardiac output, decreased ventricular end-diastolic volume, and normalization of neurohormonal status such that a small fraction of patients can be weaned from the device without the need for subsequent cardiac transplantation. Current research focuses on the mechanisms of cardiac recovery, identification of patients who could achieve recovery, and specifics such as the timing and duration of therapy; a key goal is to identify potential predictors and novel therapeutic targets capable of enhancing myocardial repair.<sup>170</sup>

## ARRHYTHMIAS

Arrhythmias generally occur as a result of disorders of electrical impulse formation, disorders of electrical impulse conduction, or a combination of the two. The underlying anatomic substrates for arrhythmogenesis are many. Many cardiomyopathies can present with arrhythmias, including those with genetic (eg, HCM, ARVC, and the ion channelopathies), mixed (eg, dilated cardiomyopathy), and acquired (eg, myocarditis, sarcoidosis and amyloidosis) etiologies. A common cause of arrhythmias and sudden death (especially in the older adult population) is ischemic heart disease, both in patients with and without a prior myocardial infarction. Myocardial hypertrophy and fibrosis of any etiology (eg, secondary to valvular heart disease, hypertension, or a remote infarction) also can provide the anatomical and functional substrate for the development of an arrhythmia. These underlying processes and pathologic anatomy increase the risk of spontaneous lethal arrhythmias in the setting of acute initiating events such as acute ischemia, neurohormonal activation, changes in electrolytes, and other metabolic stressors.<sup>171</sup>

Treatments for arrhythmias and their complications include pharmacologic therapy, device therapy<sup>172,173</sup> (eg, pacemakers, defibrillators), and ablation therapy.

### Pacemakers and Implantable Cardioverter-Defibrillators

Modern cardiac pacing is achieved by a system of interconnected components consisting of (1) a pulse generator that includes a power source and electric circuitry to initiate the electric stimulus and to sense normal activity; (2) one or more electrically insulated conductors leading from the pulse generator to the heart, with a bipolar electrode at the distal end of each; and (3) a tissue, or blood and tissue, interface

between electrode and adjacent stimulatable myocardial cells, which is of critical importance in the proper functioning of the pacemaker. Typically, a layer of nonexcitable fibrous tissue forms around the tip of the electrode. This fibrosis may be induced by the electrode itself or may result from myocardial scarring from some other cause, most commonly a healed myocardial infarction. The thickness of this nonexcitable tissue between the electrode and excitable tissue determines the stimulus threshold, or the strength of the pacing stimulus required to initiate myocyte depolarization, and thus the amount of energy required from the pacemaker. Attempts to reduce the thickness of this layer (thereby extending battery life) include improved lead designs<sup>174</sup> with active fixation and the use of slow, local release of corticosteroids from the lead tip. Implantable cardioverter-defibrillators (ICDs) are used in the treatment of patients who have life-threatening ventricular arrhythmias that are refractory to medical management and unsuitable for other surgical or ablative therapy, and have similar components to the pacemaker described in the preceding. These devices sense arrhythmias that can lead to sudden death and deliver therapy in the form of rapid ventricular pacing and/or a defibrillation current to terminate the dysrhythmic episode. ICDs also must overcome the barrier posed by the interfacial fibrosis at the electrode tip.

Complications from the use of pacemakers include lead displacement, vascular or cardiac perforation leading to hemothorax, pneumothorax or tamponade, lead entrapment, infection, erosion of the device into adjacent tissues owing to pressure necrosis, rotation of the device within the pocket, thrombosis and/or thromboembolism, and lead fracture, in addition to malfunction of the device itself. If the lead needs to be extracted for chronic infection or device-related defects, damage to the myocardium and/or tricuspid valve may occur secondary to encasement of the lead in fibrous tissue. Similar complications affect ICDs, with additional considerations being the consequences of repeated defibrillations on the myocardium and vascular structures, including myocardial necrosis, and the risk of oversensing (with resultant unnecessary shocks) or undersensing (with resultant sudden death). Increased attention has been paid of late to malfunctioning ICDs because of electrical flaws in a specific model that resulted in failure to terminate fatal arrhythmias.<sup>175</sup>

### Ablation

Ablation involves the directed destruction of arrhythmogenic myocardium, accessory pathways, or conduction system structures to control or cure a variety of arrhythmias, including atrial flutter and fibrillation, ventricular tachycardias, and paroxysmal supraventricular tachycardias that are refractory to medical management.<sup>176,177</sup> Ablation can be carried out as part of a surgical procedure, or through percutaneous catheter means. Electrophysiologic (EP) studies can be used to (1) provide information on the type and location of rhythm disturbance, (2) terminate a tachycardia by electrical stimulation, (3) evaluate the effects of therapy, (4) ablate myocardium involved in the tachycardia, and (5) identify patients at risk for sudden cardiac death.

**FIGURE 5-31** Site of ablation of arrhythmogenic focus by radiofrequency ablation (arrows).

Radiofrequency ablation acutely produces coagulation necrosis within the myocardium directly underneath the source tip, eliminating the source or pathway of the arrhythmia. The characteristic histologic changes include loss of myocyte striations, loss or pyknosis of nuclei, hypereosinophilia, and contraction bands. The edge of the fresh lesion is often hemorrhagic with interstitial edema (Fig. 5-31) and inflammation. The area undergoes the usual progression of healing similar to that in an infarct, with an early neutrophilic infiltrate, followed by macrophages to handle the necrotic debris, followed by granulation tissue formation and eventual scarring. Through the use of irrigated, cooled catheters, the lesions can penetrate deeply into the myocardium. Techniques using other forms of energy, including cryoablation, microwave, and lasers, have been used to create lesions in the myocardium for the treatment of arrhythmias.

## NEOPLASTIC HEART DISEASE

Although metastatic tumors to the heart are present in 1 to 3% of patients dying of cancer, primary tumors of the heart are unusual.<sup>178,179</sup> The most common tumors, in descending order of frequency, are: myxomas, lipomas, papillary fibroelastomas, angiomas, fibromas, and rhabdomyomas, all benign and accounting for approximately 80% of primary tumors of the adult heart. The remaining 20% are malignant tumors, including angiosarcomas, other sarcomas, and lymphomas. Many cardiac tumors have a genetic basis.

The most frequent cardiac tumors are illustrated in Fig. 5-32.

### Myxoma

Myxomas are the most common primary tumor of the heart in adults, accounting for about 50% of all benign cardiac tumors. They typically arise in the left atrium (80%) along the interatrial septum near the fossa ovalis. Occasionally, myxomas arise in the right atrium (15%), the ventricles (3–4%),

or valves. These tumors arise more frequently in women and usually present between the ages of 50 and 70 years. Sporadic cases of myxoma are almost always single, whereas familial tumors can be multiple and present at an earlier age.

Myxomas range from small (<1 cm) to large (up to 10 cm) and form sessile or pedunculated masses that vary from globular and hard lesions mottled with hemorrhage to soft, translucent, papillary, or villous lesions having a myxoid and friable appearance (see Fig. 5-32A). The pedunculated form frequently is sufficiently mobile to move into or sometimes through the ipsilateral atrioventricular valve annulus during ventricular diastole, causing intermittent and often position-dependent obstruction. Sometimes, such mobility exerts a wrecking ball effect, causing damage to and secondary fibrotic thickening of the valve leaflets.

Clinical manifestations are most often determined by tumor size and location; some myxomas are incidentally detected in patients undergoing echocardiography for other indications, whereas others may present with sudden death. Symptoms are generally a consequence of valvular obstruction, obstruction of pulmonary or systemic venous return, embolization, or a syndrome of constitutional symptoms. Intracardiac obstruction may mimic the presentation of mitral or tricuspid stenosis with dyspnea, pulmonary edema, and right-sided heart failure. Fragmentation of a left-sided tumor with embolization may mimic the presentation of infective endocarditis with transient ischemic attacks, strokes, and cutaneous lesions; emboli from right-sided lesions may present as pulmonary hypertension. Constitutional symptoms such as fever, erythematous rash, weight loss, and arthralgias may result from the release of the acute-phase reactant interleukin-6 from the tumor leading to these inflammatory and autoimmune manifestations. Echocardiography, including transesophageal echocardiography, provides a means to non-invasively identify the masses and their location, attachment, and mobility. Surgical removal usually is curative with excellent short- and long-term prognosis. Rarely, the neoplasm recurs months to years later, usually secondary to incomplete removal of the stalk.

The Carney complex is a multiple neoplasia syndrome featuring cardiac and cutaneous myxomas, endocrine and neural tumors, as well as pigmented skin and mucosal lesions. Previously described cardiac myxoma syndromes such as LAMB (lentiginos, atrial myxoma, mucocutaneous myxomas, and blue nevi) and NAME (nevi, atrial myxomas, mucinosis of the skin, and endocrine overactivity) are now encompassed by the Carney complex. The Carney complex is inherited as an autosomal dominant trait, and is associated with mutations in the *PRKAR1 $\alpha$*  gene encoding the R1 $\alpha$  regulatory subunit of cyclic AMP-dependent protein kinase A.

Histologically, myxomas are composed of stellate or globular cells (myxoma cells), often in formed structures that variably resemble poorly formed glands or vessels, endothelial cells, macrophages, mature or immature smooth muscle cells, and a variety of intermediate forms embedded within an abundant acid mucopolysaccharide matrix and covered by endothelium. Although it had long been questioned whether

**FIGURE 5-32** Gross features of primary cardiac tumors. (A) Resected left atrial myxoma, as irregular polypoid, gelatinous friable mass. The resection margin that surrounds the proximal portion of the stalk is at right. (B) Papillary fibroelastoma. (C) Massive pericardial angiosarcoma, subepicardial and with deep myocardial invasion at multiple sites. ([C] Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989.)

cardiac myxomas were neoplasms, hamartomas, or organized thrombi, it is now widely believed that they represent benign neoplasia. These tumors are thought to arise from remnants of subendocardial vasoformative reserve cells or multipotential primitive mesenchymal cells, which can differentiate along multiple lineages, giving rise to the mixture of cells present within these tumors.

### Other Cardiac Tumors and Tumor-like Conditions

Cardiac lipomas are discrete masses that are typically epicardial, but may occur anywhere within the myocardium or pericardium. Most are clinically silent, but some may cause symptoms secondary to arrhythmias, pericardial effusion,

intracardiac obstruction, or compression of coronary arteries. Magnetic resonance imaging is useful in the diagnosis of adipocytic lesions because of its ability to identify fatty tissues. Histologically, these tumors are composed of mature adipocytes, identical to lipomas elsewhere. A separate, non-neoplastic condition called lipomatous hypertrophy of the interatrial septum is characterized by accumulation of unencapsulated adipose tissue in the interatrial septum that can lead to arrhythmias. Histologically, this tissue is composed of a mixture of mature and immature adipose tissue and cardiac myocytes, in contrast to the pure mature adipose tissue of a proper lipoma.

Papillary fibroelastomas<sup>180</sup> are usually solitary and located on the valves, particularly the ventricular surfaces of semilunar valves and the atrial surfaces of atrioventricular valves. The most common site is the aortic valve, followed by the mitral valve. They constitute a distinctive “sea anemone-like” cluster of hair-like projections up to 1 cm or more in length, and can mimic valvular vegetations echocardiographically (see Fig. 5-32B).<sup>181</sup> Histologically, they are composed of a dense core of irregular elastic fibers, coated with myxoid connective tissue, and lined by endothelium. They may contain focal platelet-fibrin thrombus and serve as a source for embolization, commonly to cerebral or coronary arteries. Surgical excision is recommended to eliminate these embolic events. Although classified with neoplasms, fibroelastomas may represent organized thrombi, similar to the much smaller, usually trivial, whisker-like Lambl’s excrescences that are frequently found on the aortic valves of older individuals.

Rhabdomyomas comprise the most frequent primary tumor of the heart in infants and children.<sup>182</sup> They are usually multiple and involve the ventricular myocardium on either side of the heart. They consist of gray-white myocardial masses up to several centimeters in diameter that may protrude into the ventricular or atrial chambers, causing functional obstruction. These tumors tend to spontaneously regress, so surgery is usually reserved for patients with severe hemodynamic disturbances or arrhythmias refractory to medical management. Most cardiac rhabdomyomas occur in patients with tuberous sclerosis, the clinical features of which also include infantile spasms, skin lesions (hypopigmentation, shagreen patch, subcutaneous nodules), retinal lesions, and angiomyolipomas. This disease, in its familial form, exhibits autosomal dominant inheritance, but about half the cases are sporadic owing to new mutations. Histologically, rhabdomyomas contain characteristic “spider cells,” which are large, myofibril-containing, rounded, or polygonal cells with numerous glycogen-laden vacuoles separated by strands of cytoplasm running from the plasma membrane to the centrally located nucleus.

Cardiac fibromas, although also occurring predominantly in children and presenting with heart failure or arrhythmias, or incidentally, differ from rhabdomyomas in being solitary lesions that may show calcification on a routine chest radiograph.<sup>183</sup> Fibromas are white, whorled masses that are typically ventricular. There is an increased risk of cardiac fibromas in patients with Gorlin’s syndrome (nevroid basal cell carcinoma syndrome),<sup>184</sup>

an autosomal dominant disorder characterized by skin lesions, odontogenic keratocysts of the jaw, and skeletal abnormalities. Histologically, fibromas consist of fibroblasts showing minimal atypia and collagen with the degree of cellularity decreasing with increasing age of the patient at presentation. Although they are grossly well circumscribed, there is usually an infiltrating margin histologically. Calcification and elastin fibers are not uncommon in these lesions.

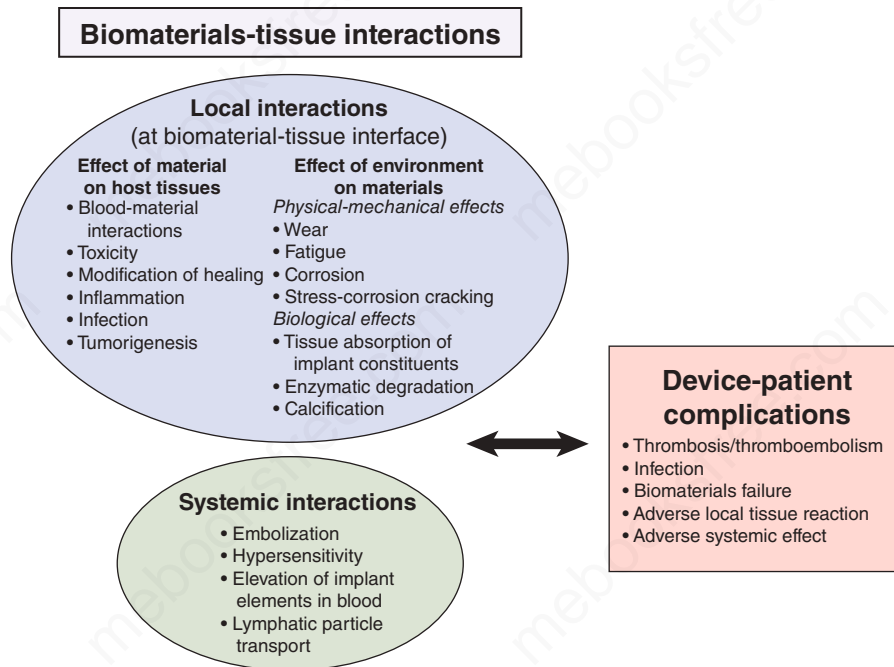

Sarcomas, with angiosarcomas, undifferentiated sarcomas, and rhabdomyosarcomas being the most common, are not distinctive from their counterparts in other locations. They tend to involve the right side of the heart, especially the right atrioventricular groove (see Fig. 5-32C). The clinical course is rapidly progressive as a result of local infiltration with intracavity obstruction and early metastatic events.

Peculiar microscopic-sized cellular tissue fragments have been noted incidentally as part of endomyocardial biopsy or surgically removed tissue specimens, either free-floating or loosely attached to a valvular or endocardial mass.<sup>185</sup> Termed mesothelial/monocytic incidental cardiac excrescences (MICE), they appear histologically largely as clusters and ribbons of mesothelial cells and entrapped erythrocytes and leukocytes, embedded within a fibrin mesh. These “masses” are considered artifacts of no clinical significance formed by compaction of mesothelial strips (likely from the pericardium) or other tissue debris and fibrin, which are transported via catheters or around an operative site on a cardiomy suction tip.

## BIOMATERIALS AND TISSUE ENGINEERING

Biomaterials are synthetic or modified biologic materials that are used in implanted or extracorporeal medical devices to augment or replace body structures and functions.<sup>186,187</sup> Biomaterials include polymers, metals, ceramics, carbons, processed collagen, and chemically treated animal or human tissues, the latter exemplified by glutaraldehyde-preserved heart valves and pericardium. Biomaterials in medical devices interact with the surrounding tissues. The first generation of biomedical materials (eg, metals used for early valve substitutes) was generally designed to be inert; the goal was to reduce the host inflammatory responses to the implanted material. By the mid-1980s, a second generation of technology, comprising *bioactive* biomaterials, was emerging that could interact with the host in a beneficial manner (eg, biodegradable polymer sutures, drug delivery systems, textured bladder surfaces in ventricular assist devices). In the recent past, with a greater understanding of material-tissue interactions at the cellular and molecular levels, materials are being designed to stimulate specific cellular and tissue responses at the molecular level.<sup>188,189</sup> These materials are intended to be *regenerative*, and to yield functional tissue and organs, in approaches called *tissue engineering* (discussed later).

Biomaterial-tissue interactions comprise effects of both the implant on the host tissues and the host on the implant,

**FIGURE 5-33** Overview of potential interactions of biomaterials with tissue, comprising local, distant, and systemic effects of the biomaterial on the host tissue, as well as the physical and biologic effects of the environment on the materials and the device. These interactions comprise the pathophysiologic basis for device complications and failure modes. (Modified with permission from Ratner BD, Hoffman AS, Schoen FJ, et al: *Biomaterials Science: An Introduction to Materials in Medicine*, 2nd ed. Orlando: Elsevier; 2004.)

and are important in mediating prosthetic device complications (Fig. 5-33).<sup>190</sup> These interactions have local and potentially systemic consequences. Complications of cardiovascular medical devices, irrespective of anatomical site of implantation, can be grouped into six major categories: (1) thrombosis and thromboembolism; (2) device-associated infection; (3) exuberant or defective healing; (4) biomaterials failure (eg, degeneration, fracture); (5) adverse local tissue interaction (eg, toxicity, hemolysis); and (6) adverse effects distant from the intended site of the device (eg, biomaterials/device embolism/migration, systemic hypersensitivity).

### Blood-Surface Interaction

Thromboembolic complications of cardiovascular devices cause significant mortality and morbidity. Thrombotic deposits can impede the function of a prosthetic heart valve, vascular graft, or blood pump, or cause distal emboli. As in the cardiovascular system in general, surface thrombogenicity, hypercoagulability, and locally static blood flow (called *Virchow's triad*), present individually or in combination, determine both the relative propensity toward thrombus formation and the location of thrombotic deposits with specific devices. No known synthetic or modified biologic surface is as thromboresistant as the normal, unperturbed endothelium. Like a blood vessel denuded of endothelium, foreign materials on contact with blood spontaneously and rapidly (within seconds) absorb a film of plasma components, primarily protein, followed by platelet adhesion.<sup>191</sup>

If conditions of relatively static flow are present, macroscopic thrombus can ensue. The specific physical and chemical characteristics of materials that regulate the outcomes of blood-surface interaction are incompletely understood.

Coagulation proteins, complement products, other proteins, and platelets are activated, damaged, and consumed by blood-material interactions. The clinical approach to control of thrombosis in cardiovascular devices is generally through systemic anticoagulants, particularly Coumadin (warfarin) or antiplatelet agents. Coumadin inhibits thrombin formation but does not inhibit platelet-mediated thrombosis and induces a risk of hemorrhage. Coumadin is also teratogenic, causing a risk of fetal malformations in pregnant women. Hemolysis (damage to red blood cells) in implants and extracorporeal circulatory systems can result from both cell-surface contact and turbulence-induced shear forces.

### Tissue-Biomaterials Interaction

Synthetic biomaterials elicit a *foreign body reaction*, a special form of nonimmune inflammatory response with an infiltrate predominantly composed of macrophages.<sup>192,193</sup> For most biomaterials implanted into solid tissue, encapsulation by a relatively thin fibrous tissue capsule (composed of collagen and fibroblasts) resembling a scar ultimately occurs, often with a fine capillary network at its junction with normal tissue. Ongoing mild chronic inflammation associated with this fibrous capsule is common with clinical implants.

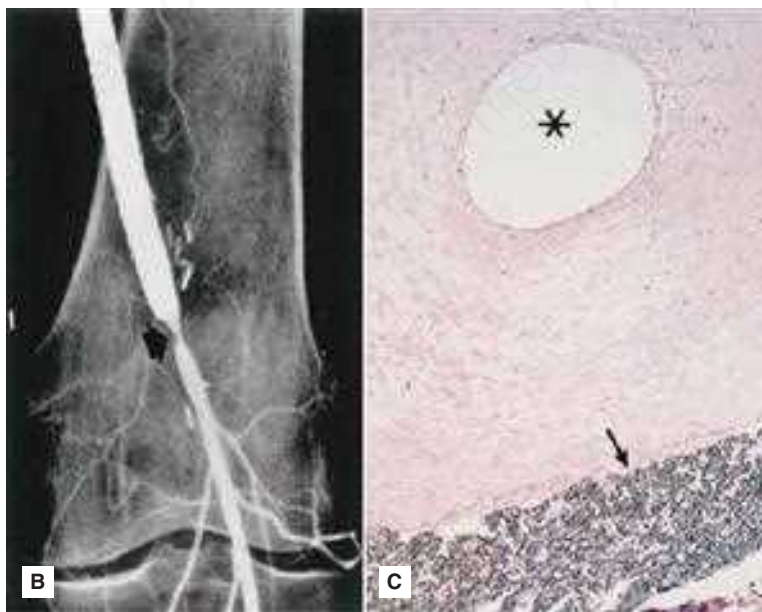

Although immunologic reactions have been proposed rarely for synthetic biomaterial-tissue interactions,<sup>194</sup> and antibodies can be elicited by implantation of some materials in finely pulverized form, proven clinical cardiovascular device failure owing to immunologic reactivity is rare.

### Healing of a Vascular Graft, Heart Valve Sewing Cuff, or Endovascular Stent

Healing of a vascular graft, heart valve sewing cuff, or endovascular stent derives principally from overgrowth from the host vessel across anastomotic sites; this tissue is called *pannus*. Grafts, fabrics, and stents used as cardiovascular implants heal primarily by ingrowth of endothelium and smooth muscle cells from the cut edges of the adjacent artery, and contact points with vessels

and/or myocardium; where endothelium is present, the tissue is called a *neointima*. Additional potential mechanisms of endothelialization include (1) tissue ingrowth through the fabric of a graft with interstices large enough to permit ingrowth of fibrovascular elements arising from capillaries extending from outside to inside the graft, which may permit endothelial cells to migrate to the luminal surface at a large distance from the anastomosis; and (2) deposition of functional endothelial cell progenitors from the circulating blood.<sup>195</sup>

Exuberant fibrous tissue can occur at a vascular anastomosis as an overactive but physiologic repair response (Fig. 5-34). Synthetic and biologic vascular grafts often fail because of generalized or anastomotic narrowing mediated by connective tissue proliferation in the intima, and heart valve prostheses can have excessive pannus that occludes the orifice. Intimal hyperplasia

**FIGURE 5-34** Vascular graft healing. (A) Schematic diagram of pannus formation, the major mode of graft healing with currently available vascular grafts. Smooth muscle cells migrate from the media to the intima of the adjacent artery and extend over and proliferate on the graft surface. The thin smooth muscle cell layer is covered by a proliferating layer of endothelial cells. (B and C) Anastomotic hyperplasia at the distal anastomosis of synthetic femoropopliteal graft. (B) Angiogram demonstrating constriction of distal graft anastomosis (*arrow*). (C) Photomicrograph demonstrating Gore-Tex graft (*arrow*) with prominent intimal proliferation and very small residual lumen (*asterisk*). (Reproduced with permission from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia: Saunders; 1989.)

results primarily from smooth muscle cell migration, proliferation, and ECM elaboration following and possibly mediated by acute or ongoing endothelial cell injury. Important contributing factors include (1) surface thrombogenesis; (2) delayed or incomplete endothelialization of the fabric; (3) disturbed flow across the anastomosis; and (4) mechanical “mismatch” at the junction of implant and host tissues.

Diminished healing also is clinically important in certain circumstances, such as periprosthetic leak associated with heart valve prostheses. Moreover, markedly diminished endothelialization owing to toxicity of the cytostatic agents, paclitaxel and sirolimus, has been implicated in late thrombosis of drug-eluting coronary stents. For uncertain reasons, humans have a limited ability to completely endothelialize cardiovascular prostheses beyond a zone near an anastomosis, typically 10 to 15 mm, thereby allowing healing of intracardiac fabric patches and prosthetic valve sewing rings, but not long vascular grafts. Thus, except adjacent to an anastomosis of a vascular graft, a compacted platelet-fibrin aggregate (*pseudointima*) comprises the inner lining, even after long-term implantation. Because firm adherence of such linings to the underlying graft may be impossible, dislodgment of the lining and formation of a flap-valve can occur and cause obstruction.<sup>196</sup> Current research focuses on novel vascular graft materials that enhance endothelial cell attachment, grafts, and other implants preseeded with unmodified or genetically engineered endothelial cells, attempts to block smooth muscle cell proliferation, and engineered tissue vascular grafts (see the following).<sup>197</sup>

## Infection

Infection is a common complication of implanted prosthetic devices and a frequent source of morbidity and mortality.<sup>198,199</sup> Early implant infections (<1 to 2 months postoperatively) most likely result from intraoperative contamination or early postoperative wound infection. In contrast, late infections generally occur by a hematogenous route, and can be initiated by bacteremia induced by therapeutic dental, gastrointestinal, or genitourinary procedures. Antibiotics given prophylactically at the time of device implantation and shortly before subsequent diagnostic and therapeutic procedures may protect against implant infection.

The presence of a foreign body potentiates infection in several ways. Microorganisms may inadvertently be introduced into deep tissue locations by contamination at device implantation, bypassing natural barriers against infection. Some devices, such as current left ventricular assist devices, require a percutaneous driveline, providing a continuous potential means of entry for microorganisms. Infections associated with medical devices are characterized microbiologically by a high prevalence of organisms capable of forming protective biofilms (ie, a multicellular consortium of microbial cells that is irreversibly associated with a material surface and enclosed in a self-produced ECM composed primarily of polysaccharides),<sup>200</sup> including gram-positive bacteria such as *S. epidermidis*, *S. aureus*, *Enterococcus faecalis*, and *S. viridans*, gram-negative bacteria such as *Escherichia coli* and *Pseudomonas*

*aeruginosa*, and fungi such as *Candida albicans*. Some of these organisms, especially *S. epidermidis* and *S. viridans*, are of relatively low virulence in the absence of a foreign body, but are frequent causes of medical device infection. The production of a *biofilm* by an organism is protective against the humoral and cellular immune response of the host<sup>201</sup> and inhibits the penetration and effectiveness of opsonizing antibodies, inflammatory cells, and antibiotics. Moreover, vasculature may be diminished and there may be necrotic tissue in the vicinity of an implant. Consequently, an implant-associated infection often persists until the device is removed.

## Tissue Engineering and Cardiovascular Regeneration

*Tissue engineering* comprises therapeutic approaches that use endogenous or exogenously delivered living cells together with natural materials or synthetic polymers to develop or regenerate functional tissues.<sup>202-204</sup> In the most widely used generic strategy to engineering tissues, cells are initially seeded on a synthetic polymer scaffold (usually a bioresorbable polymer in a porous configuration) or natural material (such as collagen, decellularized tissue, or otherwise chemically treated tissue), in the desired geometry for the engineered tissue, and a tissue is matured *in vitro*. The *in vitro* phase is done in a vessel (a *bioreactor*), containing a metabolically and mechanically supportive environment with growth media. The cells, which may be either fully differentiated or stem cells, proliferate and an elaborate ECM is created in the form of a “new” tissue (the *construct*). In the second step, the construct is implanted *in vivo* into the appropriate anatomical location. Following implantation remodeling of the construct *in vivo* is intended to recapitulate normal functional architecture of an organ or tissue. Another collection of methods uses the *in vivo* environment as the bioreactor and thereby aims to recruit endogenous cells to build tissues from within. Key processes occurring during the *in vitro* and *in vivo* phases of tissue formation and maturation are: (1) cell proliferation, sorting, and differentiation; (2) ECM production and organization; (3) degradation of the scaffold; and (4) remodeling and potentially growth of the tissue.

The principles and processes of tissue engineering have been applied to vascular grafts, myocardium, and heart valves, as discussed next.

## Engineered Vascular Grafts

Tissue-engineered vascular grafts blood vessels of small caliber are actively being investigated.<sup>205-207</sup> Vascular cells have been applied onto tubular resorbable polymer scaffolds and matured *in vitro* in a bioreactor prior to *in vivo* implantation.<sup>208</sup> Exposure to pulsatile physical forces during tissue formation generally enhances graft properties; pulsed grafts are thicker, have greater suture retention, and higher cell and collagen density than nonpulsed engineered grafts, and have a histologic appearance similar to that of native arteries. Other investigators have fabricated mechanically sound engineered

tissue vascular grafts by constructing a cohesive cellular sheet of smooth muscle cells, rolling this sheet to form the vessel media, analogous to a jelly roll, wrapping a sheet of human fibroblasts around the media to serve as an adventitia, and seeding endothelial cells in the lumen.<sup>209</sup> Vessel “equivalents” composed of collagen and cultured bovine fibroblasts, and smooth muscle and endothelial cells have been investigated, but despite reinforcement with a Dacron mesh, such grafts have been unable to withstand burst strengths for in vivo applications.<sup>210</sup> Another approach to vascular graft engineering utilizes naturally derived matrices with or without cell repopulation prior to implantation.<sup>211</sup> Vascular grafts fabricated from small intestine submucosa used as experimental vascular grafts in dogs were reported to be completely endothelialized and histologically similar to arteries.<sup>212,213</sup>

Another approach to vascular tissue engineering extends the concept of Sparks’ silicone mandril-grown graft used clinically in the 1970s, in which a collagenous fibrous capsule tube was formed around an implanted cylindrical foreign body (silicone mandril) adjacent to a diseased vessel; the mandril was subsequently removed yielding an autologous tissue tube that could be anastomosed to the vessels proximal and distal to an obstruction.<sup>214</sup> However, owing to the variability of the quality of tissue generated in older patients in areas of circulatory insufficiency, such vascular replacements often developed aneurysms when used clinically. Grafts grown as the reactive tissue that forms around silicone tubing inserted into the peritoneal cavity of rats, rabbits, and dogs, everted (so that a mesothelial cell lined surface become the blood-contacting surface), and grafted into the carotid artery of the same animal remained patent up to 4 months.<sup>215</sup>

Initial clinical studies of tissue-engineered blood vessels as pulmonary artery segments and hemodialysis access grafts have been reported.<sup>216,217</sup> Clinically employed conventional ePTFE vascular grafts have been seeded with endothelial cells at the time of implantation, yielding reportedly better outcomes than unseeded grafts.<sup>218-224</sup>

## Regeneration of Cardiac Tissue

The adult heart responds to mechanical overload by hypertrophy (increase in cell size) and to severe ischemic or other injury by cell death (see earlier). Functional increase in cardiac myocyte number by cell regeneration or hyperplasia has generally not been considered possible. Nevertheless, several lines of research raise enthusiasm that clinically important cardiac regeneration and/or engineered cardiac tissue may indeed be possible.

Recent evidence suggests that myocyte regeneration and death occur physiologically, and that these cellular processes are enhanced in pathologic states, challenging the dogma that the heart as a postmitotic organ. Some investigators believe that heart homeostasis may be regulated by a stem cell compartment in the heart characterized by multipotent cardiac stem cells having the ability to acquire the distinct cell lineages of the myocardium. In this view, humans are capable of regenerating myocytes and coronary vessels throughout life

and have the capacity to adapt to increases in pressure and volume loads.<sup>225</sup> Moreover, adult bone marrow cells may be able to differentiate into cells beyond their own tissue boundary and create cardiomyocytes and coronary vessels. Myocardial tissue generated from cells, scaffolds, and bioreactors has been encouraging with respect to construct survival, vascularization, and integration, but significant and sustained functional improvement has yet to be demonstrated.<sup>226,227</sup> Application of cyclic mechanical stretch and electrical signals have been shown to enhance cell differentiation and force of contraction.<sup>228</sup>

Animal experiments and some early-phase clinical trials lend credence to the notion that cell-based cardiac repair may be an achievable therapeutic target, including (1) the possibility that the heart may have endogenous mechanisms of repair; (2) cell-based therapies in which fetal or adult cardiomyocytes, skeletal myoblasts or nonmuscle stem or differentiated cells are injected into the heart; and (3) experimental generation of functional myocardium by cell-scaffold-bioreactor tissue engineering approaches yielding a prosthetic myocardial patch.<sup>229-231</sup> Clinical trials have used cells derived from skeletal muscle and bone marrow, and basic researchers are investigating sources of new cardiomyocytes, such as resident myocardial progenitors and embryonic stem cells to achieve structural and functional integration of the graft with the host myocardium. Nevertheless, the most appropriate form of cellular therapy for myocardial injury remains to be identified. Moreover, it remains unclear at present whether the beneficial effects observed in some studies are a result of functional and electrically integrated myocytes (the ideal), enhancement of angiogenesis owing to a local and nonspecific inflammatory reaction at the site of injection, or a “paracrine” effect, whereby transplanted cells produce growth factors, cytokines, and other local signaling molecules that are beneficial to the infarct through neovascularization and/or scar remodeling.

## Tissue-Engineered Heart Valves

Recent scientific and technological progress has stimulated the goal of generating a living valve replacement that would obviate the complications of conventional valve replacement, adapt to changing environmental conditions in the recipient, and potentially grow with a growing patient.<sup>232-235</sup> The long-term success of a tissue-engineered (living) valve replacement will depend on the ability of its living cellular components (particularly VIC) to assume normal function with the capacity to repair structural injury, remodel the ECM, and potentially grow.

Tissue-engineered heart valves (TEHV) grown as valved conduits from autologous cells (either vascular wall cells or bone marrow-derived mesenchymal stem cells) seeded on biodegradable synthetic polymers grown in vitro have functioned in the pulmonary circulation of growing lambs for up to 5 months.<sup>236,237</sup> In some studies, these grafts evolved in vivo to a specialized layered structure that resembled that of native semilunar valve. Pulmonary vascular walls fabricated from

vascular wall cells and biodegradable polymer and implanted into very young lambs enlarged proportionally to overall animal growth over a 2-year period.<sup>238</sup>

To eliminate the need for in vitro cell seeding and culture steps, an alternative tissue engineering strategy has used a scaffold of either decellularized naturally derived biomaterial (such as animal or human allograft valve, decellularized sheep intestinal submucosa [SIS]), or a porous polymer matrix implanted without prior seeding but with the intent of harnessing intrinsic circulating cells to populate and potentially remodel the scaffold.<sup>239</sup> Tissue-derived scaffolds must possess desirable three-dimensional architecture, mechanical properties, and potential adhesion/migration sites for cell attachment and ingrowth. Nevertheless, decellularized porcine valves implanted in humans had a strong inflammatory response and suffered structural failure.<sup>240</sup> Work is also being done on cell-seeded, engineered tissue valves for transcatheter implantation.<sup>241</sup>

Translation of heart valve tissue engineering and regenerative medicine from the laboratory to the clinical realm has exciting potential but also formidable challenges and uncertainties. Key hurdles include selection and validation of suitable animal models, development of guidelines for characterization and assurance of the quality of an in vitro fabricated TEHV for human implantation, and strategies to understand, monitor, and potentially control patient-to-patient variability in wound healing and tissue remodeling in vivo.

# Computed Tomography of the Adult Cardiac Surgery Patient: Principles and Applications

Andreas A. Giannopoulos • Frank J. Rybicki  
• Tarang Sheth • Frederick Y. Chen

Advances in computed tomography (CT) technology have revolutionized the diagnosis of cardiovascular disease. CT has dramatically reduced, and for some clinical scenarios eliminated, the need for additional testing such as diagnostic arterial catheterization. In the process, CT has become invaluable in cardiac diagnosis and surgical planning.

CT is based on an x-ray source and detector system mounted on the “CT gantry” that rotates around the patient. Major technology advances have enabled CT to image the beating heart, and routine CT at Brigham and Women’s Hospital (BWH) has noninvasively excluded coronary artery disease in one heart beat (Fig. 6-1) for over 7 years.<sup>1</sup> However, the role of CT extends far beyond the coronary arteries alone. Using roughly the same CT acquisition strategies, native coronary imaging can be extended to coronary bypass grafts, the beating myocardium, valve motion, the ventricles and ventricular outflow tracks, and cardiac lesions.

In order to understand the clinical contribution of CT and to avoid pitfalls in image interpretation, it is essential for the surgeon to appreciate the basic principles of CT used in cardiac imaging. This chapter is divided into two parts. The first part describes the technical considerations for cardiac CT. By understanding each component, the surgeon will be better able to distinguish image artifacts from pathology. The second part reviews those CT examinations that are most frequently performed in the noninvasive cardiovascular imaging program at BWH, detailing the strengths and limitations of each exam.

## PART 1. CARDIAC CT PROTOCOLS

Most advances in cardiac CT, for example in coronary CT angiography (CTA), have focused on the development of protocols consistent with the rapid incremental technology

improvements. One of the major technological advances has been the incorporation of multiple elements into the CT detector system, called Multi-Detector CT (MDCT). MDCT is synonymous with multislice CT. Since all modern scanners have multiple detectors, the semantics can and should be eliminated; this chapter simply uses “CT” to describe the technology.

Data from each of CT detector is used to reconstruct an axial slice perpendicular to the long axis, or z-axis, of the patient. The width of the detectors determines the minimum slice thickness and thus the ability to resolve small anatomic detail (spatial resolution) of the scanner. Thinner slices yield superior spatial resolution; however, comparing two scanners that produce the same number of slices, the scanner with thinner slices will have less z-axis (ie, craniocaudal) coverage per gantry rotation and thus will have a longer scan time. To date, the minimum detector width and largest number of detector rows is 0.5 mm and 320, respectively.<sup>2,3</sup> This yields 16 cm (0.5 mm × 320) z-axis coverage per gantry rotation, and thus the entire heart can be imaged with data acquired over a single R-R interval.

## TEMPORAL RESOLUTION

Successful cardiac imaging by any modality relies on the ability of the hardware to produce motion-free images or, in other words, to image faster than the heart beats. Because it requires that the gantry be rotated around the patient, CT is inherently slower than digital subtraction angiography (DSA) where each frame corresponds to a single projection image. As described below, CT has become faster so that cardiac CT is now being routinely performed.

*Temporal resolution* is the metric that measures imaging speed. For a CT scanner with a single photon source, the temporal resolution is one half of the CT gantry rotation time.

**FIGURE 6-1** Selected coronary computed tomography angiography (CTA) image of the proximal left coronary arterial system in a patient scheduled for isolated mitral valve surgery. Using the protocol detailed in this chapter, CT demonstrated normal coronary arteries in this patient, eliminating the need for arterial catheterization.

This is because image reconstruction requires CT data acquired from one half ( $180^\circ$ ) of a complete gantry rotation. All manufacturers have gantry rotation times on order of 300 ms or less. Using this gantry rotation time as an example, an electrocardiogram (ECG)-gated cardiac image can be reconstructed (using single-segment reconstruction, described below) with CT data acquired over 150 ms of the cardiac cycle. Thus, the reconstructed images inherently display the average of the cardiac motion over the roughly 150 ms during which the data was acquired. This is how ECG gating enables cardiac CT. Without gating, cardiac images are nondiagnostic because the reconstruction “averages” the motion over the entire R-R interval, for example, over 1000 ms for a patient with a heart rate of 60 beats per minute.

There are important strategies to improve temporal resolution. The first uses two independent x-ray CT sources and two independent (64 or greater slice) detector systems built into the CT gantry.<sup>4</sup> The second x-ray source is positioned  $90^\circ$  from the first x-ray source, and the second detection system is positioned  $90^\circ$  from the first detection system. With respect to temporal resolution, the practical consequence of this CT configuration is that  $180^\circ$  of gantry rotation can be achieved in half the time (eg, 75 ms as opposed to 150 ms). This halves the temporal resolution (to 75 ms), and thus for this “dual-source” CT configuration, motion is averaged over only 75 ms. Another strategy uses both X-ray CT source-detector systems to sample the entire heart within a single R-R interval by rapidly moving the patient through the scanner.<sup>5</sup> Both implementations have technical advantages and disadvantages that are beyond the scope of this chapter. However, cardiac imaging in a single heart beat can be achieved using the same heart rate control as noted below.

For single-source scanners, temporal resolution can be improved by adopting a so-called “multisegment” image reconstruction. The difference between single-segment and multisegment reconstruction is that in the former,  $180^\circ$  of data is acquired from a single heart beat, while multisegment reconstruction uses several heart beats to obtain the one half gantry CT data. For example, in a two-segment reconstruction, two heart beats are used to generate a single axial slice, and thus the temporal resolution is halved. Similarly, if four heart beats are used (four-segment reconstruction), only  $45^\circ$  of data are used from each heart beat. This yields a fourfold reduction in the effective temporal resolution, making it theoretically possible to perform high spatial resolution cardiac CT in patients with a rapid (eg,  $>70$  beats per minute) heart rate. However, since multiple heart beats are used to fill the  $180^\circ$  of gantry rotation necessary for the reconstruction, stable periodicity of the heart is essential. When beat-to-beat variations in heart rate occur, image quality is degraded significantly. In our experience, multisegment reconstruction works well in patients with high heart rates who are being studied for clinical indications where the highest image quality may not be required (eg, studies of graft patency or pericardial calcification). For more demanding applications (eg, native coronary CTA) we still routinely employ beta-blockade for heart rates  $>60$  beats per minute.

## BETA-BLOCKADE FOR HEART RATE CONTROL

As suggested above, beta-blockade is an important component of most coronary-based CT examinations. As the temporal resolution of cardiac CT improves, the dependence on lowering the heart rate will naturally be mitigated. However, the speed of all CT scanners is inferior to coronary catheterization, and thus beta-blockade is recommended for the large majority of patients in whom it is safe. In our experience, many surgical patients have standing orders for beta-blockers as part of their medical therapy, and image quality is excellent. When this is not the case, either oral and/or IV metoprolol is routinely administered.

## ECG GATING

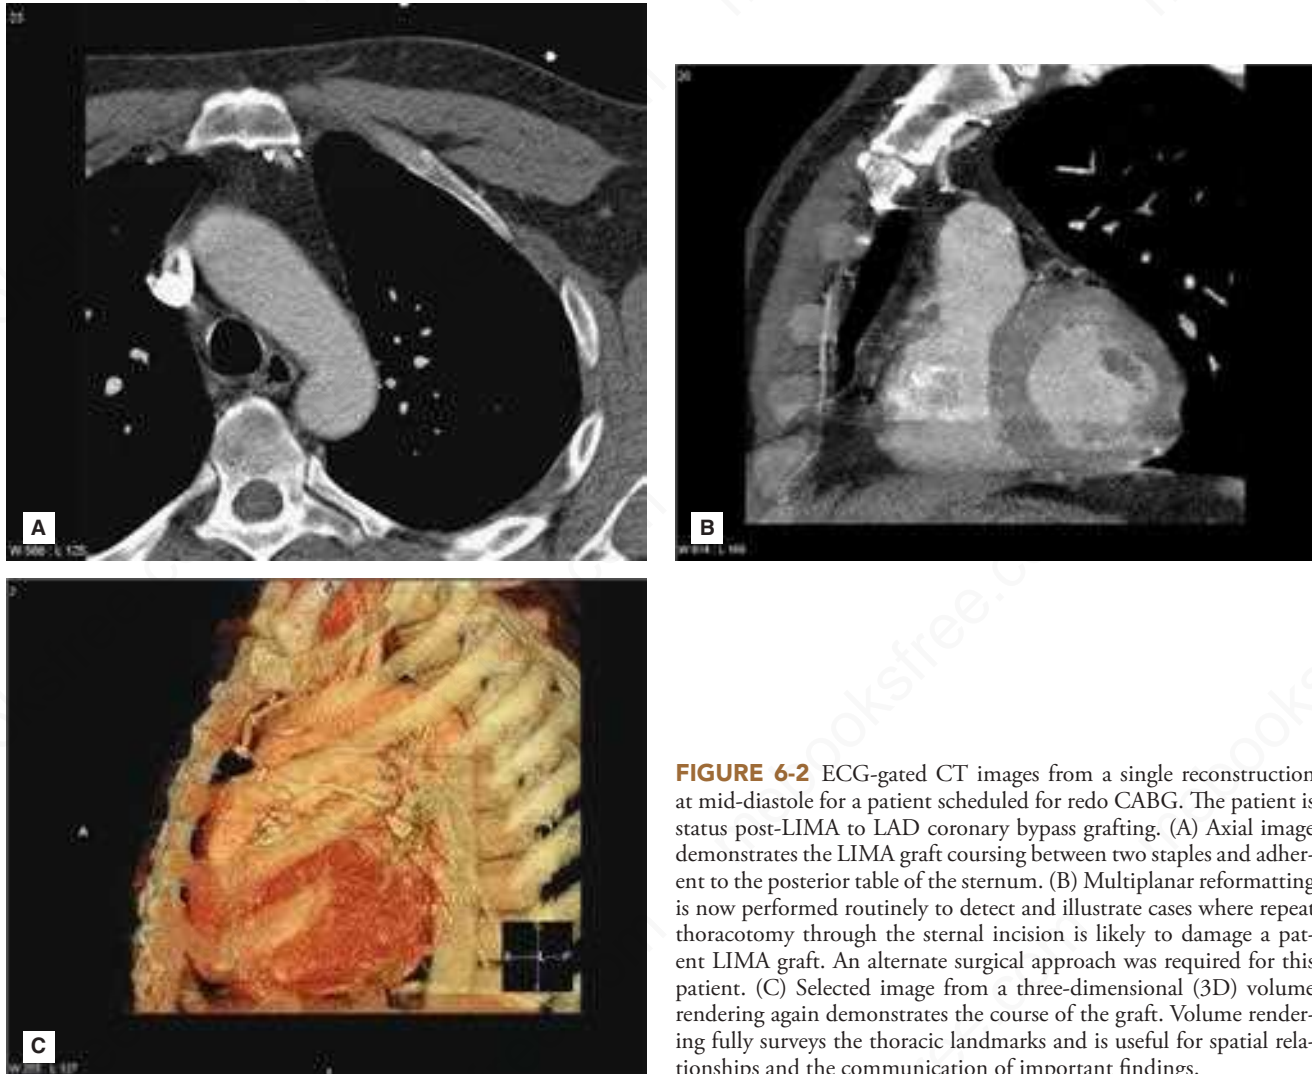

ECG gating refers to the simultaneous acquisition of both the patient’s ECG tracing and CT data. By acquiring both pieces of information, CT images can be reconstructed using only a short temporal segment of the R-R interval. Each segment is named by its “phase” in the cardiac cycle; the common nomenclature is to name the percentage of a specific phase with respect to its position in the R-R interval. For example, reconstruction of 20 (equally spaced) phases would be named as 0%, 5%, 10%, ..., 95%. The period in which the heart has the least motion is usually (but not always) in mid-diastole, near 75%. Thus, the CT exposure (and subsequent patient radiation level) can be lowered by limiting

the exposure to a small part of the R-R interval where coronary motion is expected to be a minimum. This is termed “prospective” ECG gating since the reconstruction phase and width is determined prospectively. The disadvantage of this approach is that cine loops of the entire R-R interval cannot be reconstructed because a complete data set is not acquired throughout the R-R interval. If this is desired, the so-called “retrospective” ECG gating can be used, at the expense of higher radiation levels.

For patients who require imaging of bypass grafts, it is important to note that periodic displacement of both saphenous vein grafts (SVG), radial grafts, and internal mammary artery (IMA) grafts is far less than the motion of the native coronary arteries. Thus, for these vessels, a single reconstruction at mid-diastole is usually sufficient (Fig. 6-2), and prospective ECG gating is routinely used. However, the benefits of lower radiation in this population are relatively moot, since the latent period for a radiation-induced malignancy

is roughly a decade for blood tumors and significantly longer for solid tumors. Patients under consideration for repeat bypass surgery typically have a shorter life expectancy based on cardiac status. Thus, it is *essential* that the surgeon not only recognizes that motion has degraded image quality, but also realizes that additional reconstructions, and even repeat imaging, *can and should* be performed. If the entire course of the graft is not clear to the surgeon at a single cardiac phase, it is almost always the case that another phase will yield motion-free depiction of the graft segment that was poorly seen. Open communication between the radiologist and the surgeon for every case has eliminated this pitfall and ensures that the maximum amount of imaging data is incorporated into presurgical planning.

In cine CT, such as imaging the aortic valve over the entire R-R interval, images are acquired with retrospective ECG gating and subsequently reconstructed throughout the cardiac cycle and then played, in cine mode, to demonstrate function.

**FIGURE 6-2** ECG-gated CT images from a single reconstruction at mid-diastole for a patient scheduled for redo CABG. The patient is status post-LIMA to LAD coronary bypass grafting. (A) Axial image demonstrates the LIMA graft coursing between two staples and adherent to the posterior table of the sternum. (B) Multiplanar reformatting is now performed routinely to detect and illustrate cases where repeat thoracotomy through the sternal incision is likely to damage a patient LIMA graft. An alternate surgical approach was required for this patient. (C) Selected image from a three-dimensional (3D) volume rendering again demonstrates the course of the graft. Volume rendering fully surveys the thoracic landmarks and is useful for spatial relationships and the communication of important findings.

**FIGURE 6-3** ECG-gated CT image through the left ventricle and the aortic valve in a patient status post aortic root repair. Note the pacemaker (*right heart wires*); magnetic resonance imaging (MRI) was contraindicated. The repair is well visualized and without complication, with only mild aortic valve calcification (cine images showed a tricuspid valve with no significant stenosis). This image also demonstrates a punctate calcified plaque along the superior course of the proximal left main coronary artery, without a significant stenosis.

Each individual image (Fig. 6-3) offers an outstanding assessment of the aortic valve and root structure. Cine CT can also be used to assess ventricular-wall motion. In comparison with magnetic resonance imaging (MRI), the reference standard for global- and regional-wall motion abnormalities, CT often has inferior temporal resolution. However, it is important to emphasize that cine CT does not require a separate image acquisition. The entire CT data set (coronary, valve, myocardium, and pericardium) is acquired in a single breath hold; cine CT is simply part of the image postprocessing.

For surgical patients, CT has the distinct advantage over MR, in that it is by far the best imaging modality to identify and quantify calcification. Also, the most common contraindications for cardiac CT (eg, impaired renal function as measured by glomerular filtration rate or alternatively by serum creatinine) differ from those for MR (pacemaker), and thus CT can often be used for patients who cannot have MR. As noted above, single heart beat cardiac CT is now a clinical reality, with an entire cardiac acquisition in approximately one second.<sup>1</sup> In addition to the fact that patient radiation is decreased, multiple scans can be performed with the same injection of iodinated contrast material, creating the opportunity for a host of additional studies including myocardial perfusion<sup>6-10</sup> that are, at present, largely in the domain of cardiac MR and nuclear cardiology.

## PATIENT IRRADIATION

Because ECG gating is required, ascending aorta and cardiac CT delivers more patient irradiation than CT of any other

body part. While details regarding cardiac CT dosimetry are beyond the scope of this chapter, discussions regarding CT dose must be based on sound principles. The radiation risk most commonly quoted relates to the probability that the CT scan will result in the development of a fatal radiation-induced neoplasm.<sup>11</sup> Human data for radiation at this low level (the level delivered in ECG-gated cardiac CT) is very sparse; all anecdotal reports support a long latency period as described above. For this reason, patients should be separated into two groups: those with a life expectancy of roughly 10 to 15 years or less, and those with a longer life expectancy. In the former group, the only dose consideration is whether the radiation could cause a skin burn (the only short-term complication of any consequence). X-ray skin burns are extremely uncommon, particularly in CT (even for ECG-gated studies), and typically result from multiple exams repeated at short-term intervals. Thus, for this subset of patients, *radiation dose should not be a consideration* in determining a modality for cardiac imaging. For those patients for whom radiation is an important consideration, prospective ECG gating should be used. X-ray current modulation is standardly used to lower the radiation dose. The tube current (expressed as the mA) is modulated over the course of the cardiac cycle so that the desired (high) diagnostic current is delivered only in diastole. The patient dose is decreased because the tube current is reduced for the remainder of the cardiac cycle. While current modulation is helpful in many cases (eg, pediatric patients), the decision to use it should be made after consultation between surgeon and radiologist because the potential drawbacks are significant. Most importantly, when current modulation is used, images reconstructed during phases with low tube current are relatively noisy because less tube current is used to generate them.

## SCANNING PARAMETERS

The *scan time* refers to the time required to complete the CT acquisition along the z-axis of the patient. As described above, better temporal resolution decreases the scan time, not only decreasing cardiac motion, but also enabling breath hold CT. This is important in cardiac CT because in comparison to nongated CT, ECG gating not only increases patient radiation but also increases the scan time.

In practical terms, a 64-slice ECG-gated cardiac CT scan (craniocaudal, or z-axis imaging over ~15 cm) can be performed in roughly 10 seconds, versus 20 to 25 seconds with a 16-slice scanner. One great benefit of wide area detector CT is faster (single heart beat) scans. If this option is not available, increasing the thickness of the detectors increases the z-axis coverage per rotation and thus decreases the scan time. For example, in a patient that cannot perform the breath hold, using thicker detectors (eg, 1 mm thickness as opposed to 0.5 mm thickness) will decrease the scan time by providing more z-axis coverage per rotation. However, routinely increasing the width of the detectors for cardiac applications is undesirable since it degrades the *spatial resolution* of the examination. In general, spatial resolution refers to the ability to

differentiate small detail in an image. This is essential component to coronary imaging since the diameter of the proximal coronary arteries are on the order of 3 to 4 mm. Substitution of 0.5 mm reconstructed images with 1 mm images thus impacts the ability to see detail that may be required for accurate diagnoses. Routine consultation between the surgeon and radiologist is essential to best understand and optimize the tradeoff between scan time and slice thickness. For example, imaging of the myocardium and aorta almost never requires submillimeter slices, because the pathology is larger. Thus, for dyspneic patients who require only imaging of the ascending aorta, thicker slices should be used to cut the scan time.

The scanning parameters that primarily determine the number of photons used to create a CT image are termed “mAs,” or milliamperes-seconds and “kV,” or kilovolts. The former represents the X-ray tube current; the latter refers to the voltage applied within the tube. For the surgeon, choosing the best numbers (typical values are 550 to 700 effective mAs, 120 kV) is far less important than understanding the fact that modern cardiac CT pushes the limits of technology, and thus creates tradeoffs with respect to the x-ray CT source. The source generates photons that are either attenuated by the patient or reach the detectors. When more photons reach the detectors, the image quality is higher because there is less noise. The decision to image with thinner slices (eg, 0.5 mm as opposed to 1 mm) means that fewer photons reach the detector; thus, thinner slices have more noise. This is especially important in obese patients because their increased body mass absorbs more photons than thin patients. For the same effective mAs and kV, images of obese patients can be dramatically degraded by greater image noise.

If there were no limit to the number of photons that an X-ray CT source could produce, the solution would be to simply increase the number of photons (and the radiation dose) until image noise was satisfactory. Unfortunately, because the X-ray CT tube heats excessively when pushed to its maximum, there is a limit to the number of photons that can be produced. This is why image noise becomes problematic with thin slice imaging of obese patients. When this is the case, consultation between the surgeon and radiologist is important because diagnostic images can often be obtained by increasing the image thickness, scanning a smaller z-axis field of view (FOV), or both. The latter can be particularly useful if the examination can be tailored to the most important structure. Scanning a smaller z-axis means that more photons can be generated and used before the X-ray CT tube reaches its heat limit.

On the other hand, whenever possible, the z-axis FOV should be generous, as unexpected pathology can extend in both cranially and caudally. For example, an ECG-gated cardiac and ascending aorta examination to evaluate extension of the intimal flap into the coronary arteries can reveal extension into the great vessels. Also, scanning must allow for variations in the FOV induced by breath holding. As a general rule, for scanning the native coronaries alone, the superior border of the FOV is set at the axial slice corresponding to the top of the carina. This is typically 2 to 3 cm superior to the origin of the left main coronary artery. The inferior border should

scan through the entire inferior wall of the heart and should include several slices of the liver to account for cardiac displacement during breath holding. For bypass graft imaging, the superior border of the FOV must include the subclavian arteries and the origin of both IMAs.

## CONTRAST MATERIAL

Most CT examinations are performed with iodinated contrast material. The exceptions are scans performed solely for the assessment of cardiac and aortic calcification, plus imaging of the aorta and great vessels for aneurysm size measurements alone. Contrast is administered from a peripheral vein, typically with a dual injection system. This injector has two reservoirs to inject contrast followed by saline. For coronary imaging, the contrast and saline delivery are timed so that the left heart, aorta, and coronary arteries are enhanced with contrast while the right heart is filled with saline. The use and the timing of the saline are essential parts of the examinations because artifacts that limit interpretation of the RCA will be induced if the right heart and central veins are densely enhanced with contrast (as opposed to saline).

## PART 2. APPLICATIONS IN CARDIAC SURGICAL PATIENTS

### CORONARY DISEASE

#### Native Coronary CTA

One of the most common clinical indications for cardiac CT is to evaluate the native coronary arteries for stenosis (Figs. 6-4 to 6-7). Numerous validation studies have evaluated cardiac CT for this purpose.<sup>12-25</sup> In these studies, data are typically reported on a per coronary artery segment basis, comparing CTA and DSA. A significant stenosis is generally defined as >50%, determined by quantitative coronary angiography. Data are also analyzed on a per patient basis regarding the value of CTA in ruling-in or excluding CAD. Literature to date reports on patient populations with a relatively high prevalence of CAD (ie, patients already scheduled for DSA). Among the most consistent findings is a very high negative predictive value (NPV) of coronary CTA when performed with 64 or greater detector row scanners. The data and our experience with 320 row scanners suggest a very high NPV, arguing that cardiac CTA can effectively exclude CAD in patients with low to intermediate pretest probability of disease. Furthermore, noncontrast CTA for evaluation of coronary calcium score, an independent predictor of adverse cardiac events and all-cause mortality, is considered to be appropriate for intermediate-risk patients as well as for low-risk patients with family history of premature CAD.<sup>26-28</sup>

Consequently, CTA has become increasingly useful for the cardiac surgeon in managing patients scheduled for noncoronary cardiac surgery. If the clinical suspicion is low, but not

**FIGURE 6-4** Proximal RCA 50% stenosis diagnosed by coronary CT angiography and confirmed by conventional angiography. Double oblique maximum intensity projection image (4 mm thick) through proximal RCA (A) and LAO projection still image from conventional angiogram (B) demonstrate a segment of approximately 50% stenosis (*arrows*).

Proximal reference

Lesion

**FIGURE 6-5** Proximal left circumflex greater than 50% stenosis diagnosed by coronary CT angiography and confirmed by conventional angiography. Double oblique maximum intensity projection image (4 mm thick) through proximal LCX (A) demonstrates a segment of calcified and noncalcified plaque with significant luminal narrowing (*arrow*). Finding is confirmed by true vessel short axis multiplanar reformatted images through the proximal reference (B-left) and the lesion (B-right) which demonstrate minimal residual lumen at the level of the lesion. AP-Caudal projection still image from conventional angiogram (C) confirms a greater than 50% in the proximal LCX (*arrow*).

**FIGURE 6-6** Right coronary artery greater than 50% stenosis diagnosed by CT and confirmed by conventional angiography. Double oblique maximum intensity projection images (4 mm thick) through ongoing RCA at 90° angles (A, B) demonstrate a segment of noncalcified plaque with nonvisualization of lumen (*black arrows*). The PIV is also partially demonstrated (*white arrow*). Finding is confirmed by LAO (C) and AP-cranial (D) projection still images conventional angiogram (*black arrow*). The PIV is also seen (*white arrow*).

insignificant, CTA affords the surgeon a method of assessing coronary disease without subjecting the patient to femoral arterial puncture with its known complications. For example, patients undergoing isolated mitral valve surgery for degenerative, myxomatous disease have a low prevalence of CAD, making CTA an ideal alternative to conventional angiography to exclude significant CAD. When the CT protocol described in Part 1 is followed, high-quality imaging is *routine*, and when CTA excludes CAD, surgeons have increased confidence in using CTA alone. Follow-up with DSA can be reserved for those patients who might benefit from catheter-based intervention.

Current guidelines from all major societies support the use of cardiac CT for evaluation of low- to intermediate-risk

patients while also being appropriate even for the high-risk CAD patients.<sup>28-32</sup>

#### CORONARY ARTERY BYPASS GRAFT CTA—REOPERATIVE SURGERY

Cardiac CT provides the cardiac surgeon with a noninvasive method to assess graft patency after coronary artery bypass graft (CABG). Studies using early 16 detector row CT scanners suggest 100% sensitivity and specificity for identifying occluded versus patent grafts,<sup>33-35</sup> with benefits from advanced image postprocessing tools.<sup>36</sup> In similar fashion, 64- and 320-slice CTA have demonstrated good diagnostic accuracy in the evaluation of significant venous or arterial

**FIGURE 6-7** Proximal LAD less than 50% stenosis diagnosed by coronary CT angiography. Double oblique maximum intensity projection image (4 mm thick) through proximal LAD (A) demonstrates a segment of noncalcified plaque that is not associated with any significant luminal narrowing (*arrow*). True vessel short axis multiplanar reformatted images through the lesion (B-right) and through proximal reference segment (B-left) confirm minimal luminal narrowing. Low-density (ie, noncalcified) plaque with positive vessel remodeling is seen (*arrow*). This case highlights the ability of CTA to detect early stages of subclinical atherosclerosis. This lesion would presumably not have been detected at a conventional angiogram.

grafts stenosis, nongrafted, and recipient vessels.<sup>37,38</sup> The additional prognostic value of CTA helps enable long-term risk stratification of CABG patients.<sup>39</sup> In clinical practice, this application is of value in the evaluation of the symptomatic patient in the early postoperative period in whom graft failure is being considered (Fig. 6-8). It is particularly useful for the demonstration of graft patency in patients with a remote

surgical history and unknown graft anatomy prior to DSA, and in patients in whom conventional angiography fails to demonstrate a known graft (Fig. 6-9). In the reoperative setting, such data has virtually revolutionized surgical decision-making and planning prior to surgery in patients who have already undergone CABG. Knowledge of anatomic placement of prior grafts, cannulation sites, and previous incisions

**FIGURE 6-8** (A) Postoperative cardiac CT performed for evaluation of graft patency. Three-dimensional volume-rendered image demonstrates patent LIMA to LAD (*black arrows*), T-graft RIMA to obtuse marginal (*white arrows*), and SVG to RCA (*grey arrows*). This study was obtained in a patient 1-day follow off-pump coronary artery bypass grafting. The patient had developed recurrent chest pain and an elevated troponin. Cardiac CT ruled out early graft failure as a cause for the patient's presentation. (B) Companion case in a different patient. Oblique multiplanar reformatted images demonstrate an acutely occluded saphenous vein graft to obtuse marginal. Note the patent graft stump (*black arrow*) and thrombosed graft body (*white arrows*).

**FIGURE 6-9** Cardiac CT performed to evaluate possible radial graft occlusion. The patient had surgery 1 month prior and presented with recurrent angina. The radial to RCA graft could not be selective catheterized at conventional angiography and was also not seen at aortic root injection. Three-dimensional volume-rendered image demonstrates patent radial graft (*white arrows*) to RCA (*black arrow*). The anastomosis is not seen on this orientation.

have impacted preoperative planning of the reoperative cardiac surgery patient.

Patients with recurrent angina after bypass surgery may have developed stenosis or occlusion in bypass grafts, or may have progression of native coronary disease. In these patients, CTA can be more limited. For example, exclusion of significant stenosis in a graft may be problematic due to metallic surgical clips that cause artifact (Fig. 6-10). Moreover, native CAD in these patients is often advanced and heavily calcified. A large volume of calcium may result in an uninterpretable study for many segments of the native coronaries (Fig. 6-11). CTA for plaque assessment in such patients may not be definitive; consequently conventional angiography may be preferred in this population.<sup>40</sup> CTA is increasingly useful for patients with less calcification and less metal artifact.

In the research context, graft patency is an important outcome in the evaluation of different surgical techniques. Randomized controlled trials utilizing conventional angiography for assessment of graft patency typically demonstrate a 10 to 20% rate of noncompliance. This noncompliance is at least partly attributable to the invasive nature of the test.<sup>41-43</sup> Cardiac CT is an attractive, noninvasive, and very accurate method to assess graft patency for clinical trials, again obviating a traditional arterial puncture with its risks and known

**FIGURE 6-10** Surgical clip artifacts can limit cardiac CT evaluation of coronary bypass grafts. Double oblique maximum intensity projection image (10 mm thick) demonstrates multiple surgical clips placed along the length of a radial to PIV graft (*black arrows*). Artifact from these metallic clips can partially or completely obscure the adjacent vessel lumen precluding evaluation of these segments for the presence or absence of stenosis. Although CT can unequivocally demonstrate graft patency based on the delivery of contrast throughout the entire course of the graft, surgical clip artifact usually does not allow complete graft evaluation to rule out graft stenosis.

complications. Cardiac CT may also be used for routine postoperative control of grafts following implementation of a new surgical technique in a local center practice (Fig. 6-12). However, to our knowledge, there are no published guidelines for appropriate use of cardiac CT in patients status post CABG.

## REOPERATIVE SURGERY

Reoperative cardiac surgery with live coronary grafts after previous CABG represents one of the most difficult problems in cardiac surgery. Reoperative sternotomy is challenging secondary to adhesions, loss of tissue planes, and the potential for injury to patent grafts, the aorta, and the right ventricle. Injury to a patent left internal thoracic artery graft to the left anterior descending artery (LAD) is associated with a mortality of 50%.<sup>44,45</sup> Cardiac CT has been revolutionary in precisely defining the relationship of important structures (including the aorta, right ventricle, and live grafts) to the midline and sternum for reentry planning (Fig. 6-13). At BWH, every reoperative surgery includes a preoperative CTA with z-axis coverage to include all grafts and the entire course of the IMAs. Preoperative identification of all structures at risk is mandatory, and different, specific operative approaches always remain in consideration.<sup>46</sup> Experience suggests that preoperative cardiac CT will lead to a modification in surgical strategy for 1 in 5 patients undergoing re-do cardiac surgery.<sup>36</sup> For example, if CT demonstrates a patent left internal

**FIGURE 6-11** Cardiac CT is often limited in its evaluation of native coronary arteries in the postcoronary artery bypass graft patient due to the presence of advanced and heavily calcified coronary atherosclerosis. Double oblique maximum intensity projection image (4 mm) demonstrates (A) the proximal LAD (*black arrows*) and a large first diagonal branch (*white arrow*) and (B) the proximal right coronary artery (*white arrows*). The white areas are very high attenuation and represent calcification. All vessel segments demonstrated are heavily calcified. The extent of calcification completely obscures the vessel lumen and presence or absence of stenosis cannot be reliably assessed.

mammary artery (LIMA) is close to the midline or a right ventricle directly adherent to the posterior table of the sternum, cardiopulmonary bypass is instituted prior to reentry. Definition of live grafts with respect to their proximal placement of the aorta is instrumental in determining, *before the operation*, the precise manner in which those grafts will be handled. For example, in reoperative surgery for conventional

**FIGURE 6-12** Cardiac CT obtained for postoperative graft control in patient who underwent MVST. Three-dimensional volume-rendered image demonstrates patent LIMA to LAD (*white arrows*) and radial T-graft to obtuse marginal (*black arrows*).

aortic valve replacement (AVR) in the setting of live grafts, CTA allows the surgeon to plan preoperatively whether or not those grafts will have to be divided in carrying out the aortotomy for the AVR. As described above, CT also allows the cardiac surgeon to preoperatively plan the precise location of the aortotomy itself.

### Minimally Invasive Surgery Coronary Artery Bypass Grafting (MIDCAB)

Minimally invasive coronary artery bypass surgery is becoming an alternative to open surgery. With limited intraoperative access for direct visualization, aspects of coronary artery anatomy such as vessel diameter, extent of calcification, and the presence of intramyocardial segments become even more important to define preoperatively (Fig. 6-14). In addition, 3D models that combine visualization of a partially transparent thoracic cage over mediastinal structures allow the surgeon to obtain detailed preoperative understanding of the patient's cardiothoracic anatomy (Fig. 6-15). Preoperative CT has demonstrated usefulness for MIDCAB<sup>47</sup> and totally endoscopic coronary artery bypass surgery,<sup>48</sup> whereas postoperative CT has been utilized for graft patency evaluation in a prospective study.<sup>49</sup> CT is also expected to become invaluable for procedures such as multivessel small thoracotomy coronary revascularization.

**FIGURE 6-13** Planning for reoperative coronary artery bypass grafting. Laterally orientated 3D volume-rendered image (A) from a patient who had previously undergone left internal mammary artery (LIMA) coronary bypass grafting. The LIMA (*white arrows*) is grafted to the left anterior descending coronary artery. Note the relatively large distance between the grafted LIMA and the sternum (*grey arrow*). Axial image (B) clearly shows the LIMA graft (*white arrow*) to be clear of midline and well posterior to the sternum (*grey arrow*). Since the most common surgical approach in a redo CABG is repeat thoracotomy through the sternal incision, this study demonstrates that surgical revascularization through sternal reentry has no significant risk of damage to the patent LIMA graft.

**FIGURE 6-14** Preoperative planning for minimally invasive cardiac surgery (MIDCAB). Two chamber plane maximum intensity projection image (6 mm thick) demonstrates the LAD. A segment of heavy calcification is identified in the proximal vessel (*black arrow*), this corresponds to the site of the stenotic lesion. No significant calcification is present in the remainder of the vessel. Immediately beyond the calcified segment an intramyocardial segment is present (*white arrows*).

**FIGURE 6-15** Preoperative planning for minimally invasive cardiac surgery (MIDCAB). Specialized display protocols for 3D volume-rendered images can be used to provide combined visualization of a semi-transparent thoracic cage and underlying cardiac and mediastinal structures. These models can be rotated and viewed from any angle or degree of magnification. With cardiac CT, 3D localization of target vessels, accessibility from proposed incision site, and position of LV apex with respect to chest wall can all be understood preoperatively.

## CARDIAC VALVES

In patients with suspected valve dysfunction based on echocardiography, cine CT from retrospective ECG gating as described in Part 1 provides valuable additional data. As noted earlier, reconstruction is performed for all phases of the cardiac cycle, and the reformatted data can be played in a cine loop. This has relevance in assessment in native, bioprosthetic, and mechanical aortic valves. Recent experience suggests an excellent correlation between planimetric valve areas obtained by CT, MRI and transesophageal echocardiography (TEE).<sup>50</sup> Consequently, CT can be used as an alternate modality for evaluation of aortic valve area. This is relevant if trans-thoracic echocardiography (TTE) is of poor technical quality or discrepant with a clinically expected result. Since patients may be evaluated with CT for concomitant aortic aneurysm or CAD prior to aortic valve surgery, valve area may be obtained from CT with no additional scanning and only a small amount of image postprocessing. CT can be used in correlation with valve area as determined with echocardiography (Fig. 6-16).

Postoperative evaluation of bioprosthetic valves may also be conducted using CT scanning. Although echocardiography determined trans-valvular gradients are the reference standard for determination of “effective” orifice area, CT provides a useful correlative modality—particularly when the echo is technically challenging or discordant with clinical findings. In patients with unexpectedly high gradients post-valve implantation, increasing use of CT will provide more information to guide management (Fig. 6-17). In patients with suspected bioprosthetic valve endocarditis, CT can be an invaluable modality to delineate para-valvular and valvular sequela of the infection (Fig. 6-18).

**FIGURE 6-16** Reformatted CT angiography through the aortic valve shows calcification and stenosis with a valve area of 1.00 cm<sup>2</sup> measured by direct planimetry.

**FIGURE 6-17** Seventy-seven-year-old man with a #23 Medtronic Mosaic valve. The patient developed shortness of breath approximately 1 year following surgery. Echocardiography which demonstrated a peak gradient of 78 mm Hg; the effective orifice area was reported at 0.9 cm<sup>2</sup>. Subsequent cardiac CT showed a normal valve area of 1.7 cm<sup>2</sup>, providing reassurance to both patient and surgeon.

Cardiac CT also permits high-resolution functional evaluation of mechanical aortic valve prostheses without artifact (Fig. 6-19). CT can be readily incorporated to evaluate valve dysfunction, measure opening angles, and to elucidate the underlying cause of valve failure. Figure 6-20 illustrates correlation between CT and surgical specimen in a mechanical aortic valve patient with restricted opening angle and elevated gradients. CT readily made the preoperative diagnosis of pannus in-growth.

## Transcatheter Aortic Valve Replacement (TAVR)

Although cardiac CT is traditionally a second line imaging modality for the evaluation of aortic valve disease, it holds a key role in preintervention planning for TAVR.<sup>51,52</sup> Contrast-enhanced CTA is considered by appropriateness criteria guidelines as reference standard for both aortic valve plane planning as well as for supravalvular aorta and iliofemoral system planning.<sup>53</sup> The volumetric data and high spatial resolution afforded by CT makes it ideal for accurate 3D measurements of the aortic annulus, the aortic root, and the ascending aorta; precise measurements of the aortic annulus are particularly important in choosing the appropriate prosthesis size (Fig. 6-21). There is a potential risk that the native valve leaflets will be displaced superiorly during prosthetic valve placement, potentially blocking the coronary artery

**FIGURE 6-18** Patient with clinically suspected bioprosthetic valve endocarditis. Left image shows a pseudoaneurysm originating below the aortic valve ring and exerting mass effect on the adjacent left atrial wall. The right image shows nodular thickening of the aortic valve leaflets consistent with vegetations.

ostia. This risk can be assessed from the CT images by measuring the coronary ostia heights from the leaflet hinge points as well as the leaflet lengths. The optimal fluoroscopic projections, oriented to the aortic valve plane, can also be identified by CT, allowing for improved periprocedural planning.

For TAVR planning, additional CTA images of the abdomen and pelvis enables evaluation of candidate peripheral access vessels, including diameter, distribution of calcification, tortuosity, and angulation. This information is important given the large size of the introducer sheath and delivery catheter used for TAVR.

Although postintervention evaluation of TAVR requires a multidisciplinary imaging approach (MR, TEE, TTE), potential complications can be readily identified with CTA.<sup>54</sup> CT findings correlated with findings from echocardiography allow for excellent assessment of both the postoperative aortic root as well as functional information in patients with paravalvular leak or infection. We note that despite the critical role for CT in TAVR planning, to our knowledge there are no published guidelines for appropriate use of CT for postprocedural TAVR assessment.

## AORTA AND GREAT VESSELS

Surgery of the aortic root, the ascending aorta, the arch, and the descending aorta is becoming increasingly commonplace as the population ages. CT has been used for many years to assess the thoracic aorta and is considered to be the currently preferred imaging modality.<sup>55</sup> Non-ECG-gated CT is highly accurate in the assessment of the aortic arch and descending thoracic aorta since they are not subject to significant cardiac motion. However, ECG-gating cardiac CT adds motion-free imaging of the aortic root, aortic arch, and ascending aorta. Gated cardiac CTA is particularly useful for measuring

the true short-axis diameters of the aorta in assessing aortic aneurysmal growth and decision making regarding intervention. As supported by appropriateness criteria guidelines<sup>56</sup> and without question from a clinical perspective, any surgery involving the aorta (whether the root, the arch, the ascending, or the descending portion) requires preoperative and postoperative CTA for surgical decision-making and follow-up.

## Noncontrast CTA for Cross-Clamping

The superior imaging of ECG-gated CTA better defines the pathology and hence facilitates the preoperative planning. For example, noncontrast CTA is by far the best imaging modality to clearly define aortic calcification. If portions of the aorta are calcified on CTA, then aortic cross clamping and cannulation for cardiopulmonary bypass at those sites are contraindicated in order to avoid embolic phenomenon and stroke. Studies have supported the routine use of noncontrast enhanced CTA for identifying ascending aortic calcification and selecting the optimal surgery strategy in patients with aortic stenosis or hemodialysis.<sup>57,58</sup> Preoperative cardiopulmonary bypass strategy and myocardial protection are often critically altered by preoperative CTA. At BWH, the majority of elderly patients increasingly undergo noncontrast CT to assess aortic calcifications.

## Aortic Aneurysm

As with calcification, CT is the most accurate modality to evaluate the aortic root, with both 2D and 3D visualization (Fig. 6-22). Not only can the aortic root be sized from multiple imaging planes, but also the exact location of the aneurysmal pathology with respect to the valve and sinotubular junction can often be defined.<sup>59</sup> This assessment is critical

**FIGURE 6-19** Evaluation of mechanical valve function with cardiac CT. Coronal oblique multiplanar reformatted images (A) demonstrate closed and open positions of mechanical AVR in a patient with suspected valve dysfunction based on echo-Doppler. Axial oblique slab maximum intensity projection images (B) demonstrate closed and open position of mechanical AVR in a patient in atrial fibrillation at the time of cardiac CT. Although image quality is degraded by arrhythmia, optimization of the dataset with ECG-editing can result in diagnostic quality images. Four-chamber oblique multiplanar reformatted images (C) demonstrate closed and open positions of a mechanical MVR. Images can be generated over the cardiac cycle and displayed in a cine movie format to allow dynamic evaluation of valve function. Since the study is performed with contrast, thrombus or perivalvular abscess can also be identified if present.

**FIGURE 6-20** Patient with mechanical aortic valve. Low density material restricting leaflet opening on the undersurface of the valve is suspicious for pannus in-growth causing restricted opening angle (*left*). Photograph of explant (*right*) demonstrates the pannus with high correlation with presurgical imaging.

for preoperative decision-making and surgical planning. In patients with ascending aortic aneurysm, if the aortic root is determined to be aneurysmal near the coronary ostia, surgical decision-making changes from a simple tube graft repair for the aneurysm to a much more complex composite root repair with coronary reimplantation. Three-dimensional volume rendering optimally depicts other aortic root pathologies such as coronary anomalies or a sinus of Valsalva aneurysm (Fig. 6-23). In patients with a sinus of Valsalva aneurysm, as opposed to a root aneurysm, CT alters surgical strategy for repair.

For known ascending aortic aneurysms that do not meet size criteria for surgery, CTA is excellent to periodically assess size or change. For those patients who require surgery, CTA

with 3D volume-rendered images provides the surgeon with preoperative visualization of aneurysm size and extent. The extension of an ascending aortic aneurysm into the arch can be demonstrated and, as mentioned above, the expected location of aortic cross-clamping can be determined preoperatively (Fig. 6-24). The location of normal aorta distally and the extent of arch involvement will preoperatively determine the arterial cardiopulmonary bypass cannulation site as well as the need for concomitant arch repair, circulatory arrest, or selective antegrade perfusion. Selective antegrade cerebral perfusion itself is dependent on intact right axillary and innominate arteries, and CTA is optimal for defining this anatomy. Since the success of a procedure can be compromised by unexpected intraoperative

**FIGURE 6-21** Multiplanar reformatted image of the annulus of the aorta in a patient under evaluation for TAVR. The right-hand image shows the routine annotation for measuring the annular area and dimensions in both short and long axis. Measurements are used for to determine the best sizing before the procedure.

**FIGURE 6-22** Demonstration of aortic root and aortic valve. Axial oblique multiplanar reformatted image from a systolic dataset demonstrates an open bicuspid aortic valve. Note the precise definition of the aortic wall, free from the cardiac motion related artifacts that are present at conventional thoracic CT scanning. Aortic root size measurements are highly accurate due to lack of motion artifacts and the high spatial resolution of the cardiac CT scanning ( $<0.5$  mm).

**FIGURE 6-23** Cardiac CT provides optimal visualization of complex aortic root pathology. Prior echocardiogram suggested the entire aortic root to be aneurysmal at greater than 4.5 cm. Three-dimensional volume-rendered image from cardiac CT demonstrates a 2.6 cm sinus of Valsalva aneurysm arising off of the right coronary sinus (*white arrow*). The remainder of aortic root is normal.

**FIGURE 6-24** Comprehensive evaluation of ascending aortic aneurysm for preoperative planning. On the left, 3D volume-rendered image demonstrates an aneurysmal ascending aorta. Sagittal oblique maximum intensity projection image (20 mm thick) can be used to demonstrate aortic size measurements. The aneurysm can be seen to extend into the aortic arch. As the entire ascending aorta and proximal arch needed to be replaced, cross-clamping could not occur proximal to the innominate in this patient and would have to occur in the mid-distal arch altering the surgical risk of the procedure.

findings, CT has contributed enormously to surgical planning by defining anatomy that would not be preoperatively visualized with any other imaging modality.

### Aortic Dissection and Aortic Intramural Hematoma (AIH)

CTA enjoys a sensitivity and specificity of almost 100% for detection of aortic dissection and intramural hematoma,

thus allowing the surgeon to understand the extent of the intimal flap.<sup>56</sup> In particular, ECG-gated CT offers information regarding dissection of the ascending aorta (the proximal extent of the dissection flap and its relationship to the coronary arteries and the aortic valve) that was not available before gating was routinely performed. In addition, motion-free images obtained with ECG gating allow for definitive exclusion of type A dissection (Fig. 6-25). The location of the true and false lumen is critical in the preoperative planning,

**FIGURE 6-25** Although multiple modalities may be used for evaluation of the aortic root, cardiac CT is the gold standard for all pathology of the aorta, including the exclusion and characterization of type A dissection. Parasternal long-axis image from trans-thoracic echocardiogram (A) demonstrates a linear area of echogenicity (*white arrow*) above the noncoronary cusp of the aortic valve concerning for an intimal flap. The finding was detected incidentally in a patient with recent stroke and possible PFO. Subsequent trans-esophageal echocardiogram (B) again demonstrated the finding. Axial image from cardiac CT scan (C) provides excellent visualization of the aortic root and definitively excludes the present of an intimal flap. Sagittal oblique maximum intensity projection image (D) demonstrates aortic root and ascending aorta to be normal. No further evaluation is needed. Echocardiographic findings were presumed to be from artifact.

the operative sequence, and the extent of repair. For example, in dissection of the descending aorta, end-organ perfusion is assessed by demonstrating contrast enhancement of individual organs and related compromise of the celiac, superior mesenteric, inferior mesenteric or renal arteries. As is the case for a nonsurgical aneurysm, if a descending thoracic aortic dissection is stable and to be followed expectantly, CTA remains the reference standard for periodic assessment. Emergency nonenhanced CT, followed by CT contrast-enhanced angiography is the guideline endorsed recommendation,<sup>60</sup> in particular when IMH or aortic dissection are suspected. Contrast-enhanced CTA is the appropriate,<sup>61</sup> definitive test in patients with suspicion of aortic dissection.

### Traumatic Aortic Injury

For patients with suspected trauma of the aorta and the great vessels contrast-enhanced CT is the guideline-endorsed<sup>60,62</sup> reference standard. Almost all polytrauma diagnostic algorithms include a combination of chest radiography plus CTA for initial patient evaluation. The sensitivity and specificity of CT are close to 100% and it is the only imaging modality that has NPV of 100%.<sup>63,64</sup>

Aside direct visualization of traumatic aortic injury, CT allows for simultaneous imaging of indirect signs including widened mediastinum, pulmonary contusion, left scapula fracture, hemothorax, and pseudoaneurysm of the aortic wall (Fig. 6-26).<sup>65</sup>

### Pulmonary Embolism

Growing evidence from recent studies and known societies guidelines<sup>66,67</sup> support CT pulmonary angiography (CTPA) as the first-line imaging test to confirm or exclude the clinical suspicion of acute pulmonary embolism (PE).<sup>68</sup> Combined with careful clinical assessment and specific biomarkers (D-Dimers, NT-pro-BNP, Troponin I), CTPA can further guide management in patients of low to moderate risk. Right ventricular dysfunction as demonstrated by an enlarged RV diameter,<sup>69,70</sup> abnormal position of interventricular septum and inferior vena cava contrast reflux, provides aside to diagnostic assistance, prognostic value and may predict adverse outcomes and patient mortality (Fig. 6-27).<sup>71</sup>

### HEART FAILURE

Heart transplantation is the definitive therapy for end-stage heart failure whereas left ventricular assist devices (LVAD) represent a bridge to transplantation, a destination therapy, or a bridge to recovery.<sup>72,73</sup> Complications can appear either acutely or gradually. Aside providing important anatomical information preoperatively, CT can be utilized for the assessment of proper device function and the early identification of complications. Since this patient population often has impaired renal function, iodinated contrast-induced nephrotoxicity is an important risk that should be carefully considered in discussion between the surgeon and radiologist. Scans

**FIGURE 6-26** Patient status post motor vehicle accident. (A) Multiplanar reformatted image demonstrates traumatic aortic injury with a contained pseudoaneurysm (*arrow*) at the level of the ligamentum arteriosum. (B) Image from conventional angiography were obtained at intervention. The modern diagnosis and exclusion of traumatic injury of the aorta rests almost entirely on CT.

can sometimes be performed with a reduced iodine load with satisfactory image quality.

### Implantable Devices for Heart Failure

For patients with implantable cardiac devices, ECG-gated cardiac CT is feasible, accurate, and enhances the diagnostic evaluation of suspected LVAD dysfunction, further modifying management.<sup>74,75</sup>

For LVAD assessment, CT is superior to echocardiography that has limited imaging depth and coverage volume with regards to the limited acoustic window and acoustic shadowing.<sup>76</sup> Common complications such as in-device-thrombus formation, hemorrhage, cannula/driveline obstruction, pericardium tamponade, or infections can be recognized; the

**FIGURE 6-27** Patient with acute hypoxia. (A) Saddle pulmonary embolus (*arrow*) demonstrated by a large contrast (*white*) filling defect. Note the enlargement of the main pulmonary artery and (B) relative enlargement of the RV (\*) with respect to the LV. This finding strongly suggests right heart strain.

orientation of the device can be assessed using multiplanar reformatted images (Fig. 6-28).<sup>77</sup>

The diagnosis of tamponade in patients with LAVD almost entirely relies on CT, and common findings include inferior vena cava dilatation, right ventricle compression, and contrast material reflux into the azygos vein.<sup>77</sup> Peridevice presence of gas or fluid accumulation are indicative of infections, and given the contraindication of MR, cardiac CT is considered to be the test of choice to evaluate for mycotic pseudoaneurysm.<sup>78</sup> CT is recommended by guidelines<sup>79</sup> for visualization of the native heart and LVAD components and may be valuable when other imaging modalities have not been revealing.

**FIGURE 6-28** Heart failure patient status post VAD placement. (A) Axial image demonstrates a fluid attenuation lesion containing a punctate amount of gas (*arrow*) at the level of the ventricular insertion. (B) Reformatted image shows the orientation of the ventricular insertion pointed superiorly to the long axis of the left ventricle with impingement on the anterior heart.

In patients with implantable pacemakers and defibrillators, ECG-gated CT with multiplanar reformatting is useful for identifying late (>1 month postimplantation) lead malposition, and in conjunction with echocardiography findings can evaluate possible cardiac perforation.<sup>80</sup>

## Heart Transplantation

The role of cardiac CT is secondary for the diagnosis of acute transplantation complications, namely acute cardiac allograft rejection, as echocardiography and MR are used as the first-line imaging modalities.<sup>81</sup> Coronary allograft vasculopathy (CAV) affects almost half of the transplant recipients and represents one of the major mortality causes. CTA offers a reliable diagnostic tool alternative to the traditionally used interventional coronary angiography (ICA) and intravascular ultrasound. By offering an excellent NPV in relation to reference ICA, CT can be utilized as a noninvasive approach, thereby minimizing invasive procedures.<sup>82, 83</sup> Important limitation is the inability to adequately visualize distal coronary vasculature with a diameter of <1.5 mm where early CAV is usually recognized. Cardiac CT can exclude significant CAV within the larger, major coronary segments that may be suitable for stenting.<sup>84</sup>

## VARIOUS

### Imaging of the Pericardium

In patients with clinically suspected constrictive pericarditis, cardiac MR or CT can be used to confirm and measure pericardial thickening. In comparison with MR, CT far better demonstrates the presence and extent of calcification as well as the localization and characterization of pericardial effusion, cysts, or masses. This may be of value in confirming chronic calcific pericardial thickening, supporting the diagnosis of constrictive pericarditis (Fig. 6-29). In these cases, 3D volume rendering illustrates regional localization and distribution of pericardial abnormality; CT is an outstanding preoperative planning tool prior to pericardial stripping (Fig. 6-30). Furthermore, retrospectively ECG-gated studies can guide functional evaluation of septal bounce or pericardial tethering.<sup>85</sup>

Primary or metastatic pericardial masses are rare. CT and MRI offer additional information on the localization and sizing, detection of calcification, and tissue characterizations (presence of blood, thrombus, or fat). Usual image findings include contrast enhancement and high-signal intensity T2W images in CT and MR, respectively. Uncommon lesions such as pericardium cysts and diverticula have typical appearance on CT as well-circumscribed, thin-walled fluid collection most frequently found in the right cardiophrenic angle.

### Cardiac Masses

Cardiac MRI is the preferred modality for high spatial resolution cross-sectional imaging to evaluate cardiac and

pericardial masses. However, CT may be desired, and potentially required, if the mass is known to extend into the mediastinum, chest wall, or lung, or if the patient has a contraindication to MRI. CT also evaluates extra-cardiac thoracic structures with high spatial resolution; thus, it can define the full extent of disease (Fig. 6-31). CT is also useful as a single follow-up examination in patients with metastases to the heart and lungs because it avoids the need for periodic assessment with both conventional chest CT and cardiac MRI. Fat-containing lesions are very amenable to evaluation by CT, since these low attenuation lesions have a characteristic appearance, appearing black relative to water (Fig. 6-32).

### Cardiac Infections

Infective endocarditis (IE) may involve native or prosthetic cardiac valves. The diagnosis is typically suggested on clinical assessment. However, imaging confirms the clinical suspicion and demonstrates cardiac valve vegetations, paravalvular abscesses, complications, and further identifying and grading heart failure. ECG-gated CT in IE may be appropriate by guidelines,<sup>86,87</sup> depending on the clinical presentation, and is complimentary to echocardiography (TTE and TEE) for the evaluation of suspected paravalvular and myocardial abscesses, pseudoaneurysms and infections of prosthetic heart valves (Fig. 6-33). CTA may be appropriate, again depending on the clinical scenario, for identifying the coronary arteries origin prior to surgery.<sup>87</sup> Vegetations smaller than 1 cm are hard to detect with CT (NPV = 55.5%).

**FIGURE 6-29** Calcific constrictive pericarditis. Short axis multiplanar reformatted image from cardiac CT demonstrates extensive thickening and calcification involving left-sided pericardium. In the appropriate clinical setting, these findings would support the diagnosis of constrictive pericarditis. Short axis double inversion recovery fast spin echo image from cardiac MR in the same patient also shows abnormal pericardial thickening, but is insensitive to calcification.

**FIGURE 6-30** Preoperative evaluation of chronic calcific pericardial thickening prior to pericardial stripping. Three-dimensional volume-rendered images from cardiac CT demonstrate extensive regional pericardial calcification (*white areas*). This includes over the RVOT, right ventricle, right atrium, and entire inferior wall extending inferolaterally. Anterior and anterolateral pericardium was normal.

**FIGURE 6-31** Cardiac CT of undifferentiated LV sarcoma performed to evaluate cardiac and extra-cardiac extent of disease. Four chamber multiplanar reformatted image (A) demonstrates invasive myocardial mass centered on the lateral wall beginning at the mid-ventricular level with extension to involve the base of both papillary muscles and distal circumferential involvement of the LV apex. Large epicardial component is noted intimate with pericardium (*white arrows*). There is no evidence of chest wall invasion. Left pleural effusion is seen (*black arrow*). Sagittal oblique maximum intensity projection image (B) (12 mm thick) shows encasement but patency of the LAD (*black arrow*) by tumor (*white arrows*) at the LV apex over a 2.5 cm length. Full field of view axial image (C) shows LV mass without gross chest wall invasion (*black arrows*), evidence of prior mastectomy (*white arrow*), and left pleural effusion.

**FIGURE 6-32** Lipomatous hypertrophy of the interatrial septum. Oblique axial multiplanar reformatted image (A) demonstrates a low attenuation mass (*white arrow*) insinuated between SVC (*grey arrow*) and left atrium (*black arrow*). Second more caudal image (B) demonstrates characteristic sparing of the fossa ovalis (*white arrow*). This lesion is nonencapsulated and can be quite extensive as in this case. Note presence of leads from pacemaker which precluded an MR study.

**FIGURE 6-33** Intravenous drug user who presented with fever of unknown origin. The four panels of the CT images demonstrate complex fluid (\*) at the level of the aortic root, consistent with abscess (confirmed by sampling). The three orthogonal images (*upper panels and lower right panel*) show the relationship with the elongated and narrowed left main coronary artery (*arrow*). The bottom left pane shows a 3D volume rendering that can be viewed at any angle for interventional planning.

Additional imaging utilizing CT or MRI in acute infectious pericarditis can be considered for association with clinical findings and echocardiography in complicated cases. Non-calcified pericardial thickening along with contrast enhancement of visceral and parietal surfaces of the pericardial sac are common findings. CT provides information on the nature of the effusion fluid by distinguishing between exudative versus transudative fluid (usually <10 HU), or hematomas.

## CT VERSUS MRI OF THE HEART

Throughout this chapter, comparisons between CT and MRI have illustrated the strengths and limitations of each. Both modalities give the surgeon valuable pre- and postoperative information. While the modality best suited for specific clinical indications evolves with the technology, at present certain generalizations can be made. Cardiac CT is invaluable in reoperative cardiac surgery as it offers higher quality noninvasive angiography of native coronary arteries and bypass grafts. Since 3D volume rendering with CT has higher quality and better spatial resolution, it is preferred for preoperative planning for reoperative CABG or minimally invasive cardiac surgery. All calcifications are poorly seen on MRI and superbly seen with CT, and thus CT is far superior in demonstrating coronary, myocardial, pericardial, and valvular calcifications. The same is true for mechanical valve prostheses; because of large areas of artifact on MR images, functional evaluation is only possible with CT. Finally, all patients with a surgical problem of the aorta require evaluation with CT.

The strengths of MRI include high temporal resolution, greater blood-myocardial image contrast, multiparametric functional evaluation, and techniques for myocardial tissue characterization. In addition, cardiac MRI is invaluable in assessing myocardial function, contractility, and actual tissue perfusion and viability. For these reasons, MRI remains the reference standard to assess biventricular volumes, function, and myocardial mass. A variety of MRI pulse sequences can accurately delineate areas of chronic myocardial infarction, identify certain specific cardiomyopathies, and confirm the presence of neoplasm. With the use of parallel imaging techniques to increase the speed of the MRI acquisition, very high temporal resolution (20–30 ms) can be obtained to study bioprosthetic and native valve function. In addition, measurements of flow parameters through a vessel cross-section can be used to, for example, accurately quantify valvular regurgitant lesions.

One distinct advantage of MRI over CT is that MRI delivers no patient radiation. As detailed in Part 1, the radiation exposure in ECG-gated CT is higher than that for CT of any other body part. In younger patients, who typically have less comorbid disease and may require multiple follow-up examinations over years or decades, MRI should be used when possible.

Dramatic progress in CT technology has enabled advanced cardiac imaging for cardiac surgery patients. CT has rapidly demonstrated broad ranging applicability, and in particular CT has revolutionized the preoperative assessment of patients

for reoperative surgery. Understanding the technical considerations will allow the surgeon to appreciate the inherent strengths and weaknesses of cardiac CT and to optimally communicate with the radiologist. This, in turn, will result in the best quality diagnostic examination in the vast majority of cardiac surgery patients.

# Risk Assessment and Performance Improvement in Cardiac Surgery

Victor A. Ferraris • Fred H. Edwards • Jeremiah T. Martin

Assessing risk to improve outcomes is not a new principle. Formal assessment of patient care to improve outcomes dates back millennia. While it may be hard to establish an exact beginning, there are historical times and iconoclastic health-care providers who stand out as important contributors to the modern concepts of quality assessment and performance improvement. At least six individuals stand out as iconoclasts in the field of performance improvement in surgery (Table 7-1). From the practice-changing observational studies of medieval surgeons like Albucasis and Trotula to the twentieth century insistence on evidence-based studies and randomized controlled trials (RCTs) by Archie Cochrane, many individuals served as champions of performance improvement using the tools of their times. The six people outlined in Table 7-1 had exceptional effects on differentiating good from bad outcomes and on implementing process improvements that benefit our patients today. Each of these six shared a common life experience. At some time in their careers, they were outcasts among their peers. Their peers, and in some cases the public, chastised them for stating the obvious. Thankfully, they persisted despite these unpopular reactions. Reading the historical accounts of these six individuals reminds one that today's public resistance to straightforward observations is a long-standing perpetual obstacle that surgical leaders overcame.

## ASSESSMENT OF CARDIAC OPERATIONS

### Measures of Successful Operations

#### PERFORMANCE MEASURES—OUTCOMES, STRUCTURE, AND PROCESS

In the early 1960s, Donabedian suggested that quality in health care is defined as improvement in patient status after accounting for the patient's severity of illness, presence of comorbidity, and the medical services received.<sup>1</sup> He further proposed that quality could best be measured by considering three domains: structure, process, and outcome. Only

recently has the notion of measuring health-care quality using this Donabedian framework been accepted and implemented. In 2000, the Institute of Medicine (IOM) issued a report that was highly critical of the US health-care system, suggesting that between 50,000 and 90,000 unnecessary deaths occur yearly because of errors in the health-care system.<sup>2</sup> The IOM reports created a heightened awareness of more global aspects of quality. For most of the history of cardiac surgery an outcome measure, operative mortality, defined surgical quality. After the IOM report appeared, change occurred, and other aspects of Donabedian's framework surfaced to measure quality. In addition to operative mortality, health-care quality measurement gave way to a broader analysis that included additional performance measures including *operative morbidity, processes of care, and structural measures of care*. The Joint Commission on Accreditation of Healthcare Organizations (formerly JCAHO now officially called The Joint Commission) proposed the following definitions of important quality measures:

- **Performance measure**—A quantitative entity that provides an indication of an organization's or surgeon's performance in relation to a specified process or outcome.
- **Outcome measure**—A measure that indicates the results of process measures. Examples are operative mortality, the frequency of postoperative mediastinitis, renal failure, and myocardial infarction.
- **Process measure**—A measure that focuses on a process leading to a certain outcome. Intrinsic in this definition is a scientific basis for believing that the process will increase the probability of achieving a desired outcome. Examples include the rate of internal mammary artery (IMA) use in coronary artery bypass graft (CABG) patients or the fraction of CABG patients placed on anti-platelet agents postoperatively.
- **Structural measure**—A measure that assesses whether an appropriate number, type, and distribution of medical personnel, equipment, and/or facilities are in place to deliver optimal health care. Examples include enrollment in a national database, adequate intensive care unit (ICU) facilities, or procedural volume.

TABLE 7-1: Shaping the Quality of Surgical Care Over Millennia

Health-care Provider (Surgeon, Midwife, or Nurse)	Time Period	Contributions
Albucasis of Andalusia	Around 900 A.D.	<ul style="list-style-type: none"> <li>• Most frequently cited surgical author of the middle ages.<sup>121</sup></li> <li>• Greatest contribution to medicine is the <i>Kitab al-Tasrif</i>; a thirty-volume encyclopedia of medical practices.</li> <li>• Instrumental in <i>transforming medicine from “philosophy” to an actual discipline</i>. Met with great resistance from peers who favored less invasive interventions.</li> <li>• May be the “father of modern surgery” because of his insistence on <i>observational studies, proper training, and use of operative techniques</i>.</li> <li>• Firsts include—description of ectopic pregnancy; hereditary nature of hemophilia; performance of bowel surgery; use of surgical instruments for procedures including breast surgery, urethral exam, tooth implant, stone removal (kidney, bladder, and gall bladder), important advances in pharmacology (prepared medicines by sublimation and distillation).</li> </ul>
Trota of Salerno	Around 1200 A.D.	<ul style="list-style-type: none"> <li>• Advised women on conception, menstruation, pregnancy, caesarian sections, and childbirth as a female faculty member of the Medical School of Salerno.</li> <li>• Wrote a textbook that impacted practice for 300-400 years.<sup>122</sup></li> <li>• Her radical ideas on conception shocked the medical and social community. Based on <i>observational studies</i>, Trotula believed that not only women, but men, both have physiologic and anatomic defects that cause conception difficulties.</li> <li>• Defined the <i>concept of “laudable pus”</i> for wound abscess drainage.</li> </ul>
Angelique du Coudrey of France	Mid 1700s	<ul style="list-style-type: none"> <li>• As a practicing midwife, Mme du Coudray violated the majority of standards demanded of midwives; she had no children of her own, was not married, and believed in the organization and training of midwives.<sup>123</sup></li> <li>• In 1759, Mme du Coudray released the first edition of her midwifery manual <i>Abrege de L’art des Accouchements</i> that ultimately updated the textbook of Trotula of Salerno.</li> <li>• Trained more than 40,000 midwives in France and dramatically improved the newborn infant mortality rate. By 1780, <i>two-thirds of the midwives in France were Madame du Coudray’s pupils</i>.</li> <li>• Designed child-bearing machines/models for <i>simulation training</i> of vaginal delivery.<sup>124</sup></li> </ul>
John Hunter (England)	Late 1700s	<ul style="list-style-type: none"> <li>• Premier anatomist/surgeon of his time. Insisted that <i>diseases were caused by anatomic abnormality</i> not abstract explanations of illness like “humors” or “spirits.”<sup>125</sup></li> <li>• Outspoken critic of many medications claiming to cure common diseases of the times (eg, gonorrhea). Devised an experiment to test the effect of pills made of bread to show that gonorrhea “mostly cured itself.” One of the first records of the <i>placebo effect</i>.</li> <li>• Impact of Hunter’s anatomic explanations carried forward to modern day (eg, Hunter’s canal.)</li> <li>• Friends included Benjamin Franklin, Edward Jenner, Lord Byron, Casanova, and Adam Smith. List of enemies probably equally as distinguished.</li> </ul>
Florence Nightingale (England)	Early 1800s	<ul style="list-style-type: none"> <li>• Battlefield nurse in Crimean War. <i>Elevated nursing to honorable profession</i>. Famous quote: “<i>It may seem a strange principle to enunciate as the very first requirement in a Hospital that it should do the sick no harm.</i>”<sup>126</sup></li> <li>• Troubled by observation that hospitalized patients in London hospitals died at higher rates than those in rural hospitals or treated at home.</li> <li>• Studied <i>epidemiology of hospital deaths</i>. Introduced <i>quality improvement</i> projects that included better sanitation, less crowding, and location of hospitals at a distance from crowded cities.</li> <li>• Observed that some patients admitted to urban hospitals were sicker than others and were more likely to die—beginning of <i>risk assessment</i>.</li> </ul>
Ernest Amory Codman (United States)	Early 1900s	<ul style="list-style-type: none"> <li>• Classmate of Harvey Cushing—together they instituted <i>intraoperative records</i> to document complications.</li> <li>• Passionate about <i>outcome analysis</i>—claimed that most adverse outcomes were the “surgeons’ fault.” Believed in “<i>End Result Idea</i>.”</li> <li>• Founded his own hospital after being dismissed from Mass General. Became very unpopular because of his insistence on surgeon-related causes of adverse outcomes.</li> <li>• Co-founder of the <i>American College of Surgeons</i> and ultimately the precursor of the <i>Joint Commission, the ACS tumor registry, and National Trauma Databank</i>.<sup>127</sup></li> </ul>

Health-care Provider (Surgeon, Midwife, or Nurse)	Time Period	Contributions
Archie Cochrane (Scotland)	Mid-twentieth Century	<ul style="list-style-type: none"> <li>• Volunteered with the International Brigade, Spanish Civil War. Branded as a “Tortyskite” and “socialist” because of insistence on a National Health Service.</li> <li>• Captain, Royal Army Medical Corps. Taken prisoner of war in June 1941 in Crete.</li> <li>• POW medical officer in various German POW camps. Developed questions about the best treatment of TB that triggered his <i>insistence on randomized trials</i>.</li> <li>• Strong advocate of <i>randomized controlled trials</i> to provide actionable evidence to support evidence-based interventions.</li> <li>• 1960-1974: Director, Medical Research Council Epidemiology Research Unit, Cardiff, Wales.</li> <li>• Published <i>Effectiveness and Efficiency—Random Reflections on Health Services</i> that summarized rationale for evidence-based medicine.</li> <li>• Driving force behind the creation of the <i>Cochrane Collaboration</i> that serves as the repository of RCT’s and systematic reviews today.</li> </ul>

Data from Quality Performance Measures. The Society of Thoracic Surgeons.

Birkmeyer and coworkers outlined advantages and disadvantages associated with each of these three specific types of performance measures.<sup>3</sup> The fact that *structural measures* can be readily tabulated in an inexpensive manner using administrative data is a distinct advantage. On the other hand, many structural measures do not lend themselves to alteration. Particularly in smaller hospitals, there may be no way to increase procedural volume or to introduce costly ICU design changes in an attempt to improve their performance on structural measures. Attempts to alter structure might even have adverse consequences (eg, unnecessary operations, costly and unnecessary new beds). Links between health-care quality and *process measures* exist and they are usually actionable on a practical level. Their major disadvantage lies in the fact that their linkage to outcomes may be weak. Although *outcome measures* are the most important endpoint for patients, inadequate sample size and lack of appropriate risk-adjustment limit accurate assessment of these outcomes.

Several national organizations develop and evaluate performance measures. Perhaps the most visible of these is the *National Quality Forum (NQF)*, a public-private collaborative organization that uses a process of exhaustive, evidence-based scrutiny of candidate measures to determine their relevance to both patients and healthcare providers. The NQF considers whether candidate measures can be assessed accurately and whether actionable interventions can improve performance for these measures. Because of this scrutiny, NQF-endorsed measures have a high level of national credibility (Table 7-2).

#### PATIENT SATISFACTION—PATIENT-REPORTED OUTCOMES

Other outcomes following cardiac procedures, such as patient satisfaction and health-related quality of life, are less well studied but extremely important in the assessment of

performance. Meeting or exceeding patients’ expectations is a major goal of the health-care system. While all recognize the importance of performing safe surgery, one must also acknowledge that a safe operation with minimal patient benefit is to be avoided. The growing importance of patient-reported outcomes (PRO) also reflects the increasing prevalence of chronic disease in our aging population. The goal of therapeutic interventions is often to relieve symptoms and to improve quality of life, rather than cure a disease and prolong survival. This is especially important in selecting elderly patients for cardiac operations. Recent studies suggest that CABG results in excellent health-related quality of life 10 to 15 years following operation in most patients,<sup>4</sup> and that this benefit extends to those patients older than 80 years of age.<sup>5</sup> Future research into patient-perceived performance assessment is inevitable given the aging of populations in the developed countries.

Statistical models to adjust for patient risk are essential to determine the probability of procedural outcomes. Traditionally, risk models predict the probability of death or other postprocedural complications such as stroke, infection, or renal failure. These traditional models are clearly important to assess procedural risk, but the safety of an operation is only part of the decision-making process as to whether to recommend a given procedure. Patient benefit must be considered as well. Just because one can do a procedure safely does not mean it should be done—if it affords the patient only minimal benefit, then the patient has received poor treatment.

Patient benefit can be represented by using appropriate metrics other than procedural mortality and morbidity. PRO can be objectively determined from a variety of published scoring protocols. These scores can be considered to be an objective measure of patient benefit. In turn, the scores provide information necessary to develop statistical models that

### NQF endorsed adult cardiac surgery measures

#### Composite Measure

1. STS CABG Composite Score composed of six outcome measures and five process measures.

#### Outcome Measures

2. Risk-Adjusted Deep Sternal Wound Infection Rate.
3. Risk-Adjusted Operative Mortality for Aortic Valve Replacement (AVR).
4. Risk-Adjusted Operative Mortality for AVR + CABG Surgery.
5. Risk-Adjusted Operative Mortality for CABG.
6. Risk-Adjusted Operative Mortality for Mitral Valve (MV) Repair.
7. Risk-Adjusted Operative Mortality for MV Repair + CABG Surgery.
8. Risk-Adjusted Operative Mortality for MV Replacement.
9. Risk-Adjusted Operative Mortality for MV Replacement + CABG.
10. Risk-Adjusted Postoperative Renal Failure.
11. Risk-Adjusted Prolonged Intubation (Ventilation).
12. Risk-Adjusted Stroke/Cerebrovascular Accident.
13. Risk-Adjusted Surgical Re-exploration.

#### Process Measures

14. Anti-Lipid Treatment at Discharge.
15. Anti-Platelet Medication at Discharge.
16. Beta Blockade at Discharge.
17. Duration of Antibiotic Prophylaxis for Cardiac Surgery Patients.
18. Preoperative Beta Blockade.
19. Selection of Antibiotic Prophylaxis for Cardiac Surgery Patients.
20. Use of Internal Mammary Artery in CABG.

#### Structural Measure

21. Participation in a Systematic Database for Cardiac Surgery.

\*<http://www.sts.org/quality-research-patient-safety/quality/quality-performance-measures>.

predict the probability of PRO scores, in much the same way that traditional models predict the probability of procedural complications. The results of these models should serve as a meaningful measure of predicted patient benefit. Clinical registries are now collecting data that will permit an objective estimate of both patient risk and patient benefit. Statistical risk models should soon be available to predict not only procedural mortality and major non-fatal complications, but also the probability of patient benefit.

### COMPOSITE MEASURES THAT REFLECT PROCESS, STRUCTURE, AND OUTCOME DOMAINS

The best approach to assessing surgical quality is uncertain. Operative mortality for most cardiac procedures is low and performance assessment requires large patient numbers to

discriminate between hospitals and providers. For this reason other measures surface for performance assessment. There is growing interest in the use of *composite measures* to assess provider and hospital performance. Composite measures combine multiple quality indicators into a single score and can include outcome, structural, and process measures in various combinations. Evidence suggests that composite variables that incorporate multiple outcome measures as well as structural and process performance measures are better reflections of quality than are individual outcomes alone.<sup>6</sup> Examples of composite performance measures used for quality assessment include indices that combine ICU care variables with outcome measures,<sup>7</sup> and those that combine process of care variables with outcome variables and structural variables.<sup>8,9</sup>

Certain outcome variables may reflect multiple domains of performance. One such measure is *failure-to-rescue*, usually defined as the mortality rate for a subset of patients who experience postoperative complications. Studies suggest that failure-to-rescue rates depend on structural measures (eg, advanced ICU capabilities and presence of residency training), processes of care, and traditional morbidity outcome measures.<sup>10,11</sup> While traditional outcome measures such as operative mortality are thought to be mostly dependent on patient-related risk factors, it appears that failure-to-rescue rates reflect a different part of the care continuum, specifically the intensive care arena. Some consider failure-to-rescue rates to be primarily a structural measure focused on nursing care and ICU staffing. There are multiple contributions to failure-to-rescue rates, thereby qualifying this variable as a composite performance measure. Several studies are underway to determine the ability of this variable to identify and stratify quality performers.

The development of composite measures is statistically complex. The composite metric is very dependent on the statistical approach used to combine the component variables.<sup>8</sup> Despite the complexities of creating composite measures, increased reliance on composite measures of quality is inevitable, and efforts at improving the reliability and predictive accuracy are underway.

## TOOLS OF PERFORMANCE ASSESSMENT

### Basic Statistical Treatment of Outcome Data

#### RECAP, RELATE, AND REGRESS

Analysis of cardiac surgical results is purpose-driven. Use of statistics follows the purpose for which data were gathered. There are three broad uses of statistics for analysis of cardiac surgical outcomes. Perhaps the most basic use of statistics is to *recap or summarize information* about a patient group. Certain reports can only document surgical outcomes in a few patients because of the rarity of disease or limited ability to sample patient populations. A single estimate of an outcome in a limited population may be misleading. In order to

acknowledge the inaccuracy of a single estimate of a limited population, statistical measures describe this imprecision. Multiple statistical terms describe this uncertainty, including *sample, mean, standard deviation, interquartile range, confidence interval, and standard error.*

More commonly, statistics serve to *relate or compare attributes of two or more groups.* Comparisons between groups require comparisons between known reference distributions (eg, chi-square and t-distribution) and the data sample distribution. Differences between these two distributions allow calculation of a probability that there really is a difference between the sample and the reference distribution. This probability has different names including *p-value* or alpha ( $\alpha$ ) level. The most commonly used test for comparisons of two numeric variables is the Student's t-test. The t-test makes use of the symmetry of the t-distribution of a sample and compares the *t* statistic calculated from each of the two group's t-distributions with critical values. The astute reader quickly realizes that the statistical formulation of the t-test requires *computer support as the workhorse that does the calculations.* In fact, very few statistical tests do not rely on computer-intensive calculations. Reliance on computers to calculate *p-values*, and to perform statistical tests in general, provides opportunity for misuse or inaccurate use of both simple and complex statistics.<sup>12</sup> Misuse of the simplest statistical tests is common, and has been for many years.<sup>13-15</sup> It behooves the surgeon who evaluates the literature or who performs statistical analyses to understand the principles and application of various statistical tests used for comparing two or more groups.<sup>12</sup>

Comparing the outcomes between two groups based on several characteristics of each group considered simultaneously requires multivariable analysis. *Multivariate regression analysis* provides a means of accounting for multiple independent variables (also called risk factors) that predict the dependent (also called outcome) variable. The result of multivariate regression is called a "model," a slightly counter-intuitive term. Regression models allow assignment of a regression coefficient to each predictor variable that roughly corresponds to the variable contribution to outcome prediction. Again, computer software does the work; investigators do the interpretation.

## OUTCOME MODELS

There is a multitude of regression models available for analysis of cardiac surgical data. Perhaps the most common is *logistic regression.* Logistic regression models are a means of analyzing independent variables that predict a *dichotomous outcome* (eg, death, renal failure, and mediastinitis).

Regression models provide *risk-adjusted assessment* of outcomes that is often used for *performance assessment* across groups of providers. For example, logistic regression models provide a population probability (value between zero and one) of an outcome based on multiple independent predictor variables. These probabilities are called risk-adjusted probabilities and can be defined as the predicted population outcome or *expected outcome.* Individual members of the

population have an *observed outcome.* The ratio of observed outcome to predicted outcome is called *O/E ratio*, and reflects a measure of individual provider performance. There are multiple ways to assess adequacy of regression models, especially logistic regression. Hosmer and coauthors provide a particularly comprehensive, yet practical, description of regression model assessment.<sup>16</sup> The O/E ratio for an individual provider may give a rough estimate of risk-adjusted performance, but this measure alone does not strictly determine clinical competence or quality of care. *Cumulative sum (CUSUM) analysis* calculates provider O/E ratios over time and allows a graphical picture of performance that avoids point estimates.

## LATE TIME-RELATED EVENTS

Cardiac surgeons are frequently concerned about events that occur late following operations. Special statistical methods are used to determine the long-term status of patients following operative procedures.

The most common way to estimate time-related benefit employs the *Kaplan-Meier method.* This method provides an estimate of survival (or some other later time-dependent event) probability before all patients in the cohort experience the late event. This method assumes that patients who are alive at the time of analysis have the same risk of future death as those who have already died. The graphical representation of the Kaplan-Meier model gives a survival curve and allows comparisons between survival rates associated with different interventions (eg, two different valve types). The *log-rank statistic* is used most often to compare Kaplan-Meier survival curves.

At any point in time, an individual patient has a risk of experiencing the designated endpoint. This risk of reaching the endpoint is known as the *hazard.* If death is the selected endpoint, then the hazard is the risk of dying at any point in time. The *cumulative hazard function* is the negative logarithm of the Kaplan-Meier estimated survival obtained from the survival curve.

Surgeons are often interested in the multiple factors that predict long-term survival. These factors are typically the clinical risk factors for a patient population or the type of intervention performed. *Cox regression models* provide a multivariable analysis of predictors of survival using the hazard function. Using the results of Cox models, one can calculate a *hazard ratio* (HR), which adjusts for clinical factors in the process of providing a comparison of survival for two interventions at a given time. For example, to compare the survival of CABG against the survival of percutaneous coronary intervention (PCI) at a specified time after the procedure, one could determine the HR comparing the two procedures. The HR provides the relative risk of death of CABG versus PCI for risk-adjusted populations at a given point in time. This method assumes that the hazard function is constant over time; hence the proper name *Cox proportional hazards regression.* When survival curves intersect at some point in time, the proportional hazards assumption is not met and one should then use other metrics such as the risk ratio.

## Risk Adjustment and Comorbidity

### MEASURES OF COMORBIDITY

Essential for the assessment of the success of cardiac operations is the ability to arrange patients according to their severity of illness. Comorbid illness in patients with cardiac disease is common. Various measures of comorbidity compile patients' risk factors into a single variable that reflects global comorbidity (Table 7-3). The comorbidity indices in Table 7-3 adjust for the incremental risk associated with specific preoperative factors variously known as risk factors, risk predictors, comorbidities, or covariates. The comorbidity systems listed in Table 7-3 are in constant evolution and use of these indices often extends to populations that include cardiac surgical patients, despite the fact that none of the indices are derived from patients undergoing cardiac procedures.

Table 7-3 compares commonly used comorbidity measures. The Charlson Index, the CIRS, the ICED, and the Kaplan Index are valid and reliable measures of comorbidity as measured in certain specific patient populations, but

not in patients undergoing cardiac operations.<sup>17</sup> The other comorbidity measures in Table 7-3 do not have sufficient data to assess their validity and reliability and are probably less useful than the four validated measures. There are many limitations of comorbidity indices, and they are not applied widely in studies of efficacy or medical effectiveness for cardiac operations.

### RISK ADJUSTMENT SYSTEMS FOR CARDIAC OPERATIONS

Comorbidity indices, and risk factors in general, make up the variables that generate regression models that are used for risk adjustment. Most risk-adjustment models share several common features. First, the risk factors or comorbidities in the model are associated with a specific outcome. Second, if the goal is to measure provider performance, the risk factors include only patient characteristics (not hospital, physician, or regional characteristics) present prior to surgery.<sup>18</sup> Third, a sufficient number of patients must have the risk factor, and

**TABLE 7-3: Characteristics and Study Populations of Commonly Used Comorbidity Indices**

Comorbidity Index	Variables in the Index	Weights Used to Compute Index	Final Index Score	Population Used to Derive Index
Charlson Index	19 comorbid conditions	Relative risk for each comorbid condition derived from logistic regression of mortality	Sum of weights	Cancer patients, heart disease, pneumonia, elective noncardiac operations, amputees.
CIRS	13 body systems	Score from 0 to 4 for each body system	Sum of weights	Elderly patients many institutionalized for long-term care.
ICED	14 disease categories and 10 functional categories	Score of 1 to 5 for disease categories and 1 to 3 for functional categories	Scoring algorithm that sums up disease and functional scores to arrive at values from 1 to 4	Total hip replacements and nursing home patients.
Kaplan Index	Two categories—vascular or nonvascular disease	Graded 0 through 3 for each category	Most severe condition. Two grade 2 are ranked as grade 3	Diabetes and breast cancer.
BOD Index	59 diseases	0 through 4 for each disease	Sum of weights	Long-stay nursing home patients.
Cornoni-Huntley Index	3 categories	1—No comorbidity 2—Impaired hearing or vision 3—Heart disease, stroke or diabetes 4—Both 2 and 3	Graded 1 through 4	Hypertensive population and age > 75 years.
Disease Count	Number of diseases present based on ICD-9 codes	Sum number of diseases	Maximum score based on number of diseases	Breast cancer, MI, HIV, asthma, appendicitis, low back pain, pneumonia, diabetes, abdominal hernia.
Shwartz Index	21 comorbidities	Relative risks from model that predicts medical costs	Sum of relative risks for each comorbidity	Stroke, lung disease, heart disease, prostate cancer, hip fracture, and low back pain.

a sufficient number must experience the adverse outcome, in order to construct an accurate risk model. Finally, it is necessary to define the period of observation for the outcomes of interest (eg, in-hospital, 30-day mortality, or both). Table 7-4 lists risk-adjustment models used to define quality or performance based on clinical outcome measures (eg, risk of death or other adverse clinical outcomes). In addition, two of the risk adjustment models shown in Table 7-4 (the Pennsylvania Cardiac Surgery Reporting System and the Canadian Provincial Adult Cardiac Care Network of Ontario) assess risk based on resource utilization (eg, hospital length-of-stay and cost) as well as on clinical outcome measures.<sup>19,20</sup> Of the risk models listed in Table 7-4, only one, the APACHE III system, computes a risk score independent of patient diagnosis.<sup>21</sup> All of the others in the table are diagnosis-specific systems that use only patients with particular diagnoses in computing risk scores.

Once developed from a reference population, each of the risk stratification models shown in Table 7-4 is validated in

some way. There are too many individual patient and procedural differences, many of them unknown or unmeasured, to allow completely accurate validated preoperative risk assessment. The most important reason that risk-adjustment methods fail to completely predict individual outcomes is that the data set used to derive the risk score comes from retrospective, observational data that contain inherent *selection bias*, that is patients were given a certain treatment that resulted in a particular outcome because a clinician had a selection bias about what treatment that particular patient should receive. In *observational datasets*, patients are not allocated to a given treatment in a randomized manner. In addition, clinician bias may not reflect evidence-based data. Methods are available that attempt to overcome some of these limitations of observational data. These methods include use of *propensity matching* and “*bootstrap*” *variable selection*.<sup>22,23</sup> Observational datasets are much more readily available and represent “real-world” treatment and outcomes compared to RCTs. An

**TABLE 7-4: Examples of Risk Adjustment Models Used for Patients Undergoing Cardiac Surgical Procedures**

Severity System	Data Source	Classification Approach	Outcomes Measured
APACHE III	Values of 17 physiologic parameters and other clinical information	Integer scores from 0 to 299 measured within 24 hours of ICU admission	In-hospital death
Pennsylvania	Clinical findings collected at time of admission	Probability of in-hospital death ranging from 0 to 1 based on logistic regression model and MediQual's Atlas™ admission severity score	In-hospital death and cost of procedure
New York	Condition specific clinical variables from discharge record	Probability of in-hospital death ranging from 0 to 1 based on logistic regression model	In-hospital death
Society for Thoracic Surgeons	Condition-specific clinical variables from discharge record	Originally used Bayesian algorithm to assign patient to risk interval (percent mortality interval). More recently used logistic and hierarchical regression methods	In-hospital death and morbidity
EuroSCORE	Condition specific clinical variables from discharge record	Additive logistic regression model with scores based on presence or absence of important risk factors	30-day and in-hospital mortality
Veterans Administration	Condition-specific clinical variables measured 30 days after operation	Logistic regression model used to assign patient to risk interval (percent mortality interval)	In-hospital death and morbidity
Canadian	Condition specific clinical variables entered at time of referral for cardiac surgery	Range of scores from 0 to 16 based on logistic regression odds ratio for six key risk factors	In-hospital mortality, ICU stay and postoperative length of stay
Northern New England	Condition specific clinical variables and comorbidity index entered from discharge record	Scoring system based on logistic regression coefficients used to calculate probability of operative mortality from 7 clinical variables and 1 comorbidity index	In-hospital mortality

excellent review of the subtleties of evaluating the quality of risk-adjustment methods is given in the book by Iezzoni and this reference is recommended to the interested reader.<sup>24</sup>

Within the last decade the Society of Thoracic Surgeons (STS) published the most comprehensive set of cardiac surgery risk models yet available. Twenty-seven risk models encompassed nine endpoints for each of three major groups of cardiac procedures (isolated CABG, isolated valve, and valve + CABG).<sup>25-27</sup> These risk models provide the framework for measurement of risk-adjusted outcomes for cardiac operations and, ultimately, for performance assessment of individual cardiac programs or for individual providers. The NQF has endorsed most of the STS risk adjustment models for use in determining cardiac surgery quality measures (see Table 7-2).

Ideally, differences in risk-adjusted outcomes are due to differences in quality of care, but *caution is necessary in the interpretation of provider differences based on differences derived from risk adjustment models*. One study simulated the mortality experience for a hypothetical set of hospitals assuming perfect risk adjustment and with prior perfect knowledge of poor quality providers.<sup>28</sup> These authors used various simulation models, including Monte Carlo simulation, and found that under all reasonable assumptions, sensitivity for determining poor provider quality was less than 20% and the predictive error for determining high outliers was greater than 50%. Much of the observed mortality rate differences between high outliers and nonoutliers were attributable to random variation. Park and coauthors suggest that providers identified as high outliers using conventional risk adjustment methods do not provide lower quality care than do nonoutliers, and that most of the outcome differences are due to random variations.<sup>29</sup>

## Performance of Risk Adjustment Models

Many risk stratification models for cardiac operations are used to assess surgical performance. Before a risk model and its component risk factors are used to evaluate provider performance, these models are tested for accuracy. Many patient variables are candidate risk factors for operative mortality following coronary revascularization. Examples include serum blood urea nitrogen (BUN), cachexia, oxygen delivery, HIV, case volume, low hematocrit on bypass, the diameter of the coronary artery, and resident involvement in the operation. On the surface, these variables seem like valid risk factors, but many are not. All putative risk factors should be subjected to rigorous scrutiny. Tests of risk model prediction including regression diagnostics (eg, *receiver operating characteristics (ROC) curves* and *cross-validation studies*) performed on the models included in Tables 7-4 suggest that the models are good, but not perfect, at predicting outcomes. In statistical terms this may mean that all of the variability in outcome measurement is not explained by the set of risk factors included in the regression models. Hence, it is possible that inclusion of new putative risk factors in the regression equations may improve the validity and precision of the models. New regression models, and new risk factors, must

be scrutinized and tested with regression diagnostics before acceptance. However, it is uncertain whether inclusion of many more risk factors will significantly improve the quality and predictive ability of regression models, and there is an ongoing tension between parsimonious models and robust models that contain many variables. For example, the STS risk stratification model described in Table 7-4 includes many predictor variables, while the Toronto risk adjustment model includes only five predictor variables. Yet the regression diagnostics for these two models are similar, suggesting that both models have equal precision and predictive capabilities for identifying outcome measures. Studies show that much of the predictive ability of risk models is contained in a relatively small number of risk factors.<sup>30,31</sup> Other studies suggest that the limiting factor in the accuracy of current risk models may be a failure to understand and account for all the important factors related to risk.<sup>32</sup> Additionally, risk models are useful for predicting the average outcome for a population of patients with specific risk factors, but not necessarily accurate for predicting the outcome for a specific patient. Further work needs to be done, both to explain the differences in risk factors seen between the various risk models and to determine which models are best suited for studies of quality improvement and performance assessment.

## Study Designs to Compare Outcomes

### RANDOMIZED CONTROL TRIALS

After World War II, there was a rapid expansion of therapeutic options, especially drugs, for treatment of previously untreatable acute and chronic diseases. With the advent of this new drug therapy came the introduction of RCTs to define the efficacy of various drug regimens. Archie Cochrane, a Scottish pulmonary medicine specialist, championed RCTs as the most reliable means of deciding on optimal treatment (Fig. 7-1). He suggested that RCTs were the best means of identifying interventions that have a causal influence on

**FIGURE 7-1** Portrait of Archie Cochrane and significant life events and accomplishments. (Used with permission from the Cochrane Collaboration.)

outcomes. His efforts eventually led to the creation of the Cochrane Collaboration, a repository for works of evidence-based medicine (EBM). He is arguably the father of EBM and is largely responsible for the current preeminence of RCTs as the “holy grail” of decisions about treatment options. RCTs provide the best evidence to decide about surgical treatment options for cardiac diseases, as well as providing the best means of identifying cause and effect relationships. The impact of Cochrane’s insistence on wide dissemination of published high-quality evidence, including RCTs, and summaries of RCTs and observational data including *meta-analyses and systematic reviews* (collectively referred to as EBM publications), is felt today, even more than in previous decades. In 2014, a Pub Med search identified 27 EBM publications concerning various treatment options related to cardiac operations and associated diseases.

### NONRANDOMIZED COMPARISONS FOR CAUSAL INFERENCE

Not every question about cardiac operations can be answered by RCTs. For many reasons the majority of the published cardiac surgical studies are *observational studies*, not RCTs. In nearly all observational studies, there may be *selection bias*. Patients underwent a treatment for nonrandom reasons. The nonrandom nature of observational studies mandates statistical methods to account for variables (usually preoperative variables) that affect the outcome (typically operative mortality and/or morbidity). Shortly after the creation of the Cochrane Collaboration in the 1970s, publications suggested that observational studies may weight outcomes in favor of new therapies, much more so than RCTs that address the same comparisons.<sup>33</sup> Almost 20 years later reassessment of the value of nonrandomized comparisons suggested that well-done observational studies using carefully selected controls (either *cohort or case-control designs*) do not overestimate treatment benefit.<sup>34</sup>

There are multiple ways to address bias in observational studies. Perhaps the most widely used technique involves careful matching of treatment and control groups using various statistical techniques, the most popular method being *propensity score matching*.<sup>35</sup> The propensity score is constructed in as robust a manner as possible given the population variables. Typically logistic regression with all preoperative independent variables forced into the regression equation is used to compute the propensity score for comparison of two groups.<sup>36</sup> Matching control and experimental groups based on their propensity scores (ie, probability of a given outcome based on the logistic regression-derived probability) provides a “pseudo-randomized” group from the total population. Comparisons using carefully matched groups approximate RCTs in most cases.<sup>34</sup>

### STUDY DESIGN: THE TENSION BETWEEN RANDOMIZED TRIALS AND OBSERVATIONAL STUDIES

There are clear advantages and disadvantages associated with both RCT and observational studies. Because of the absence of confounding and selection bias, the RCT remains the “gold

standard” for comparing results. RCTs focus on relatively small, highly select populations that may have little in common with patients typically seen in practice. Small sample size often precludes meaningful subgroup analysis and statistical analyses may be underpowered. RCTs are also quite costly and so time-consuming that results may often be outdated by the time they are reported. On the other hand, observational studies usually involve large populations of “real-world” patients. Subgroup cohorts with adequately powered statistical analysis are commonly seen in observational studies. Since these studies often use registry data, they can be carried out in a timely fashion with minimal expense. Cohort balancing using propensity scoring techniques and other statistical approaches provides useful comparisons that can approximate RCTs, but careful matching techniques for group comparisons never completely rule out bias or confounding.

## GOALS OF CARDIAC SURGICAL PERFORMANCE ASSESSMENT

### Using Quality Assessments to Create Guidelines

One goal of assessment of cardiac procedures is to define best practices. Wide dissemination of global assessment of cardiac operations can provide evidence that helps surgeons know the best alternative for surgical treatment of cardiovascular disorders. Recognizing the difficulties in defining “best practices” for a given illness, professional organizations opted to promote practice guidelines or “suggested therapy” for cardiac surgical diseases.<sup>37,38</sup> These *practice guidelines* represent a compilation of available published evidence, including randomized trials and observational studies. For example, the practice guideline for CABG is available for both practitioners and the lay public on the Internet (<http://circ.ahajournals.org/content/124/23/e652.full.pdf+html>).

Guidelines are a list of recommendations that have varying support in the literature. The strength of a guideline recommendation is often graded by class and by level of evidence used to support the class of recommendation. A typical rating scheme used by the STS Workforce on Evidence Based Surgery and by the Joint American College of Cardiology/American Heart Association Task Force on Practice Guidelines has three classes of recommendations as follows:

- Class I—Conditions for which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective.
- Class II—Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.
- Class IIa—Weight of evidence/opinion is in favor of usefulness/efficacy.
- Class IIb—Usefulness/efficacy is less well established by evidence/opinion.
- Class III—Conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful.

Evidence supporting the various classes of recommendations ranges from high-quality RCTs to consensus opinion of experts. Three categories describe the level of evidence used to arrive at the Class of Recommendation:

- Level A—Data derived from multiple randomized clinical trials or meta-analyses.
- Level B—Data derived from a single randomized trial or nonrandomized studies.
- Level C—Consensus opinion of experts, case studies, or standard-of-care.

Guidelines, derived from assessment of cardiac operations, provide surgeons with accepted evidence-based standards of care that most would agree upon, with an ultimate goal of limiting deviations from accepted standards.

### Other Goals of Performance Assessment (Cost Containment and Altering Physician Practices)

Financial factors are a major force behind health-care reform. America's health-care costs amount to 15 to 20% of the gross national product and this figure is rising at an unsustainable rate. Institutions who pay for health care are demanding change, and these demands are fueled by studies that suggest that 20 to 30% of care is inappropriate with services both underused and overused compared to evidence-based practice standards.<sup>39</sup> This resulted in a shift in emphasis, with health-care costs being emphasized on equal footing with clinical outcomes of care. Sometimes health-care costs and clinical outcomes are combined into a metric that reflects *health-care value* for service rendered.

Variations in physician practice distort the allocation of health-care funds in an inappropriate way. Research suggests that there is a 17-year lag time between medical discovery and when most patients benefit from the discovery. The failure on the part of some surgeons to implement innovation has a huge cost in terms of morbidity and mortality.<sup>40</sup> Solutions to this problem involve altering physician practice patterns to be consistent with best available evidence, something that is difficult to achieve.<sup>41</sup>

### Rewarding High Performers ("Pay for Performance")

Many believe that additional incentives for quality improvement can be obtained by linking quality scores to reimbursement.<sup>42</sup> This concept, commonly called *pay-for-performance* (P4P) or *value-based purchasing*, is supported by a variety of organizations. Effective performance-based payments show positive results in private industrial applications and, in spite of the absence of convincing evidence, there is widespread belief that similar results can be obtained in medicine. P4P is particularly popular among third party payers. Historically payment was based on the number and the complexity of services provided to patients, but with P4P, some portion of payment is determined by the quality rather than the quantity of

services. It remains to be seen whether reimbursement incentives will lead to meaningful improvements in quality of care.

There are several reimbursement models associated with P4P, the most common of which is the *tournament model*. In the tournament approach, there are unequivocal winners and losers. Top performers get bonuses which come from reduced payments to the lower performers. Although popular because of its simplicity, this budget-neutral approach in which one "robs Peter to pay Paul," penalizes precisely the group which most needs financial resources for improvement.<sup>43</sup> Regardless of the mode of implementation, it is obvious that performance measures are destined to be an important and intrinsic part of the surgical milieu in the upcoming years.

### Problems with Assessing Quality of Care—Underuse, Misuse, and Overuse

Assessing the quality of cardiac care is a worthy goal of measuring performance. However, this goal is elusive and hard to define. A major problem arises in attaining this goal because uniform definitions of quality of care are not available. Performance measures are a means of assessing cardiac surgical performance. A logical construct from measuring performance standards is that providers who do not meet the performance standards outlined by these measures are guilty of *misuse* of health-care resources. But there are other indices of health-care quality not covered by these measures, including *appropriateness of care* and *disparities in care* (eg, women and minorities often receiving substandard care). Inappropriate use of procedures is often referred to as *overuse*, and failure to provide indicated care as *underuse*. Both are found in treatment of cardiovascular diseases. For example, there is substantial geographic variation in the rates at which patients with cardiovascular diseases undergo diagnostic procedures, with little, if any, evidence that these variations affect survival or improved outcome. In one study, coronary angiography was performed in 45% of patients after acute myocardial infarction for patients in Texas compared to 30% for patients in New York State.<sup>44</sup> Another study showed large variations in care delivered to patients having cardiac operations.<sup>45</sup> Among six Veteran's Administration Medical Centers that treated very similar patients, there were large differences in the percentage of elective, urgent, and emergent cases, ranging from 58 to 96% elective, 3 to 31% urgent, and 1 to 8% emergent.<sup>45</sup> There was also a tenfold difference in the preoperative use of intra-aortic balloon counterpulsation for control of unstable angina, varying from 0.8 to 10.6%.<sup>45</sup> Similar variations in physician-specific practices exist for mitral valve procedures, carotid endarterectomy and for blood transfusion during cardiac procedures.<sup>46-48</sup> This variation in clinical practice may reflect uncertainty about the efficacy of available interventions or differences in practitioners' clinical judgment.

While wide differences in the use of cardiac interventions initially fueled charges of overuse in certain areas,<sup>49</sup> further evaluations suggest that underuse of indicated cardiac interventions (either PCI or CABG) may be a cause of this variation.<sup>50,51</sup> Whether caused by underuse or overuse of

cardiovascular services, regional variations in resource utilization suggest that a rigorous definition of the “correct” treatment of acute myocardial infarction, as in other cardiovascular disease states, is elusive and the definition of quality of care for such patients is imperfect. Regional variations in cardiovascular care delivery are only a few of the examples of *unclear best practices*. Age, gender, race, community size, patient preference, and hospital characteristics influence utilization of diagnostic and operative interventions without much evidence that these factors should direct the appropriate treatment for various cardiac disorders.<sup>52</sup> While measures that define performance assessment may be a way to judge quality of care among providers, much more work needs to be done to define best practices and to limit practice variations before performance measures accurately reflect quality of care.

## TYPES OF ASSESSMENT OF CARDIAC PROCEDURES

### Assessment Using Operative Mortality

By far, the bulk of available experience with outcome assessment in cardiothoracic surgery deals with operative mortality, particularly in patients undergoing operative coronary revascularization (CABG). Table 7-5 is a partial list of risk models used to assess operative mortality in patients undergoing coronary revascularization. Risk stratification models like those shown in Table 7-5 evaluate mortality outcomes in CABG patients, because mortality is such an unequivocal endpoint of greatest interest to patients and is recorded with high accuracy. For the diagnosis of ischemic heart disease having operative repair, Table 7-5 lists the significant risk factors found to be important for each of the various risk stratification systems. The definition of operative mortality varies among the different systems (either 30-day mortality and/or in-hospital mortality), but the risk factors identified by each of the stratification schemes in Table 7-5 show many similarities. Regression diagnostics validated each of the models in Table 7-5; hence, there is some justification for using any of the risk stratification methods both in preoperative assessment of patients undergoing CABG and in assessing provider performance (either physicians or hospitals). Using the risk models in Table 7-5 for performance assessment of surgeons or hospitals must be done with caution, since, as described previously, risk models are imperfect. Results indicating that a provider is a statistical outlier should always be corroborated by clinical review, and preferably with constructive quality improvement initiatives.

There are many critical features of any risk-adjustment algorithm that must be considered when determining its suitability for profiling provider performance. Daley provides a summary of the key features that are necessary to validate any risk adjustment model.<sup>53</sup> Differences in risk-adjusted mortalities across providers may reflect differences in the process and structure of care,<sup>54</sup> rather than simple outcome assessment, an issue that needs further study.

### Assessment Using Postoperative Morbidity and Resource Utilization

Patients with non-fatal outcomes following operations for ischemic heart disease make up more than 95% of the pool of patients undergoing operation. Obviously all non-fatal operative results are not equivalent. Patients who experience renal failure requiring lifelong dialysis, or a serious sternal wound infection, have not had the same result as a patient who leaves the hospital with no major complications, as occurs in about 85% of patients entered in the STS Database. The complications occurring in surviving patients range from serious organ system dysfunction to minor limitation or dissatisfaction with life style, and account for a significant fraction of the cost of the procedures. We estimate that as much as 40% of the yearly hospital costs for CABG are consumed by 10 to 15% of the patients who have serious complications after operation.<sup>10,55</sup> This is an example of a statistical principle called the *Pareto principle* and also suggests that reducing morbidity in *high-risk* cardiac surgical patients has significant impact on cost reduction.

A great deal of information exists on non-fatal complications after cardiac operations. Several large databases identify risk factors for both non-fatal morbidity and increased resource utilization. Table 7-6 is a summary of some of the risk factors identified by available risk stratification models that are associated with either serious postoperative morbidity or increased resource utilization as measures of undesirable outcomes.

For many years, operative mortality was the sole criterion for a successful CABG procedure. This concept gave way to a broader focus on the entire hospitalization associated with CABG. There is universal agreement that non-fatal complications play a central role in the assessment of CABG quality, but many morbidity outcomes are relatively difficult to define and track. Risk adjustment is particularly difficult because of the fact that risk factors for most complications are not well-established. The low frequency of some complications also creates statistical challenges.

Shroyer and coworkers used part of the large national experience captured in the *STS Database* to examine five important postoperative CABG complications: stroke, renal failure, reoperation within 24 hours after CABG, prolonged (>24 hours) postoperative ventilation, and mediastinitis.<sup>56</sup> Revised morbidity models using contemporary statistical approaches followed this landmark study by Shroyer and coworkers.<sup>26,57,58</sup> In 2009, the STS morbidity risk models were updated using data from 2002 to 2006, with specific models for isolated CABG, isolated valve, and combined CABG + valve procedures. Given the contemporary data and large reference populations, these risk models will undoubtedly play an important role in future attempts at performance assessment.

### Patient Satisfaction as an Outcome

Patients' assessment of surgical outcome is an alternate means of judging performance. There are several difficulties with

measurement of PRO, and consequently cardiothoracic surgeons are not deeply involved with systematic measurements of patient satisfaction after operation. Considerable research deals with instruments that measure patient satisfaction. At least two of these instruments, the *Short-Form Health Survey or SF-36*<sup>59</sup> and the *San Jose Medical Group's Patient Satisfaction Measure*,<sup>60</sup> are used to monitor patient satisfaction over time. The current status of these and other measures of patient satisfaction does not allow accurate comparisons among providers, because the quality of the data generated by these measures is poor. These instruments are characterized by low response rates, inadequate sampling, infrequent use, and unavailability of satisfactory benchmarks. Nonetheless, available evidence indicates that feedback on patient satisfaction data to physicians may impact physician practices.<sup>61</sup> Managed care organizations and hospitals use PRO measures to compare institutions and individual providers.

Risk stratification methodology can identify patients who are optimal candidates for coronary revascularization based on quality of life and functional status considerations. Multivariate risk factors associated with unimproved postoperative

quality of life after CABG include female gender,<sup>62</sup> patients with depressive disorders,<sup>63</sup> and operations complicated by sternal wound infection.<sup>64</sup> One comparative study found no difference between patients older than 65 years and those younger than or equal to 65 with regard to quality of life outcomes after cardiac operations (symptoms, cardiac functional class, activities of daily living, and emotional and social functioning).<sup>65</sup> This study identified a direct relationship between clinical severity and quality of life indicators, since patients with less comorbid conditions and better preoperative functional status had better quality of life indicators six months after operation than those with significant comorbidities. In contrast, Rumsfeld and coworkers found that improvement in the self-reported quality of life (from Form SF-36) was more likely in patients who had relatively poor health status before CABG compared to those who had relatively good preoperative health status.<sup>66</sup> Interestingly, these same authors found that poor preoperative self-reported quality of life indicator was an independent predictor of operative mortality following CABG.<sup>67</sup> These findings suggest that the risks of patient dissatisfaction after CABG are poorly understood but

may be dependent on preoperative comorbid factors as well as on the indications for, and technical complexities of, the operation itself. At present, there is no well-established risk model to identify patients who are likely to report dissatisfaction with operative intervention following CABG.

## USING DATA TO IMPROVE PERFORMANCE—CASE STUDIES

### Management Philosophy and Performance Assessment

American health care made almost unbelievable strides in the last 100 years. We are at the brink of being able to treat disease at the genotypic molecular level. Further, cardiac surgeons treat patients considered inoperable as recently as a decade ago. Yet almost no one is happy with the health-care system. It costs too much, excludes many, is inefficient, and is ignorant about its own effectiveness. A similar state of confusion existed with Japanese industry after World War II. Out of the confusion and crisis of post-World War II, Japan became a monolith of efficiency. Two major architects of this transformation were an American statistician, W. Edwards Deming,

and a Romanian-American theoretician, J. M. Juran. They led the way in establishing and implementing certain principles of management and efficiency based on quality. Their efforts are recognized in Japan by the annual awarding of the *Deming Prizes* in recognition of achievements in attaining high quality. Deming's and Juran's books are some of the classics of quality management in industry.<sup>68,69</sup>

Deming's and Juran's management philosophy are sometimes referred to as *total quality management* or *TQM*. The amazing turn-around in Japanese industry led many organizations to embrace and modify the principles of TQM, including organizations involved in delivery and assessment of health care. Table 7-7 outlines the key features of TQM. A TQM project starts from critical observations. For example, excessive blood transfusion after operation may result in increased morbidity, including disease transmission, increased infection risk, and increased cost. Tools such as *flow diagrams* that document all of the steps in the process are used in a TQM project (eg, steps involved in the blood transfusion process after CABG). A logical starting point for efforts to improve the quality of the blood transfusion process would be to focus on a high-risk subset of patients who consume a disproportionate amount of blood resources. An Italian

**TABLE 7-7: Principles of Total Quality Management (TQM) Applied to Health Care**

Principle	Explanation
Health-care delivery is a process.	The purpose of a process is to <i>add value</i> to the input of the process. Each person in an organization is part of one or more processes.
Quality defects arise from problems with the process.	Former reliance on quotas, numerical goals, and discipline of workers is unlikely to improve quality, since these measures imply that workers are at fault and that quality will get better if workers do better. The problem is with the process not with the worker. Quality improvement involves “driving out fear” on the part of the worker, and breaking down barriers between departments so that everyone may work effectively as a team for the organization.
Customer-supplier relationships are the most important aspect of quality.	<i>A customer is anyone who depends on the organization.</i> The goal of quality improvement is to improve constantly and to establish a long-term relationship of loyalty and trust between customer (patient) and supplier (health-care organization) and, thereby, meet the needs of the patient. The competitive advantage for an organization that can better meet the needs of the customer is obvious. The organization will gain market share, reduce costs, and waste less effort in activities that do not add value for patients.
Understand the causes of variability.	Failure to <i>understand variation in critical processes</i> within the organization is the cause of many serious quality problems. Unpredictable processes are flawed and are difficult to study and assess. Managers must understand the difference between random (or common-cause) variation and special variation in a given outcome.
Develop new organizational structures.	<i>Managers are leaders not enforcers.</i> Eliminate management by objective numerical goals. Remove barriers that rob workers of their right to pride of workmanship. Empower everybody in the organization to achieve the transformation to a quality product.
Focus on the most “vital few” processes.	This is known as the <i>Pareto principle</i> (first devised by Juran) and states that whenever a number of individual factors contribute to an outcome, relatively few of those items account for the bulk of the effect. By focusing on the “vital few,” the greatest reward for effort will occur.
Quality reduces cost.	<i>Poor quality is costly.</i> Malpractice suits, excessive use of costly laboratory tests, and unnecessarily long hospital stay, are examples of costly poor quality. The premise that it is too costly to implement quality control is incorrect.
Statistics and scientific thinking are the foundation of quality.	Managers must make decisions based on <i>accurate data</i> , using <i>scientific methods</i> . Not only managers, but all members of the organization, utilize the scientific method for improving processes as part of their normal daily activity.

economist, Vilfredo Pareto, made the observation that a relatively few factors account for the majority of the outcomes of a complex process. This has been termed the *Pareto Principle*, also known as the “80-20 rule.” Juran was one of the first to apply this principle to manufacturing in the United States and Japan.<sup>69</sup> In medicine, this principle is commonly used to point out that most of the observed complications come from a small part of the overall patient population. Applying the Pareto Principle, one should logically focus attention not on the entire population, but rather on that small population associated with the majority of the problem. A graphical method of identifying the spectrum of outcomes in a process is included in most statistics programs, and is termed a Pareto diagram. Figure 7-2 is an example of a Pareto diagram for blood product transfusion in cardiac operations. Figure 7-2 suggests that about 20% of the patients consume 80% of the blood products transfused following cardiac procedures. Substantial savings in cost and morbidity should result by focusing on decreasing the amount of blood transfusion in these 20% “high-end” users. For TQM purposes, strategies can be devised and tested to decrease blood product consumption in the high-risk subset, and ultimately, monitors are set up to measure the effectiveness of the new strategies. Other tools of TQM such as data sampling strategies and use of control charts play an important role in the process.

One example of using the principles of TQM to improve patient care is to isolate high-risk subsets obtained from population-based risk models. These retrospective risk models (ie, effectiveness studies) are examined to define key elements of the processes of care that contribute to outcomes. The key components of the process are then used as test interventions to improve outcome in high-risk subsets using RCTs (ie, efficacy studies). For example, a population-based risk model of postoperative blood transfusion revealed that the following factors were significantly associated with excessive blood

transfusion (defined as more than 4 units of blood products after CABG): (1) template bleeding time, (2) red blood cell volume, (3) cardiopulmonary bypass time, and (4) advanced age.<sup>70</sup> Based on these retrospective effectiveness studies, investigators hypothesized that process improvement interventions aimed at reducing blood transfusion after CABG would most likely benefit high-risk patients with prolonged bleeding time and low red blood cell volume. A prospective clinical trial tested this hypothesis using two components of the blood conservation process, platelet-rich plasma saving and normovolemic hemodilution, in patients undergoing CABG. Results showed that these two blood conservation interventions reduced bleeding and blood transfusion only in the high-risk subset of patients.<sup>71</sup> These studies imply that more costly interventions such as use of platelet-rich plasma savers are more efficacious in high-risk patients, with the high-risk subset defined by risk stratification methodologies. This approach of using observational risk adjustment models to devise and test hypotheses using efficacy studies is a valuable use of risk assessment models and embodies principles of TQM.

A limitation of any outcomes-based quality improvement project is that knowing outcomes does not necessarily provide the answer to producing better outcomes, rather, it requires the elements of TQM to make meaningful advances. The principles of TQM, including transparent self-assessment and identification of process deficits, are the foundations of quality improvement. Participating in databases like the STS Adult Cardiac Surgery database or the American College of Surgeons National Surgical Quality Improvement Project database does not guarantee adequate performance assessment and quality improvement.<sup>72,73</sup> Leadership, educational tools, EBM guidelines, practice standards, and benchmarking of improvement processes are important, and essential, additions to outcomes measurement for quality improvement.

**FIGURE 7-2** Pareto diagram of blood transfusion in 4457 patients undergoing cardiac procedures over a 4 year period. (Reproduced with permission from Ferraris VA, Ferraris SP, Saha SP, et al.: Perioperative blood transfusion and blood conservation in cardiac surgery: the Society of Thoracic Surgeons and The Society of Cardiovascular Anesthesiologists clinical practice guideline, *Ann Thorac Surg* 2007 May;83(5 Suppl):S27-86.)

## STS Database and Quality Improvement—Transparent Risk Assessment

The STS recognized a compelling need for a national standard in cardiac surgery as early as 1986 with the creation of an STS committee to develop a national database of cardiac surgery. This committee gathered and analyzed data in order to establish a national standard of care in cardiac surgery. The *STS Database* is a voluntary registry that currently collects perioperative patient data from more than 90% of cardiac centers in the United States. Individual participant sites enter extensive clinical data on each patient undergoing cardiac surgery. This information is harvested quarterly and aggregated at the *Duke Clinical Research Institute* (DCRI). The data are analyzed and reports, which include *benchmark data* and risk-adjusted outcomes, are provided to each site. This reporting process allows sites to pinpoint areas in need of improvement so that tailored quality assessment and performance improvement programs can be developed. The database has numerous important practical applications that allow performance assessment and document workload.

The STS database allows accurate determination of thoracic surgeons' workload. Much of the recommendations for surgeon reimbursement stems from the *American Medical Association/Specialty Society Relative Value Scale Update Committee, or RUC* (rhymes with "truck") for short. The RUC's recommendations to the Centers for Medicare and Medicaid Services (CMS) influence the relative values assigned to physician services and, as a result, how much physicians are paid. STS data allows monitoring of trends in the patient profile of cardiac surgery patients over the years. This kind of information impacts negotiations with RUC. Deliberations with the RUC were traditionally based on small surveys but the use of STS data allowed a more accurate presentation of objective information that provides a truly fair and meaningful workload analysis.<sup>74</sup>

The STS database reporting and feedback process to individual sites produced impressive *performance improvements in surgical outcomes*. Database information showed a progressive increase in CABG operative risk from 1993 to 2008. In spite of this risk increase, the observed operative mortality steadily declined from over 4% to approximately 2% during this period. Improvements in process measures like use of the IMA in CABG accompanied these impressive advances in outcome measures.

### Peer-Directed Outcomes Assessment

A superb example of a TQM-based approach to improving cardiac surgery quality is the Northern New England Cardiovascular Study Group (NNECVDSG). Founded in 1987, this voluntary consortium of clinicians, scientists, and administrators represents cardiac surgery programs in Northern New England. Its mission is to study and improve the quality of cardiovascular care provided to patients through the use of systematic data collection and feedback. Shortly after its formation, this group developed and validated a logistic risk

model to account for case mix differences across its member institutions.<sup>75</sup> Using this model, the group analyzed CABG outcomes for 3055 patients operated upon at five medical centers in Maine, New Hampshire and Vermont between July 1987 and April 1989.<sup>76</sup> Overall unadjusted CABG mortality was 4.3% but this varied substantially among centers (3.1 to 6.3%). Even after case-mix adjustment, significant variability persisted among medical centers ( $p = 0.021$ ) and surgeons ( $p = 0.025$ ). In 1990, the NNECVDSG initiated a regional intervention aimed at reducing both absolute CABG mortality and inter-institutional variability.<sup>76</sup> The three major components of this TQM approach included feedback of outcomes data, training in continuous quality improvement techniques, and site visits to each program. During the latter, visitors from each discipline focused on the practice of their counterparts at the host institutions. Numerous changes were implemented as a result of these site visits including technical aspects, processes of care, personnel organization and training, decision-making, and methods of evaluating care. Following these interventions, observed mortality declined to less than expected in all categories of patient acuity.

Following publication of these landmark papers, the Northern New England consortium continued to grow in size, and their registry forms the basis for numerous publications aimed at improving the care of cardiac surgical patients. Their publications cover a wide range of topics including the impact of preoperative variables on hospital and long-term mortality, the optimal conduct of cardiopulmonary perfusion, the prevention of specific postoperative complications, on-pump versus off pump CABG operations, and modes of death following CABG.<sup>77-79</sup> Over two decades since its inception, the NNECVDSG serves as the "poster child" of efforts to improve cardiac surgery quality through voluntary, confidential, and collaborative TQM.

## CONTROVERSIES IN THE ASSESSMENT OF PERFORMANCE

### Dangers of Outcome Assessment

After the introduction of provider report cards in New York and Pennsylvania in the early 1990s, studies emerged suggesting that providers were changing their practice patterns in response to public reporting. The release of risk-adjusted data may alienate providers and result in the sickest patients having less accessibility to care. This may have happened in New York State<sup>80</sup> and in other regions where risk-adjusted mortality and cost data were released to the public.

Of even more concern is the selection bias that may exist in managed care Health Maintenance Organization (HMO) enrollment. Morgan and coworkers suggested that Medicare HMOs benefit from the selective enrollment of healthier Medicare recipients and the dis-enrollment or outright rejection of sicker beneficiaries.<sup>81</sup> This form of separation of patients into unfavorable or favorable risk categories is a direct result of risk assessment and may be an unintended consequence of performance assessment methodology. This type of discrimination

undermines the effectiveness and appropriateness of care. Omoigui and colleagues addressed this issue in a report about the effect of publication of surgeon-specific report cards in New York state.<sup>82</sup> These authors concluded that surgeons in that state were less willing to operate on high-risk patients. Patients in New York state were subsequently transferred in disproportionately large numbers to the Cleveland Clinic, where both their expected and observed adverse outcomes exceeded those of other referral areas without report cards. Although some public figures challenged this “outmigration” phenomenon, additional studies in New York and Pennsylvania suggest that the concept of risk aversion may have some validity.<sup>83,84</sup> Subsequent and more comprehensive analyses of CABG public reporting in New York state could not document any systematic exclusion of high-risk patients from CABG operations, and showed that the severity of illness and comorbidities of operated patients actually increased over the years.<sup>85,86</sup> There may be some degree of risk aversion in public reporting environments, and this could result in denial of care to the high-risk patients that might benefit most from intervention. Others suggest that it may redirect such patients to the most experienced providers, which could be a more positive result.<sup>87</sup>

## Validity and Reliability of Assessment Methods

### ACCURACY OF DATABASES—ADMINISTRATIVE VERSUS CLINICAL DATA

Perhaps the most important tool of any outcome assessment endeavor is a database that is made up of a representative sample of the study group of interest. The accuracy of the data elements in any such database cannot be overemphasized. Factors such as the source of data, the outcome of interest, the methods used for data collection, standardized definitions of the data elements, data reliability checking, and the time frame of data collection are essential features that must be considered when either constructing a new database or deciding about using an existing database.<sup>88</sup>

Data obtained from *claims or administrative databases* are less reliable than those obtained from *clinical databases*. Because claims data are generated for the collection of bills, their clinical accuracy is inadequate and it is likely that these databases overestimate complications for billing purposes. They may incorrectly classify some surgical procedures, and this in turn may result in erroneous and misleading outcomes results.<sup>89,90</sup> Furthermore, claims data underestimate the effects of comorbid illness and contain major deficiencies in important prognostic variables for CABG, such as left ventricular function and number of diseased vessels. The Duke Data-bank for Cardiovascular Disease found major discrepancies between clinical and claims databases, with claims data failing to identify more than half of the patients with important comorbid conditions such as congestive heart failure (CHF), cerebrovascular disease, and angina.<sup>91</sup> The quality of databases used to generate comparisons cannot be overemphasized.

Health-care experts recognize the shortcomings of claims or administrative databases. The primary reason for continued

reliance on these types of data sources is their ease of use and readily available access. Current information suggests that discharge coding accuracy is the major problem in the use of administrative databases for outcomes comparisons. Recent reviews found that coding accuracy improved with renewed emphasis on accuracy.<sup>92</sup> It is likely that the low cost and ready availability of administrative data will continue and even increase as health-care resources are ratcheted down.

### LOGISTIC REGRESSION AND HIERARCHICAL REGRESSION MODELS

One of the most common yet controversial applications of logistic regression models is provider profiling, sometimes mandated by governmental organizations,<sup>93,94</sup> in which case the results are usually published as report cards and made available to the public. The statistical methodology previously used to develop most such report cards is straightforward. The probability of mortality for each of a provider's patients during a given time period is estimated using logistic regression or some other multivariate method based on a large database containing multiple surgeons' patients. These probabilities are aggregated to determine a particular provider's expected mortality, or *E*. The observed mortality, *O*, is simply the counted number of operative deaths. An *O/E ratio* has a value close to one if the performance is what would be predicted from the model. Ratios significantly greater than 1.0 imply worse than expected performance, and ratios significantly less than 1.0 suggest better than expected performance. Often, the *O/E ratios* are multiplied by the population unadjusted mortality rate to obtain the *risk-adjusted mortality ratio* (RAMR).

Statisticians realize that, although intuitively appealing, it is not ideal to aggregate patient-level data to make inferences about providers using logistic regression.<sup>93</sup> Assessing operative mortality among hospitals and among surgeons is inherently multilevel. Multiple levels exist that may alter operative mortality, including surgeons, hospitals, referring physicians, etc. In such situations simply aggregating between levels may lead to erroneous conclusions. Multilevel or *hierarchical models* are available for such situations. These models address most of the major concerns regarding the use of standard logistic regression models. Hierarchical models “shrink” the observed mortality rates of lower volume providers toward the mean of the overall population of providers, a way of borrowing strength or pooling the data from multiple levels of hospitals and providers. The resulting estimates are more accurate and stable. Standard logistic models do not accurately partition the multiple levels of variability (between and within providers), which is one of the central questions to be answered by profiling. Hierarchical models correctly partition this variability and account for sample size variation and compensate for multiple comparisons. Numerous studies investigated the difference in the results of provider profiling obtained from traditional logistic regression versus hierarchical modeling. For example, Goldstein and Spiegelhalter compared a hierarchical model of operative mortality of surgeons in New York state to a traditional single level logistic model, and found reduced number of surgeon outliers using the

hierarchical models.<sup>95</sup> A logical objection to the use of hierarchical models is that, by reducing the chance of false outlier identification, it may also reduce the sensitivity to detect true outliers. Ultimately, this tradeoff is a health policy and regulatory decision.<sup>93</sup> Hierarchical models are complex and require not only extensive computer resources but also close planning and oversight by a statistician experienced in these methods. Most investigators regard them as the best model for multi-level comparisons, and hierarchical modeling is used both by the state of Massachusetts and by the STS for the development of provider profiles.

## The Downside of Performance Assessment

### COST AND IMPERFECTION

Collecting risk-adjusted data for performance assessment and quality improvement adds to the administrative costs of the health-care system. It is estimated that 20% of health-care costs (\$150–\$180 billion/year) are spent on the administration of health care.<sup>96</sup> The costs of implementing a risk-adjustment system are substantial. Additional costs are incurred in implementing quality measures that are suggested by risk-stratification methodology. A disturbing notion is that the costs of performance assessment may outweigh the payers' willingness to pay for these benefits. For example, Iowa hospitals estimated that they spent \$2.5 million annually to gather MedisGroups severity data that was mandated by the state. Because of the cost, the state abandoned this mandate and concluded that neither consumers nor purchasers used the data anyway.<sup>97</sup> Similarly, reports suggest that public release of quality indicators neither improves composite hospital performance nor changes consumer behavior.<sup>98,99</sup> It is possible that quality improvement may cost rather than save money; although one of the principles of TQM (often quoted by Deming) is that the least expensive means to accomplish a task (eg, deliver health care) is the means that employs the highest quality in the process. Ultimately, improved quality will be cost-efficient, but start-up costs may be daunting. In order to be cost-effective, any cost savings realized from performance assessment must be factored into the total costs of gathering risk-adjusted data and implementing performance improvement. Further, given the considerable costs of a single serious complication, such as stroke, dialysis-dependent renal failure, or a sternal infection, the cost savings of avoiding these complications using performance assessment and quality improvement programs may be substantial.

### INTERPRETATION OF RISK-ADJUSTED OUTCOMES

One of the least well understood aspects of performance report cards is the correct interpretation of risk-adjusted or risk-standardized outcomes, which are derived by comparing observed outcomes with those predicted by statistical risk models. There is a tendency by the public, by insurance companies, and by government officials to regard Risk-Adjusted Mortality Ratios (eg, O/E ratios) and Risk-adjusted or

Standardized Mortality Rates as the ultimate metric of provider performance. Compared to unadjusted rates these are certainly superior approaches, but their limitations must be recognized. First, all risk models are only approximations of reality, and they cannot adjust for all possible combinations of risk factors. These models are useful for predicting population average outcomes given a particular patient mix, but they are less useful for predicting the outcome for specific patients and providers. Second, even if there were perfect risk adjustment, the results for a particular provider must be correctly interpreted. The risk-standardized or risk-adjusted mortality for a hospital reflects its performance for its specific patient case mix, compared to what would have been expected had these same patients been cared for by an average provider in the reference population. Because *indirect* rather than *direct standardization* is used for virtually all risk models used in profiling, it may not be appropriate to directly compare the risk-adjusted results of one institution with those of another. The risk-adjusted mortality of a small community hospital is based largely on a low-risk population. Even though it is adjusted, it cannot be compared directly to the risk-adjusted rate of a quaternary referral center, which is based largely on a population of patients that the community program rarely if ever sees. In this extreme example, these two hospitals may have virtually no types of patients in common, and even though their rates are adjusted they should not be directly compared with one another.

### RANKING PROVIDERS—LEAGUE TABLES VERSUS FUNNEL PLOTS

There is a problem with report cards of provider results that appear in the lay press and on the Internet. Most report cards rank providers in the form of *league tables*, similar to tables used in sports to rank teams or individuals. League tables always have someone on top and someone on the bottom. In general, the public does not understand that there is no meaningful difference for the vast majority of names published in league tables of cardiac surgeons' performance.<sup>100</sup> The limited sample size of any individual surgeon or hospital leads to wide fluctuation in outcomes over time. Reporting of one surgeon as being better (ie, higher in the league table) than another is inaccurate and probably unethical. Spiegelhalter addressed this concern and suggested better options for reporting surgeons' and hospitals' results.<sup>101</sup> He advocated *funnel plots* as a far better alternative than league tables to report provider outcomes. A funnel plot is a plot of individual surgeons' volume (x-axis) versus risk-adjusted mortality (y-axis) with population confidence intervals. The plot allows immediate identification of outliers (ie, providers outside the confidence intervals) and gives the viewer an estimate of the larger uncertainties (ie, increased confidence intervals) of risk-adjusted mortality of low-volume providers compared to high-volume providers. The limits of uncertainty (ie, *control limits*) form a funnel around the provider outcome. The United Kingdom Central Cardiac Audit Database (<http://www.ic.nhs.uk/services/national-clinical-audit-support-programme-ncasp/>)

heart-disease/adult-cardiac-surgery) and the STS Congenital Heart Surgery Database Report use funnel plots to identify outliers.<sup>100</sup>

## FUTURE DIRECTIONS

### Effectiveness, Appropriateness, Guidelines, and Standards

#### EFFECTIVENESS VERSUS SAFETY

Since the IOM report on medical errors that appeared in 2000,<sup>2</sup> reducing medical errors both by physicians and by hospitals garnered significant resources. Since then, several authors suggested that the culture of safety in hospitals is unchanged.<sup>102,103</sup> Brennan and coauthors point out that the IOM distinguishes safety from effectiveness. *Effectiveness* is defined as an evidence-based intervention that improves quality, whereas *safety* encompasses a much narrower definition of limiting accidental injury.<sup>102</sup> These authors suggest redirection of health-care goals toward effectiveness interventions and away from accident reduction interventions. An important advantage of focus on effectiveness is the ease with which effectiveness outcomes can be measured compared to safety outcomes. There is some evidence that focus on evidence-based interventions (eg, providing aspirin to cardiac patients when they leave the hospital) improves the effectiveness of treatment with secondary benefit of reducing errors.<sup>104</sup> Furthermore, there is still a reluctance to deal transparently with medical mistakes and identifying problems with safety may be difficult. Health-care providers may not spend significantly increased resources on safety and error management largely because the return on this type of investment is very hard to measure. On the other hand, quality improvement efforts based on evidence of effectiveness are likely to be more readily embraced and may save more lives than will safety-related interventions that lack an evidence base.<sup>102</sup>

#### PRACTICE GUIDELINES AND APPROPRIATENESS CRITERIA

An important part of implementing effectiveness of care is knowing what evidence-based interventions represent best practice. *Practice guidelines provide evidence-based recommendations* for cardiovascular interventions and serve as a template for effectiveness.<sup>37</sup> Professional societies attempted to enhance adherence to evidence-based practice guidelines by introducing *appropriateness criteria*. Appropriateness criteria are lists of appropriate indications for interventions in common clinical scenarios based on available evidence. They document indications for drug or device intervention with a scale metric. For example, the AHA/ACC/STS Joint Task Force generated appropriateness criteria for coronary revascularization that used a scale of 1 to 10.<sup>105</sup> Values of 7 through 10 indicated that coronary revascularization is appropriate for patients with a particular set of risk factors. Scores of 1 to 3 indicate revascularization is inappropriate and unlikely to improve health outcomes or survival. The mid-range scores

(4–6) suggests that improvement in survival or other health-care outcomes with coronary revascularization is uncertain. The aim of appropriateness criteria is to guide physician decision making toward use of evidence-based interventions. It is likely that expansion of the appropriateness criteria concept will occur.

#### GUIDELINES VERSUS STANDARDS

Practice guidelines gained a hallowed position in the hierarchy of evidence starting with Archie Cochrane in the 1950s (see Fig. 7-1). Cochrane championed RCTs as a means of testing medical hypotheses in order to make decisions about best treatment for diseases. His work ultimately led to establishment of the Cochrane Collaboration and the Cochrane Library, a repository of RCTs, meta-analyses, and systematic reviews. Cochrane is arguably the father of EBM, although his definition of EBM in the 1960s was much narrower than the current definition. Today's definition of EBM encompasses practice guidelines that reflect available evidence. The basic principles of EBM are that decisions about medical care should be based on research and that these research recommendations should be ranked based on specific norms (ie, the level of evidence).

Several pieces of evidence suggest that adherence to guidelines and incorporation into clinical practice is suboptimal.<sup>106-108</sup> For example, blood conservation guidelines for cardiac surgery developed by the STS were circulated widely and are among the most cited articles in the thoracic surgery literature.<sup>37</sup> Nonetheless, wide variation in the transfusion of blood products in patients having a standard operation for coronary revascularization persists.<sup>109</sup> A Physician Consortium of the American Medical Association and The Joint Commission identified transfusion as one of the five most overused procedures in the United States ([http://www.jointcommission.org/overuse\\_summit/](http://www.jointcommission.org/overuse_summit/)).

There are many reasons for guideline nonadherence,<sup>106</sup> but it is apparent that implementation strategies need to accompany evidence-based recommendations and dissemination. Professional organizations recognize the limits of guideline development and take a different approach to implementation of evidence-based recommendations. These implementation strategies have various names like standardized practice design, standardized EBM protocol, evidence-based algorithm, decision aids, or perhaps most euphemistically, "organizational recommendations." Collectively implementation strategies define a term called *practice standards*. Standards are a means of operationalizing EBM and practice guidelines. For example, the Society for the Advancement of Blood Management (SABM) recognized the limitations of blood management guidelines as a means of improving transfusion practice. SABM developed blood management practice standards to address this problem. This organization defined twelve patient blood management standards that operationalize blood conservation guidelines and provide a roadmap for the creation of an infrastructure that leads to implementation of evidence-based guidelines. Simply stated, *standards allow conversion of guidelines into bedside practice*. Accompanying the standards are hard outcome measures that are monitored

by multidisciplinary teams. The efforts that go into creating standards parallel the rigor accompanying development of guidelines. While guidelines reflect available evidence, standards indicate how to implement EBM and monitor the success of those efforts in a continuing cycle of implementation and measurement. The introduction of practice standards guides quality assessment, and their increased use is virtually assured given the changing health-care environment.

## Human Factors Research and Performance Assessment

Surgeons make errors in the operating room. The causes of these errors and their ultimate impact on outcomes are an important measure of performance. Human factors are responsible for many errors that affect performance. Human factors research is concerned primarily with the performance of one or more persons in a task-oriented environment interacting with equipment, other people, or both. Structured observation of surgeons by experts in human factor analysis can provide performance assessment and improve outcomes.<sup>110</sup> The airline industry had success in limiting errors by instituting human factor analysis of pilots during simulated flight. This industry is used as a model of successful implementation of error avoidance behavior and process improvement.<sup>111</sup> Several authors report application of these same principles of human factors analysis to pediatric cardiac operations with some success.<sup>112,113</sup> They employed self-assessment questionnaires and human factors researchers who observed behavior in the operating room, an approach similar to the quality improvement steps used in the airline industry. These studies highlight the important role of human factors in adverse surgical outcomes. More importantly, they found that appropriate behavioral responses in the operating room can mitigate potentially harmful events during operation. Such studies emphasize that human factors are associated with outcomes, both good and bad. Behavior modification and process improvement that involves human factor analysis hold promise for error reduction in cardiac surgery.

## Public Reporting and Provider Accountability

Today there is an unprecedented call for accountability and public reporting. That call comes from consumer groups and insurers as it has in the past, but today it is coming from governmental organizations including the US Congress as well. There is now federal legislative force mandating the collection and the release of this information. The Centers for Medicare and Medicaid Services (CMS), for example, made it quite clear that their upcoming “pay for performance” programs will include mandated public reporting of data.

The World Wide Web provides ready access to a wide variety of medical facts, particularly concerning cardiothoracic surgery. Simple Internet searches provide the public with literature reviews of cardiac procedures, the results of randomized trials, new innovations, and surgeon and hospital-specific

outcomes. This ready public access will undoubtedly increase. There is limited external scrutiny or validation of many of the information sources. Most information available on these sites is accepted at face value by the public and quality control of the information sources is limited to self-imposed efforts on the part of the website authors. The *Agency for Healthcare Research and Quality (AHRQ)* attempted to empower the public to critically evaluate the various web-based sources of health-care information in order to limit the spread of misinformation. The success of the AHRQ efforts is uncertain but becomes extremely critical as the amount of health-care information available on the web skyrockets.

The goal of public reporting of performance is to empower consumers to seek optimal care and to modify provider practices to improve outcomes. The ability of public reporting of performance to accomplish these goals is uncertain. Evidence suggests that public reporting does not accomplish any of these stated goals. A Cochrane Review found that public release of performance data neither changes consumer behavior nor improves care.<sup>99</sup> Despite shortcomings associated with web-based public information sources, the national cry for public reporting continues unabated. Recognizing the inevitability of this national movement, the *STS* initiated a project to develop a *public reporting* format that contains clinical data that is meaningful, audited, totally transparent and clinically relevant both for physicians and for the public. In collaboration with *Consumers Union*, the STS began publishing the composite CABG performance measures for those program participants that agreed to do so.<sup>114,115</sup> This information appeared in *Consumer's Report* and was one of the most widely read issues of this magazine ever (<http://www.consumerreports.org/cro/2011/08/looking-for-a-heart-surgeon/index.htm>). There is obvious public interest in information transparency about cardiac operations. The uncertainty is how, or if, the public changes behavior in response to this publically available information. This type of partnership may well become the paradigm for other professional organizations as they manage public reporting. Public reporting of cardiac surgical outcomes provides transparency and has public appeal.

## Information Management: Electronic Medical Records

Medical records are an invaluable source of information about patient risk factors and outcomes. Inevitably computer applications are applied to medical records. Pilot studies assessed the importance of *computerized medical records* in a variety of clinical situations. Perhaps the most important example of successful implementation of computerized medical records lies within the *Veterans Health Affairs (VHA)* medical system in the United States.<sup>116</sup> Over a 20 year period the VHA system of hospitals completed a dramatic conversion from problematic, fragmented care to a nationally recognized health-care delivery system.<sup>116</sup> This transformation was aided, if not completely caused by, the implementation of a costly but highly successful computerized medical record system.

Iezzoni pointed out the difficulties with computerized medical records and suggests that they may not adequately reflect the importance of chronic disability while at the same time prolonging the time that physicians spend documenting care into the computer system.<sup>117</sup> Yet the advantages of reduced medical errors, improved efficiency, and expanded access to medical information all overshadow most objections to implementation of an electronic information system.

Legislation passed by Congress allocates health-care reforms that include an investment of \$50 billion to promote *health information technology*.<sup>118</sup> Further, in its economic recovery package, the Obama administration will spend \$19 billion to accelerate the use of computerized medical records in doctors' offices (<http://www.nytimes.com/2009/03/01/business/01unbox.html>). Medical experts agree that electronic patient records, when used wisely, can help curb costs and improve care. Pending legislation indicates that physicians will be paid a bonus only for the "meaningful use" of digital records, although the government has not yet defined that term precisely. The new legislation also calls for creation of "regional health I.T. extension centers" to help doctors in small office practices use electronic records. It is apparent that the need for data about large groups of patients exists, especially for managed care and capitation initiatives. It is reasonable to expect that efforts to computerize medical records will expand. Applications of electronic medical records that may be available in the future for cardiothoracic surgeons include monitoring of patient outcomes, supporting clinical decision making, and real-time tracking of resource utilization.

Computer applications were applied to the electronic medical record in hopes of minimizing physician errors in ordering. *Computerized physician order entry* (CPOE) is one of these applications that monitors and offers suggestions when physicians' orders do not meet a predesigned computer algorithm. CPOE is viewed as a quality indicator and private employer-based organizations used the presence of CPOE to judge whether hospitals should be part of their preferred network (<http://www.leapfroggroup.org/>). One of these private groups is the *Leapfrog Group* and an initial survey by this Group in 2001 found that only 3.3% of responding hospitals currently had CPOE systems in place (<http://www.ctsnet.org/reuters/reutersarticle.cfm?article=19325>). In New York State, several large corporations and health-care insurers agreed to pay hospitals that meet the CPOE standards a bonus on all health-care billings submitted. Other computer-based safety initiatives that involve the electronic medical record are likely to surface in the future. The impact of these innovations on the quality of health care is untested and any benefit remains to be proven.

The success of information technology used to reduce medical errors is mixed. Innovations that employ monitoring of electronic medical records may reduce errors.<sup>119</sup> However, with the increasing implementation of commercial CPOE systems in various settings of care, evidence suggests that some implementation approaches may not achieve previously published results or may actually cause new errors or

even harm.<sup>120</sup> Much work needs to be done before computer-aided methods lead to medical error reduction but the future will see more efforts of this type made. The increasing role of CPOE systems in health care invites much more scrutiny about the effectiveness of these systems in actual practice.

# Simulation in Cardiac Surgery

Jennifer D. Walker • Philip J. Spencer • Toni B. Walzer  
• Jeffrey B. Cooper

Of the many developments in cardiothoracic surgery, the introduction of a broad spectrum of simulation techniques for education and training of students and residents as well as ongoing faculty training are among the most exciting and critical for the continued advancement of the specialty. There are increasing demands for safety during training, for training to be more effective and efficient, and have minimal impact on the process of patient care. The productivity of training for physicians has advanced in many ways; simulation is one approach to teaching that offers solutions to challenges in training in general and especially in cardiac surgery. In this chapter, we describe a spectrum of simulation technologies and techniques that are being applied to address these challenges. We also address approaches to using simulation to its greatest effect and speculate about future technologies and applications and how they will be integrated into education at all levels of experience.

## BACKGROUND

Simulation has been described as a “technique, not a technology, to replace or guide real experiences with guided experiences that evoke or replicate substantial aspects of the real world in a fully interactive manner.”<sup>1</sup> The roots of simulation in medicine can be traced back for centuries. More recent applications in the 1960s and 1970s for training in specific tasks include the Sim One for teaching in anesthesia residency, Resusci Anne for training in cardiac life support, and Harvey for teaching about cardiology to medical students.<sup>2</sup> The more modern era of simulation began in earnest in the late 1980s with the development of more realistic mannequins for teaching basic skills and management of crises in anesthesia. Surgeons have long used various forms of simulation, from tying knots on paperclips placed in clay to cadavers and animals. The first use of a model simulator was introduced by Howard in 1868 in which a mannequin was created to teach hernia repair.<sup>3</sup> But, more technology-based forms of task trainers for various surgical and procedural skills appeared beginning in the late 1980s.<sup>2</sup>

For many reasons, the use of simulation is growing in all of healthcare, and specifically in cardiac surgery. Ziv and colleagues described the adoption of simulation in surgical training as an ethical imperative noting patient safety as their cause.<sup>4</sup> With patients having increased acuity, practicing outside of the operating room is critical for mastering tasks to quickly develop critical skills without exposing patients to increased risk. Practice via simulation has been shown to increase speed for completion of coronary anastomosis<sup>5</sup> as well as increase speed and accuracy of mitral valve annuloplasty.<sup>6</sup> Through deliberate practice (rehearsing a task or behavior repeatedly), simulation provides the ability to advance the mastery of some skills more quickly, reducing operating time related to training. Simulation is also the preferred modality to improve teamwork and communication and to practice emergencies not frequently seen during training. It enables surgeons and teams to work out complex problems in a nonthreatening setting and apply the lessons to urgent and emergent situations.

Surgical simulation may provide an important modality for measuring proficiency for certification, recertification, or for judging appropriateness of clinical advancement within a training program. For example, a particular task such as anastomosis of one small vessel to another has many components that can be evaluated for simple tasks such as instrument use, suture handling, and tissue handling. The same tasks can be integrated into a more complex scenario on a higher fidelity simulator; for example, rather than sewing a simple anastomosis, anastomoses may be incorporated into a beating-heart coronary artery bypass graft (CABG) on the simulator. Graft measurement, appropriateness of anastomotic site, vessel opening, and preparation can be evaluated. In addition, these tasks can be incorporated into the entire bypass procedure for more advanced learning as training progresses.

Simulation education has gained significant traction in cardiac anesthesia training as well. Bruppacher and colleagues performed a randomized controlled trial in which anesthesia residents were randomized to simulation training and no simulation training for cardiopulmonary bypass weaning.<sup>7</sup> The residents were evaluated using an internally validated

**FIGURE 8-1** Porcine heart in Ramphal Simulator.

scoring system administered by blinded attending anesthesiologists before and after simulation training. The residents who underwent two hours of simulation training improved significantly more than the residents who underwent two hours of didactic instruction.

The most exciting advancement in cardiac surgical simulation training occurred in 2005 when Ramphal created a relatively high realism porcine beating-heart model to address the shortage of cardiac surgery cases being afforded to residents in training in Jamaica<sup>8</sup> (Figs. 8-1 and 8-2). The simulator was adapted by a leadership group in cardiothoracic surgery in the United States and incorporated into focused programs to advance simulation-based learning. The Thoracic Surgery Foundation for Research and Education's (TSFRE) annual Boot Camp conference and "Senior Tour" are sponsored by the Thoracic Surgery Directors' Association and the American Board of Thoracic Surgery and the Joint Counsel on Thoracic Surgical Education (JTSE).<sup>9</sup> The three-day, well-orchestrated simulation curriculum has been conducted since

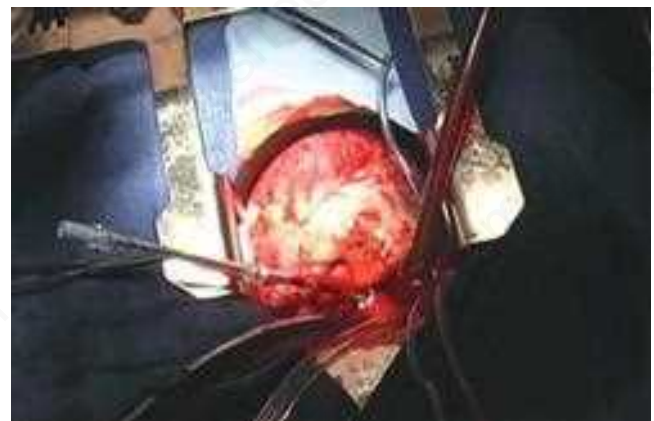

**FIGURE 8-2** Anesthesia monitor during simulation with the Ramphal Simulator.

2008 and provides focused learning for first-year cardiothoracic residents with feedback and standardized evaluations. Standardized evaluation of first-year residents participating in the "Boot Camp" consistently show improvement in time to complete basic cardiothoracic techniques as well as accuracy.<sup>10,11</sup>

Creating a successful cardiac simulation program requires understanding and application of the principles of adult learning. In 1993, Reznick<sup>12,13</sup> described the process of adults learning surgery and the relationship between the trainee and expert instructor. He referenced key educational literature describing Kopta's three stages of adult learning, perception, integration, and automatation<sup>14</sup> as well as Collins' framework for the apprenticeship model characterizing the roles the teacher plays as the student progresses from novice to expert.<sup>15</sup> Those principles are applied to how we approach simulation-based training in all aspects. We next present the current state of how this is done for training in basic skills, what specific procedures currently can be simulated, and what existing simulators are available for cardiac and thoracic surgery.

## BASIC SKILLS TRAINING

For cardiothoracic surgery, simulation training begins with teaching of component tasks, starting at the most basic level and combining those into multiple tasks and then full procedures. A consortium of six hospitals (Massachusetts General Hospital, University of North Carolina Chapel Hill, Johns Hopkins, University of Rochester, Stanford University, Vanderbilt University, and University of Washington) developed a 7-week syllabus, broken down into multiple key concepts and procedures consisting of cardiopulmonary bypass (Fig. 8-3), CABG (Figs. 8-4 to 8-7), valve replacement (Figs. 8-8 to 8-10), air embolism, and acute intraoperative aortic dissection (Fig. 8-11). First, fundamentals of cardiopulmonary bypass are taught step by step, including cannulation of the aorta, right atrium, and cardioplegia perfusion with repetitive practice on a perfused porcine heart. Concomitant

**FIGURE 8-3** Porcine heart in the Ramphal Simulator cannulated for cardiopulmonary bypass.

**FIGURE 8-4** Synthetic artery and vein grafts for coronary artery bypass simulation.

**FIGURE 8-7** "Dry" porcine heart with synthetic grafts simulating distal anastomosis for CABG.

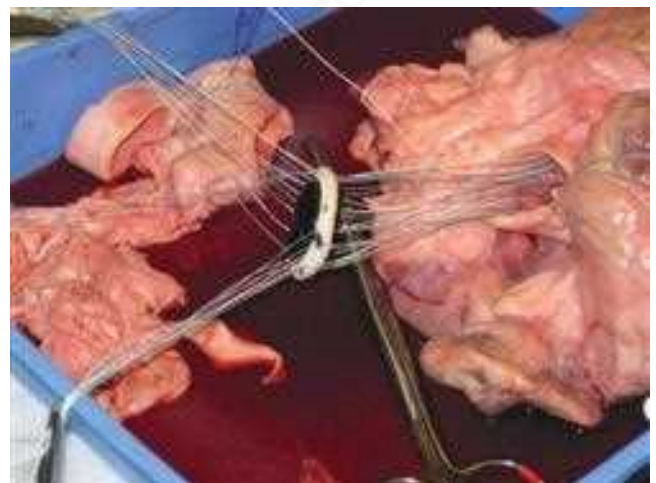

**FIGURE 8-5** Synthetic graft anastomosis to synthetic aorta to simulate the proximal anastomosis of coronary artery bypass graft.

**FIGURE 8-8** Mitral valve repair on Chamberlain Group synthetic mitral valve model.

**FIGURE 8-6** Chamberlain Group synthetic internal thoracic artery for use in coronary artery bypass graft simulation.

**FIGURE 8-9** "Dry" porcine heart simulation of mechanical aortic valve repair.

**FIGURE 8-10** Simulation of mechanical aortic valve repair on Ramphal beating heart simulator.

with learning the technical aspects of these tasks is a memorization and understanding of the concept of initiating and weaning from cardiopulmonary bypass. The component tasks are then combined with the knowledge base on a higher fidelity model after practicing on the dry porcine heart. The student then integrates these steps using a beating-heart model to fully cannulate, institute bypass, arrest the heart, wean from bypass, and decannulate. The trainee is assessed in a standardized fashion by the expert instructor. The same process of moving from simpler tasks with low-fidelity models to more sophisticated and integrated tasks on higher fidelity simulators is conducted for the five components of the curriculum.

Deliberate practice prepares trainees to apply the basic principles of cardiac surgery to more complicated groupings of tasks. In the CABG component of the curriculum, the resident performs large and small vessel anastomoses, first on a component simulator and later on a porcine heart. The

**FIGURE 8-11** Aortic anastomosis on “dry” porcine model.

trainee will later combine the steps to perform a full coronary bypass operation on the beating-heart simulator. This process is repeated with the basics of aortic valve surgery. That training begins by teaching the resident about the anatomy of the aortic valve and root and exposing it in the anatomic dissection on the porcine heart. The resident will next practice excising the valve, placing sutures in the annulus repetitively, ultimately seating and tying in all different types of valves until they become proficient. Once this task is mastered, it is incorporated with the previously mastered bypass skills to perform an aortic valve replacement on the beating-heart simulator.

In a similar fashion, mitral valve surgery can be learned. After these basic techniques have been practiced repeatedly, more advanced teaching that incorporates team training and dealing with emergencies can be simulated.

The training via simulation can include creating a plan, implementing that plan with the team in a dry model, and then carrying it out on the beating heart simulator. As noted above, specific emergencies that have been vetted on a simulator include managing aortic dissection at the cannulation site, managing massive air embolism and problems that can occur when weaning off cardiopulmonary bypass, for example, right heart failure, kinked or twisted grafts that can be too long or too short, leaks around the valve, and aortic root dissection. Simulation training is reaching beyond OR-based procedures to bedside invasive resuscitation and surgery.

In cardiac surgery, research has demonstrated that a model neck-cannulation trainer can improve trainee's ability to cannulate the neck vessels for extracorporeal membranous oxygenation (ECMO) resuscitation.<sup>16</sup> Chan and colleagues used a similar model but included a full pediatric intensive care unit (PICU) team in their ECMO training and evaluation.<sup>17</sup> These were not evaluated by assessing participants' skills during the cannulation of a live patient, however. Simulation is also being used to train perfusionists. Morris and Pybus describe a simulated (Orpheus) perfusion machine that can be used for training in the operating room or in a simulation center.<sup>18</sup> Lansdowne and colleagues describe using the same simulator for training perfusionists and respiratory therapists on ECMO management.<sup>19</sup> A new, exciting, and different use of simulation is 3-D printing for operative planning.<sup>20-22</sup> Valverde and colleagues used magnetic resonance imaging (MRI) and angiography to design a 3-D-printed model to plan endovascular stenting of an aortic arch coarctation in a 15-year-old boy.<sup>23</sup> Costello and colleagues even used 3-D printing as an educational model to train residents on ventricular septal defect (VSD) repair.<sup>24</sup>

Trainees can also be led to assimilate hemodynamic information and practice communication skills with other personnel, including anesthesiologists, perfusionists, and nurses. While basic skills can be taught in a laboratory setting, teamwork skills can be taught in a high-realism operating room setting. This multimodal approach, with the gradation from low technology to high fidelity makes a rich environment not only for teaching but also for performance evaluation (see below).

## SIMULATORS

In order to accomplish the teaching goals discussed above, many simulators have been developed over the years. These include full mannequin simulators, part task trainers, and virtual reality systems.<sup>25</sup> These are used in various forms to meet the specific training objectives. For training on specific cardiac surgical tasks, various forms of models of the heart and blood vessels have been developed. Virtual reality simulators generally are most useful for laparoscopic procedures. In cardiac surgery, mannequin simulators are mostly used as part of an overall cardiac surgical operating room environment, especially for team training and can also be used for practice of an entirely new procedure.

For training in cardiac surgical procedures, part task trainers have been developed to enable practice on a range of tasks from the most simple and to some more complex. Some of the most realistic cardiac surgery simulation tools have come from the Chamberlain group [Great Barrington Massachusetts] (Figs. 8-4, 8-6, and 8-8). Limbs and Things [Savannah Georgia] and the Wet Lab facility in the United Kingdom (Fig. 8-12) have all been instrumental in providing synthetic and tissue-based simulators. Despite the simulators that are available, many tasks that are required in cardiac surgery do not fit into a typical commercial simulation product. As a result, porcine hearts have become the mainstay for teaching cannulation and many of the other elements of cardiac surgery such as CABG and valve replacement and repair mentioned above. As shown in the accompanying figures, much work has been done to develop perfused pig heart models to more realistically simulate the cannulation scenarios (Figs. 8-1, 8-3, and 8-10).

There is now a 25-year history of using simulation for training in communication and other teamwork skills.<sup>2,26</sup> Generally, this has involved the use of full-body, mannequin simulators of varying degrees of realism and fidelity. The early work of Gaba and colleagues has been widely disseminated and such mannequin simulators are used in thousands of

**FIGURE 8-12** Disposable Wet Lab station. (Used with permission from Wetlab Ltd.)

centers around the world. The mannequins typically have the features that are needed to simulate many of the characteristics of patient physiology during surgical procedures, for example, audio of a beating heart, respiration, pulses, blinking eyes, and constricting pupils. Placed in a realistic operating room setting, complete with all surgical, anesthesia, nursing, and other paraphernalia, the mannequins enable creation of a setting that is realistic enough to engage teams of operating room professionals into scenarios that mimic many types of critical events that occur during surgical procedures (Fig. 8-13). The mannequins can be enhanced by incorporation of cardiac surgical anatomy and bypass, allowing simulation of an entire procedure and are especially useful for team training and practice for emergencies (see section below) (Fig. 8-14).

## SIMULATION AND TEAMWORK TRAINING IN CARDIAC SURGERY

The importance of teamwork to patient safety and efficiency is now well recognized in healthcare.<sup>27</sup> It has been more than two decades since anesthesiologist David Gaba and colleagues brought Crew Resource Management principles from aviation to healthcare and developed a training program he called Anesthesia Crisis Resource Management (ACRM) to teach anesthesiologists to handle critical events in the OR.<sup>26,28</sup> ACRM recognizes that anesthesiology has many similarities to aviation. The environment of the OR, including all of the professionals who work there, is complex and dynamic requiring effective coordination of skills and resources for safe patient care. Similar to aviation, a majority of incidents and accidents in anesthesia involved some level of human error despite technical expertise.<sup>28</sup> There is similar evidence that the same is true for surgery in general and cardiac surgery in particular.<sup>29,30</sup>

The patient safety movement is giving increasing attention to improving team performance in delivery of care. Healthcare professionals from different disciplines and professions must coordinate their activities to make patient care safe and efficient. Those working in a healthcare team, including in cardiac surgery, typically have diverse educational backgrounds and have different experience and perspectives; and they are rarely trained together. Simon and colleagues were the first to demonstrate that formal teamwork training can lead to improvement in staff attitudes toward teamwork, quality of teamwork, and a significant reduction in observed clinical errors in teamwork-trained emergency departments.<sup>31</sup> Despite recognition of the importance of teamwork and existence of teamwork programs, there does not yet seem to be deep penetration or routine training for healthcare professional teams. Interprofessional training in general is lacking in healthcare.<sup>32</sup>

The complexity of medical care is a challenge to the effective communication and teamwork essential for the delivery of high quality and safe patient care. Poor communication and poor teamwork have been shown to be one of the major

**FIGURE 8-13** Simulated operating room viewed from control room.

contributors to adverse events.<sup>33</sup> Communication failures are the leading cause of inadvertent patient harm. Teamwork failures in the operating room have been linked to a higher risk of complications and death.<sup>33</sup> The clinicians providing care had very different views of what was expected to happen; they did not share the same mental model and often did not have an environment to speak up when there were safety concerns. Even the most skilled, experienced, and highly motivated clinicians have performance limitations and will make mistakes. Effective communication can help prevent these mistakes from becoming consequential and harming patients.<sup>34</sup>

The practice of surgery is an area of major risk for malpractice insurers. Root-cause analysis of claims from the Harvard-affiliated malpractice insurer Controlled Risk

Insurance Company, Risk Management Foundation (CRICO/RMF) and other major insurers show that errors in surgical care most commonly occurred in the operating room. Communication breakdowns were the second most common factors identified in contributing to error, after technical performance.<sup>35</sup>

A growing body of evidence links teamwork in surgery to improved outcomes.<sup>36</sup> Elements of the Surgical Safety Checklist can be used as an actual briefing to enhance teamwork. Voicing one's name, role, and concerns not only gets the entire team on the same page but makes the environment more open for any team member to speak up throughout the case. This struggle over speaking up in a clinical domain is consistent with research in the organizational behavior domain.<sup>37</sup> Interviews with employees have shown that they perceived risks of speaking up to be personal and immediate, whereas they were uncertain of the benefit of sharing their ideas. There was a powerful protective instinct that inhibited speech; employees played it safe by keeping quiet.<sup>38</sup> People have difficulty in speaking up across a hierarchical gradient; such gradients exist in the operating room environment.

Communication breakdowns and lapses in teamwork are a leading cause of errors in the operating room resulting in preventable patient harm, second only to technical errors. Analyses from closed claims from both the American Society of Anesthesiologists and the American College of Surgeons found poor communication both inside and outside the operating room to be a significant cause of preventable adverse events. Technical errors were significantly more likely to be deemed preventable if they were also accompanied by communication failures.<sup>39,40</sup> Studies have supported the concept that interventions designed to improve teamwork and

**FIGURE 8-14** Simulated cardiac surgical field.

communication may have beneficial effects on technical performance and patient outcome.<sup>41</sup>

Risk management data for CRICO/RMF has shown that the anesthesiologists' already good malpractice profile improved, since the anesthesia staff began participating in Anesthesia Crisis Resource Management training.<sup>42</sup> Encouraged by their success, CRICO/RMF promoted simulation-based team training as a risk control strategy for obstetrical providers. CRICO/RMF later concluded that formal training in communication and teamwork for obstetric clinicians could ultimately mitigate or prevent adverse perinatal events. An interprofessional simulation-based team-training course for obstetric clinicians was systematically designed as advocated by Salas and Cannon-Bowers and modeled after the successful ACRM training. Risk management data from CRICO/RMF has shown that the number of claims has been trending down in the Harvard-affiliated institutions' obstetric departments since their faculty obstetricians and midwives have participated in this course. As a result of this trend, CRICO continues to offer a significant reduction in malpractice insurance premiums to obstetricians and certified nurse midwives who participate in this training.<sup>43,44</sup>

Arriaga and colleagues note that there is a growing call for simulation team training programs with the entire operating room teams on a large scale.<sup>45</sup> They described a standardized multicenter high-fidelity simulation-based team-training pilot program. This program was developed with the interprofessional make-up of the team in mind, ensuring that it was clinically relevant to all of the participants. Simulation scenarios that had been used effectively to train anesthesiologists were adapted to include tasks for the surgeons, nurses, and other professions on the operating room team. Surgical props and models were used to keep the surgeons engaged (Fig. 8-14). Ninety-two percent of participants found the scenarios to be realistic, appropriately challenging, and clinically relevant toward providing safer care.<sup>45</sup> Debriefing of the cases was done by faculty who received training in giving feedback in a direct, clear, and respectful way that was supportive and consistent with "debriefing with good judgment."<sup>46</sup> They found that, despite the simulated crises with chaotic operative environments, more than 96% of participants were comfortable being open and honest with each other in the debriefing. Surgeons commented on the value of improving their communication skills and anesthesiologists and nurses on their desire to improve assertiveness. The vast majority of participants believed the course had a meaningful impact on their approach to clinical practice.

Cardiac surgery is a particularly stressful and intense environment which requires effective teamwork and communication for resolution of acute events and prevention of adverse outcomes. Cardiac surgery operating room teams are generally large interprofessional teams with established hierarchy and requiring seamless coordination. The procedures can be technically challenging and emergencies are common. There can be many challenges with complex bypass equipment, multiple drug infusions, and lack of standardization allowing for individual surgeon's preferences for equipment and

cardioplegia. Communication is even more essential with complicated patients and the interruption of continuity of care with work hour limitations.

Stevens and colleagues sought to provide a comprehensive program to sharpen performance of experienced cardiac surgical teams in acute crisis management.<sup>47</sup> They developed and implemented a program of simulation-based training with high enough realism, including a bypass simulator, to engage an entire cardiac surgery team, including surgeon, anesthesiologist, nurses, perfusionists, and physician assistants. Realistic simulated scenarios engaged the team in critical events that elicited teamwork skills, including effective leadership of event management and specific communication skills. As is always done in such training, the simulated cases were each followed by a debriefing by trained facilitators. Critical elements of information sharing in the cardiac surgical environment were identified and ways to optimize their interpersonal communication and team response were discussed. The program also included an interactive, four-hour workshop for the entire hospital cardiac surgical service.<sup>47</sup>

Based on perceptions of the participants, this program was judged to have positive impact within the cardiac surgical service. Focus group participants noted feeling that patient care had improved as a result of this training. The surgeons interviewed reported that they were conducting briefings and other participants described desirable teamwork behavior changes prompted by the program. Eighty-two percent of participants recommended repeat simulation training every 6 to 12 months. The interactive workshop participants identified speaking up about critical information and interprofessional information-sharing as the areas of highest priority.

Involving the full operating room team in teamwork training has presented challenges including logistical and financial barriers. While simulations for operating room professionals have been conducted for many years, the inclusion of practicing surgeons appears still to be rare. Where OR teamwork training is conducted, the role of the surgeon is often played by a member of the team who is of a different profession. Indeed, the use of simulation-based training for surgery to date has been on acquisition of technical skills for surgeons. Less importance is given to the nontechnical skills of communication, leadership, and teamwork. Despite these challenges and small sample size of studies that include attending surgeons, the results suggest a significant positive impact on team performance.<sup>48</sup> As a result of the perceived success of surgical teamwork training pilot programs, CRICO/RMF expanded its malpractice insurance premium incentive program to include surgeons in high-risk specialties. Cardiac and other surgeons participating once every two years in a six-hour simulation-based training with a full operating room team qualify for a ten percent lower annual premium.<sup>a</sup>

<sup>a</sup>Personal communication, William Berry, MD.

## SIMULATION AS AN EVALUATION TOOL

While simulation has predominantly been used in cardiac surgery as a method for training cardiothoracic surgical residents, simulation also holds the potential to be used as a standardized evaluation tool. This would provide objective criteria for certifying trainees as possessing the competence required to operate independently. In 1997, Martin and colleagues validated the Objective Structured Assessment of Technical Skills for general surgery skills.<sup>49</sup> In 2013, de Montbrun and colleagues validated a similar tool to assess technical competence for colorectal surgical skills.<sup>50</sup> Methods for using simulators to assess task-specific competency for coronary anastomoses, mitral valve surgery, and perfusion management are currently being developed and tested<sup>5,6,51</sup> (Tables 8-1 and 8-2). In 2013, Lee et al. evaluated the Joint Council on Thoracic Surgery Education Coronary Artery Assessment Tool for interrater reliability.<sup>52</sup> The JTSE tool for coronary anastomosis consists of 13 assessment parameters, which are scored on a Likert scale from 1 (poor) to 5 (outstanding). Lee had 10 attending-level surgeons ranging from 2 to 33 years of practice watch videos of a medical student, a resident, a fellow, and two attending surgeons operate on a low-fidelity simulator, high-fidelity simulator, and in a human CABG. The study reported high interrater reliability and internal consistency for this scoring system suggesting it may be useful for assessing trainee's competence for coronary anastomosis.<sup>52</sup> Currently, however, no assessment tools have been validated as a standard assessment tool in cardiothoracic surgery.

## FUTURE DIRECTIONS

Ericsson presented evidence that achievement of expert performance in challenging professional domains requires on the order of 10,000 hours of deliberate practice, including mentoring via a coach.<sup>53</sup> Modern clinical residents do not complete their training with nearly 10,000 hours of operating time, not to mention deliberate practice time, and it is doubtful they ever could. Simulation has the promise of offering the opportunity to acquire more deliberate practice particularly in technical skills both during training and throughout a lifetime of surgical practice. Furthermore, because of both safety and efficiency demands, the modern resident should enter the operating room coached on basic skills prior to first being involved in direct patient care. Training programs are moving in that direction, but much more needs to be done before all aspects of pre-training can be accomplished, especially for challenging technical tasks and even more so for all of the areas of surgical care that involve judgments before and during an actual procedure.

This chapter has described a number of the current simulation paradigms available in cardiothoracic training from synthetic to tissue-based, from low- to high-fidelity. However, we are far from a systematic curriculum utilizing these tools. Future training programs will need to develop a training paradigm where residents spend time in simulation with a coach prior to entering the operating room. Baker and colleagues suggested one possible method to design such a curriculum in 2012.<sup>54</sup> Training should begin on low-fidelity simulators where interns and junior residents can learn basic suture

 **TABLE 8-1: Components of Performance Rating Scores**

1. Graft orientation (proper orientation for toe-heel, appropriate start and end points)	1	2	3	4	5
2. Bite appropriate (entry and exit points, number of punctures, even and consistent distance from edge)	1	2	3	4	5
3. Spacing appropriate (even spacing, consistent distance from previous bite, too close vs too far)	1	2	3	4	5
4. Use of Castroviejo needle holder (finger placement, instrument rotation, facility, needle placement, pronation and supination, proper linger and hand motion, lack of wrist motion)	1	2	3	4	5
5. Use of forceps (facility, band motion, assist needle placement, appropriate traction on tissue)	1	2	3	4	5
6. Needle angles (proper angle relative to tissue and needle holder, consider depth of field, anticipating subsequent angles)	1	2	3	4	5
7. Needle transfer (needle placement and preparation from stitch to stitch, use of instrument and band to mount needle)	1	2	3	4	5
8. Suture management/tension (too loose vs too tight, use tension to assist exposure, avoid entanglement)	1	2	3	4	5
9. Knot tying (adequate tension, facility, linger and hand follow for deep knots)	1	2	3	4	5

Scores: 1, excellent. Able to accomplish goal without hesitation, showing excellent progress and flow; 2, good, able to accomplish goal deliberately, with minimal hesitation, showing good progress and flow; 3, average, able to accomplish goal with hesitation. Discontinuous progress and flow; 4, below average, able to partially accomplish goal with hesitation; 5, poor, unable to accomplish goal, marked hesitation (adapted from the Objective Structured Assessment of Technical Skill<sup>®</sup>).

techniques and knot tying progressing to high-fidelity simulation such as the synthetic-beating heart simulator where they can practice aortic cannulation and coronary anastomoses.<sup>54</sup> We expect that competency-based training programs such as described by Ferguson et al. for orthopedic surgery will become more widely used throughout surgery and rely heavily on all of the various forms of simulation.<sup>55</sup>

Simulation for team training likewise is at the early stages of integration into surgical practice. For all types of simulation and other experiential training outside of the direct patient care setting, there is a substantial economic and cultural barrier. The current apprenticeship form of training does not easily accommodate simulation since it requires removing the training from patient-care-related activities, which of course have their own value in developing expertise and are challenged by increasing complexity of care, the need for sub-specialization, and work-hour restrictions.

Another area of utility for cardiac surgical simulation will be for introducing new technologies into the flow of established operations. Opening of a new operating room or suite of rooms, introducing a new type of procedure or new technologies can benefit from conducting simulations before initial utilization. This has been done for numerous other healthcare domains, but we are not aware of a specific published application in cardiac surgical care.<sup>56,57</sup>

Currently, most simulator technologies have a limited repertoire of patient pathology and variations from the normal distribution of anatomy aberrations. And, there are few simulation tools designed to develop judgment for pre- and intra-procedure decision-making. Thus, for the advances above to be achieved, much more technically accurate and biologically diverse simulations must be developed. The increasing use of 3-D printing of patient-specific, anatomically correct organ and body area by combining 3-D imaging and using 3-D printing to build a simulated surgical site is also likely to gain

more widespread use and will further enable optimization of surgical approach, practice in performing a complex, atypical procedure and team training required to do that safely and efficiently.

We expect that simulation in all its various forms will be increasingly applied in cardiac surgery as the technology advances and as innovation responds to the demands for greater safety and process efficiency.

# The Integrated Cardiovascular Center

*T. Konrad Rajab • Lawrence Lee • Vakhtang Tchantchaleishvili  
• Mandeep R. Mehra • John G. Byrne*

Cardiovascular care is the diagnosis, treatment, and prevention of cardiovascular disease. Cardiovascular disease includes pathology of the heart and the peripheral vasculature. It remains the number one killer in the United States. The 2010 overall rate of death attributable to cardiovascular disease was 235.5 per 100,000. On the basis of this death rate, more than 2150 Americans die of cardiovascular disease each day, which corresponds to 1 death every 40 seconds. However, the death rate attributable to cardiovascular disease has declined by 31% from 2000 to 2010.<sup>1</sup> The reasons for this include progress in preventive medicine as well as better treatment of risk markers like hypertension and hyperlipidemia, timely application of reperfusion therapy for acute myocardial infarction and better access to cardiovascular operations and procedures. This has correlated with a dramatic increase in the volume of cardiovascular care. For example, there were approximately 6,000,000 inpatient cardiovascular operations and procedures in 2000, which increased by 25% to approximately 7,500,000 inpatient cardiovascular operations and procedures in 2010.<sup>1</sup> As a result of these trends, cardiovascular care comes at a larger cost to society. The total direct and indirect costs of cardiovascular disease and stroke in the United States in 2010 were estimated at \$315.4 billion.<sup>1</sup>

## EVOLUTION OF CARDIOVASCULAR SUBSPECIALTIES

Cardiovascular care is provided by a number of different cardiovascular subspecialties. This includes cardiac surgeons, cardiovascular physicians, interventional cardiologists, interventional and noninterventional radiologists, vascular surgeons, cardiovascular anesthesiologists, critical care specialists, and primary care physicians. Each of these subspecialties has evolved from very different historical roots. For example, cardiac surgery emerged from general surgery during the Second World War, when Dwight Harken successfully removed foreign bodies in and around the heart of some 130 injured soldiers.<sup>2</sup> In contrast, interventional cardiology emerged from radiology when Dr. Charles Dotter performed the first-ever

angioplasty procedure in a leg artery at the Oregon Health and Science University in Oregon<sup>3</sup> and, building on his work, Dr. Andreas Gruentzig performed the first balloon angioplasty procedure on a coronary artery.<sup>4</sup> Similarly, each of the other subspecialties that contribute to cardiovascular care has evolved from distinct historical roots. As a result of these different historic roots, providers of cardiovascular care were originally organized in separate medical school departments according to the patient populations that their disciples historically served and the instruments that were historically used in their clinical practice.

## EVOLUTION OF CARDIOVASCULAR CENTERS

The departments of early medical schools were initially formed by individual professors and their assistants. Subsequent expansion of the departments increased their organizational complexity but they continued to operate as separate units under the leadership of autonomous chairmen.<sup>5</sup> Advances in medical research in the twentieth century resulted in the emergence of departmental subspecialists who predominantly treated one specific organ. Consequently, many medical school departments established divisions that focused on particular organ systems.<sup>5</sup> As the divisions became ever more specialized, the clinical interests of individual divisions of separate departments began to overlap more with each other than with the rest of their respective departments. In particular, the emergence of cardiac surgery as a subspecialty resulted in a symbiotic relationship between cardiac surgeons and cardiologists.<sup>5</sup> Moreover, cardiac surgeons and cardiologists increasingly relied on specialized cardiovascular radiologists and cardiovascular anesthesiologists. Over time, these relationships between the cardiovascular subspecialties evolved into formal associations and eventually dedicated cardiovascular centers were formed. These cardiovascular centers allowed physicians of different subspecialties to cooperate at an unprecedented level to optimally orchestrate the cardiovascular care of their patients.

## ADVANTAGES OF PROVIDING CARDIOVASCULAR CARE IN CARDIOVASCULAR CENTERS

Cardiovascular centers that integrate multiple cardiovascular subspecialties provide a number of important advantages. Firstly, integrated cardiovascular centers improve the clinical care for patients. For example, clinical care is improved by increasing patient volume. The relationship between patient volume and quality of care has been demonstrated in many areas of cardiovascular care. For example, a large body of evidence shows that increasing procedural volumes in cardiac surgery results in improved quality with decreased complication rates. Moreover, there is evidence that increased surgeon volume results in improved quality of care.<sup>6</sup> Therefore professional organizations have recommended that cardiac surgery programs performing fewer than 125 coronary artery bypass graft (CABG) procedures annually consider affiliation with high-volume tertiary centers.<sup>7</sup> A similar relationship between volume and quality of care exist in interventional cardiology. Among hospitals in the United States that have full interventional capabilities, a higher volume of angioplasty procedures was found to be associated with a lower mortality rate among patients undergoing primary angioplasty.<sup>8</sup> On the basis of this and other studies, professional organizations recommended that patients with ST elevation myocardial infarction undergo primary angioplasty by cardiac catheterization laboratories performing at least 36 primary angioplasties as well as at least 200 total angioplasties per year.<sup>9</sup> Integrated cardiovascular centers are ideally suited to deliver such high procedural numbers by concentrating cardiovascular care in dedicated centers, attracting referrals, co-marketing, and by sharing patients among the physicians. Higher quality of care can also be delivered by building up specialized expertise within narrow boundaries, multidisciplinary management of patients, and co-locating services. Finally, a substantial clinical research effort facilitates participation in multicenter trials that give patients access to the latest clinical treatment modalities.

Secondly, integrated cardiovascular centers improve the efficiency of patient flow pathways. This allows coordination of hospital visits to minimize intrusion in the patients' lives. For example, preoperative tests such as echocardiography, cardiac catheterization, and evaluation by cardiac anesthesia can occur on the least number of visits possible. Besides enhancing the patients' satisfaction with their care, the cost of cardiovascular care to society is reduced by minimizing time off work and allowing patients to participate in other activities.

Finally, integrated cardiovascular centers provide improved efficiency in practice management and reduced expenses. For example, an audit of the merger of a five-physician vascular surgery group, its noninvasive laboratory, and a three-physician interventional radiology group showed that integrating these cardiovascular subspecialties into a single center resulted in increased efficiencies that allowed the total expenses of the merged group to fall by 13% compared with the 12-month period that immediately preceded the merger.<sup>10</sup>

## THE INTEGRATED CARDIOVASCULAR CENTER OF THE FUTURE

In the future, the advantages provided by cardiovascular centers will be maximized by full integration at the level of clinical care, education, and research. Integration of clinical care will result in multidisciplinary management at all levels of patient care. This will include multidisciplinary outpatient clinics, conferences, in-patient rounds, and procedures. For example, outpatient clinics for cardiac surgery, cardiology, and preoperative cardiovascular anesthesia will ideally be located in the same physical space and coordinated at the same time. One model could involve clinicians sharing a centralized physician work-space and patients being seen in designated clinic cubicles. This means that patients could be seen by physicians from different subspecialties without having to leave their designated cubicle. Physicians could see their patients together with other providers from different subspecialties at the same time, or sequentially based on the complexity and needs of individual patients. In practice, this may involve taking a joined preoperative history and physical examination by anesthesia and cardiac surgery mid-level providers. Cardiologists and cardiac surgeons could engage in a joined discussion with patients regarding the risks and benefits of the multimodality treatment options, which might include medical management, interventional management, or surgery. Finally, an integrated electronic medical record would minimize redundancy and increase efficiency.

Similarly, interpretation of cardiovascular studies by cardiologists and radiologists will take place in a shared reading room to pool the expertise of the providers. For example, cardiologists could contribute their clinical knowledge and their understanding of cardiovascular pathophysiology, whereas radiologists could offer imaging and information technology expertise.

Multidisciplinary conferences that benefit from the joint expertise of cardiac surgeons, cardiologists, and cardiovascular anesthesiologists include high-risk preoperative conferences for example. During these conferences each specialty can contribute toward an accurate assessment of the overall risk and benefit ratio of different treatment modalities for high-risk patients.

Finally, integration of clinical care will mean that procedures will increasingly take place in shared treatment spaces. The prime example for this is the hybrid operating room. Hybrid operating rooms have the usual features of an operating room with additional cardiac catheterization and endovascular capabilities (Fig. 9-1). This creates a shared work-space where cardiac surgeons, interventional cardiologists, and vascular surgeons can cooperate during joined procedures. Combining the tools of the catheterization laboratory and operating room greatly enhances the options available to surgeons and cardiologists to treat complex patients. One example is hybrid coronary revascularization wherein a left internal mammary artery graft is placed on the left anterior descending (LAD) artery either by minimally invasive or open technique and combined with percutaneous intervention of

**FIGURE 9-1** A hybrid operating room combines the usual features of an operating room with additional cardiac catheterization and endovascular capabilities.

non-LAD vessels.<sup>11</sup> Another example is minimally invasive valve surgery combined with percutaneous intervention to coronary lesions in order to convert high-risk valve and CABG operations into a low-risk isolated minimally invasive valve procedures. Yet, other possibilities include hybrid endomyocardial and epicardial arrhythmia procedures<sup>12</sup> and hybrid open and endovascular approaches for the descending thoracic aorta and pathologies of the aortic arch and distal ascending aorta.<sup>13</sup> Finally, the hybrid operating rooms represent an optimal setting for transcatheter aortic valve replacement.<sup>14</sup> This has already resulted in a new paradigm, the Hybrid Paradigm, where providers of the different cardiovascular subspecialties consider themselves cardiovascular proceduralists.

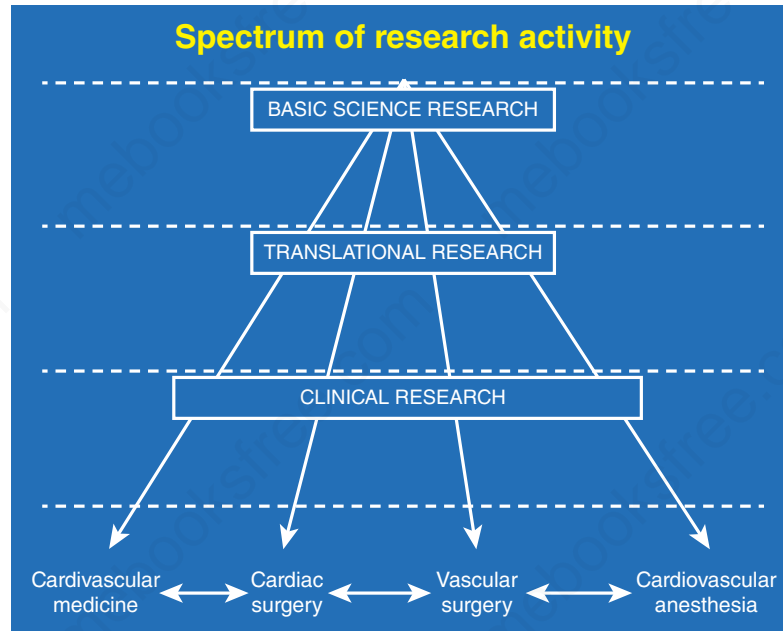

From the close clinical collaboration between the cardiovascular subspecialties follows that education and training need to be integrated in order to create a common culture and knowledge base. For example, free standing cardiothoracic surgery and vascular surgery residencies are evolving that allow better integration of the cardiovascular subspecialties during training than previous models which depended on general surgery training. For example, residents of a free-standing cardiothoracic surgery residency may rotate with cardiology during their early years of training. Another example is a TAVR fellowship that involves mandatory training with interventionalists in the catheterization suite. Conversely, cardiology fellows subspecializing in heart failure frequently accompany the cardiac surgery teams during heart procurements and are observers in the operating room during recipient implant procedures. Finally, the integration

of cardiovascular centers will allow trainees to participate in more related cases that are not part of their primary specialty.<sup>10</sup>

Research will also be facilitated by integrated cardiovascular centers that attract a critical mass of multidisciplinary research teams focusing on cardiovascular disease. In particular, center will provide organized leadership and the ability to distribute research activity at the level of subgroups. Faculty will also benefit from the close interaction with researchers outside of their divisions. Research support structures that can be custom focused on cardiovascular research include a wide range of areas from basic science core facilities to statistical support, specialized research grant administrators, and maintenance of an institutional clinical outcomes database. Multidisciplinary cardiovascular research conferences, common cafeteria, and leisure space will also facilitate the exchange of ideas between subspecialties. Ideally, integrated cardiovascular centers will participate in basic, translational, and clinical outcomes research focusing on cardiovascular disease since all of these fields benefit from a concentration of cardiovascular knowledge and clinical experience (Fig. 9-2).

In addition, there are specific advantages for each level of research. At the level of basic research, the differences between cardiovascular subspecialties nearly disappear. As a result, integrated cardiovascular centers offer ideal conditions for pooling and conducting such research. At the level of translational research there is also a convergence of interests since cutting edge translational research frequently involves multidisciplinary fields that transcend conventional departmental boundaries. Since basic and translational research

**FIGURE 9-2** Integrated cardiovascular centers participate in basic science research, translational research, and clinical outcomes research. At each level there are different opportunities for cooperation between the cardiovascular subspecialties.

is often dependent on large amount of funding, integrated cardiovascular centers will be able to provide laboratories with common small and large animal spaces and provide shared equipment which would otherwise be too expensive for individual departments. Large multidisciplinary laboratories can be set up in cardiovascular centers which would otherwise be hard to assemble or maintain. The larger size of cardiovascular centers will also make it easier to bring in additional multidisciplinary expertise such as stem cell experts, tissue engineering, mechanical and bioengineering, valve hemodynamics, and 3D printed modeling capabilities that can contribute to research efforts of different cardiovascular subspecialties. Finally, clinical outcomes research is more efficient because follow-up of patients involves multiple specialties which can each contribute relevant data to a jointly maintained database.

In summary, the cardiovascular center of the future will be a multidisciplinary and collaborative entity encompassing clinical care, education, and research. This structure has the potential to improve quality of care, reduce costs, improve training, and accelerate research.

# PERIOPERATIVE/ INTRAOPERATIVE CARE

*This page intentionally left blank*

# Preoperative Evaluation for Cardiac Surgery

Christian T. Ruff • Patrick T. O’Gara

Advances in surgical techniques and improved patient outcomes have enabled the application of cardiac surgery in patient populations previously considered ineligible for an intervention of this magnitude. The decision to intervene surgically, as well as the type of intervention best suited to the patient, should be based on an individual risk-benefit analysis. The risks of the procedure, including major morbidities and short- and intermediate-term mortality, must be weighed against the expected benefits with respect to longevity, symptom relief, and improved functional capacity. This chapter reviews the essential information that the cardiologist and surgeon must collect and review to evaluate a patient for cardiac surgery (Table 10-1). This information includes patient and disease characteristics as well as surgical considerations that can be integrated into scoring systems that provide a semi-quantitative risk assessment. With the ever-evolving complexity of patients requiring specialized cardiovascular care, the refinement of surgical techniques, and the emergence of less invasive alternatives for high-risk patients, it has become apparent that there are important limitations to these scores in that they do not adequately account for procedure-specific impediments, major organ system compromise, and patient frailty. In addition, there has been recognition that risk assessment must occur in a framework of shared decision making that ensures that patients and their families have a thorough understanding of the relative risks and benefits of the various treatment options and, most importantly, that their wishes and preferences are respected in the therapeutic plan. There has been increasing recognition that a Heart Team approach that draws on the strength of multidisciplinary participation in decision making may be ideally suited to meet this challenge.

## RISK ASSESSMENT

### Patient Characteristics and Conditions

#### AGE

The volume of cardiac surgical procedures in the elderly continues to increase as life expectancy improves and the benefits of surgery outweigh the risks in appropriately selected

individuals. While perioperative mortality rates do not vary significantly by age, mortality 1 year after surgery is generally higher in patients over 75 years of age, compared with those who are younger.<sup>1</sup> Octogenarians have nearly double the mortality rate compared with younger patients (4.1 vs 2.3%) and more than 60% of octogenarians have at least one nonfatal postoperative complication.<sup>2,3</sup> The most frequent complications include the need for prolonged ventilatory support in intensive care units, reoperation for bleeding and pneumonia—all resulting in longer hospital stays.<sup>3</sup> A higher proportion of complications occur in elderly patients with low body weight ((body mass index) BMI < 23).<sup>4</sup> With improved surgical techniques and careful patient selection, nonagenarians can safely undergo cardiac surgery with a 95% 30-day survival and 93% survival to hospital discharge.<sup>5-7</sup>

#### GENDER

Some but not all epidemiologic studies suggest that female gender is an independent predictor of postoperative morbidity and mortality.<sup>8-10</sup> Gender differences are present in both traditional coronary artery bypass graft (CABG) and off-pump surgery.<sup>11</sup> Several large retrospective cohort studies of patients undergoing CABG found that women had higher mortality rates than men even after adjusting for comorbidities and confounding factors, including body surface area.<sup>8,9</sup> Possible explanations for worse outcomes in women include smaller coronary arteries (which might enhance the technical difficulty of performing anastomoses and limit graft flow), differences in referral for surgery (ie, women being referred at later disease stages), and gender differences in self-reported outcomes.<sup>12</sup> Data suggest that benefit in terms of QOL after cardiac surgery is similar for men and women.<sup>13</sup>

#### RACE

Although crude post-CABG mortality rates differ significantly by race, data suggest that after controlling for patient and hospital variables, these differences are small.<sup>14,15</sup> However, in the United States, self-reported black race is associated

**TABLE 10-1: Risk Assessment Combining STS Risk Estimate, Frailty, Major Organ System Dysfunction, and Procedure-Specific Impediments**

	Low Risk (Must Meet ALL Criteria in This Column)	Intermediate Risk (Any 1 Criterion in This Column)	High Risk (Any 1 Criterion in This Column)	Prohibitive Risk (Any 1 Criterion in This Column)
STS PROM <sup>†</sup>	<4%	4–8%	>8%	Predicted risk with surgery of death or major morbidity
Frailty <sup>‡</sup>	AND None	OR 1 Index (mild)	OR ≥2 Indices (moderate to severe) OR	(all-cause) >50% at 1 year OR
Major organ system compromise not to be improved postoperatively <sup>‡</sup>	AND None	OR 1 Organ system	OR No more than 2 organ system	OR ≥3 Organ systems
Procedure-specific impediment <sup>§</sup>	AND None	OR Possible procedure-specific impediment	OR Possible procedure-specific impediment	OR Severe procedure-specific impediment

<sup>†</sup>Use of the STS PROM to predict risk in a given institution with reasonable reliability is appropriate only if institutional outcomes are within 1 standard deviation of STS average observed/expected ratio for the procedure in question.

<sup>‡</sup>Seven frailty indices: Katz Activities of Daily Living (independence in feeding, bathing, dressing, transferring, toileting, and urinary continence) and independence in ambulation (no walking aid or assist required or 5-m walk in <6 s). Other scoring systems can be applied to calculate no, mild-, or moderate-to-severe frailty.

<sup>‡</sup>Examples of major organ system compromise: Cardiac—severe LV systolic or diastolic dysfunction or RV dysfunction, fixed pulmonary hypertension; CKD stage 3 or worse; pulmonary dysfunction with FEV1 < 50% or DLCO<sub>2</sub> < 50% of predicted; CNS dysfunction (dementia, Alzheimer's disease, Parkinson's disease, OVA with persistent physical limitation); GI dysfunction—Crohn's disease, ulcerative colitis, nutritional impairment, or serum albumin < 3.0; cancer—active malignancy; and liver—any history of cirrhosis, variceal bleeding, or elevated INR in the absence of VKA therapy.

<sup>§</sup>Examples: Tracheostomy present, heavily calcified ascending aorta, chest malformation, arterial coronary graft adherent to posterior chest wall, or radiation damage.

CKD, chronic kidney disease; CNS, central nervous system; CVA, stroke; DLCO<sub>2</sub>, diffusion capacity for carbon dioxide; FEV1, forced expiratory volume in 1 s; GI, gastrointestinal; INR, international normalized ratio; LV, left ventricular; PROM, predicted risk of mortality; RV, right ventricular; STS, Society of Thoracic Surgeons; and VKA, vitamin K antagonist.

(Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *Am Coll Cardiol* 2014 Jun 10;63(22):e57-e185.)

with an increased risk of postoperative complications, including prolonged ventilatory support, length of stay, reoperation for bleeding, and postoperative renal failure.<sup>16</sup>

## DIABETES

Patients with diabetes have significantly worse outcomes following cardiac surgery.<sup>17-19</sup> Studies have shown diabetes to be an independent predictor of in-hospital mortality after CABG although emerging evidence indicates that the severity of diabetes, specifically target organ damage, may be important in risk stratification.<sup>20,21</sup> Postoperative mortality does not differ significantly between nondiabetic and diabetic patients without diabetic sequelae, though diabetic patients with vascular disease and/or renal failure have an increased risk of mortality.<sup>21</sup> Patients with insulin-dependent type II diabetes in particular are at increased risk of major postoperative complications including renal failure, deep sternal wound infection, and prolonged hospital stay.<sup>22,23</sup> Strict perioperative glucose control has been shown to lower operative mortality and the incidence of mediastinitis.<sup>24,25</sup> Off-pump surgery also appears to decrease postoperative morbidity in diabetic patients.<sup>26</sup>

## RENAL FUNCTION

Renal dysfunction is common in patients undergoing cardiac surgery. Approximately half of patients undergoing CABG have at least mild renal dysfunction and one quarter have at

least moderate renal dysfunction.<sup>27</sup> There is a graded increase in operative mortality and morbidity with worsening preoperative renal function.<sup>27-29</sup> Renal insufficiency is associated with greater risk of both 30-day (odds ratio, OR = 3.7) and 1-year mortality (OR = 4.6).<sup>30</sup> Even mild renal dysfunction (serum creatinine 1.47–2.25 mg/dL) is associated with increased rates of operative and long-term mortality, need for postoperative dialysis, and postoperative stroke.<sup>31</sup>

Renoprotective drugs, such as fenoldopam and *N*-acetylcysteine, have no effect on the deterioration of renal function in high-risk patients.<sup>32,33</sup> Off-pump CABG (OP CABG) is associated with a lower prevalence of the need for postoperative renal replacement therapy; larger studies are needed to determine if this correlates with improved outcomes.<sup>34</sup>

## PULMONARY FUNCTION

It is well established that patients with compromised pulmonary function, predominantly due to chronic obstructive pulmonary disease (COPD), have a higher mortality and increased incidence of postoperative complications including arrhythmias, reintubation, pneumonia, prolonged intensive care unit (ICU) length of stay (LOS), and increased LOS.<sup>35,36</sup> Postoperative respiratory failure is a common complication (14.8% in a New York State database) with a higher incidence (14.8%) in combined CABG and valve operations.<sup>37</sup> Optimizing respiratory status prior to surgery, including smoking cessation,

antibiotics for pneumonia, and treatment of COPD flares with bronchodilator therapy and steroids is a critical part of preoperative management.<sup>38</sup> There is evidence that intensive inspiratory muscle training prevents postoperative pulmonary complications in high-risk patients.<sup>39</sup>

## Surgical Considerations

### REOPERATION

Hospital mortality among patients undergoing reoperative cardiac surgery has traditionally been higher than among patients undergoing primary operation.<sup>40-42</sup> This is likely due to the higher-risk profile of patients undergoing reoperation (older, more extensive vascular and coronary disease, multiple comorbidities) and the demanding surgical aspects including sternal reentry, pericardial adhesions, in situ arterial grafts and diseased saphenous vein grafts.<sup>43</sup>

Despite these factors, hospital mortality rates associated with coronary reoperation have decreased with greater surgical experience and now approach those observed with primary CABG.<sup>43,44</sup> With careful preoperative risk evaluation and surgical management, reoperation can be performed safely.

### PRIOR RADIATION

Patients receiving thoracic radiation for treatment of malignancies before cardiac surgery have poorer short- and long-term outcomes.<sup>45,46</sup> Thoracic radiation exposure is heterogeneous with respect to different malignancies and there is a gradient of risk.

A study dividing patients undergoing cardiac surgery into three levels of radiation exposure: extensive (Hodgkin's disease, thymoma, and testicular cancer), variable (non-Hodgkin's lymphoma and lung cancer), and tangential (breast cancer), demonstrated that patients with extensive radiation exposure had longer radiation-to-operation interval, poorer pulmonary function, and more severe aortic regurgitation, diastolic dysfunction and left main coronary

stenosis.<sup>47</sup> Hospital deaths (13% vs 8.6% vs 2.4%) and respiratory complications (24% vs 20% vs 9.6%) were higher after more extensive radiation and 4-year survival was poorer (64% vs 57% vs 80%).

### SURGICAL COMPLEXITY AND TECHNIQUE

It is important to consider the type of cardiac surgical procedure (CABG, valve, or combined) as well as the surgical technique (on-pump, off-pump, minimally invasive, robotic, and hybrid) when providing preoperative risk assessment as mortality and morbidity risks may vary.

Valve surgeries generally have a higher complication rate than isolated CABG, and combined surgeries have the highest risk (Fig. 10-1). Participants in the Society of Thoracic Surgeons National Adult Cardiac Surgery Database collected data between 2002 and 2006 on more than 3.6 million procedures.<sup>48-50</sup> They reported 30-day mortality and a composite end point of mortality and major in-hospital morbidity including stroke, renal failure, prolonged ventilation, deep sternal wound infection, and reoperation. CABG mortality was 2.3% with a 14.4% rate for the combined end point of mortality and major morbidity.<sup>48</sup> Isolated valve procedures had higher mortality rates, including 3.2% for aortic valve replacement (AVR), 5.7% for mitral valve replacement (MVR), and 1.6% for mitral valve repair (MVP).<sup>49</sup> Combined mortality and major morbidity was also higher for valve surgery at 18.3% (AVR 17.4%, MVR 26.7%, MVP 12.7%). Combined CABG and valve procedures had the highest mortality rate at 6.8% (AVR + CABG 5.6%, MVR + CABG 11.6%, and MVP + CABG 7.4%) with a combined mortality and major morbidity of 30.1% (AVR + CABG 26.3%, MVR + CABG 43.2%, and MVP + CABG 33.5%).<sup>50</sup>

Minimally invasive surgical techniques can be divided by approach and use of cardiopulmonary bypass (CBP). The use of alternatives to standard median sternotomy has been increasingly adopted in surgical centers for performance of both CABG and valve procedures. The potential benefits of minimally invasive surgery are earlier extubation, reduced

**FIGURE 10-1** Thirty-day mortality and a composite end point of mortality and major in-hospital morbidity (stroke, renal failure, prolonged ventilation, deep sternal wound infection, and reoperation) from the Society of Thoracic Surgeons National Adult Cardiac Surgery Database (STS NCD).<sup>48-50</sup> CABG = coronary artery bypass graft surgery.

discomfort, lower rates of wound infection, less blood loss, and shorter recovery times.<sup>51</sup>

Off-pump CABG is performed with stabilization devices to reduce motion of target vessels while anastomoses are performed without CBP. Current surgical approaches to valve surgery require CBP and cardioplegic arrest. Meta-analyses of observational and randomized trials of OP CABG versus on-pump CABG have not demonstrated a clear advantage of OP CABG with respect to mortality or morbidity.<sup>52,53</sup> Postoperative complications with OP CABG generally show consistent reductions in postoperative AF, blood loss, wound infections and myocardial injury with nonsignificant trends toward lower death, myocardial infarction (MI) and stroke.<sup>53-55</sup> The benefits of OP CABG are particularly notable in the elderly and in patients with heavily calcified aortas.<sup>54</sup>

There have been continued advances in optics, instrumentation and perfusion technology that have facilitated use of totally endoscopic robotic cardiac surgery.<sup>56</sup> This technology has been applied to many cardiac surgical procedures, in particular MVP and totally endoscopic coronary artery bypass grafting (TECAB). Short-term results are promising in some series but long-term studies are lacking and a steep learning curve characterizes the early phase of application.

Simultaneous “hybrid” percutaneous coronary intervention with drug-eluting stents and minimally invasive surgical bypass grafting procedures in a specially designed operating suite (hybrid OR) are also gaining more widespread acceptance. Hybrid procedures require close cooperation between surgical and interventional teams. Although there are limited data available, hybrid patients have similar angiographic vessel patency and major adverse cardiac events (MACE) at six months with shorter hospital lengths of stay, intubation times and less blood loss despite aggressive antiplatelet therapy.<sup>57</sup>

## RISK SCORES

Preoperative risk assessment has important implications not only for individual patient well-being but as a qualitative tool to serve as a reference standard to compare outcomes among surgeons, institutions, or assessment of new procedures and techniques. There are numerous risk stratification scores and systems that have been developed from large databases to quantify the mortality and morbidity risks of cardiac surgery. Both patient and surgical factors are considered preoperatively and assessed for their ability to predict postoperative complications. This section will focus on two of the most widely used risk scoring systems: European System for Cardiac Operative Risk Evaluation (EuroSCORE) and Society for Thoracic Surgeons (STS) risk estimate (Table 10-2).

### The European System for Cardiac Operative Risk Evaluation (EuroSCORE)

The EuroSCORE, initially published in 1999, is the most rigorously evaluated scoring system in cardiac surgery.<sup>58</sup>

**TABLE 10-2: Comparison of Preoperative Risk Factors for Risk Stratification Models**

Preoperative Risk Factor	EuroSCORE	STS
Age	X	X
Gender	X	X
Race	X	X
Weight/BSA		X
IABP/inotropes		X
LV function	X	X
Renal disease	X	X
Lung disease	X	X
PVD	X	X
Diabetes		X
Neurologic dysfunction	X	X
Active endocarditis	X	
UA or recent MI	X	X
Previous cardiac surgery	X	X
Combined surgery	X	X
Aortic involvement	X	X
Valve surgery	X	X
Emergency surgery	X	X

The score is calculated by assessing 17 risk factors (patient, cardiac, and operation) known to affect outcome. There are two available methods: the original additive model and the more recent logistic model.<sup>59,60</sup> Studies have indicated that the additive model overestimates mortality in low-risk patients and underestimates mortality in high-risk patients.<sup>60-62</sup> The logistic model was designed to address these issues but there is still concern that this model overestimates mortality in many risk groups.<sup>60</sup> The logistic EuroSCORE is more accurate at predicting mortality in combined CABG and valve surgery.<sup>63</sup> The EuroSCORE calculator is available online ([www.euroscore.org](http://www.euroscore.org)).

### Society for Thoracic Surgeons Score

The STS has an extensive database with an online calculator ([www.sts.org](http://www.sts.org)). Compared with the EuroSCORE calculator more extensive data entry is required to calculate an STS score. Models have been developed and revised for CABG, valve surgery, and combined procedures.<sup>48-50</sup> These models include mortality as well as multiple morbidity end points including stroke, renal failure, prolonged ventilation, deep sternal wound infection, and prolonged postoperative stay. Studies demonstrate that STS score showed similar discriminative capability and predictive performance compared with EuroSCORE and other risk algorithms.<sup>64,65</sup>

All risk models share important limitations. Preoperative risk factors included in the model can change significantly over time, leading to substantial under- or overestimation of postoperative risk.<sup>66</sup> Caution should also be used when

interpreting the results of a model with respect to an individual patient's risk. The models are derived from large databases and do not include important considerations for an individual's specific risk profile such as surgeon experience and comorbidities not incorporated in the model's derivation. These models also do not capture patient frailty, which has been increasingly shown to have a decisive influence on procedural outcomes.

## FRAILTY

Frailty is a syndrome that reflects a state of decreased physiological reserve and vulnerability to stressors.<sup>67,68</sup> The prevalence of frailty ranges from 10 to 60%, depending on the cardiovascular burden of the population as well as the specific frailty measures and thresholds utilized for its assessment.<sup>69,70</sup> Following surgery, or any other physiologic stressor, frail patients are at a marked risk for clinical decompensation, procedural complications, prolonged recovery, functional

decline, disability, and mortality.<sup>71</sup> The emerging biology of frailty implicates systemic dysregulation of the immune, hormonal, and endocrine systems resulting in up-regulation of inflammatory cytokines, decreased testosterone levels, and insulin resistance.<sup>72-78</sup> The subsequent catabolic state that ensues precipitates a progressive decline in muscle mass and strength (sarcopenia).<sup>79</sup>

Many tools have been developed to measure frailty.<sup>80</sup> Most tools focus on 1 or more of the 5 core domains that define the frailty phenotype: slowness, weakness, low physical activity, exhaustion, and shrinking. Slowness is measured by a comfortable-pace gait speed test, weakness by a maximal handgrip strength test (using a dynamometer), and other domains by questionnaire or more specialized instruments. These domains may be considered individually or combined into a variety of scales (Table 10-3). The Fried scale and the Short Physical Performance Battery (SPPB) are two of the most frequently utilized and cited scores.<sup>81-83</sup> Although in contrast to these multi-item assessments, single measures of

 **TABLE 10-3: Recommended Frailty Assessment Tools**

Domain	Tool(s)	Operational Definition	Common Cutoffs for Frailty
Slowness	5-m gait speed test	Patient is positioned behind start line and asked to walk at a comfortable pace past 5-m finish line; cue to trigger stopwatch is first footfall after start line and first footfall after finish line; repeated 3 times and averaged	Slow: <0.83 m/s (>6 s) Very slow: <0.65 m/s (>7.7 s) Extremely slow: <0.50 m/s (>10 s)
	Handgrip strength test	Patient is asked to squeeze a handgrip dynamometer as hard as possible; repeated 3 times (once with each hand and then with strongest hand); maximum value is recorded	Men: <30 kg Women: <20 kg
Weakness	Knee extensor strength test	Patient is seated on the dynamometer machine and asked to extend his/her knee against resistance; maximum isotonic force is recorded	Frailty cutoffs not yet established
	Physical activity questionnaire	Many questionnaires have been validated; those that provide a measure of activity in kcal/week are recommended (eg, Minnesota Leisure Time Activity, PASE, Paffenbarger Physical Activity Questionnaire)	Men: <383 kcal/week Women: <270 kcal/week
Low physical activity	Portable accelerometer	Patient is asked to wear a portable accelerometer for a period of 1 to 7 days; total kcal expenditure is recorded	Frailty cutoffs not yet established
Exhaustion	CES-D questionnaire	Patient is asked 2 questions: How often in the past week did you feel like everything you did was an effort?/like you could not get going? (often [ie, ≥3 days] or not often [ie, 0-2 days])	Positive if often is the answer to either question
	Anergia questionnaire	Patient is asked 7 questions pertaining to lack of energy over the past month	Positive if major criterion "sits around a lot for lack of energy" + any 2 of 6 minor criteria
Shrinking	Weight loss	Self-reported or measured unintentional weight change not due to dieting or exercise	≥10 lbs in past year
	Appendicular muscle mass	Measured muscle mass in arms and legs using a dual-energy x-ray absorptiometry scan	Frailty cutoffs not yet established; general cutoffs >2 SD from controls Men: ≤7.23 kg/height in m <sup>2</sup> Women: ≤5.67 kg/height in m <sup>2</sup>
	Serum albumin	Measured serum albumin	≤3.3 g/dl

frailty such as the 5-m gait speed, and to a lesser extent hand-grip strength, often outperform the more elaborate and time-consuming scales.<sup>84-86</sup>

The Frailty ABCs (Frailty Assessment Before Cardiac Surgery) prospective study showed that slow 5-m gait speed was associated with a threefold increase in postoperative mortality or major morbidity and provided incremental value above the STS risk score.<sup>87</sup> Patients with slow gait speed and a high-risk score had a 43% incidence of mortality/major morbidity, whereas those with normal gait speed and a low- to intermediate-risk score had a 6% incidence. Additional studies have demonstrated that preoperative frailty is associated with postoperative mortality at 30 days and 1 to 2 years.<sup>88-90</sup>

## HEART TEAM

The concept of the “Heart Team” originated from two randomized trials comparing percutaneous and surgical strategies in patients with coronary artery disease and aortic stenosis: SYNTAX (Synergy between PCI with Taxus and Cardiac Surgery) and PARTNER (Placement of Aortic Transcatheter Valves).<sup>91-93</sup> In these trials, the Heart Team was composed of an interventional cardiologist and a cardiovascular surgeon but membership has expanded in many centers to include specialists from imaging, neurology, pulmonology, anesthesia, geriatrics, palliative care, social work, information technology, administration, and finance.<sup>94</sup> The Heart Team approach is central to the care of high-risk or prohibitive surgical risk patients with severe aortic stenosis. It has a Class I recommendation from American and European valve guidelines and is required for reimbursement for transcatheter AVR in the United States.<sup>95,96</sup>

The goal of this collaborative approach in patients with aortic stenosis is to improve outcomes by optimization of patient selection, utilization of synergistic procedural skill sets, standardization of intra- and post-procedural care pathways, and establishment of post-discharge follow-up.<sup>97</sup> An additional focus is to deliver more patient-centered care, through processes such as shared decision making (SDM).<sup>95,96</sup> With the obvious broad applicability of the Heart Team approach to many of the surgical and percutaneous decisions that patients with advanced heart disease face, it will be critical to focus health services research on the key metrics of patient-centered outcomes, clinician outcomes, and health system outcomes in order to advance our care delivery to our highest risk patients (Table 10-4).

## SHARED DECISION MAKING

Clinicians often think that patients do not want to take an active role in decision making and that patients prefer their clinicians to make decisions on their behalf.<sup>98,99</sup> This sentiment does not appear to be reflective of patients’ attitudes regarding their roles in health care decisions. Studies have found that the vast majority patients (~70%) prefer a shared role in which both they and their clinicians contribute equally

**TABLE 10-4: Potential Outcomes of Effective Heart Team Interventions**

	Patient	Clinician	Health System
Improved knowledge	X	X	
Reduced decisional conflict	X		
Greater satisfaction (with care delivery process)	X	X	
Involvement in shared decision making	X	X	
Improved quality of life (functional status [patient] or workplace [clinician])	X	X	
Expanded clinical and procedural skill set		X	
Reduction in variability both in access and outcome			X
Greater adherence to guidelines			X
Lower readmission rates			X
Shorter length of stay			X
Faster time to decision			X
Lower cost			X
Improved care coordination and communication			X

(Reproduced with permission from Coylewright M, Mack MJ, Holmes DR Jr, et al: A call for an evidence-based approach to the Heart Team for patients with severe aortic stenosis. *J Am Coll Cardiol* 2015 Apr 14;65(14):1472-1480.)

to treatment decisions.<sup>100</sup> Health policy has firmly embraced SDM and there is recent advocacy for SDM in cardiovascular clinical practice guidelines.<sup>98,101,102</sup>

One of the biggest challenges remains the logistics of incorporating SDM into routine clinical practice. A helpful first step is to identify and review the various tools and resources available. Three comprehensive publically available resources include Ottawa Decision Aids Repository (available at <http://decisionaid.ohri.ca/decaids.html>), the Mayo Shared Decision Making Resource Center (available at <http://shareddecisions.mayoclinic.org/>), and a repository of Option Grids (available at <http://www.optiongrid.org/>). A key component of SDM beyond just the dissemination and discussion of “facts” is the emphasis placed on developing a therapeutic relationship with the patient to allow him/her to feel comfortable expressing an informed preference.<sup>97</sup>

## FUTILITY

Advances in surgical and minimally invasive techniques, as well as coordinated multidisciplinary perioperative care, have successfully extended treatment options to patients previously thought to be too high risk due to advanced age, frailty, and burden of comorbidities. However, there are many patients who are unlikely to benefit from a procedure even if it can be

performed successfully. Therapeutic futility has been defined as a lack of medical efficacy—when the therapy is unlikely to produce its intended clinical result, as judged by the physician; or lack of a meaningful survival, as judged by the personal values of the patient.<sup>103,104</sup>

This issue of how to assess futility and incorporate it into the dialogue between patients and caregivers has become increasingly important with the emergence of transcatheter aortic valve replacement (TAVR) as a less invasive alternative to surgical valve replacement.<sup>92,93,105</sup> TAVR is a transformative innovation that has extended treatment to numerous patients with severe aortic stenosis who previously were not referred for or were denied surgical treatment.<sup>103</sup> However, clinical experience demonstrates that some patients die soon after the procedure or have little improvement in QOL or functional status.<sup>106,107</sup> The decision regarding futility is one of the most challenging in medicine and surgery and should be made collaboratively by the care team with the patient. As the ability to distinguish patients who will benefit from therapy from those who will not continue to evolve, it is important to emphasize to patients and families not only that decisions not to offer invasive treatment do not equate with abandonment of care but also that continued efforts will be made to promote patient goals and well-being.<sup>103</sup>

## CORONARY REVASCULARIZATION

### Coronary Artery Disease, Surgical Revascularization, and Myocardial Oxygen Supply: Demand

Heart disease is the leading cause of death in the United States, accounting for 600,000 fatalities annually.<sup>1</sup> Coronary artery disease (CAD) is a complex and multifactorial process, primarily characterized by the progressive and silent accumulation of atherosclerotic plaques, fibrous materials, and inflammatory mediators within the coronary arteries, potentially leading to obstruction of flow and resultant myocardial hypoperfusion.<sup>2</sup> Manifestations of this disease tend to present in males 40 years and older and in females 50 years and older. Risk factors include a strong family history of the disease, hypercholesterolemia, hypertension, diabetes, obesity, and smoking. If left untreated, CAD can lead to angina, heart failure, arrhythmias, and sudden death. Although medical therapy and percutaneous coronary interventions are often mainstay treatments for milder forms of the disease and most single- and double-vessel lesions, the gold standard for most multi-vessel lesions remains surgical revascularization.<sup>3,4</sup>

Anesthesiologists should be acutely aware of the heightened risks of myocardial ischemia for patients during revascularization surgery due to their obstructed coronary vessels and the critical dependence on oxidative phosphorylation for cardiac energy production. Myocardial oxygen supply is the product of arterial oxygen content and coronary blood flow.

$$\text{O}_2 \text{ content} = [(1.34)(\text{hemoglobin concentration}) (\% \text{ oxygen saturation}) + (0.003)(\text{PaO}_2)]$$

Maximizing oxygen release at the tissue level involves maintaining high hemoglobin concentration, high oxygen saturation, warm temperature, and increased 2,3-diphosphoglycerate. The myocardium tends to maximally extract oxygen from its blood supply while at rest, and therefore, can only increase myocardial oxygen delivery during stress by increasing coronary blood flow. If this flow is obstructed by CAD, then the risk of myocardial ischemia is greatly increased.

Coronary artery blood flow is proportional to coronary perfusion pressure (CPP), where

$$\text{CPP} = (\text{aortic diastolic blood pressure}) - (\text{left ventricular end-diastolic pressure})$$

and is inversely proportional to coronary vascular resistance. Normal coronary arteries have autoregulated flow at CPPs between 50 and 150 mm Hg. Coronary vascular resistance is determined by hormonal and metabolic factors, the autonomic nervous system, endothelial modulation, and in diseased vessels, by atherosclerotic plaques. Left ventricular (LV) endocardial blood flow occurs entirely during diastole, when the vast majority of the remaining myocardium is oxygenated (Fig. 11-1). Therefore, the anesthesiologist attempting to maximize CPP and oxygen supply should target normal to increased diastolic blood pressure, low left ventricular end-diastolic pressure (LVEDP), and a slow heart rate to maximize time during diastole. Additionally, myocardial oxygen demand can be minimized by avoiding tachycardia, minimizing LVEDP, reducing chamber size, and reducing contractility. This general principle of optimizing myocardial oxygen supply while minimizing demand should be an over-reaching goal for the anesthesiologist caring for a patient undergoing coronary revascularization surgery.<sup>5,6</sup>

### Preoperative Considerations

When evaluating a patient prior to a coronary revascularization procedure, the anesthesiologist should be mindful of the anesthetic goals common to all surgeries: providing amnesia, analgesia, and a quiet surgical field while ensuring optimal myocardial oxygen supply and demand to minimize ischemic risk. In addition, the anesthesiologist should provide optimal hemodynamic control to optimize cardiac performance, and be prepared to help guide the surgery while rapidly diagnosing cardiac complications, often by using advanced noninvasive and invasive hemodynamic monitors including transesophageal echocardiography (TEE).

Initial preoperative patient assessment should include a comprehensive history and physical examination focused on

**FIGURE 11-1** Wiggers diagram depicting relationship of left coronary artery pressure and flow with the phase of the cardiac cycle. Note that left coronary flow occurs primarily during ventricular diastole, even though the head pressure of the vessel is higher during systole. This is due to the high transmural ventricular pressure during systole, and the relatively low pressure in diastole as the myocardium relaxes, as governed by the coronary perfusion equation:  $CPP = DBP - LVEDP$ , where  $CPP$ =coronary pressure,  $DBP$ =diastolic blood pressure, and  $LVEDP$ =left ventricular end diastolic pressure. LCA=left coronary artery, LV=left ventricle. (Reproduced with permission from Lee J, Smith NP: The multi-scale modelling of coronary blood flow, *Ann Biomed Eng* 2012 Nov;40(11):2399-2413.)

the cardiac and pulmonary systems, along with a standard airway examination. Though direct laryngoscopy is routinely used to facilitate tracheal intubation, a predicted difficult airway may prompt alternative intubation strategies. A thorough review of the medical record is in order, with careful attention to patient medications, laboratory studies (complete blood count, electrolytes, creatinine, troponin, B-type natriuretic peptide, coagulation panels, blood cross matches), electrocardiogram, carotid ultrasound studies, chest radiograph, cardiac stress tests, cardiac catheterization, and echocardiography reports. The anesthesiologist should be aware of the coronary anatomy and lesions, along with any invasive pressure measurements as described by the catheterization report. Close review of any preoperative echocardiography studies is essential to assess both systolic and diastolic ventricular function and to examine the cardiac valves.

A comprehensive preoperative assessment is important to determine the perioperative risk. The two most widely used risk stratification tools are the Society of Thoracic Surgeons (STS) Risk Calculator and EuroSCORE II, each based on large historical patient databases. These formulae use sophisticated mathematical modeling techniques to allow the user to

determine predicted mortality and other complications based on a variety of entered criteria, including age, gender, ejection fraction, urgency of surgery, renal function, and other variables. Risk assessment calculators can be valuable preoperative planning tools for the patient, surgeon, and anesthesiologist, and their use should be considered prior to each case.<sup>7,8</sup>

While concluding the preoperative visit, the anesthesiologist should ensure informed consent and provide the opportunity for any patient questions to be answered. The anesthesiologist's visit itself is a powerful means to allay patient fears and helps address patient and family members' concerns.<sup>9</sup> Additionally, the anesthesiologist should consider any premedications to administer, include anxiolytics as necessary. Beta-blocker medications are recommended preoperatively to reduce the risk of postoperative atrial fibrillation, myocardial ischemia, and mortality. Statins should be administered unless contraindicated to reduce the rate of myocardial ischemia, graft atherosclerosis, and mortality.<sup>10,11</sup> In general, antihypertensives should be continued on the day of surgery, while use of angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists is associated with intraoperative hypotension and remains controversial. The use of antiplatelet and anticoagulation agents should be discussed with the surgeon.<sup>12</sup>

Finally, the anesthesiologist should have an active preoperative meeting with the surgeon and the surgical team, as necessary, in order to facilitate the procedure and minimize complications. Checklist and protocol-driven processes have demonstrated reduced complications and improved mortality.<sup>13</sup> Cardiac anesthesiologists with formal fellowship training and skill in TEE are recommended to provide care for high-risk patients.<sup>14</sup>

## Monitoring

A vigilant cardiac anesthesiologist is the best single monitor for patients undergoing revascularization procedures. Standard American Society of Anesthesiology monitors should also be used, including  $FiO_2$  monitor, pulse oximeter, end-tidal  $CO_2$  monitor, continuous electrocardiogram, noninvasive blood pressure monitor, and a temperature measurement device. In addition to these standard monitors, a urinary catheter often with bladder thermistor, an arterial catheter most commonly placed in the radial artery, and a central venous catheter are all used routinely. Central venous catheter placement using real-time ultrasound guidance is safer than using an anatomic-guided approach, and is the recommended technique when available.<sup>15</sup>

The risk of intraoperative awareness is increased during cardiac surgery due to the lower use of volatile anesthetics and increased hemodynamic instability in comparison to non-cardiac surgery.<sup>16</sup> Processed electroencephalograms, such as the bispectral index (BIS) monitor, have been used to detect inadequate patient amnesia with recent meta-analysis data suggesting that their use reduces the risk of intraoperative awareness in high-risk patients with an odds ratio of 0.24.<sup>17</sup> Although this risk reduction is not universally found<sup>18</sup> and

the use of the BIS remains controversial, the National Institute for Health and Clinical Excellence recommends “the use of electroencephalography-based depth of anesthesia monitors...during any type of general anesthesia in patients considered at higher risk.”<sup>19</sup>

The technique of near-infrared spectroscopy allows for cerebral regional oxygen saturation to be measured using skin sensors placed on the scalp. Low cerebral tissue oxygen values are associated with increased long-term surgical risk and can also detect cerebral hypoperfusion states caused by problems with bypass cannulae, emboli, and obstruction of cerebral vessels. Cerebral oximetry is often used with aortic surgery involving circulatory arrest, and less commonly with isolated coronary artery bypass grafting (CABG) procedures.<sup>20</sup> Cerebral oximetry has yet to be clearly demonstrated to be beneficial in high-quality randomized intervention trials, and its use remains controversial.<sup>21,22</sup>

The pulmonary artery catheter (PAC) is frequently used during revascularization procedures as a means of measuring cardiac output via thermodilution and directly measuring pulmonary artery pressures. Additionally, LVEDP, as a marker of LV preload, can often be inferred from the pulmonary artery occlusion pressure or the pulmonary artery diastolic pressure. The use of a PAC is not without risk however, and it has been associated with rare but often lethal complications including pulmonary artery rupture. PAC use for revascularization surgery became widespread by the 1980s but its current use is declining due to the proliferation of less-invasive cardiac output monitoring devices, TEE, and some data which fails to demonstrate an association with improved outcome.<sup>23,24</sup> Even so, PACs remain popular with more than two-thirds of anesthesiologists reporting that they use this catheter more than 75% of the time in cases requiring cardiopulmonary bypass (CPB).<sup>25</sup> The perioperative use of a PAC remains recommended in patients with cardiogenic shock (Class I indication), hemodynamic instability (Class IIa), and its use may be reasonable in stable patients undergoing revascularization procedures (Class IIb).<sup>26</sup>

TEE has become a routine monitor during cardiac surgery, and has been shown to have a significant favorable influence on intraoperative surgical management and outcomes.<sup>27</sup> Current practice guidelines recommend that unless contraindicated, TEE be used for all valvular heart procedures and should be considered in CABG surgeries.<sup>28</sup> Recent global survey data suggest that TEE is used in 61 to 69% of isolated CABG procedures.<sup>29</sup> In addition to serving as the gold standard for valve evaluation, TEE can be used to monitor volume status, ventricular function, and gauge regional-wall motion patterns to detect and assess myocardial ischemia—all useful assessments during revascularization surgery.<sup>29</sup>

## Anesthetic Techniques and Agents

Historically, general anesthesia was commonly induced and maintained with high-dose fentanyl (50 to 100 mcg/kg) and pancuronium (Table 11-1). This high-dose opiate technique purportedly avoided myocardial depression associated with

other anesthetic agents while providing stable hemodynamics and effective blunting of surgical stresses.<sup>30</sup> In the 1990s, efforts at cost reduction spurred the evolution of “fast-track” cardiac anesthetic techniques using volatile anesthetics and low-dose opiates, with early extubation and reducing ICU stays as primary goals. Fast-track techniques have subsequently been demonstrated to be as safe as historical anesthetics in low- and medium-risk patients.<sup>31</sup> Around the same time, the concept of ischemic and pharmacological preconditioning was described, whereby certain maneuvers or pharmacologic agents including volatile anesthetics could minimize the extent of myocardial damage to subsequent myocardial ischemia.<sup>32</sup> As a result, contemporary approaches to coronary revascularization surgery commonly involve induction with thiopental, propofol, etomidate, or midazolam, followed by a balanced anesthetic technique employing a volatile anesthetic (ie, isoflurane, desflurane, or sevoflurane) as its primary component. The volatile anesthetic is accompanied by a low-dose semisynthetic opiate (ie, fentanyl, sufentanil, or remifentanyl) and a paralyzing agent. There is no significant difference in extubation times between fentanyl, sufentanil, and remifentanyl using fast-track protocols.<sup>33</sup> The use of a volatile anesthetic, and therefore induction of pharmacologic preconditioning, has now become a more common standard anesthetic approach. Meta-analyses suggest that cardiac surgery mortality is reduced when using a volatile anesthetic as compared to a propofol-based intravenous anesthetic, with an odds ratio of 0.51 in favor of volatile anesthetics.<sup>34</sup> Xenon is a promising inhalational anesthetic agent that purports to improve recovery from myocardial stunning, preserve hemodynamic control, and provide neuroprotective qualities. Early trials have been favorable, but its use remains experimental.<sup>35</sup>

Neuroaxial techniques are occasionally used during revascularization surgery. However, systemic heparinization increases the concern of epidural hematoma and resultant spinal cord injury thereby limiting their use, although the actual incidence of this complication is very low.<sup>36</sup> Preoperative intrathecal opiate injection and continuous thoracic epidural local anesthetics can provide good analgesia and facilitate recovery; however, current data do not demonstrate a reduction in the risk of mortality, myocardial infarction, or neurological complications as compared to general anesthetic alone.<sup>37</sup> Awake cardiac surgery is performed in a very small number of centers using thoracic epidural anesthesia and may offer rapid recovery benefits in select patients.<sup>38</sup>

## Hemodynamic Optimization

Patients undergoing coronary revascularization frequently develop hypotension and/or low cardiac output, particularly following CPB. Risk factors for low cardiac output syndrome include renal disease, significant regional-wall motion abnormalities, CABG with mitral valve (MV) surgery, reoperation, moderate-to-severe mitral regurgitation (MR), prolonged aortic cross clamp time, left ventricular ejection fraction (LVEF) < 40%, cardiac index < 2.5 L/min/m<sup>2</sup>, and LVEDP ≥ 20 mm Hg.<sup>39,40</sup> Strict attention to

**TABLE 11-1: General Anesthetic Regimens**

	Agent	Dose	Notes
High-dose opiate technique	Fentanyl	50-100 mcg/kg load	Technique now less commonly used due to increased risk of delayed extubation, increased risk of intraoperative awareness, and lack of ischemic preconditioning volatile anesthetic.
	Pancuronium	0.1 mg/kg load, then 0.01 mg/kg as needed	Mild tachycardic effect may help offset bradycardia associated with high opiate technique. Must reduce dose in renal impairment. Routinely used.
Fast-track balanced anesthetic			
Induction	Propofol	1-3 mg/kg	
IV induction agent	Thiopental	3-5 mg/kg	
	Etomidate	0.2-0.4 mg/kg	Associated with adrenal suppression.
	Midazolam	0.05-0.15 mg/kg	
Maintenance			
Opiates	Fentanyl	10-20 mcg/kg	Typically given as initial load during induction, with intermittent boluses as necessary.
	Sufentanil	0.5-2.0 mcg/kg	Typically given as initial load, with intermittent boluses or infusion as necessary.
	Remifentanil	0.05-1.0 mcg/kg/min	Administer long-acting analgesics prior to discontinuing remifentanil.
Volatile anesthetic	Isoflurane	MAC 1.13%	Titrate to effect, target 1 MAC for ischemic preconditioning.
	Sevoflurane	MAC 2.05%	Titrate to effect, target 1 MAC for ischemic preconditioning.
	Desflurane	MAC 7.25 %	Titrate to effect, target 1 MAC for ischemic preconditioning.
Paralytic	Rocuronium	0.6 mg/kg load, then 0.15 mg/kg as needed	
	Vecuronium	0.1 mg/kg load, then 0.01 mg/kg as needed	
	cis-Atracurium	0.15-0.20 mg/kg load, then 0.02 mg/kg as needed	Safe for renal failure patients.
Total IV anesthetic			
	Propofol	50-150 mcg/kg/min	Combine with opiate and paralytics as above. Lacks benefit of volatile anesthetic-mediated ischemic preconditioning. Likely increased mortality when compared to volatile anesthetic-based technique.

hemodynamic monitors coupled with a command of cardiac physiology and pharmacology will aid the anesthesiologist in maintaining adequate systemic perfusion. Markers of inadequate systemic perfusion include low cardiac index, hypotension, oliguria, metabolic acidosis, increased base deficit, and elevated serum lactate.

The anesthesiologist is tasked with preventing, diagnosing, and treating inadequate systemic perfusion, and implementing an algorithmic approach may help direct therapy (Fig. 11-2). By using a combination of traditional hemodynamic monitors, invasive and noninvasive cardiac output

monitoring devices, dynamic indexes, changes in end-tidal carbon dioxide, arterial blood gas analysis, and echocardiography, systemic perfusion can be assessed and treatment adjusted. A number of vasoactive medications are available and their use should be individualized based on each patient's hemodynamic needs (Table 11-2). A recent addition is levosimendan, a novel inotrope that increases troponin C affinity to calcium without increasing myocardial oxygen consumption or impairing ventricular relaxation, while also exerting pharmacologic preconditioning effects by opening mitochondrial  $K_{ATP}$  channels. Levosimendan

Cardiac physiology flowchart

**FIGURE 11-2** Algorithm for diagnosing, preventing, and treating inadequate systemic perfusion. (Data from Johnston WE: Applied Cardiac Physiology. *ASA Refresher Courses in Anesthesiology*, 2012;40(1):73-79.)

is recommended for treatment of acute heart failure in Europe<sup>41</sup> and has shown mortality benefits when compared to dobutamine, but is not yet available in the United States. If after optimizing volume status and maximizing pharmacologic support the patient remains hypoperfused, then mechanical assist devices should be considered.<sup>42</sup> The intra-aortic balloon pump (IABP) is well established and technically easiest to place; however its efficacy has been recently questioned.<sup>43</sup> In centers trained in their use, ventricular assist devices (VAD) and extra-corporeal membranous oxygenators (ECMO) may confer a survival benefit and should be considered.

## Overview of Procedural Considerations

The anesthetic care of a patient undergoing CABG is a complex, multi-step process. After the anesthesiologist completes a thorough preoperative evaluation, a large bore peripheral IV is placed followed by an arterial catheter, usually placed in the radial artery. Anxiolytics are routinely administered in

the preoperative area. In the operating room, standard ASA monitors are applied, and intravenous induction and tracheal intubation are performed, most commonly with a fast-track approach (Table 11-1), targeting early extubation unless contraindicated. A central venous catheter is then placed if not placed prior to induction, often with PAC. Then, the patient is positioned and draped for surgery while a TEE is performed and results are discussed with the surgeon. Prior to incision, an antifibrinolytic is commonly administered (eg, aminocaproic acid, tranexamic acid) to reduce perioperative bleeding. Antibiotics (typically vancomycin and cefuroxime) are given as infection prophylaxis. Anesthetic depth is adjusted to match changes in surgical stimulation with attention to hemodynamic control and myocardial oxygen supply/demand optimization. Heparin is administered several minutes prior to bypass cannulae placement (usually 300 to 400 units/kg), and its effect confirmed by measuring an activated clotting time (ACT) value of 480 seconds or greater prior to initiating bypass. Inadequate ACT values must prompt action by the anesthesiologist to determine the cause and achieve proper

**TABLE 11-2: Vasoactive Agents**

	a	$\beta_1$	$\beta_2$	$V_1$	HR	CO	SVR	MAP	RBF	Dosing	Notes
Epinephrine	+	++	++	0	++	++	+/-	+	--	0.01-0.20 mcg/kg/min	May give up to 1 mg intravenously at a time during hemodynamic collapse, repeating as necessary.
Norepinephrine	+++	++	0	0	-	-	+++	+++	---	0.01-0.20 mcg/kg/min	
Dopamine	++	++	+	0	+	+++	+	+	+++	2-20 mcg/kg/min	
Dobutamine	0	+++	+	0	+	+++	0	+	++	2-20 mcg/kg/min	Mild vasodilation at low doses, vasoconstriction at higher doses.
Isoproterenol	0	+++	+++	0	+++	+++	--	+/-	-	0.01-0.07 mcg/kg/min	Use generally limited to heart transplants.
Ephedrine	++	+	+	0	++	++	+	++	--	10-25 mg SIVP	Marked tachyphylaxis. Not used as infusion.
Phenylephrine	+++	0	0	0	-	-	+++	+++	---	50-100 mcg SIVP, 0.3-10 mcg/kg/min	Routinely used to treat mild vasodilation. Causes reflexive bradycardia.
Vasopressin	0	0	0	+++	0	0	+++	+++	-	Up to 40 units IV bolus, 0.01-0.1 units/min	
Milrinone	0	0	0	0	+	+++	--	--	-	Bolus up to 50 mcg/kg over 10-30 min, then 0.125-0.75 mcg/kg/min	Phosphodiesterase inhibitor. May be effective for pulmonary hypertension and right ventricular dysfunction can cause systemic hypotension.
Levosimendan	0	0	0	0	+	++	-	-	+	Bolus 12-24 mcg/kg over 10 min, 0.05-0.3 mcg/ kg/min	Inodilator and calcium sensitizer, not available in the United States.

Data from Stoelting RK, Hillier SC: *Pharmacology and Physiology in Anesthetic Practice*, 4th ed. Philadelphia, Lippincott Williams and Wilkins; 2005 and Overgaard CB, Dzavik V: Inotropes and asopressors: review of physiology and clinical use in cardiovascular disease, *Circulation* 2008 Sep 2;118(10):1047-1056.

Heart rate (HR), cardiac output (CO), systemic vascular resistance (SVR), mean arterial pressure (MAP), renal blood flow (RBF). No effect (0), minimal increase (+), moderate increase (++), marked increase (+++), minimal decrease (-), moderate decrease (--), marked decrease (---).

anticoagulation before initiating CPB. The surgeon and perfusionist should be kept notified of the ACT values and any difficulties in anticoagulation. Heparin resistance may require treatment with fresh frozen plasma or antithrombin III concentrate to achieve adequate heparin effect.

After heparinization, the surgeon places an arterial cannula and a venous cannula. Upon initiation of CPB, mechanical ventilation is stopped, the heart is arrested, and revascularization is performed. During this time, volatile anesthetic is typically administered via the bypass circuit by the perfusionist under the anesthesiologist's and surgeon's direction. ACT, hematocrit, arterial blood gases, and blood sugar should be checked periodically during CPB, and any aberrations treated. Serum glucose levels > 180 mg/dL should be treated with insulin infusion.

After the revascularization is complete, the patient should be weaned from bypass. The anesthesiologist should anticipate bypass separation and be prepared, following a standardized routine. Separation preparation steps include: ensuring function of intravascular catheters, ensuring adequate depth of anesthesia, assessing for intracardiac air with TEE, ensuring that core temperature  $\geq 36^{\circ}\text{C}$ , performing a lung recruitment maneuver, and resuming normal ventilation. Establishing an adequate cardiac rhythm and rate, generally 80 to 100 beats per minute may require a pacemaker. Normalizing electrolytes, treating anemia, and preparing vasoactive medications are also important considerations. Though most patients will have adequate cardiac function with a ventricular pacemaker lead, some patients dependent on active atrial contraction for ventricular filling (eg, severe diastolic dysfunction) will require atrial pacing. Biventricular pacing may improve cardiac output to a small degree, which may be clinically important in patients with severe cardiac dysfunction. The actual process of separation requires intense focus and frequent communication amongst the surgeon, anesthesiologist, and perfusionist, and therefore should be conducted in a quiet, "sterile cockpit" environment.<sup>44</sup>

Once the anesthesiologist, surgeon, and perfusionist are prepared to wean from CPB, the anesthesiologist should work to ensure systemic perfusion and cardiac performance by optimizing heart rate and rhythm, infusing volume from the CPB machine to achieve normovolemia, adjusting afterload with vasodilators or vasopressors as necessary, and optimizing contractility with inotropes as needed. This dynamic process occurs while gradually reducing CPB machine flows to minimal support, at which point cardiac function is reassessed, and then pump flow is stopped completely. If cardiac function is not adequate, then steps to correct this are taken prior to separation.

Immediately after separation, the heart is assessed for adequate function, particularly for markers of ischemia (eg, wall motion abnormalities, worsened ventricular function, inadequate graft flow), valvular abnormalities, and for preload, afterload, and contractility. Frequently, adjustments in volume therapy and vasoactive medicines are made, guided primarily by TEE and hemodynamic monitors. After achieving sufficient hemodynamic parameters generally targeting SBP

100 to 120 mm Hg, and a CI  $\geq 2.2$  L/min/m<sup>2</sup>, protamine is slowly given prior to the bypass cannulae being removed.

Following separation, the anesthesiologist must remain vigilant and continue to control and optimize patient hemodynamics. Hemostasis should be assessed by examining the surgical field, measuring ACT and heparin concentration, and in certain cases with thromboelastography. Cardiac output should be measured again after chest closure and support adjusted as necessary. Transfer to the ICU should conclude with a detailed, clear handoff to the ICU team in order to minimize communication failures.

Surgical coronary revascularization can also be performed on a beating heart without CPB, and is termed "off-pump" coronary artery bypass (OPCAB). OPCAB typically utilizes a heart stabilization device that isolates a localized region of surgical interest immobile while allowing the rest of the heart to beat. OPCAB became popularized in the late 1990s and early 2000s, eventually becoming the surgical approach for nearly one-third of coronary revascularizations in the United States. OPCAB purported to reduce the surgical inflammatory stress response, mortality, stroke, cognitive dysfunction, and kidney injury. However, recent meta-analyses suggest that there is no significant difference in cognitive dysfunction between OPCAB and CABG,<sup>45</sup> and that all-cause mortality in OPCAB (3.7%) was slightly higher than CABG (3.1%).<sup>46</sup> Furthermore, the need for subsequent revascularization may be higher in OPCAB.<sup>47</sup> As a result, the use of beating heart techniques in the United States is declining.

The OPCAB lends itself to fast-track anesthetic regimens, and in some centers, this is augmented with thoracic epidural analgesia. Heparinization protocols for OPCAB are variable, though many surgeons target ACT values of 300 seconds. Ischemic preconditioning techniques should definitely be considered, given that transient ischemia is likely during the grafting procedure. Surgical exposure may lead to marked alterations in the heart's position within the chest, potentially dramatically impacting cardiac output. The anesthesiologist should be prepared to monitor systemic perfusion most commonly with TEE and continuous cardiac output monitors, and treat hypoperfusion with volume and inotropes as necessary. Occasionally, despite hemodynamic optimization, adequate perfusion cannot be maintained, necessitating conversion to an on-pump procedure. As a result, a perfusionist and CPB machine should be available during OPCAB.

Minimally invasive approaches to coronary revascularization, either on- or off-pump are becoming more common, and involve either a shorter sternotomy incision or any of various small thoracotomies for access to the coronary arteries. Robotic-assisted techniques allow for remote surgical access via small incisions or ports into the chest cavity. The anesthesiologist must communicate with the surgeon preoperatively to discuss the operative strategy and plan accordingly. Often, lung isolation with a double-lumen endotracheal tube or bronchial blocker facilitates surgical visualization. Anesthesiologists should also be prepared to aggressively avoid hypothermia and ensure that external defibrillator pads are placed due to the limited direct access to the heart.<sup>48</sup>

## VALVE SURGERY

The perioperative care of patients with valvular heart disease creates a considerable challenge for anesthesiologists, surgeons, and intensivists. A great deal of challenge stems from the wide diversity of pathophysiologic derangements found in these patients. This diversity can, in part, be appreciated by comparing representative LV pressure-volume loops for the different left-sided valvular lesions (Fig. 11-3). Clearly, there are significant and important distinctions in end-diastolic LV volume, intracavitary pressure, and stroke volume. However, not only do the major valvular lesions differ from one another in terms of adaptive ventricular responses and hemodynamic profiles, but patients with the same valvular lesion may present with entirely different degrees of symptomatology and hemodynamic compromise depending on the clinical situation and time course over which the valve pathology develops. Again, LV pressure-volume loops illustrate this concept. The patient who develops acute, severe aortic regurgitation (AR) due to endocarditis will present with notably different LV filling volumes and pressures when compared to a patient with a similar regurgitant fraction whose AR develops gradually due to progressive aortic root dilatation (Fig. 11-4). Clinical management must be appropriately adapted.

Another complicating factor in the management of patients with valvular heart disease is the frequent occurrence of multiple valvular lesions in the same patient. General hemodynamic goals for patients with left-sided valve pathology can be easily summarized (Table 11-3). However, not uncommonly, two valve lesions coexist in which hemodynamic goals are opposite. For example, selecting an ideal heart rate for the patient with aortic stenosis (AS) becomes more difficult in the setting of concomitant MR. In these situations, the physician either determines which lesion contributes most to the patient's symptoms, signs, and hemodynamic profile or

**FIGURE 11-3** Representative left ventricular pressure-volume loops depicting a normal ventricle (black), mitral stenosis (blue), aortic stenosis (red), mitral regurgitation (green), and aortic regurgitation (yellow).

**FIGURE 11-4** Representative left ventricular pressure-volume loops comparing a normal ventricle (black) to a patient with acute aortic regurgitation (orange) and chronic aortic regurgitation (purple).

chooses a management strategy that represents a compromise between competing goals.

Although the spectrum of valvular heart disease encompasses a wide variety of hemodynamic findings and adaptive ventricular responses, the natural history of many valve disorders often follows a similar general course. During the initial development of valvular stenosis or regurgitation, the patient remains asymptomatic. Ventricular remodeling serves to normalize indices such as wall tension or stroke volume. Atrial enlargement may mitigate increases in pulmonary or systemic venous pressure. Eventually, following a variable latent period, adaptive responses fail leading to the elevation of cardiac filling pressures, exhaustion of preload reserve, and declining cardiac output. Signs and symptoms of congestive heart failure (CHF) develop or evidence of ventricular dysfunction manifests during imaging studies prompting surgical intervention. The optimal timing of surgical intervention for valvular heart disease continues to evolve, guided by clinical investigations and expert consensus.<sup>49</sup>

## Aortic Stenosis

Aortic stenosis represents the most common valve disorder in the United States.<sup>50</sup> Two reasons help explain this observation. First, a congenital bicuspid aortic valve (AV), which has an increased tendency to become stenotic over time, is found in 1 to 2% of the population. Second, risk factors for degenerative calcification of a trileaflet AV such as hyperlipidemia,

**TABLE 11-3: Hemodynamic Goals for Patients with Valvular Heart Disease**

	Preload	Afterload	Heart Rate
Aortic stenosis	↑	↑	n/↓
Aortic regurgitation	↑	↓	↑
Mitral stenosis	n/↑	↑	↓
Mitral regurgitation	0	↓	↑

hypertension, smoking, and advanced age are also common. Obstruction to outflow creates abnormal systolic pressure (P) within the LV cavity, which in turn, increases wall tension (T) according to the law of Laplace:

$$T = \frac{PR}{2h}$$

where R represents the radius of the ventricular cavity and h represents myocardial wall thickness. Increases in wall thickness by the process of concentric myocyte hypertrophy serve to normalize wall tension, although this remodeling invariably leads to diastolic dysfunction and creates the setting for oxygen supply and demand mismatch. Thus both LV outflow restriction and the pathophysiology of concentric hypertrophy guide perioperative management. For example, tachycardia is particularly deleterious. Increased heart rates disproportionately encroach on diastolic filling and coronary perfusion time in a ventricle where myocardial relaxation is delayed. At the same time, tachycardia increases myocardial oxygen consumption. Elevated end-diastolic pressures in an LV with reduced compliance limit coronary perfusion to subendocardial regions of the hypertrophied myocardium. Reduced LV compliance also makes the LV more dependent on atrial contraction for diastolic filling and atrial fibrillation may be poorly tolerated. Synchronized cardioversion should be employed early in the patient with severe AS who develops atrial fibrillation with signs of low cardiac output.

The anesthesiologist must consider the pathophysiology of outflow obstruction as well as consequences of concentric LV hypertrophy when selecting a perioperative management plan. Since patients with severe AS are very sensitive to anesthetic-induced decreases in preload and afterload, an arterial line is often placed prior to induction to allow early recognition of blood pressure changes and response to treatment. The choice of induction agent is probably not as important as adherence to key hemodynamic goals that include the maintenance of preload and afterload along with a heart rate in the low to normal range. Hypotension is treated promptly, usually with an  $\alpha$ -adrenergic agonist. Opioids such as fentanyl are often included in a balanced anesthetic induction and maintenance regimen since they tend to lower heart rate and minimally impact myocardial contractility. High-dose opioid anesthetic regimens, more popular in preceding decades, provide hemodynamic stability but may hamper early postoperative extubation. Drugs that increase heart rate, such as ketamine or pancuronium, should be used cautiously or in conjunction with vagotonic agents such as opioids. However, while avoidance of tachycardia represents an important perioperative goal, anesthesiologists must also avoid severe bradycardia.<sup>51</sup> In patients with AS, flow across the AV limited and cardiac output declines with heart rates less than 50 beats per minute. When treating bradycardia, drugs such as  $\beta$ -adrenergic agonists or anticholinergics should be titrated carefully to avoid overshoot and the development of tachycardia.<sup>51</sup> Atrial or atrio-ventricular pacing represents an attractive option for

the cardiac surgical patient since it allows precise titration of heart rate.

In addition to an arterial line, central venous access along with a PAC is generally selected for patient undergoing aortic valve replacement (AVR). Central venous access is desirable for the administration of vasoactive medications although central venous pressure (CVP) does not accurately reflect LV filling pressures in patients with severe AS. Likewise, the pulmonary capillary wedge pressure (PCWP) also does not provide a reliable assessment of LV filling in the setting of AS and reduced ventricular compliance. Measuring end-diastolic LV cavity area with TEE provides a more accurate reflection of preload compared with PAC-derived measurements.<sup>51</sup> Nonetheless, despite the limited ability to assess preload and the small risk of arrhythmia during insertion, the PAC offers several advantages including the opportunity to track cardiac output, measure pulmonary artery (PA) pressure, and serve as a conduit for a temporary pacing wire.

## Aortic Regurgitation

Aortic regurgitation (AR) leads to significant volume overloading of the LV and when chronic, the pressure-volume loop shifts farther to the right than for any other valvular lesion (Fig. 11-3). The eccentric LV hypertrophy and chamber dilatation that develop in the setting of chronic AR serve to normalize wall tension and accommodate very large end-diastolic volumes without significant increases in end-diastolic pressure. Patients may remain asymptomatic for years, though eventually compensatory changes are exhausted and in the face of progressively larger ventricular volumes, LV systolic function declines. In cases of acute severe AR, compensatory LV changes are not present. End-diastolic pressure rises quickly and may reach aortic diastolic pressure. In such cases, the combination of a low aortic diastolic pressure and a high LV end-diastolic pressure limit CPP, creating the potential for ischemia.

The hemodynamic goals for patients with severe AR differ from those used to manage AS patients. When the regurgitant fractions exceed 60%, maintenance of cardiac output requires an increase in heart rate.<sup>51</sup> A faster heart rate also reduces the diastolic period available for regurgitant flow into the LV. Avoidance of opioid-induced bradycardia along with the use of a muscle relaxant that increases heart rate such as pancuronium may prove useful. A reduction in afterload promotes forward flow. Propofol, which reduces afterload and displays minimal effects on myocardial contractility at usual clinical doses, represents a reasonable option for the induction of anesthesia.<sup>52</sup> Additional afterload reduction in the form of vasodilators such as sodium nitroprusside may be selected. Because the LV may be severely dilated and LV systolic may be depressed even in asymptomatic patients,<sup>51</sup> inotropic support should be readily available. Agents with  $\beta$ -adrenergic agonist activity, such as dobutamine along with phosphodiesterase inhibitors such as milrinone, increase myocardial contractility while favoring a reduction in afterload.

The hemodynamic monitors chosen for patients with severe AR undergoing AVR are similar to those selected for patients with AS. Intra-arterial pressure monitoring, central venous cannulation, and PAC placement are generally used together with intraoperative TEE. As in the case of AS, the measurement of PCWP may not accurately reflect LV filling, particularly in the case of severe, acute AR where the rapid rise of LV end-diastolic pressure may promote closure of the MV in late diastole. However, many anesthesiologists find the ability to obtain serial measurements of cardiac output to be beneficial. Furthermore, a PAC provides an easy route by which a pacing lead may be placed prior to sternal opening, facilitating the maintenance of an elevated heart rate.

## Mitral Stenosis

Rheumatic disease accounts for most cases of acquired mitral stenosis (MS) in developed countries. Patients with rheumatic MV disease may remain asymptomatic for many years as the left atrium (LA) progressively dilates. Symptoms develop when severe MS limits LV filling and cardiac output. Alternatively, patients with moderate MS may become symptomatic during periods of increased transvalvular flow such as pregnancy or conditions associated with tachycardia.<sup>51</sup> As shown in the simplified Gorlin equation, for a given valve area, when transvalvular flow increases, the pressure gradient also rises.

$$\text{Valve area} = \frac{\text{Flow}}{\sqrt{\text{Pressure gradient}}}$$

Rising LA pressure promotes pulmonary venous congestion and leads to feelings of dyspnea. Over time, pulmonary hypertension develops which may, in turn, lead to right ventricular (RV) enlargement, RV systolic dysfunction, and functional tricuspid regurgitation (TR). A major goal in the perioperative care of patients with severe MS is the identification and quantification of RV impairment.

The anesthetic management of patients with severe MS undergoing MV replacement is guided by several principles. First, tachycardia, which shortens diastolic LV filling time and increases LA pressure, should be treated promptly. The judicious use of preoperative sedation may ameliorate anxiety-induced tachycardia although excess sedation promotes hypoventilation with the attendant risk of increased pulmonary vascular resistance. A number of different agents may be chosen to reduce heart rate including calcium channel blockers,  $\beta$ -blockers, or amiodarone. Atrial fibrillation is commonly found in patients in this patient group and is generally tolerated provided the ventricular rate is controlled. Therefore, unlike patients with severe AS who develop atrial fibrillation, the immediate focus in patients with MS should be to maintain a low to normal ventricular rate rather than conversion to sinus rhythm. Second, because LV filling is already impaired by the stenotic MV, additional reductions in preload caused by anesthesia or blood loss should be carefully corrected. Vasodilation resulting from inhaled or intravenous anesthetics may be treated with incremental doses of an  $\alpha$ -adrenergic

agonist or vasopressin, ideally while monitoring PA pressures. Surgical blood loss should be replaced though overly zealous fluid administration should be avoided to prevent pulmonary vascular congestion and further RV impairment. While the PCWP does not reflect LV end-diastolic pressures in the setting of severe MS, display of PA pressures and serial measurement of cardiac output may be useful in guiding fluid administration. A third principle in the management of these patients involves control of PA pressures and augmentation of the RV systolic function. Because of the aforementioned need to maintain preload, the use of systemic vasodilators, though they may reduce PA pressure, may be poorly tolerated in this group. Instead, a select pulmonary vasodilator such as inhaled prostaglandin or nitric oxide should be considered for those with pulmonary hypertension and RV dysfunction. Additionally, arterial blood gas management is essential. The avoidance of hypoxia together with mild hyperventilation, combine to reduce pulmonary vascular resistance.

Following MVR with normalization of left-sided preload, LV systolic performance is expected to improve. However in a subset of patients, LV systolic performance may be impaired following valve replacement. Possible causes include rheumatic endocarditis or an unfavorable position of the ventricular septum in the setting of pulmonary hypertension and RV enlargement.<sup>51</sup> Intraoperative TEE readily detects abnormalities of ventricular septal position and RV dysfunction in addition to providing a qualitative and quantitative assessment of LV systolic performance. Inotropic support may be required.

## Mitral Regurgitation

Mitral regurgitation shares some similarities with AR. Both conditions increase the preload of the LV and over time, eccentric hypertrophy develops. Like those with AR, patients with MR may remain asymptomatic for long periods. Similar to AR patients, those with MR present for surgery with a spectrum of clinical and imaging findings. The patient with MV prolapse who is followed with serial echocardiograms over a decade differs in important ways from the patient with acute, severe MR due to papillary muscle rupture. The former may well remain asymptomatic or minimally symptomatic and be referred for surgery due to abnormalities in LV size or function, while the latter is likely to present in heart failure with florid pulmonary edema and require intra-aortic balloon pump support preoperatively.

In patients with chronic MR, the contractile appearance of the LV in MR patients often improves initially in response to preload augmentation according to the Frank-Starling principle. Furthermore, the ejection of large quantities of blood into the low pressure LA leads to increases in the calculated ejection fraction although forward cardiac output may decline. An LVEF < 60% identifies reduced systolic performance in patients with severe MR and represents an indication for surgery.<sup>49,53</sup> Physicians have also recognized that an early decline in LVEF following MV surgery for MR is common. Although sometimes considered an inevitable consequence of MV surgery for MR, significant reductions

in LV function postoperatively associated with an ejection fraction < 40% may identify a group at increased risk for premature death.<sup>54</sup> Several reasons have been postulated to explain reduced LV systolic performance following MV surgery, including reduced preload and ischemic cross-clamp injury<sup>55</sup> as well as unrecognized, preexisting systolic dysfunction.<sup>54</sup> Impaired preoperative LV systolic impairment may be underappreciated by echocardiography.<sup>56</sup> Several risk factors identify patients with MR who are at increased risk for low ejection fraction following mitral surgery, including preoperative pulmonary hypertension, preoperative atrial fibrillation, and a preoperative LV end-systolic diameter > 36 mm which confers a 6.5-fold increased risk of having a postoperative LVEF < 40%.<sup>54,55</sup> By assessing preoperative risks factors, anesthesiologists and surgeons can better prepare for the possible use of pharmacologic and mechanical circulatory support after MV surgery. Inotropic agents such as epinephrine and milrinone should be available. Early consideration should be given to placement of an IABP if hemodynamic compromise is refractory to drug therapy.

Hemodynamic goals for patients with severe MR include a reduction in the regurgitant fraction with augmentation of forward flow. For those patients with longstanding MR and pulmonary hypertension, support of the RV is also important. Providing that LV systolic function is not severely impaired, most patients tolerate an intravenous induction of anesthesia. Agents such as propofol reduce afterload and promote forward flow. Bradycardia is avoided since lower heart rates facilitate greater LV filling and distention. Inhalation agents are good choices for the maintenance of anesthesia as they also provide vasodilatation and may increase heart rate slightly. In patients with chronic MR, the LA is usually dilated. Atrial fibrillation may be present but is generally well tolerated since LV filling is unimpeded.

## Robotic and Minimally Invasive Mitral Valve Surgery

The popularity of robotic and other minimally invasive approaches to MV surgery continues to grow. Advantages of these approaches include reduced time to extubation, shortened hospital length of stay, lower blood product transfusion rates, and improved postoperative respiratory function.<sup>57,58</sup> The use of robotic and minimally invasive techniques necessitates changes in anesthetic management. These changes include the need for one-lung ventilation, the percutaneous placement of cannulae for CPB and retrograde cardioplegia, the expanded use of TEE (Table 11-4), and altered strategies for defibrillation. Smaller incisions and reduced need for opioid medications also create the potential for more rapid extubation and the expanded use of regional anesthesia.

Both thoracoscopic and robotic mitral repair utilize a small working incision and additional port access in the right chest. This approach requires deflation of the right lung. Either a double-lumen endotracheal tube or a bronchial blocker may be used to facilitate the operation.<sup>59</sup> Oxygen desaturation associated with one-lung ventilation is particularly problematic

**TABLE 11-4: Uses of Transesophageal Echocardiography During Robotic Mitral Valve Surgery**

- Assess valvular heart disease
- Assess valve repair/replacement
- Detection of additional findings (eg, patent foramen ovale)

following CPB and may be treated by the application of continuous positive airway pressure (CPAP) to the nonventilated right lung, the use of positive end-expiratory pressure (PEEP) with the left lung, or intermittent two-lung ventilation.<sup>60</sup>

Cannulation for CPB for these operations usually consists of femoral arterial and venous access with or without supplementary venous drainage in the form of a vent line in the pulmonary artery or a superior vena cava cannula placed percutaneously from the right internal jugular vein. Surgeon preference and institutional experience guide the cannulation strategy. Intraoperative TEE is used to verify the position of the guidewire and femoral venous cannula. Inadvertent placement of a femoral venous guidewire across a patent foramen ovale is possible and should prompt redirection (Fig. 11-5). Supplementary venous drainage from the main pulmonary artery can be accomplished by means of a specialized endo-vent, the tip of which should be located in the main PA, near the bifurcation (Fig. 11-6A). Again, intraoperative TEE is used to ensure proper placement. TEE imaging can be difficult in these cases requiring the placement of multiple lines in the right heart (Fig. 11-6B).

Aortic cross clamping and cardioplegia administration can be accomplished by several different mechanisms. An endo-aortic balloon may be advanced from the femoral artery into the ascending aorta where inflation serves to isolate the aortic root and facilitate antegrade cardioplegia delivery from the end of the delivery catheter. A percutaneous coronary sinus catheter may also be placed via the right internal jugular vein using TEE or fluoroscopic guidance to allow for the administration of retrograde cardioplegia. Lastly, an antegrade cardioplegia and vent line may be placed via a parasternal stab incision, a strategy similar to many open cardiac operations (Fig. 11-7A). In this last scenario, a long transthoracic aortic cross-clamp is used via a small lateral thoracic incision. The position of this cardioplegia line (Fig. 11-7B) and subsequent cardioplegia delivery (Fig. 11-7C) can be monitored with TEE.

Small incisions preclude the use of internal paddles for defibrillation and cardioversion in robotic MV surgery. Instead, external patches are applied in an anterior-posterior orientation on the left chest.<sup>61</sup> Should defibrillation prove difficult,

**FIGURE 11-5** Transesophageal echocardiographic images showing a guidewire inserted via the femoral vein crossing a patent foramen ovale (A) before being redirected into the superior vena cava (B).

consideration should be given to inflating the right lung to improve electrical impedance.<sup>59</sup>

Minimally invasive mitral surgery facilitates rapid extubation, particularly when regional anesthesia is used.<sup>57</sup> Multiple regional anesthetic techniques have been used in these cases including intrathecal opioid administration, intercostal nerve block, and paravertebral nerve block. The use of preoperative paravertebral nerve block together with a limited opioid dosing strategy was shown to facilitate extubation in the operating room following robotic mitral repair in approximately 90% of cases in one study.<sup>57</sup>

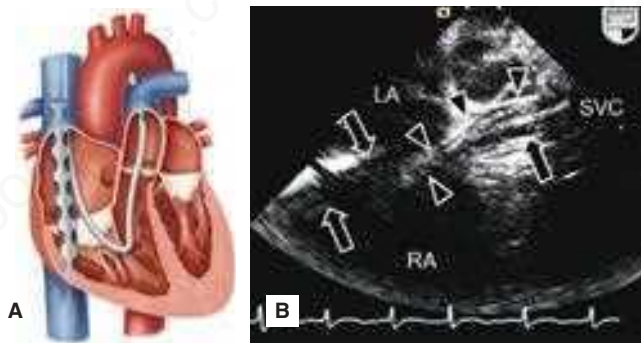

### Tricuspid Regurgitation

Tricuspid regurgitation (TR) found in patients presenting for cardiac surgery is most often functional in nature and occurs secondary to left-sided valve disease, pulmonary

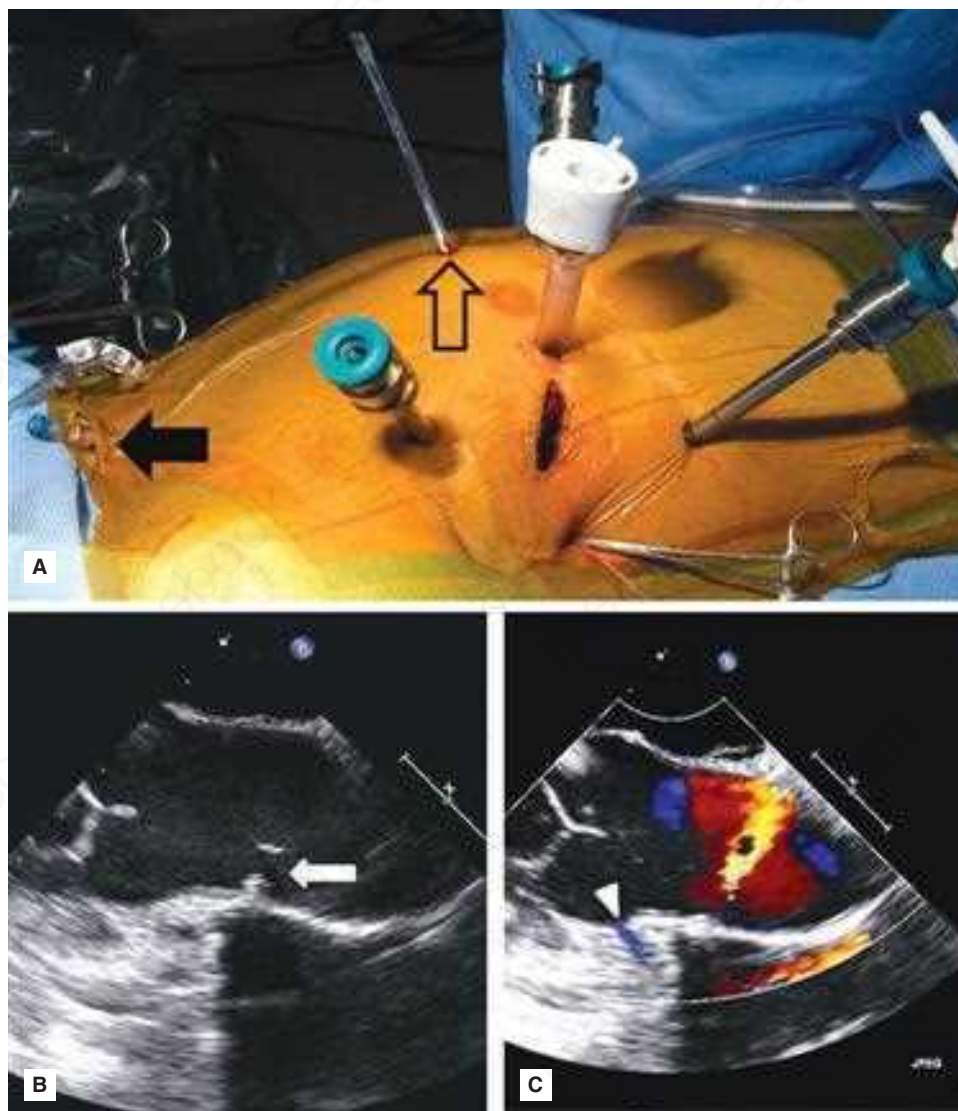

hypertension, or RV dysfunction. As such, the anesthetic management of these patients is usually dictated by the primary condition. However, patients may present with TR due to isolated, organic tricuspid valve (TV) disease. Examples include endocarditis, carcinoid valvulopathy, trauma, or pacemaker-induced valve dysfunction.

General hemodynamic goals for patients with severe TR include support of RV contractility, maintenance of a mildly elevated heart rate, and reduction of RV afterload by reducing pulmonary vascular resistance. Phosphodiesterase inhibitors such as milrinone may augment RV contractility while reducing RV afterload. Dobutamine and isoproterenol represent other possible options. As in cases of pulmonary hypertension or RV systolic dysfunction, careful attention to arterial blood gas values provides an important nonpharmacologic means by which the anesthesiologist can manipulate pulmonary vascular resistance.

In addition to direct arterial pressure monitoring, CVP monitoring is nearly always used for patients undergoing TV surgery even though CVP is a poor indicator of RV filling in the setting of severe TR. Although it may be difficult to advance in the face of severe TR, consideration can be given to PAC placement especially if TV repair or replacement with a tissue prosthesis is contemplated. A PAC facilitates assessment of pulmonary vascular resistance and thermodilutional cardiac output measurement becomes more feasible following TV surgery. The measurement of cardiac output by arterial waveform analysis provides the anesthesiologist with a reasonable alternative to placement of a PAC. These devices can be connected to any invasive arterial monitoring line. Early comparative studies with thermodilutional techniques were disappointing though the updated software in newer models may deliver more robust results.<sup>62,63</sup> The use of TEE can be invaluable in assessing not only valvular pathology but RV function as well. An additional important use of TEE in isolated TV surgery is the identification of intracardiac shunts since in the absence of shunting, CPB without a cross clamp becomes feasible.

**FIGURE 11-6** (A) A potential venous cannulation strategy for robotic mitral valve repair using a multi-orificed cannula inserted via the femoral vein and positioned with its tip in the superior vena cava along with supplemental drainage provided by a vent placed percutaneously into the pulmonary artery. (C) Antegrade cardioplegia administration via a percutaneously placed line.

## THORACIC AORTIC SURGERY

The spectrum of diseases of the thoracic aorta may be classified according to pathology, etiology, timing, clinical presentation, location, and management options.<sup>64-66</sup> Thorough preoperative assessment including a comprehensive history and physical exam, review of preoperative imaging studies, and patient stability all play a role in determining whether the patient can be treated medically with continued surveillance, or surgically with definitive intervention.<sup>64-66</sup> When surgery is warranted, the urgency and planned surgical approach to repair significantly influence the anesthetic plan. Factors such as the cannulation strategy for CPB, the need for temporary cessation of blood flow, and anticipated methods for organ protection determine the optimal anesthetic technique and monitoring

choices during thoracic aortic surgery. While routine monitoring involved in all cardiac surgery patients applies to aortic surgery as well, the anesthesiologist must further individualize management to the patient's disease and the surgeon's operative approach. Hemodynamic goals, especially blood pressure management, can be significantly different from those of the cardiac surgical patient presenting for nonaortic surgery. Maintaining organ perfusion and protecting major organs, specifically those subjected to periods of ischemia, is crucial in allowing for optimal outcomes. Additional monitoring to detect and treat end-organ ischemia is another factor in procedural success. Furthermore, complex thoracic aortic surgery associated with prolonged procedure times and hypothermia frequently results in postoperative coagulopathy that can be effectively managed with anticipation of bleeding and

transfusion requirements. In addition, reliance on intraoperative TEE in guiding the operation, managing isolated single-lung ventilation to allow for adequate surgical exposure, and placement of lumbar cerebrospinal (CSF) drainage catheters are also essential aspects of the operation that give the cardiac anesthesiologist a key role in the surgical treatment of thoracic aortic disease. Recent multi-disciplinary guidelines for thoracic aortic diseases include evidence-based recommendations regarding anesthetic techniques and intraoperative monitoring.<sup>64-66</sup> This review of anesthetic and monitoring considerations for thoracic aortic surgery will be presented in the following three sections: (1) aortic root/ascending aorta; (2) aortic arch; and (3) descending thoracic aorta.

## Aortic Root and Ascending Aorta

Surgical intervention for the aortic root and ascending aorta may be isolated to these aortic segments or may continue distally into the arch and beyond. Surgery for ascending aorta pathology above the root may often involve partial reconstruction of the aortic arch as well.<sup>67</sup> When isolated to the level of the aortic root, the aortic arch may not be included in the surgical intervention. Typically, surgical indications for ascending aortic intervention include dissection, intramural hematoma, and aneurysm.<sup>64-67</sup> Factors such as patient age, connective tissue disorder, family history, and bicuspid aortic valve must all be taken into account when finalizing the surgical plan.<sup>64-67</sup>

The surgical approach to these cases is via a midline sternotomy, and therefore, patients will be positioned supine with both arms tucked and padded at their sides. Along with a balanced general endotracheal anesthetic, these patients typically have an arterial line and PAC placed for hemodynamic monitoring. The maintenance of normotensive blood pressure is suitable for patients with chronic aortic disease. When presenting for elective surgery, preoperative antihypertensive therapy should be titrated to achieve a blood pressure less than 140/90 mm Hg or less than 130/80 mm Hg in patients with diabetes or chronic renal disease (Class I recommendation; Level B evidence).<sup>64,65</sup> Preoperative therapy may even be titrated in known aortic aneurysm patients to achieve the lowest possible blood pressure that is tolerated without adverse effects (Class IIa recommendation; Level B evidence).<sup>64,65</sup> In acute pathologies of the ascending aorta such as dissection, more aggressive treatment to a systolic pressure of 100 to 120 mm Hg is recommended since aortic rupture is a major concern in this phase.<sup>64,65</sup> This strict control of systolic blood pressure is typically achieved with adequate anesthetic depth, titrated analgesia with opioids such as fentanyl and morphine, and vasodilator therapy with agents such as beta-blockers, nitroprusside, nicardipine, or morphine. Intravenous beta-blockade is typically avoided in the settings of significant aortic regurgitation and/or cardiac tamponade since cardiac output in these presentations remains rate-dependent.<sup>64,65,68</sup> Since acute aortic dissection is dynamic and progressive, patients may become acutely hemodynamically unstable, emphasizing the importance for not only being

prepared for these scenarios, but also the importance of a prompt anesthetic induction to minimize delays and control patient anxiety and hypertension.

Anesthetic induction should involve a smooth intravenous induction with adequate anesthetic depth and blood pressure control for laryngoscopy and endotracheal intubation. If presenting emergently, concerns for a full stomach should lead to a 'modified' rapid sequence induction, where cricoid pressure is applied but gentle mask ventilation is used prior to endotracheal intubation. The choice of a left or right radial arterial line depends on disease extent and cannulation strategy. High-quality communication between all members of the operating room team streamlines this process. Indications for a left radial arterial line include innominate disease, and planned right axillary arterial cannulation. A right radial arterial line is often indicated for monitoring of cerebral perfusion pressure in antegrade cerebral perfusion during periods of systemic circulatory arrest.<sup>69-71</sup> The institutional practices for cannulation and monitoring will often determine preferences for which side is chosen. This may include a requirement for bilateral upper extremity arterial lines.

TEE is reasonable in all open surgical repairs of the thoracic aorta, unless a specific contraindication to its use exists (Class IIa recommendation; Level B evidence).<sup>65</sup> When used specifically for the ascending aorta or root surgery, there is a strong consensus that TEE is particularly suited for aortic imaging in unstable patients with suspected acute aortic syndromes.<sup>64,65</sup> TEE can also verify the aortic diagnosis, interrogate the aortic valve comprehensively, and confirm important aortic diameters.<sup>64-66,72</sup> Precise measurements of the aortic root diameters can provide data to guide decision making about whether to replace or spare the root, depending on the clinical scenario (Fig. 11-8).<sup>65-67</sup> Similarly, TEE can be used to assess the extent of proximal dissection within the root and whether the dissection flap crosses the AV to cause AR (Fig. 11-9). This information can provide data to guide the surgical plan for the aortic valve.<sup>73,74</sup> In addition to identifying the presence of a pericardial effusion with or without tamponade, the origin of the primary tear, the extent of the dissection, and regional wall motion abnormalities from coronary dissection, TEE can also guide the surgeon's successful placement of the arterial inflow cannula when direct central cannulation through the dissection is chosen.<sup>75</sup> In this scenario, the echocardiographer must identify the true lumen on TEE with certainty in order to verify correct wire placement (Fig. 11-10).<sup>75</sup> Checking for appropriate flow in the true lumen after initiation of CPB can then further verify adequate cannula location. In addition to assessment of the thoracic aorta, TEE also serves to exclude other cardiac pathology and evaluate the surgical repair and ventricular function after CPB. In the setting of aortic root replacement with coronary reimplantation, TEE can analyze ventricular wall motion after CPB to verify adequate blood flow. While the indications described above are more specific to ascending aorta pathology, TEE plays a similar role in open aortic arch and descending aorta surgical procedures. In addition to TEE, intraoperative monitoring of the carotid arteries with

**FIGURE 11-8** Aortic valve long-axis transesophageal echocardiography (TEE) views in two patients with ascending aorta aneurysms. The benefits of TEE in aortic surgery include the ability to quantify dilation, as well as identify structural integrity of the aortic valve and root. Panel A demonstrates definition of the sinotubular junction (*arrowheads*), while Panel B demonstrates effacement requiring root replacement.

ultrasound can be beneficial in aortic dissection to confirm bilateral carotid flow prior to CPB, while on CPB, and after cross-clamping. In this scenario, brachiocephalic malperfusion may result from factors such as retrograde arterial perfusion, loss of flow through intimal fenestrations, and loss of pulsatile flow.<sup>76</sup> If detected, changes in cannulation site and/or intimal fenestration can restore normal cerebral perfusion.<sup>76</sup>

While midline sternotomy with CPB is the typical operative plan for ascending aorta pathology, endovascular approaches in patients deemed too high risk for open repair have been performed with success.<sup>77,78</sup> Transapical access allows antegrade stenting of the ascending aorta with verification of wire placement and assistance with stent positioning provided by TEE (Fig. 11-11).<sup>78</sup> Just as in transapical

**FIGURE 11-9** Aortic valve long-axis transesophageal echocardiography (TEE) views in a patient with a type A dissection. Aortic regurgitation may not necessarily be due to structural valve disease. TEE demonstrates that in systole (Panel A), the dissection flap (*red arrow*) extends into the root, but it is above the aortic valve (*yellow arrow*). During diastole (Panel B), the dissection flap (*red arrow*) prolapses across the aortic valve, thus preventing adequate coaptation of the valve leaflets.

**FIGURE 11-10** The role of transesophageal echocardiography (TEE) is again demonstrated in a patient undergoing a Type A dissection repair. Central aortic cannulation was performed over a wire placed into the distal ascending aorta. TEE of the proximal descending aorta confirms that the wire (*arrowheads*) is indeed in the true (T) lumen. TEE is also valuable in guiding venous wire and cannula placement.

transcatheter AVR, the anesthetic plan should anticipate the need for rapid ventricular pacing for stent deployment and should include appropriate resuscitative measures for hemodynamic recovery after pacing.<sup>79</sup>

### Aortic Arch

The decision to include the aortic arch in the operative plan depends on the pathology and extent of disease.<sup>64-66,80</sup> Although a hemiarch is often appropriate, total aortic arch replacement may be required in the setting of extensive arch disease.<sup>64-66</sup> Furthermore, the advent and expansion of hybrid aortic arch procedures will likely lead to a drift towards endovascular adjuncts in high-risk patients.<sup>64-66,81</sup> Direct

arch replacement typically requires temporary cessation of systemic blood flow to allow for arch reconstruction, with greater periods of hypothermic circulatory arrest frequently required for total arch replacement. Although hypothermic circulatory arrest is an established classic technique, it still carries the risk of neurological complications.<sup>82</sup> Therefore, neuroprotective strategies must be incorporated into the anesthetic and surgical plans to decrease risk to the patient (Class 1 recommendation; Level B evidence).<sup>64,65</sup> Although there are several neuroprotective options available, there still exists marked variation in the conduct of hypothermic circulatory arrest, including choice of cerebral protection strategies and preferred neuromonitoring techniques.<sup>83,84</sup>

### NEUROPROTECTION DURING ADULT AORTIC ARCH REPAIR

The high metabolic rate of the brain makes it particularly susceptible to ischemic injury during periods of circulatory arrest.<sup>85</sup> To mitigate this ischemia, hypothermia is utilized to decrease both cerebral metabolic and oxygen demands, allowing for increased periods of circulatory arrest.<sup>85</sup> The degree of hypothermia utilized for aortic arch repair has recently been defined by international consensus into four levels: profound, deep, moderate, and mild (Table 11-5).<sup>85</sup> The optimal level of hypothermia for aortic arch repair has recently been under scrutiny.<sup>85</sup> The requirement for profound or deep hypothermic circulatory arrest has recently been questioned due to concerns about the increased risks of coagulopathy, inflammatory response, and end-organ dysfunction.<sup>82-85</sup> The increasing utilization of cerebral perfusion adjuncts, such as retrograde cerebral perfusion (RCP) or selective antegrade cerebral perfusion (ACP), have enabled moderate degrees of hypothermia to be increasingly chosen for aortic arch procedures with successful outcomes.<sup>82,85-87</sup> The conduct of RCP involves retrograde perfusion through the superior vena cava cannula to achieve a CVP of 15 to 20 mm Hg, typically monitored at the level of the right internal jugular vein.<sup>88</sup> Although RCP with deep hypothermic circulatory arrest provides excellent

**FIGURE 11-11** Transesophageal echocardiography (TEE) views of a patient with an ascending aorta intramural hematoma (Panel A). Considered too high risk for sternotomy and cardiopulmonary bypass, an endovascular approach via the left ventricular apex was chosen. TEE demonstrates wire access (*red arrowheads*) across the aortic valve (Panel B) before stent deployment (*yellow arrowheads*) into the proximal ascending aorta (Panel C).

**TABLE 11-5: Consensus Classification of Hypothermia in Aortic Arch Surgery**

Level of Hypothermia	Nasopharyngeal Temperature
Profound hypothermia	≤14°C
Deep hypothermia	14.1-20.0°C
Moderate hypothermia	20.1-28.0°C
Mild hypothermia	28.1-34.0°C

outcomes for aortic arch repair with short reconstruction times, the amount of perfusate that actually provides metabolic substrate to support brain metabolic function during RCP remains low.<sup>88,89</sup>

The emerging contemporary paradigm for adult aortic arch repair is the utilization of moderate hypothermia with ACP since this guarantees cerebral perfusion, extends the duration of time for aortic arch reconstruction, and avoids the morbidity of deeper levels of hypothermia.<sup>82,84-87</sup> ACP can be performed either in a unilateral fashion with a cannula in the right axillary artery or innominate artery, or in a bilateral fashion with cannulas in both the innominate and left carotid arteries. Although ACP can be unilateral or bilateral, recent trials both in elective and emergent adult aortic arch repair suggest that unilateral ACP at adequate pressure with appropriate neuromonitoring is safe, effective, and straightforward.<sup>90-92</sup> Perfusion during ACP is often titrated to maintain flows in the range of 10 to 15 mL/kg, a right radial artery pressure of approximately 50 to 60 mm Hg, and a baseline neuromonitoring profile.<sup>93</sup> The final selection of both the degree of hypothermia and type of cerebral perfusion adjunct will depend on factors such as the patient, the aortic arch pathology, surgical preferences, and institutional practices. Despite the significant variability, it is reasonable to use the perfusion management strategy that is best suited to the team and institution (Class IIa Recommendation; Level B Evidence).<sup>65</sup>

In addition to these perfusion strategies for neuroprotection, pharmacologic agents are also often employed.<sup>83,84</sup> Thiopental or propofol may be given at doses to cause burst suppression.<sup>93</sup> Corticosteroids, magnesium, and lidocaine are also popular for their potential neuroprotective benefit.<sup>83,84,94,95</sup> Recent analysis from a large adult European registry has suggested that steroids may decrease the stroke rate after aortic arch reconstruction.<sup>95</sup> There is currently no strong evidence to guide the choice of pharmacologic agents for improving neurologic outcomes after thoracic aortic surgery. Therefore, the use of these agents should be considered an adjunct to hypothermia. Further trials are required to identify best practices in this area.

### NEUROMONITORING DURING ADULT AORTIC ARCH REPAIR

Neuroprotective strategies during aortic arch repair such as hypothermia, cerebral perfusion adjuncts, and appropriate pharmacology do not guarantee prevention of postoperative

neurologic injury. Furthermore, general anesthesia precludes a full neurological examination during the procedure. Intraoperative neurophysiologic monitoring remains important for early detection of possible neurologic injury and for assessment of adequate perfusion. The ability to identify impending injury can also allow for earlier intervention to prevent permanent injury. The use of intraoperative monitors can certainly help guide therapy, but the decision to use such monitoring will depend on individual patient needs, institutional resources, the urgency of the procedure, and the perfusion techniques being used (Class IIa Recommendation; Level B Evidence).<sup>65</sup> Furthermore, while these monitors provide valuable information intraoperatively, there are no large, randomized controlled trials that provide conclusive evidence that these monitors decrease neurologic injury after adult aortic arch repair.

Electroencephalography (EEG) measures spontaneous electrical brain activity via electrodes placed in a standardized fashion on the scalp. The electrical activity is amplified and displayed on a monitor as a continuous EEG signal. During the use of deep hypothermic circulatory arrest, gradual slowing of the EEG occurs until electrocortical silence is achieved with continued lower temperatures (Fig. 11-12).<sup>96</sup> Therefore, the degree of hypothermia needed for neuroprotection can be determined by EEG silence as a marker of brain temperature and metabolic suppression.<sup>88,96,97</sup> Without EEG, simply cooling to a target temperature such as 18 degrees Celsius may not provide adequate cerebral metabolic suppression since this approach does not guarantee EEG silence in 100% of patients.<sup>96,97</sup> EEG is also a useful monitor to detect seizures and ischemia during thoracic aortic surgery.<sup>98,99</sup> Since anesthetic agents can attenuate EEG amplitude and frequencies, high-quality communication between all intraoperative team members can minimize anesthetic interference with the EEG recordings for optimal neuromonitoring at all phases of the procedure. During systemic rewarming, the return of the EEG signal to baseline suggests neurologic injury did not occur as a result of the arch repair or unintended brain hyperthermia.<sup>97,100</sup>

An increase in jugular bulb venous oxygen saturation monitored via an oximetric catheter has also been utilized for guiding temperature-induced cerebral metabolic suppression.<sup>101</sup> Although jugular bulb saturation > 95% suggests cerebral metabolic suppression, routine jugular bulb saturation monitoring has not enhanced the neuroprotective effects of hypothermia.<sup>101</sup> As an alternative, near-infrared spectrophotometry (NIRS) offers noninvasive measurement of cerebral oxygen saturation.<sup>83,84,93</sup> A further advantage of NIRS over EEG is its ability to continue monitoring cerebral perfusion status after EEG silence has occurred. However, NIRS only provides a focal assessment due to small sample size of brain tissue being monitored, and therefore, it may not detect ischemia in other brain regions.<sup>102</sup> Similar to pulse oximetry, the NIRS device is based on different absorption characteristics of oxygenated and deoxygenated hemoglobin, as measured from two adhesive pads placed over the frontal lobes.<sup>102</sup> Cerebral oximetry values typically increase during deliberate hypothermia since cerebral oxygen demand decreases.

**FIGURE 11-12** Electroencephalography (EEG) obtained during a case of ascending aorta and hemiarch replacement using deep hypothermic circulatory arrest. As the patient is progressively cooled, amplitude and frequency decrease from baseline (Panel A) until EEG silence (Panel B) is obtained (approximately 18°C in this patient). Note the signal artifact in Panel B.

During periods of cerebral ischemia such as circulatory arrest, decreases from the baseline cerebral oximetry values suggest inadequate perfusion.<sup>102</sup> Whether RCP or ACP is being employed, perfusion pressures via RCP cannulas or ACP cannulas can be adjusted to seek an improvement in NIRS values. Similarly, when unilateral ACP is being employed, a drop in the contralateral NIRS monitor suggests inadequate contralateral hemispheric perfusion due to an incomplete circle of Willis or due to inadequate ACP flow. Increasing ACP unilateral flow and/or instituting bilateral ACP typically restore the NIRS values to baseline, which may correlate with better perioperative neurologic outcomes.<sup>103,104</sup> While the use of NIRS is becoming more standard in the conduct of adult aortic arch repair, further trials are required to delineate best practices with this novel technology.<sup>102</sup>

## Descending Thoracic Aorta

The main diseases of the descending thoracic aorta and/or the thoracoabdominal aorta that require surgical intervention are aneurysm and dissection.<sup>64-66</sup> The repair options include open replacement, thoracic endovascular aortic repair (TEVAR) and hybrid procedures that involve both techniques.<sup>105</sup> The anesthetic plan for descending thoracic aorta repair must be tailored according to the surgical approach, with a major goal for all surgical techniques to prevent distal ischemic injury to the visceral organs and the spinal cord. This ischemia can occur during the repair itself when flow may be intermittently occluded or due to loss of aortic branches. To prevent organ injury and neurologic deficit, emphasis should be placed on strategies to minimize ischemia, as well as quickly identify and treat ischemia.

## OPEN SURGICAL REPAIR

Access for open repair of the descending thoracic aorta is achieved by a left thoracotomy with the patient in the right lateral decubitus position. When the disease process extends into the abdominal aorta, an extensive thoracoabdominal incision is indicated for retroperitoneal access to the abdominal aorta.<sup>106</sup> In addition to full invasive monitoring, it is preferable to have a femoral arterial line to monitor lower body perfusion. To allow for adequate visualization in the left chest, a left-sided double-lumen endotracheal tube is typically utilized for selective collapse of the left lung, although at times, aneurysmal compression of the left main bronchus may require downsizing or a switch to a bronchial blocker for effective lung separation. In addition to allowing good exposure, lung isolation also reduces the need for pulmonary retraction and may decrease unintended pulmonary contusions.<sup>65</sup> At the conclusion of the operation, the decision to exchange the endotracheal tube for a single-lumen endotracheal tube should be made after a thorough evaluation for airway edema and bleeding. A single-lumen tube is usually desired to allow for better pulmonary hygiene; however, routine exchange to a single-lumen tube is not recommended when significant upper airway edema or hemorrhage is present (Class III Recommendation; Level C Evidence).<sup>65</sup>

Prevention of postoperative spinal cord ischemia remains a major goal for descending aortic surgery (Table 11-6).<sup>107</sup> When an open repair is performed, various strategies are possible to maintain distal aortic and spinal cord perfusion. These surgical options will only be briefly discussed here, allowing for a focus on nonsurgical adjuncts and neuromonitoring. A simple aortic cross-clamp technique has been used with success when clamp time is minimized, but it does not allow

**TABLE 11-6: Strategies for Spinal Cord Protection During Descending Thoracic Aortic Repair**

Gott shunt	Augmentation of mean arterial pressure
Partial left heart bypass	Decrease CSF pressure via CSF drainage
CPB with DHCA	Reattachment of intercostal arteries
Systemic hypothermia	Somatosensory evoked potentials
Steroid administration	Motor evoked potentials

CPB, cardiopulmonary bypass; DHCA, deep hypothermic circulatory arrest; CSF, cerebrospinal fluid.

for organ protection during the ischemic period.<sup>107</sup> Prolonged cross clamp can be detrimental to organ function, especially when >30 minutes.<sup>107</sup> Distal perfusion using left heart bypass can be achieved with drainage of oxygenated blood from the left atrium being returned to a femoral artery after going through a perfusion circuit.<sup>106,107</sup> Modifications based on the presence or absence of an oxygenator dictate anticoagulation requirements. This technique has the benefit of maintaining spinal cord, mesenteric, and renal perfusion, while simultaneously allowing for a degree of proximal hypertension to maintain additional spinal cord perfusion via the vertebral artery.<sup>106,107</sup> Left heart bypass can also keep the LV unloaded in situations of extreme proximal hypertension. Alternatively, the surgeon can choose full CPB with hypothermic circulatory arrest to complete the repair when the distal aortic arch requires intervention.<sup>107,108</sup>

An additional strategy to potentially provide spinal cord protection from ischemia includes the use of mild to moderate systemic hypothermia (Class IIa Recommendation; Level B Evidence).<sup>65,106,107</sup> Hypothermia not only decreases metabolic demands, but it also attenuates the inflammatory response during reperfusion. As mentioned above, administration of steroids for neuroprotection is frequently practiced to potentially reduce spinal cord edema, but clear evidence for benefit remains uncertain (Class IIb Recommendation; Level B Evidence).<sup>65,106,107</sup> The augmentation of spinal cord perfusion is also an important perioperative technique for neuroprotection (Class IIa Evidence; Level B Evidence).<sup>65,106,107</sup> Spinal cord perfusion pressure is equal to the difference between the mean arterial pressure and the cerebrospinal fluid (CSF) pressure. Systemic vasoconstrictors such as phenylephrine, norepinephrine, and/or vasopressin to increase the mean arterial pressure can effectively treat spinal cord ischemia, and gradual continued augmentation should be continued if ischemia persists.<sup>106,107</sup> It is important to keep in mind that cardiac output augmentation with inotropes may also be necessary to improve oxygen delivery. The second option for spinal cord perfusion pressure augmentation is CSF drainage via a lumbar CSF drain. CSF drainage is recommended in all patients at high risk for spinal cord ischemia (Class IIa Recommendation; Level B Evidence).<sup>66,108</sup> Both randomized trials and

meta-analyses have demonstrated that CSF drainage results in decreased postoperative paraplegia after open thoracic aortic surgery.<sup>107</sup> Drainage of CSF should aim for a lumbar CSF pressure of 10 mm Hg, without causing rapid drainage that can result in intracranial hypotension.<sup>107</sup> Although preoperative placement of these catheters is common, postoperative placement may be indicated in patients with spinal cord ischemia. Like all neuraxial invasive techniques, the coagulation status of the patient should be normalized prior to instrumentation to avoid hematoma formation. Further reported complications from CSF drainage catheters include retained catheter fragments, spinal headaches, nerve palsy, and meningitis.<sup>107</sup> A surgical option for augmenting spinal cord perfusion is reimplantation of intercostal and segmental branches to the new aortic graft or occlusion of large vessels that backbled to prevent arterial steal.<sup>107</sup>

As equally important as it is to treat spinal cord ischemia is the ability to detect ischemia.<sup>106-108</sup> Early detection can allow for intervention to take place before permanent, irreversible ischemic damage occurs. Postoperatively, serial neurologic examinations can be performed on the patient that has recovered from general anesthesia.<sup>107</sup> This is not an option, however, for the anesthetized patient in the operating room that is undergoing an open repair. Therefore, the use of neurophysiological monitoring of the spinal cord is advocated when feasible (Class IIb Recommendation; Level B Evidence).<sup>65</sup>

The use of somatosensory evoked potentials (SSEPs) and motor evoked potentials (MEPs) allow the surgeon and anesthesiologist to respond quickly to changes seen from baseline recordings. SSEPs are performed by placing stimulating electrodes on peripheral nerves in both upper and lower extremities. Stimulation is then conducted via the posterior and lateral columns of the spinal cord to the cerebral cortex. SSEPs can influence blood pressure and CSF management, but they can also guide the need for further reimplantation of segmental vessels.<sup>107</sup> The advantage of SSEPs is that the signal is less affected by anesthetics and paralytic agents. However, anterior spinal cord ischemia can still occur without a change in SSEPs. While more complex, the use of MEPs is occasionally advocated because they rely on stimulation of the motor cortex with signals conducted through the anterior column of the spinal cord. Although more sensitive than SSEPs, MEP signal is also more influenced by anesthetic and paralytic agents.<sup>107-109</sup> The choice of SSEPs or MEPs is often also dependent on institutional culture and resources. Interpretation should be performed and guided by trained team that often includes a neurologist. It is essential to keep in mind that changes in SSEP or MEP signals from baseline are not necessarily caused by spinal cord ischemia (Fig. 11-13).<sup>107-110</sup> Hypothermia can cause global signal attenuation.<sup>110</sup> Similarly, interruption of lower extremity blood flow from infrarenal vascular clamping can also cause signal attenuation. The site of signal attenuation along the neural pathway can determine whether central or peripheral malperfusion has occurred. Close communication between the neuromonitoring team and the rest of the intraoperative team is essential to

**FIGURE 11-13** Somatosensory evoked potentials (SSEPs) are obtained from all four extremities in a patient undergoing open descending aorta repair. Overlapping signal in Panel A suggests similarity to baseline readings, while global loss of signal in Panel B (obtained at 24°C) is likely due to hypothermia and not spinal cord ischemia.

ensure appropriate and timely detection of and intervention for significant events.<sup>107-110</sup>

### ENDOVASCULAR REPAIR

Endovascular intervention for descending thoracic aortic disease has significantly increased.<sup>64-66</sup> In addition to being far less invasive and allowing for quicker recovery, TEVAR may also reduce perioperative complications.<sup>64-66,107,111</sup> Similar to open repair, the principles of preventing, detecting, and treating spinal cord and organ ischemia remain important, although the risk of spinal cord ischemia in TEVAR is significantly lower.<sup>107</sup> Risk factors for spinal cord ischemia in this setting include a long segment of aortic coverage (eg, left subclavian to celiac arteries) and patients with prior aortic repair.<sup>107</sup> Although the adjuncts of neuromonitoring and CSF drainage are not routine in TEVAR, they are strongly considered in elective patients with risk factors.<sup>107</sup> Significant attenuation of evoked potentials in this setting merit interventions such as permissive hypertension and CSF drainage, as outlined earlier.

During TEVAR, the patient remains supine with both arms tucked at the sides. For general anesthesia, a single-lumen endotracheal tube suffices since lung isolation is not required. A radial arterial line and typically large-bore central venous access are also obtained. Tracheal extubation is a reasonable goal for uncomplicated interventions. This allows for a quick neurologic examination to rule out any potential ischemia that may have occurred. Alternatively, either regional or local anesthesia may be options, depending on institutional practice and case specifics.<sup>112</sup> A continuous epidural infusion can allow for patient comfort, as well as continuous detection of neurologic function. However, it is imperative to differentiate the effects of neuraxial blockade by local anesthetics from true spinal cord malperfusion. Although not routinely performed, TEE is reasonable in endovascular aortic repair for monitoring, procedural guidance, and/or graft leak detection (Class IIa Evidence; Level B Evidence).<sup>65</sup> Comprehensive TEE can assist with quantifying vessel caliber, locating guidewires, as well as postdeployment assessment of cardiac function and interrogation of the aorta.

Involvement of the distal arch may require a very proximal landing zone for the TEVAR stent. In some instances, coverage of the left subclavian artery may be warranted and unavoidable in emergent situations. While an argument can be made to monitor left radial arterial pressure for this scenario, a right radial arterial line is more practical if preoperative revascularization has not been performed. In more elective cases of TEVAR, a prior staged procedure can include either transposition of the left subclavian to the left common carotid artery or a left carotid-subclavian bypass.<sup>113-115</sup> This revascularization option is now being endorsed when feasible due to recent meta-analysis that suggests an increased risk of arm ischemia, stroke, and spinal cord injury.<sup>113-115</sup>

## HEART FAILURE SURGERY

Despite maximal goal-directed medical therapy, a subset of patients with chronic CHF will develop advanced stages of disease.<sup>116</sup> For these patients who progressively deteriorate despite optimal goal-directed medical therapy, interventions including implantable defibrillator device or cardiac resynchronization therapy and surgical therapy including revascularization, valve, ventricular restoration and remodeling surgery, or mechanical circulatory support (VADs, heart transplantation) may be warranted.<sup>116</sup>

### Anesthetic Management of the Patient with Heart Failure

Anesthetizing patients with advanced CHF can be challenging as they commonly have the following findings consistent with poor functional reserve: severe symptoms at rest or with minimal exertion; episodes of fluid retention and/or peripheral hypoperfusion; objective evidence of severe cardiac dysfunction (ie, LVEF < 30%, restrictive mitral inflow pattern by Doppler echocardiography, elevated LV and/or RV filling pressures, elevated B-type natriuretic peptides); evidence of systemic organ injury (ie, renal and hepatic dysfunction); severe impairment of functional capacity; and history of multiple hospitalizations for CHF in the prior six months.<sup>117</sup> Hyponatremia with serum sodium < 133 mEq/L is also relatively common and is associated with worse outcomes.<sup>118</sup>

Preoperative evaluation includes an assessment of the level of the patient's dependency on cardiovascular support with medications and devices. Heart failure patients are medically managed with a variety of medications that have significant perioperative implications.<sup>119</sup> Hypotension with induction and maintenance of anesthesia is common among patients taking angiotensin-converting enzyme inhibitors (ACE-I), angiotensin-receptor blockers, milrinone, and nesiritide because all of these drugs can cause significant vasodilation.<sup>120,121</sup> Perioperative hypotension associated with angiotensin-receptor blockers may require the administration of vasopressin because it may be refractory to phenylephrine or ephedrine.<sup>122</sup>

Heart failure patients are often fully anticoagulated at the time of urgent or emergent surgery because they are taking prophylactic agents to attenuate the development of venous thromboembolic disease due to reduced cardiac output, increased systemic venous pressure, and chemical changes promoting blood clotting. As such, they may require aggressive perioperative warfarin reversal. However, instead of volume-loading patients with fresh-frozen plasma, other therapies including vitamin K and/or four-factor prothrombin complex concentrates (ie, plasma-derived concentrates of vitamin K-dependent clotting factors II, VII, IX, X, protein C and S) may be required perioperatively.<sup>123</sup> Of note, most prothrombin complex concentrates contain varying amounts of heparin and are therefore contraindicated in patients with heparin-induced thrombocytopenia (HIT).<sup>124</sup> Furthermore, many patients have had prior cardiac surgery and will need blood products (irradiated and cytomegalovirus-negative) immediately available in the operating room at the time of induction of anesthesia.

Assessment of antiarrhythmic devices and implantable cardioverter-defibrillator includes interrogation and reprogramming to a mode that is not affected by electrocautery. External defibrillator pads need to be placed and the defibrillator function temporarily deactivated.<sup>125</sup> Appropriate arterial and venous lines are placed before induction of anesthesia. Depending on the patient characteristics and the presence of a nonpulsatile VAD, arterial line placement may be difficult and may require ultrasound guided placement. If a patient does not already have a PAC, one can be placed before or after induction of anesthesia. Of note, placing a PAC in a patient with a VAD can be challenging and may have to be placed under fluoroscopic guidance in the catheter laboratory or in the operating room. Floating a PAC across the tricuspid valve is sometimes difficult and for the patient undergoing heart transplantation, the catheter tip needs to be withdrawn into the superior vena cava. In this position, the infusion ports are outside of the vein in the sheath, making them unavailable for use until the catheter is reintroduced into the correct position after the donor heart is transplanted.

Induction and maintenance of anesthesia in CHF patients with marginal reserve requires diligent titration of medications in order to maintain acceptable organ perfusion, while avoiding arrhythmias and hypotension. A balanced anesthetic is usually provided by administering a combination of narcotics, muscle relaxants, and intravenous and/or inhalational anesthetic agents with judicious use of vasopressors and inotropes. Anticoagulation for CPB is usually achieved with heparin, but because heart failure patients are often exposed to heparin, they may have antibodies, and direct thrombin inhibitors may need to be administered instead.<sup>126,127</sup>

Weaning from CPB can be challenging and intraoperative TEE can be useful in guiding patient care. As heart failure patients often have preexisting pulmonary hypertension or RV dysfunction, they are more likely to develop post-bypass right heart failure. Vigilance in prevention and early detection of post-bypass RV failure is important<sup>128</sup> (Table 11-7).

**TABLE 11-7: Management of Right Ventricular Failure After Cardiac Surgery**
**Optimization of RV rate and rhythm**

- a. Maintain sinus rhythm to maintain optimal filling of a hypertrophied, dilated right ventricle: consider pacing, early cardioversion
- b. Because of associated TR, higher heart rates may be desirable (80-100 beats/min) to reduce end-diastolic volume but if there is significant RV ischemia, excessive tachycardia may not be tolerated

**Optimize RV filling**

- a. When CVP is low, the RV may be “coping” and an elevated CVP may imply a failing RV with or without TR
- b. Although past teachings encouraged volume loading the RV to increase pulmonary blood flow and cardiac output, injudicious volume loading can result in acute RV distention resulting in RV failure

**Maintain RV coronary perfusion pressure**

- a. Inotropic support

**Reduce pulmonary vascular resistance**

- a. Optimize ventilation strategies
- b. Avoid acidosis and hyperinflation of the lungs
- c. Inhaled pulmonary vasodilators (nitric oxide, prostacyclin, iloprost, and milrinone)

**Surgical Management**

- a. RVAD
- b. ECMO

ECMO, extra-corporeal membranous oxygenators; RV, right ventricle; TR, tricuspid regurgitation; CVP, central venous pressure; RVAD, right ventricular assist device.

## Anesthetic Management for the Heart Transplantation

Heart transplantation is the gold standard for treatment of end-stage heart failure. The 1-year and 5-year survival after heart transplantation is 81% and 69% respectively, with a median survival of 11 years for all recipients, and 14 years for those surviving the first year after transplantation ([www.isHLT.org/registries](http://www.isHLT.org/registries)).<sup>129</sup> Cardiomyopathy (55%) and chronic ischemic heart disease (36%) are the leading underlying cause of heart failure among heart transplant recipients for whom the median adult recipient age is 54 years while the proportion of patients transplanted at extremes of ages continues to increase.<sup>129</sup> Not surprisingly, close to half of the recipients have undergone previous cardiac surgery, 35% have a VAD, most commonly for the LV, and 7% have an IABP. Although 1.1% of transplant recipients were on preoperative extracorporeal membrane oxygenation (ECMO), this number has increased from 0.3% in the mid-1990s.<sup>127</sup>

Heart transplantation occurs urgently or emergently and requires close coordination with the harvesting team to minimize ischemic time. As close to half of the patients have had prior sternotomy, blood availability and cannulation strategies need to be confirmed. In addition to the usual antibiotic prophylaxis, immunosuppressive medications need to be administered. Inotropic medications, IABP, or other

mechanical assistance are maintained until institution of CPB.<sup>130</sup> TEE is useful in assessing the native heart. Pretransplant TEE evaluation includes an assessment of the presence of intracardiac thrombus and degree of atheromatous plaque at cannulation sites.

Heart failure patients are at increased risk for developing HIT. Thus it is important to ascertain that heparin use is acceptable. Otherwise, alternative anticoagulation with direct thrombin inhibitors or preoperative plasmapheresis to reduce HIT antibodies may be necessary.<sup>126,127</sup> Patients who are sensitized with preformed anti-human leukocyte antigen antibodies against donor antigens are at increased risk for acute or hyperacute rejection as well as transplant vasculopathy.<sup>131</sup> Antibodies are common among patients presenting for a second transplant.<sup>131</sup> Various desensitization modalities may need to be employed (plasmapheresis, immunoglobulin, rituximab, and bortezomib), and some of the therapies may require pretreatment with acetaminophen, diphenhydramine, and corticosteroids to prevent cytokine release syndrome.<sup>132</sup>

Weaning from CPB can be challenging as post-bypass contractility can often be marginal or poor. Certain donor heart characteristics may predispose the recipient to poor prognosis after heart transplantation (Table 11-8). After weaning from CPB, right heart failure can develop and in extreme cases, primary graft failure can occur.<sup>133</sup> Careful TEE evaluation and titration of inotropes and ventilator strategies aimed at reducing pulmonary vascular resistance and use of inhaled epoprostenol or other selective inhaled pulmonary vasodilators can facilitate weaning from CPB. Occasionally, patients may develop RV failure requiring temporary support with a VAD or ECMO.<sup>134,135</sup>

## Anesthetic Considerations for Ventricular Assist Device Implantation

Mechanical circulatory support, including the use of VADs and the total artificial heart, is another therapeutic option for the advanced stage heart failure patient.<sup>116</sup> Similar to heart transplant recipients, patients eligible for VAD placement have marginal reserve and require careful titration of anesthetic drugs to induce and maintain anesthesia. Many of these patients require significant preoperative inotropic support, which often must be maintained throughout the operative course. Up to 40% of patients undergoing VAD implantation have profound vasoplegia and may require vasopressin and methylene blue administration.<sup>136,137</sup> The goal of perioperative fluid management is to maintain intravascular volume to facilitate left VAD (LVAD) function without creating RV dysfunction.<sup>138</sup> Blood transfusions are avoided if possible to prevent sensitization for future heart transplantation. Because infection is a major cause of death, VAD patients often receive multiple prophylactic antibiotics.

The key to successful LVAD implantation lies in preventing RV failure, which occurs in 25 to 50% of recipients.<sup>139</sup> Ventricular interdependence plays an important role in the development of post-LVAD failure of the RV. Because of the anatomic proximity of the RV to the LV, changes in LV

**TABLE 11-8: Donor and Recipient Characteristics Associated with a Poor Prognosis After Heart Transplantation**

#### Donor heart characteristics

##### Donor age

Increased age is associated with higher risk at 1-year and long-term mortality (12)

##### Presence of LVH

LVH > 14 mm associated with lower survival in recipients (33)

##### Gender mismatches (34)

##### Donor cause of death (35)

Intracranial bleed associated with transplant vasculopathy

##### Donor history of coronary artery disease

Can cause early and late graft failure (37)

#### Recipient characteristics

Obesity (BMI > 30 kg/m<sup>2</sup> or percent ideal body weight > 140%)

Associated with > 5-year mortality rates and shorter time to high-grade acute rejection (7)

##### Ischemic time\* > 210 min

Associated with increase in acute graft failure in 1-year and 5-year mortality rates (17)

##### Presence of donor-specific antibodies (DSA)

Increases risk for acute or hyperacute rejection and transplant vasculopathy (38)

##### Elevated pulmonary vascular resistance

Pretransplant RVAD only, ECMO, extracorporeal LVAD\*\*, TAH (32)

Associated with poor graft survival

\*Ischemic time:donor aortic cross-clamp to removal of recipient aortic cross-clamp.

\*\*Pretransplant implantable LVAD dependence was not shown to be associated with decreased graft survival.

References are shown in parenthesis. LVH, left ventricular hypertrophy; BMI, body mass index; RVAD, right ventricular assist device; ECMO, extracorporeal membrane oxygenation; LVAD, left ventricular assist device; TAH, total artificial heart.

volume can result in immediate changes to RV pressure and volume and vice versa. Monitoring the position of the septum in the immediate post-CPB period is crucial since >50% of RV function is dependent on proper septal function.<sup>128</sup>

Studies have shown that a functioning LVAD can decrease RV afterload, increase RV compliance, and decrease RV contractility.<sup>140</sup> When the LV is completely decompressed, global RV contractility can be impaired secondary to the leftward shift of the interventricular septum. Nonetheless, RV myocardial efficiency and power output are maintained through a decrease in RV afterload and increase in RV preload.<sup>140</sup> However, with preexisting right heart dysfunction, anatomic ventricular interaction is accentuated causing a greater decrease in RV contractility which can ultimately lead to RV failure.<sup>128</sup>

In order to maintain midline position of the interventricular and interatrial septum, LVAD flows, volume status, RV function, degree of tricuspid regurgitation (TR) as well as other hemodynamic variables (CVP, pulmonary artery pressures, left atrial pressures, and mean blood pressure) may need to be carefully adjusted. LVAD flows may also need to

be decreased to prevent increased venous return from overwhelming the functional capacity of the RV. Other treatment principals in preventing or mitigating RV failure need to be considered as well, including (1) maintaining sinus rhythm in order to optimize filling of a hypertrophied or dilated RV; (2) avoiding acute RV distension by overzealous volume loading; (3) maintaining RV CPP and RV inotropic therapy; (4) maintaining RV geometry; and (5) reducing pulmonary vascular resistance<sup>128</sup> (Table 11-7). In severe RV failure, RVAD placement may be necessary.

Although several preoperative risk factors for post-LVAD failure of the RV have been identified, the occurrence of RV failure is largely unpredictable.<sup>138</sup> Therefore, in addition to utilizing ventilator strategies to decrease pulmonary vascular resistance by avoiding PEEP, hypoxia, hypercarbia, and acidosis, nonselectively inhaled pulmonary vasodilators (nitric oxide, epoprostenol) at the time of weaning from bypass may be utilized.

Pre-LVAD implant intraoperative TEE evaluation includes assessment for thrombus in the apex where the inflow cannula will be inserted; evaluation for atherosclerosis of the ascending aorta where the outflow graft will be placed; evaluation for atrial septal defects or patent foramen ovale as significant right-to-left shunting post-LVAD implantation can lead to severe hypoxemia; determining the degree of AR as valve replacement or surgical closure may be required in the presence of moderate or severe AR; and a thorough evaluation of RV function.

TEE is also valuable in assisting the surgeon with the position of inflow and outflow cannulae. The LVAD inflow cannula is usually placed in the apex for destination therapy and bridge-to-transplant, and in the left atrium for those who with a previous ventriculoplasty procedure or in those with an anticipated quick recovery. Ideally, the LV inflow cannula should be angled toward the MV in alignment with the LV inflow tract, while not abutting any wall.<sup>141</sup> The outflow graft in the proximal ascending aorta can sometimes be difficult to visualize by TEE. The tip of an RVAD inflow cannula is ideally oriented in the middle of the right atrium away from the atrial septum and tricuspid valve. The outflow cannula is usually placed in the pulmonary artery, 1.5 to 2 cm beyond the annulus.

The development of smaller VADs has enabled the increasing use of minimally invasive implant strategies, including off-pump procedures. Transthoracic echocardiography (TTE) and TEE are helpful in assisting placement of the inflow cannula via a small thoracotomy or subcostal incision.<sup>142</sup>

## Total Artificial Heart

Total artificial heart (TAH) implantation is relatively rare and involves only 2.3% of all device implants.<sup>143</sup> Several management issues specific to the TAH (SynCardia, Inc., Tucson, AZ; formerly known as CardioWest) have significant clinical implications.<sup>144</sup> Anesthetic management of other total artificial heart devices that are not yet FDA-approved is not discussed in this section.

During TAH implantation, the native cardiac ventricles and arterioventricular valves are removed and in its place, an orthotopic pneumatic pulsatile device consisting of two separate artificial ventricles is implanted. Each ventricle has two single-tilting mechanical valves mounted on the housing of the artificial ventricle. Several advantages of a TAH include the ability to pump at high flow rates (>9 L/min at maximal stroke volume of 70 mL) with filling pressures of 8 to 15 mm Hg. Common indications that favor TAH versus biventricular assist device include severe myopathies that result in biventricular hypertrophy with small intraventricular chamber size, failed Fontan, failed cardiac transplantation, myocardial infarction with related ischemic cardiomyopathy resulting in intractable biventricular failure with postinfarct ventricular septal defects (VSD), large LV apical aneurysm or LV thrombus, and severe AV pathology including AR or mechanical valve prosthesis.<sup>144</sup>

When placing a perioperative central venous line, the tip of the central venous catheter must not extend into the right atrium, as central venous catheter entrapment in the right TAH mechanical inflow valve can result in fatal TAH malfunction.<sup>145</sup> Thus, placement of a PAC should not be attempted in these patients after TAH implantation. Although weaning from CPB is generally not an issue, some patients may require vasopressors to treat vasoplegia. Inotropes are not needed in these patients. Assessing adequate de-airing can be challenging because the TAH air diaphragms that drive blood out of the ventricles appear similar to intracardiac air. Thus, de-airing relies on repeated evaluation for air in the atria, pulmonary veins, ascending aorta, and main pulmonary artery.<sup>146</sup>

Cardiac tamponade in the classical sense of RV diastolic compression after TAH implantation cannot occur because of the rigid construction of the artificial ventricles. However, “tamponade” due to compression or kinking of the vena cavae (IVC compression more common than SVC) and/or pulmonary veins (left pulmonary vein compression more common than the right) can occur. Therefore, while the native heart is in place, baseline TEE of the vena cava and pulmonary veins may be useful for enabling identification and evaluation of kinking after TAH implantation.<sup>146</sup>

Peak Doppler flow velocities  $\geq 1.1$  m/s in patients following radiofrequency ablation for atrial fibrillation have been associated with pulmonary vein stenosis.<sup>147</sup> Although peak velocities > 2 m/s have been associated with no apparent hemodynamic consequences after TAH implantation, more studies are necessary to determine acceptable peak values.<sup>146</sup> In the meantime, establishing baseline post-TAH implant pulmonary vein flow velocities may provide a helpful comparison in the future when other signs of hypoperfusion point to possible kinking of the pulmonary veins.

## ELECTROPHYSIOLOGY AND CARDIAC CATHETERIZATION LABS

As technology advances and the population ages, medical interventions and surgical treatments converge, while target patient populations combine as complexity and acuity rise.

Our ability to treat conditions once outside the penumbra of “traditional” surgical and medical care continues to grow. As diagnosis and interventions become more specialized and sophisticated, the broadened scope of our medical horizon necessitates the integration of related disciplines, particularly in the case of interconnected specialties. Nowhere is this more pressing than in cardiovascular medicine. For cardiac surgeons, cardiac anesthesiologists, electrophysiologists, and interventional cardiologists, it is increasingly necessary that we understand the essential framework of each other’s medical thought process and practice in order to optimize the care we provide and the therapeutic interventions we offer.<sup>155</sup>

## Electrophysiology Lab

In a relatively short period of time, electrophysiology (EP) procedures have developed from largely diagnostic studies to complex, lifesaving interventions. Patients are more complex than ever, and demand for devices and procedures is high. Successful treatments and long-term survival of previously tenuous cardiovascular medicine patients has broadened the target population. Similarly, cardiac surgery patients often benefit from therapeutic interventions in the EP lab.

### DEVICES FOR THE MANAGEMENT OF DYSRHYTHMIAS

**Pacemakers.** Bradycardia at the level of the sinus node or AV node, either spontaneous or as a result of cardiac medications or surgeries, can be treated with pacemakers.<sup>156</sup> These devices deliver electrical impulses that depolarize myocardial cells near the lead tip and propagate into the contiguous myocardium. Pacemakers can be programmed in many ways. Pulse delivery sequences depend on how the pacemaker is programmed. Single-chamber transvenous pacemakers have a lead in the atrium or in the ventricle. Dual-chamber transvenous pacemakers typically have leads in both the right atrium and ventricle. Pacemakers capable of biventricular pacing have ventricular leads that can pace both the RV and LV. These devices are usually placed within the EP laboratory and require minimal to moderate sedation for the patient. Occasionally in the case of very frail patients, only local anesthesia is used. If the patient has psychiatric, neurological, neuromuscular, or other disorders, which preclude the use of nurse-administered sedative agents, anesthesiologists can provide deeper sedation or general anesthesia with other intravenous agents or volatile anesthetics. Surgically placed epicardial pacemakers may have electrodes that pace the heart overlying the right atrium, RV or LV. Patients often come to the EP lab with surgically implanted epicardial wires for hookup to a pacemaker, which is subsequently placed by an electrophysiologist. When necessary, hybrid surgical and transvenous systems can be created for patients with prohibitive anatomy, including those with tricuspid valve replacement, congenital heart disease or occluded vessels. Standard programmed modes for pacemaker operation are included in Table 11-9.<sup>157</sup>

**TABLE 11-9: Pacemaker Modes<sup>7</sup>**

**North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) code describing pacemaker function**

Position	I	II	III	IV	V
Category	Chambers paced	Chambers sensed	Response to sensing	Programmability, rate modulation	Multisite pacing*
Letters used	O—None A—Atrium V—Ventricle D—Dual (atrium and ventricle)	O—None A—Atrium V—Ventricle D—Dual (atrium and ventricle)	O—None T—Triggered I—Inhibit D—Dual (triggered and inhibited)	O—None R—Rate modulation	O—None A—Atrium V—Ventricle D—Dual (atrium and ventricle)

\*Not commonly used in reference to pacemaker modes.

Single-chamber pacemakers are typically programmed to pace in the cardiac chamber where the electrode is attached, only when bradycardia occurs in that chamber. For example, a single-chamber ventricular pacemaker programmed in the VVI mode with a lower rate limit of 60 bpm in a patient with atrial fibrillation and slow ventricular response will only pace when the patient's heart rate goes below 60 bpm. In contrast, a dual-chamber pacemaker programmed in the DDD mode with a lower rate limit of 60 bpm will pace the atrium if the atrial rate falls below 60 bpm but will also pace the ventricle if the programmed AV interval has elapsed. Therefore, a normally functioning dual-chamber pacemaker may at times pace the atrium, the ventricle, or both cardiac chambers.

In response to development of a rapid atrial rhythm such as atrial fibrillation, a device may “mode switch” which means that the device would switch from a tracking mode such as DDD to a nontracking mode such as VVI or DDI in response to rapidly detected atrial rates. The “mode switch” option prevents the device from inappropriate rapid pacing the ventricle when a rapid rhythm occurs in the atrium. Cardiac surgeons and cardiac anesthesiologists need to be aware of pacemaker settings both in the operating room and after surgery. A patient in the operating room with a pacemaker may develop a rapid ventricular rate in response to a rapid atrial rate on induction of anesthesia or insertion of an invasive line if “mode-switch” is not enabled. Atrial fibrillation can commonly occur after cardiac surgery as well. This can be particularly problematic for those with pacemakers without “mode-switch” who do not tolerate rapid rates, such as patients with hypertrophic obstructive cardiomyopathy.

**ICDs.** Implantable cardioverter defibrillators (ICDs) have the capability of treating rapid ventricular arrhythmias to prevent sudden death. They have pacing functions that are much the same as electronic pacemakers. In the past, patients required separate pacemaker and defibrillator units implanted in order to achieve dual-chamber pacemaker function with concomitant defibrillator capability. However, modern devices are capable of the majority of pacemaker and defibrillator functions simultaneously. ICD leads differ from pacing leads in that there is a coil present on defibrillator leads that

participates in the shocking circuit. ICDs detect ventricular arrhythmias via a small bipolar electrode at the tip of the lead. Detection rates for ventricular arrhythmia are set by the operator via a radiofrequency communication link. ICDs have two ways of responding to ventricular arrhythmia. They can be programmed to deliver antitachycardia pacing or ATP, which will deliver a burst of pacing to the ventricle slightly faster than the cycle length of the ventricular tachycardia. ATP offers the possibility of terminating the arrhythmia without delivering a potentially painful shock to the patient. If ATP is unsuccessful or if the arrhythmia is rapid enough to exceed programmed parameters, the device can also deliver a shock to terminate the tachycardia. ICDs can be implanted in the EP lab with the same anesthetic regimens as pacemakers. If patients requiring ICDs are clinically fragile they may benefit from anesthesiology oversight.

Both pacemakers and ICDs can provide Cardiac Resynchronization Therapy. In patients with low ejection fraction > 35% and ventricular dyssynchrony, pacing of both ventricles simultaneously can improve heart failure symptoms. Patients who come to the EP lab for an upgrade or implantation of a device for this purpose frequently manifest the clinical signs of chronic low perfusion. Sedation regimens must be tailored to these individuals and/or anesthesiology backup may be needed.

Electrocautery can produce electromagnetic interference that can alter the appropriate function of both pacemakers and ICDs. This can be a significant problem in the operating room. Electrocautery “noise” can initiate pacemaker failure. In the case of ICDs, electrocautery “noise” can cause inappropriate detection of ventricular arrhythmia and inappropriate delivery of shocks. Both pacemakers and ICDs have their function altered in response to magnet application. This is achieved by a reed switch which moves in response to magnet application and then returns to its original position after the magnet is removed. Pacemakers respond to magnet application by pacing in an asynchronous mode (AOO, VOO, or DOO) at a rate which is related to the remaining battery life. For ICDs, the effect of magnet application is to turn off detection for ventricular arrhythmias. No effect on pacing occurs. If a patient with an ICD is pacemaker dependent,

their device may require reprogramming in addition to magnet application for safe performance of a surgical procedure involving electrocautery.

## ELECTROPHYSIOLOGY STUDIES AND ABLATION PROCEDURES

Common indications for electrophysiology study include risk stratification for sudden death, determination of cause of syncope, diagnosis and treatment of supraventricular tachycardias, as well as diagnosis and treatment of idiopathic ventricular tachycardias. Standard electrophysiology studies are typically performed under light conscious sedation, though in the pediatric population these are sometimes performed under general anesthesia. EP studies typically require femoral vein access, occasionally bilateral. Arterial access or transseptal puncture is performed to reach left-sided structures. In an electrophysiology study, solid multi-electrode catheters are used to measure electrical impulses during sinus rhythm and arrhythmia from stereotyped locations, including the right atrium, the RV, and the His bundle. For supraventricular tachycardia ablation, a catheter is often also positioned in the coronary sinus. Radiofrequency energy is the most commonly used ablation modality, though cryoablation is also used.

**Catheter Ablation of Atrial Fibrillation.** Atrial fibrillation is the most common sustained cardiac arrhythmia. It is the most common contributor to cerebrovascular accident in the United States. Risk factors for developing atrial fibrillation include older age, hypertension, valvular heart disease, cardiomyopathy, obesity, sleep apnea, and CAD. There are also metabolic causes including hyperthyroidism and acute alcohol intoxication. Other diseases or conditions that cause cardiac irritation such as pericardial status or pneumonia can play a role. In 1998 Dr. Haïssaguerre and colleagues showed that atrial fibrillation in patients with paroxysmal atrial fibrillation and frequent atrial ectopy had rapid firing from myocardial sleeves around pulmonary veins that could initiate atrial fibrillation.<sup>158</sup> It is now understood that many patients with atrial fibrillation have at least a contribution from these myocardial sleeves in the pulmonary veins which remain a primary target for typical atrial fibrillation ablation. For patients with more persistent atrial fibrillation, other areas are also targeted, including some lines of ablation such as the roof, mitral isthmus, in an attempt to mimic the results of the Cox MAZE procedure.

Success rates for catheter ablation of atrial fibrillation are in the 80% range for patients with normal hearts, and paroxysmal atrial fibrillation. For patients with low ejection fractions or heart failure, success rates are closer to 50 to 70%. The procedure is improving with better anticoagulation and ablation techniques. Complications are in the 1 to 2% range and include a risk of stroke, myocardial infarction, tamponade, atrial esophageal fistula, pulmonary vein stenosis, pericarditis, and phrenic nerve injury. Many centers utilize esophageal temperature monitoring to avoid esophageal injury during ablation which can be life-threatening. Phrenic nerve injury can also occur during the procedure. Pacing is used

to identify the phrenic nerve and avoid injury. Ablation for atrial fibrillation is usually performed under general anesthesia. Multiple anesthetic protocols can be used, but paralysis must be avoided in order to avoid obscuring phrenic nerve injury. Anesthetic regimens should involve short acting agents since pain after the procedure is minimal and can usually be managed with nonsteroidals. Because these procedures can be long, patients often experience discomfort from lying on a hard table for long periods of time. Common comorbidities among patients with atrial fibrillation include obesity and sleep apnea, although many are otherwise healthy. Intubation and extubation require care and expertise. Care must be taken to avoid coughing at the end of the procedure to minimize potential disruption of femoral access sites and retroperitoneal bleeding.<sup>159</sup>

**Ventricular Tachycardia Ablation in Structural Heart Disease.** Ventricular tachycardia (VT) in structural heart disease is a highly morbid condition that is associated with inappropriate device discharges, and life-threatening VT storm.<sup>160</sup> Successful catheter ablation can eliminate the need for toxic antiarrhythmic drugs, and can be life-saving particularly in VT storm. Ventricular tachycardia in the setting of structural heart disease is usually the result of reentry circuits which form around regions of scar tissue. Electro-anatomic barriers to conduction due to dense fibrosis form in zones of slow conduction. Patients with scar-related VT can have ischemic heart disease due to myocardial infarction which may be remote. Cardiomyopathies due to sarcoidosis, Chagas disease, idiopathic cardiomyopathy, or viral cardiomyopathy occur as well. All of these conditions have other systemic effects as well. Scar-related VT due to prior cardiac surgery is also seen often after repair of congenital heart disease such as Tetralogy of Fallot.

Catheter ablation of scar-related VT requires thorough preoperative preparation and planning. Interdisciplinary discussion is critical because the patients can be quite tenuous. Anesthesiologists, electrophysiologists, and cardiac surgeons should be aware of the potential for possible untoward events. Echocardiography is used to screen for mobile LV thrombus. Heart failure regimens are optimized. Screening for residual ischemic heart disease is often performed. These patients are also often complex and have many comorbidities. Planning is necessary for intraprocedural and postprocedural management of other concomitant disease, including vascular, pulmonary, and renal disease. This type of ablation is typically done under general anesthesia. Often vasoactive agents are needed, and induction of anesthesia requires planning for potential arrhythmia management during airway manipulation. Invasive lines may be required prior to induction of the arrhythmia so that hemodynamic and fluid management can be optimized. If the patient's ventricular function is severely compromised, adjuvant inotropic, intra-aortic balloon pumping or percutaneous LVADs may be needed.<sup>159</sup> Anesthesiologist and electrophysiologists should both be involved in making planning decisions including when and how to decide on admission to ICU, postprocedure ventilation, and

extubation parameters. A plan for the approach to the ventricles is made and should be discussed with all team members. The LV can be accessed via a retrograde aortic or transeptal approach. Epicardial subxiphoid percutaneous puncture is often also employed. For patients in whom neither of these approaches is possible, surgical approaches to the epicardium as well as transcatheter alcohol approaches can be utilized.<sup>158</sup> The procedure itself usually consists of identification of the relevant scar substrate, induction of the clinical arrhythmia, confirmation of the location of the VT circuit by pacing, and ablation of the slow conduction areas.

## Structural Heart Disease in the Cardiac Catheterization Laboratory

The breadth of structural heart conditions now amenable to treatment in the Cardiac Catheterization Laboratory has expanded enormously in the past decade. This is a direct result of both technological advancement and an age-related increase in the size of target patient populations. Not only is the prevalence of age-related disease on the increase, but the long-term survival of surgically treated patients and congenital heart disease patients makes the advent of nonsurgical interventions preferable in a group where surgical options may be limited.

### CLOSURE OF PATENT FORAMEN OVALE

Patent foramen ovale (PFO) is a common condition estimated to be present in 25% of the population. However, the vast majority of patients with PFO have no related clinical issues. Clinical conditions that may arise as a result of the presence of a PFO include paradoxical embolism resulting in neurological injury, myocardial infarction, renal or mesenteric infarction, or limb ischemia. A PFO may also result in abnormal right to left shunting in patients with alterations in chest anatomy associated with kyphoscoliosis or after surgery resulting in positional hypoxemia also known as platypnea-orthodeoxia syndrome. At the present time, there is no FDA approved indication for PFO closure as clinical trials in patients with neurological events have not definitively shown benefit.<sup>161,162</sup> However, PFO closure is still performed in specific patients who experience neurological events or in patients with platypnea-orthodeoxia syndrome.

PFO closure requires femoral venous access for device delivery. Ultrasound guidance is required and can be achieved by intracardiac ultrasound (ICE) or TEE. If ICE is used, a second femoral venous access site is required for the delivery of the catheter. If TEE is to be utilized, patients are usually placed under general anesthesia for airway protection and comfort during the procedure. Patients undergoing PFO closure usually do not experience hemodynamic compromise, and short-acting anesthetics are advisable since post-op intubation is not usually required. The decision to use ICE versus TEE depends on comfort level of the implanting physician with either modality. ICE does have the advantage of not requiring general anesthesia and allowing the implanting

physician to control image acquisition. TEE has the advantage of greater breadth of visualization of cardiac structures.

The procedure usually does not require hemodynamic assessment as these defects are not hemodynamically significant and usually do not result in left to right shunting. The defect is crossed using any of a variety of catheters and a stiff wire is delivered to the left upper pulmonary vein. The delivery sheath is then advanced to the left atrium and the device is delivered attached to a delivery catheter. The left atrial side of the device is opened, the device pulled back to the intra-atrial septum, and then the right atrial side of the device is deployed. Once the position is confirmed by fluoroscopy and echocardiography, the device is released from the delivery cable. At the present time, there are no FDA approved devices for PFO closure. Devices that can be used for this purpose include the St. Jude Cribriform Septal Occluder (St. Jude Medical, Minneapolis, MN) or the Gore Helix septal occluder (Gore, Newark, DE).

### ATRIAL SEPTAL DEFECT

Atrial septal defect (ASD) is a much less common condition than PFO. The adult with ASD is referred for closure if they demonstrate symptoms of dyspnea or exercise intolerance, or they have evidence of right heart volume overload due to left to right shunt which is usually detected by enlargement of right heart structures on echocardiography. Percutaneous closure of ASD is the treatment of choice for ostium secundum defects. Ostium primum and sinus venosus defects require surgical closure as placement of a septal occluder device may impinge on vital adjacent structures.

Like PFO closure, ASD closure can be performed using ICE or TEE. Echocardiography is vital for device sizing. Once femoral access is obtained, right heart catheterization is performed to assess hemodynamics and shunt fraction across the defect. The defect is then crossed and occluded with a sizing balloon until color flow across the defect ceases. The waist of this balloon is then measured on echo for estimation of defect size and device size selection. Echocardiography is also vital for device placement and ensuring proper position of the device prior to releasing it from the delivery system and to ensure that nearby structures including the MV, tricuspid valve, inferior/superior vena cava have not been compromised by the placement of the device. General anesthesia is commonly utilized for these cases. Because patients develop right heart volume overload, close hemodynamic monitoring during the case is necessary. Arrhythmias are not uncommon in this population. Short-acting anesthetics are preferred, post-op intubation is usually not required. At the present time, there are two devices approved for ASD closure, the Amplatzer Atrial Septal Occluder (ASO) (St. Jude Medical, Minneapolis, MN) and the Gore Helix septal occluder (Gore, Newark, DE).

### VENTRICULAR SEPTAL DEFECT

Ventricular septal defect can be congenital or acquired. Adult cardiac catheterization labs more typically see acquired VSD

in the setting of ventricular septal rupture after myocardial infarction or as a result of trauma. Acquired VSD closure in the catheterization lab can be a very challenging procedure. Patients are critically ill, often decompensated and require intubation. In most cases, the percutaneous option is a salvage procedure. Patients with acute rupture are felt to be poor candidates for surgical repair. VSD closure requires accessing and crossing the defect which can be difficult. Precise visualization can be challenging as collateral structures are often disrupted and hard to identify. TEE guidance may be required for three-dimensional visualization. Venous access can be obtained from the right internal jugular approach or right femoral approach if the defect is to be crossed from the right heart. If the defect is to be crossed from the left heart, some operators choose to take the transseptal approach to left heart access and defect crossing. Once the defect is crossed, a wire is advanced to the other side of the circulation, and the wire is snared from an alternative access site, usually the femoral artery. The wire is retracted out of the sheath and secured, allowing the wire to serve as a rail for device delivery, which can be challenging given the tortuosity involved. There is no ideal device for acquired VSD closure and the device chosen is generally based on the location and perceived shape of the device. Closure of congenital defects is generally an elective procedure with similar techniques used for defect crossing and device delivery. A variety of VSD occluders are available for this purpose.

Anesthetic management during traumatic VSD repair can be complex and extremely demanding. It involves hemodynamic compensation during manipulation required to place and deploy the closure device. Oxygenation may be an issue and patients can present in shock. For closure, more than one device may be required because the integrity of the diseased tissue is poor. Procedures can be long. Vasoactive agents are commonly needed, and post-op intubation is usually required. Although the incision of an open heart procedure is not needed, the circulatory status of the patient is usually severely compromised and the cardiac tissue is in suboptimal condition.

### PARA-VALVULAR LEAK

Patients with significant para-valvular leak (PVL) of mitral or aortic valve prostheses who are not candidates for repeat cardiac surgery are referred to the catheterization laboratory for attempt at closure of the defect. These can be the most challenging procedures due to complexities involved in crossing the defect, delivering a closure device, and obtaining a reasonable seal of the defect with the device.

PVL closure is elective. However, patients can be compromised by their pathology. Given the potential length of the procedure as well as the importance of TEE guidance, patients usually receive general endotracheal anesthesia. Three-dimensional TEE has become an important adjunct to this procedure as it allows the operator to see where the defect is along the sewing ring of the valve, and to accurately direct guidewires across the defect. Mitral prosthesis defects are approached by obtaining transseptal access to the

left atrium, and crossing the defect into the LV. Aortic prosthesis defects are approached retrograde by gaining access in the femoral artery and crossing from aorta to LV. Once the defect is crossed, the guidewire is snared and externalized via an arterial sheath. The wire is secured and serves as a rail over which a delivery catheter can be delivered. The defect is sized with a balloon and an appropriately sized occluder device is placed across the defect. A variety of closure devices can be used to cross the defect and occlude it. There is no ideal closure device for this purpose as these defects are generally crescentic and irregularly shaped. Post-device closure assessment with TEE is vital to assess residual leak and need for further devices as well as to ensure that prosthetic valve function is not hampered by the presence of the closure device.

### AORTIC VALVE DISEASE

As the population ages, a greater number of patients are presenting with severe, symptomatic AS. Once a patient with severe AS becomes symptomatic, there is a rapid decline in functional status and development of congestive heart failure. If not corrected, the condition will ultimately be lethal within several years. Surgical AVR is the standard of care for severe AS; however, transcatheter aortic valve replacement (TAVR) is now an option for some patients. Based on recent clinical trials, TAVR is now indicated for patients who are deemed inoperable or high risk for standard surgical AVR. High risk is defined as having a Society of Thoracic Surgeons risk score of >8%.<sup>163-166</sup> There are several possible routes of access for TAVR with the preferred route being transfemoral access. However, in patients with inadequate femoral access, alternative routes can be considered, including trans-apical, direct trans-aortic, and subclavian access. Depending on the institution and route of access, TAVR can be performed in the catheterization lab or a hybrid catheterization laboratory/operating room.

In patients who are in need for urgent or emergent aortic valve intervention but are not acutely candidates for surgery or TAVR, balloon aortic valvuloplasty (BAV) may be performed to relieve the obstruction across the aortic valve and improve hemodynamics allowing the patient to recover from their acute illness. The durability of the result is limited, however, and if deemed appropriate candidates, these patients will go to need definitive aortic valve therapy.

Most TAVR procedures are performed under general anesthesia with TEE guidance; however there is a growing experience with performing transfemoral procedures under heavy sedation and TTE assessment. Given the potential for acute instability, however, these procedures are virtually uniformly performed in collaboration with anesthesia independent of the method of sedation. Echocardiography is not critical for guidance of the device placement but is necessary post-device placement to assess for complications including PVL, valve dysfunction, and pericardial effusion. For transfemoral TAVR, careful femoral access is critical as the delivery sheaths used for the procedure range in size from 14Fr to 20Fr depending on the device and size of device used. Once the diseased valve is crossed with a guidewire, a balloon dilation

of the valve may be performed depending on the device that will be used. The device is then deployed using fluoroscopic guidance and aortography.

There are two devices approved for TAVR at this time, the Sapien XT device (Edwards Lifesciences, Irvine, CA) and the CoreValve device (Medtronic, Minneapolis, MN). The Sapien XT device is a balloon expandable device. Once positioned, rapid pacing is initiated to essentially cease cardiac output and ensure valve stability during deployment. The CoreValve device is a self-expanding prosthesis that is positioned across the valve and opened by “de-sheathing” the valve in position. Rapid pacing may be utilized during the most critical portion of delivery but usually at rates of 110 beats per minute.

TEE is performed to determine if placement is appropriate and to assess PVL. Findings may guide operators to perform an additional balloon dilation to reduce PVL or perhaps consider the placement of a second device.<sup>167</sup> At the conclusion of the procedure, the delivery sheath is removed and the access site closed, usually with a suture-mediated closure device that is deployed in the artery prior to sheath delivery. For patients who have insufficient transfemoral access for TAVR, alternative access sites can be used. The Sapien XT device can be delivered via a direct trans-aortic approach or a trans-apical approach. The CoreValve device can be delivered via a direct trans-aortic approach or a subclavian approach. Each of these alternative access sites require surgical access and are therefore performed under general anesthesia in a hybrid catheterization laboratory/operating room suite.

## MITRAL VALVE DISEASE

The treatment of choice for rheumatic MS is balloon mitral valvotomy (BMV) in appropriate patients. Suitability for BMV is based on the degree of leaflet mobility, leaflet calcification, subvalvular apparatus calcification, and degree of MR. Successful BMV has a long-term outcome that is similar to surgical repair; however it is not a commonly performed procedure in developed nations as the incidence of rheumatic fever is low. BMV for rheumatic MS can be performed under conscious sedation, as echocardiography is not usually required for the performance of this procedure. However, some operators prefer the use of general anesthesia and TEE for the procedure and it may be required in patients with respiratory compromise. TEE allows for direct visualization of the intra-atrial septum during the transseptal puncture. TEE also allows for direct assessment of post-BMV MR. The procedure requires femoral vein access for balloon catheter delivery and femoral arterial access for placement of a pig-tail catheter in the LV to allow for simultaneous left atrium/ventricle pressure measurement to assess the trans-mitral gradient post-BMV. Transseptal puncture is performed and the appropriately sized balloon is advanced across the septum and MV. The balloon is inflated and then removed. Gradients are then measured to assess adequacy of the result.

The Mitra-Clip (Abbott Vascular, Santa Clara, CA) is FDA approved for patients with severe symptomatic degenerative MR who are deemed high risk or inoperable for surgical MV

repair/replacement.<sup>168</sup> This procedure requires general anesthesia and TEE guidance. The clip is usually placed on the middle anterior (A2) and posterior (P2) segments of the MV, thereby mimicking the effect provided by an Alfieri stitch of the MV, although more than one clip may be necessary. Transseptal puncture is first performed for left atrial access. The device is then delivered into the left atrium and across the MV for echo-guided deployment.

## Potential Complications

### EP LAB

Any procedure which involves the introduction of wires into the heart or great vessels incurs a risk of perforation of those structures. RV perforation can occur during pacemaker implantation as well as during radiofrequency ablation. Extraction of any hardware can cause perforation as well. Retroperitoneal hematomas can also occur, as well as pneumothoraces. Vigilance is essential on the part of electrophysiologists, anesthesiologists, and consulting surgeons. It is important to remember that some EP labs are located at a distance from the operating rooms, and transport of a rapidly decompensating patient can be difficult.

### CARDIAC CATHETERIZATION LAB

Unique risks associated with PFO/ASD closure include device malposition and/or embolization. Given the small size of most PFOs, this is a very rare complication. While also rare with ASD closure, there is a higher risk of this complication with very large defects or defects with deficient rims of atrial tissue that may not allow the device to hold onto the intra-atrial septum. Once the device is deployed, it is still retrievable if positioning or sizing is not satisfactory. Careful TEE assessment is warranted to ensure proper device seating and maintenance of integrity of nearby structures, including the mitral/tricuspid valves, coronary sinus, and vena cavae. If device embolization occurs, the device can generally be retrieved using percutaneous techniques. Rarely, however, surgical extraction may be required. Other complications include air embolism resulting in temporary coronary ischemia. Vascular complications are uncommon when access involves only venous structures.

Patients referred for acquired VSD/PVL closure are usually acutely or chronically ill with multiple comorbidities and are usually already deemed poor surgical candidates prior to referral for the procedure. Their comorbidities increase their risk for complications associated with the procedure and anesthesia. The transseptal puncture is one potential complication point of the procedure. An inappropriately performed puncture may result in aortic perforation or pericardial effusion. The risk of these complications is reduced with echocardiographic guidance. Device embolization is a risk of both of these procedures. Like with PFO/ASD devices, they can be retrieved using percutaneous techniques. In the event of inability to retrieve, these patients will likely not be candidates for surgical retrieval.

There are several points of risk during TAVR. For transfemoral TAVR, careful and safe femoral access is critical due to the size of the sheaths that will be used for the procedure. An inappropriate puncture site can increase the risk of retroperitoneal hematoma or inability to close the access site at the conclusion of the procedure. Attempts to place a delivery sheath in a femoral/iliac of borderline size could result in arterial dissection, or rupture which can be fatal. Both sheath insertion and removal are critical points for complications. During balloon valvuloplasty and valve deployment, patients can experience severe hemodynamic impairment. Since the Sapien XT requires deployment during rapid pacing, recovery of heart rate and contractile function can be compromised if the patient has poor cardiac reserve or severe un-revascularized coronary artery disease. The CoreValve procedure also results in brief severe hypotension during the point where the native aortic valve is obstructed and the prosthetic aortic valve has not fully opened. Annular rupture has been reported with both devices. Risk factors for annular rupture include severe LV outflow tract calcium, device oversizing, and balloon post-dilation. Annular rupture will likely be immediately fatal with little time for surgical repair. However, contained rupture can occur and the decision to proceed to operative repair needs to be made in real-time with the cardiac surgeon involved in the case. Para-valvular leak after valve deployment needs to be assessed carefully with TEE/TTE, aortography, and/or hemodynamics. Trace and mild PVL is generally of no concern. But moderate to severe leak can occur in up to 10% of cases. Treatment of these leaks usually requires additional post-dilation or the placement of a second prosthesis. PVL rarely results in acute hemodynamic issues, but may limit the benefit of the TAVR. Moderate to severe PVL is associated with worse long-term mortality after TAVR. It is prudent to assess for the presence of a pericardial effusion post-TAVR as perforation can occur following temporary pacemaker placement.

# Echocardiography in Cardiac Surgery

Eliza P. Teo • Michael H. Picard • Hanjo Ko • Michael N. D'Ambra

## INTRODUCTION

Echocardiography plays an important role in cardiac surgery by defining myocardial structure, function, and intracardiac blood flow velocities. Preoperatively, transthoracic and transesophageal echocardiography with color and spectral Doppler identify, quantify, and characterize cardiac disease and support decision making in terms of surgical timing and choices. Intraoperative transesophageal echocardiography (TEE) provides high-fidelity assessment of underlying pathophysiology, guides beating heart procedures in real time, supports surgical planning, and, allows for timely assessment of the results of surgical procedures. Furthermore, TEE can be critical in the early postoperative period to elucidate various etiologies of perioperative hemodynamic instability, allowing surgeons and intensivists to identify and manage complications accurately and efficiently. Lastly, transthoracic echocardiography (TTE) is often employed to evaluate and monitor long-term surgical results due to its noninvasive nature.

It is important that surgeons appreciate the potential and the limitations of perioperative ultrasound to provide case-specific predictors and intraoperative procedural guidance to improve surgical outcomes and facilitate incorporation of new technologies into current practice.

The goals of this chapter are to provide a framework for understanding the technique, and its indications for use. We summarize American Society of Echocardiography/Society of Cardiovascular Anesthiologists (ASE/SCA) guidelines for the surgical use of epicardial ultrasound, which can supplement or substitute for intraoperative TEE when TEE is contraindicated. Finally, we outline expectations that surgeons should have for intraoperative TEE images and interpretations.

## BASIC PRINCIPLES

Echocardiographic images are constructed by transmitting high-frequency sound waves into the chest from a transducer composed of piezo-electric crystals. These waves reflect off cardiac structures, and the returning signals are received by the same transducer. By knowing when the signal was sent, the speed of

the sound in the tissue, and the time it takes for the reflected signal to return to the transducer, the position of the structure responsible for the reflection can be calculated. An image from these signals can thus be created. The quality of the image relies on many factors, including the media through which the sound is traveling, the orientation of the structures in relation to the ultrasound beam, and the composition of the structure. Sound travels incredibly well through water and blood, reasonably well through tissue, but poorly through air. Therefore, the media through which the sound travels will determine the strength of the returning signal. When the ultrasound beam reflects off various portions of the heart, the signal is scattered in various directions such that some never return to the transducer. For this reason, structures that are perpendicular to the ultrasound beam and reflect stronger signals back to the transducer produce images of the most accuracy. On the other hand, strong reflectors such as calcified valvular leaflets will result in a bright picture but they also inevitably create imaging artifacts. The fact that sound transmitted from a TEE transducer has less distance to travel (which means less signal lost to scatter) and mainly travels through muscle and blood (and rarely air) explains why the quality of TEE images is usually better than TTE imaging.

Echocardiographic displays include M-mode, two-dimensional (2D) and three-dimensional (3D) imaging. The M-mode echocardiogram has superior temporal resolution and can be thought of as a display of the motion of a single cut through the heart over time. It is now used primarily to quantify the timing of intracardiac events. Two-dimensional echocardiography provides a display with better spatial resolution and excellent temporal resolution. Three-dimensional echocardiography provides the best display of the spatial relationships of various structures and flow patterns, and its resolution continues to improve.

Blood flow velocities are assessed by the Doppler principle. The wavelength of sound reflecting off moving blood particles will be shorter if blood is moving toward the transducer and longer, if moving away. By quantifying this change in frequency of the ultrasound beam, one can determine the blood velocity and direction. This calculation, however, is influenced by the angle between the ultrasound beam and the blood flow such that as this angle increases, the calculated velocity is lower

and less accurate. Thus the goal is to keep alignment of the beam as parallel to the blood flow as possible. As blood travels through a restrictive or stenotic region at a constant flow, its velocity will increase and the pressure gradient can be calculated from the simplified Bernoulli Equation ( $\Delta\text{pressure} = 4 \times \text{velocity}^2$ ). The peak and mean pressure gradients are calculated from spectral Doppler techniques. Pulse wave (PW) Doppler has excellent spatial resolution, allowing the identification of the specific locations of flow disturbances such as obstructions or leaks. Continuous wave (CW) Doppler has excellent velocity resolution and identifies the highest velocity along the path of the ultrasound beam (which is assumed to occur at the narrowest region). Color-flow mapping displays the velocities and directions of flow determined by Doppler. This technique is valuable to identify and quantify regurgitation. However, it must be remembered that the color display of a regurgitant jet represents the velocity of the blood disturbed by the regurgitation and is *not* the volume of regurgitation as one would see on an angiogram. The color display of these jets is influenced by various echocardiography machine settings.

Doppler quantitation of velocities is dependent on one's hemodynamic profiles, and since these conditions are often different during anesthesia (compared to preoperative resting state), the pressure gradients obtained by spectral Doppler and the color Doppler display of regurgitant jets may differ significantly from preoperative assessments. Thus the decision to operate should be based on preoperative values.

Finally, the echocardiographic views of the heart required to assess different pathologies as well as the necessary components of a perioperative TEE have been established by expert consensus and serve as a roadmap to understand the basic TEE.<sup>1</sup>

## SAFETY OF INTRAOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY

While TTE has some roles in the operating room, the dominant ultrasound modality for perioperative imaging is TEE. It has been in use in the operating room for over 30 years and has an excellent safety record. The incidence of complications in 7200 intraoperative TEEs performed at the Brigham and Women's Hospital was 0.2%, and no intraoperative TEE-associated mortality was noted. The most common complication was odynophagia severe enough to warrant esophagogastroduodenoscopy (0.1%) and this was followed by acute upper gastrointestinal hemorrhage (0.03% including esophageal tear but not esophageal perforation), dental injury (0.03%), arterial desaturation due to malpositioning of endotracheal tube (0.03%), and esophageal perforation (0.01%). Unsuccessful TEE probe insertion occurred in 0.18% of cases and contraindications to TEE were noted in 0.5%.<sup>2</sup> A smaller study has reported a higher rate of major upper gastrointestinal complications at 1.2% in patients undergoing intraoperative TEE with a significant proportion of the injuries manifesting greater than 24 hours after the procedure.<sup>3</sup> The reported TEE complication rate in pediatric

cardiac surgical patients is higher at 2.4%.<sup>4</sup> As a reference, an older study of the complication rates in over 10,000 TEEs performed on conscious patients outside of the operating room reported an event rate similar to that of adult intraoperative patients (0.18%) however the types of complications differed and included one death.<sup>5</sup>

An important way to reduce complications, especially esophageal and gastric injury, is to prospectively recognize those patients who are at risk and avoid TEE in those with extensive esophageal and gastric diseases. Another key principle is to balance risk and benefit ratio carefully such that TEE is only performed when its benefits outweigh its risks.<sup>6</sup> Absolute contraindications to TEE include perforated viscous, prior esophagectomy, and esophagogastrectomy. Relative contraindications to TEE include those with oropharyngeal cancer, preexisting esophageal pathologies (including varices, strictures, diverticula, esophagitis, Mallory-Weiss tears, radiation injury), and gastrointestinal pathologies (such as recent upper gastrointestinal hemorrhage, gastric ulcer or symptomatic hiatal hernia).<sup>7</sup>

## TRAINING AND QUALITY

Both cardiology and anesthesiology specialty and subspecialty societies have outlined recommendations for appropriate training required prior to independent performance of intraoperative TEE such as a minimum number of studies to maintain proficiency along with other benchmarks to guarantee imaging quality and practitioners' ability to interpret findings accurately.<sup>8-12</sup> Some surgeons have taken part in these training and certification programs, and many Cardiothoracic (CT) surgical training programs are including imaging skills-training in the curriculum.

## SURGICAL USE OF EPICARDIAL ULTRASOUND

### Epi-aortic

The cardiac surgical use of ultrasound in most practices is limited to epi-aortic scanning prior to aortic cannulation. Evidence is strong that routine use, coupled with alterations in surgical approach in the setting of significant atheromatous changes, reduces morbid neurological outcomes.<sup>82</sup> The Society of Cardiovascular Anesthesiologists (SCA)/American Society of Echocardiography (ASE) Guidelines suggest measuring (1) maximal plaque height/thickness; (2) location of the maximal plaque within the ascending aorta; and (3) presence of mobile components in each of the three ascending aortic short axis segments and for the aortic arch.<sup>80,81</sup> Figure 12-1 shows the guideline views. "Mid" is usually the aortic cross-clamp site, "distal" is usually the cannulation site.

### Epicardial

In addition to epi-aortic scanning, the epicardial probe can be utilized to supplement intraoperative TEE assessment.

**FIGURE 12-1** Short and long axis graphic of epiaortic scanning views.

The ASE guidelines assist surgeons in developing expertise in obtaining meaningful images when TEE is contraindicated. Figures 12-2 through 12-8 demonstrate the recommended views, which can be obtained in a setting of a median sternotomy incision. These ASE views serve as a general suggestion to help develop a user-dependent approach that is tailored to best suit each surgeon's individual practice.

It is suggested that surgeons take a few moments when they have the ultrasound probe in the surgical field to practice obtaining these standard ASE images. In the situation of a critical need for intraoperative ultrasound imaging when TEE is contraindicated (noted above in the section Safety of Intraoperative Transesophageal Echocardiography), a standard epicardial probe can be used if there is a full sternotomy. If there is a minimally invasive incision, placing the TEE probe in a sterile sheath filled with ultrasound gel can also provide excellent epicardial images of all structures from almost any small incision, which allows access to the pericardial space. However, in order for this to be most successful, the surgeon should practice along

with the assistance of the echocardiographer as a team to obtain useful views—with the echocardiographer manipulating the controls and the surgeon manipulating the TEE probe over the heart. The same locations used in the ASE epicardial guidelines can be used, but relevant views can be obtained from many locations in the pericardial space.

## THE DIAGNOSIS OF INTRACARDIAC AIR AFTER OPEN HEART SURGERY

Once the heart is closed and begins to beat at the end of cardiopulmonary bypass, pockets of air are often present in the left heart and the ascending aorta. Air can change locations quickly. The ability to precisely locate and evacuate air decreases the time from cross-clamp removal to successful weaning from cardiopulmonary bypass and decreases short- and long-term morbidity. Thus it behooves the surgeon to

**FIGURE 12-2** Epicardial aortic valve short-axis (SAX) view (TTE parasternal AV short-axis equivalent). With the transducer orientation marker facing toward the left shoulder, place the transducer over the aortic valve (AV) groove directly over the AV.

**FIGURE 12-3** Epicardial AV long-axis view (TTE Suprasternal AV long-axis equivalent). With the transducer orientation marker facing toward the right shoulder, place the transducer over the base of the ascending aorta.

**FIGURE 12-4** Epicardial left ventricular (LV) basal SAX view (TTE modified parasternal mitral valve basal SAX equivalent). With the transducer orientation marker facing the left shoulder, place the transducer over the body of the right ventricle (RV). View RV with tricuspid valve and LV with mitral anterior (AL) and posterior (PL) leaflets in short axis.

**FIGURE 12-5** Epicardial LV mid-SAX view (TTE parasternal LV mid-SAX equivalent). With the transducer orientation marker facing the left shoulder, place the probe over the mid-left anterior descending artery (LAD). A=anterior, S=septal, L=lateral, and I=inferior.

understand how ultrasound imaging can guide this process. The specific views most likely to elucidate air pockets are the left atrial dome view, left and right superior pulmonary vein views, left atrial appendage view, and LV apex and LV septal wall views. Figure 12-9 shows all of these views from the TEE window, but the information can also be obtained by the surgeon using an epicardial probe in the event that TEE is not available.

**FIGURE 12-6** Epicardial LV long-axis (LAX) view (TTE parasternal LAX equivalent). With the transducer orientation marker facing the right shoulder, place the probe over the mid-right ventricular outflow tract (RVOT).

**FIGURE 12-7** Epicardial two-chamber view (TTE Modified parasternal LAX equivalent). With the transducer orientation marker facing the right shoulder, place the probe over the mid-LAD artery.

**FIGURE 12-8** Epicardial RV outflow tract view (TTE parasternal SAX equivalent). With the transducer orientation marker facing the left shoulder, place the probe over the RVOT.

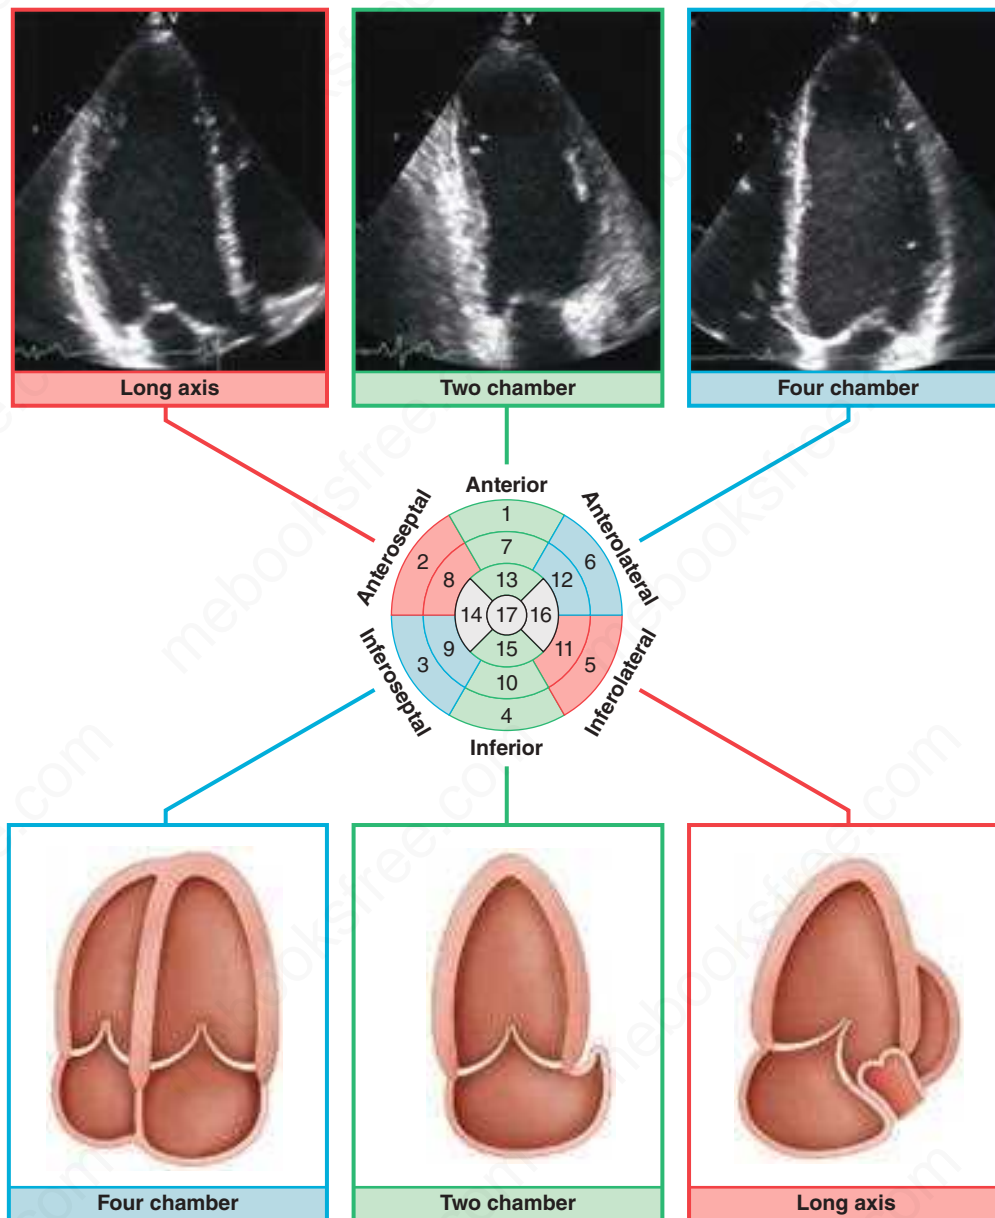

**FIGURE 12-9** Diagnosis of intracardiac air at the end of cardiopulmonary bypass—common air locations. The “A” panels show the anatomy without air, and the “B” panels show the same views with air present. Panel 1 is 120 Mid esophageal long axis (120°) with air in the LVOT, Panel 2 shows dome of the LA with air behind the aortic valve in the LA, Panel 3 is a view of the L superior pulmonary vein, and Panel 4 is the right superior pulmonary vein with two comet tail artifacts indicating air in both branches of the vein.

## USE OF ECHOCARDIOGRAPHY IN PREOPERATIVE ASSESSMENT OF SPECIFIC CARDIAC DISEASES

### Coronary Artery Disease

Echocardiography diagnoses the presence of ischemic heart disease by demonstrating resting LV wall motion abnormalities or inducing new regional wall dysfunction with stress modalities.

The ASE recommends a 16-segment model for the assessment and description of segmental LV wall motion.<sup>13</sup> This model divides the LV basal and mid-ventricular short axis views in a clockwise fashion into anterior, anterolateral, lateral, inferolateral, inferior, inferoseptal and anteroseptal segments. The apex is divided into anterior, lateral, inferior and septal segments (Fig. 12-10). A 17-segment model also exists where there is an additional apical cap to assess myocardial perfusion.

**FIGURE 12-10** Echocardiography segments of the left ventricle. Orientation of the apical four-chamber, apical two chamber and apical long axis views in relation to the bull's eye display of the LV segments. (Reproduced with permission from Lang RM, Badano LP, Mor-Avi V, et al: Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging, *J Am Soc Echocardiogr* 2015 Jan;28(1):1-39.)

To assess wall motion, each segment is evaluated in multiple views and reported to be (1) normal or hyperkinetic (normal or enhanced wall thickening), (2) hypokinetic (reduced thickening), (3) akinetic (absent or negligible thickening), or (4) dyskinetic (systolic thinning or bulging).<sup>13</sup>

Resting regional hypokinesis is indicative of ischemia or infarction in a specific coronary artery distribution that supplies the particular segment. Myocardial infarction with scar appears as a thin, highly reflective or bright, akinetic segment. An aneurysm is a thin dyskinetic segment that has a distorted diastolic shape and bulges outward in systole.

### STRESS ECHOCARDIOGRAPHY

Stress echocardiography diagnoses and localizes obstructive coronary artery disease (CAD) and is performed with exercise or pharmacological agents. Exercise with supine bicycle or treadmill is physiologic and always preferred to pharmacological stress testing. Patients unable to exercise may be stressed with inotropic drugs (dobutamine), vasodilator agents (adenosine or dipyridamole) or a combination of these. Stress echocardiography has a specificity of 76% and sensitivity of 88%, which are comparable to nuclear stress modalities.<sup>14</sup>

In a normal stress test, there is a hyperdynamic response with an increase in left ventricular ejection fraction (LVEF), decrease in LV cavity size, and absence of new regional wall motion abnormalities. A positive stress test demonstrates new inducible wall motion abnormality in the ischemic segment with stress. Decreases in global LVEF and LV dilatation suggest the presence of severe obstructive CAD such as multivessel CAD or severe left main stenosis.<sup>15</sup>

Intravenous echocardiographic contrast agents can be used to enhance endocardial definition, hence increasing the sensitivity of stress echocardiography for the diagnosis of ischemic heart disease.

### MYOCARDIAL VIABILITY

Low-dose dobutamine stress echocardiography is utilized to identify viable myocardium that is stunned or hibernating, and has the potential to recover after revascularization. Viable segments are hypokinetic at rest and typically demonstrate a “biphasic response” with an initial improvement of myocardial contractility with low-dose dobutamine infusion (2.5 to 10 mcg/kg/min). However, at higher doses of dobutamine (20 to 40 mcg/kg/min), the segmental wall motion deteriorates and appears similar or worse than at rest. There is a strong association between myocardial viability on noninvasive testing and improved survival after revascularization in patients with chronic CAD and LV dysfunction.<sup>16</sup> An area that fails to augment is indicative of a nonviable segment or scar.

### MECHANICAL COMPLICATIONS OF ISCHEMIC HEART DISEASE

Patients with acute myocardial infarction who develop hemodynamic instability should have an echocardiogram as soon as possible to differentiate mechanical complications that

require urgent surgical intervention, from cardiogenic shock secondary to primary ‘pump’ failure.

### RUPTURE OF LEFT VENTRICULAR FREE WALL AND PSEUDOANEURYSM

Rupture of the LV free wall is the second leading cause of in-hospital death, after cardiogenic shock in the setting of an acute myocardial infarction. It is usually associated with a first transmural (usually large anterior) infarct, but not infrequently it can also occur in a small area of lateral necrosis. Acute rupture is catastrophic and rapidly fatal, with death ensuing from cardiac tamponade and pulseless electrical activity. Subacute rupture is a gradual and incomplete rupture of the infarcted area with slow or repetitive bleeding into the pericardial sac causing hemopericardium, which typically occurs through small intramyocardial communications.<sup>17</sup> This leads to a moderate to large pericardial effusion, with or without features of tamponade. Often thrombus forms in the myocardial channels that communicate with the pericardial space, which prevents continued rupture. Thrombus in the pericardial space can be observed as a mass of echoes.

A postmyocardial infarction (post-MI) LV pseudoaneurysm is a rupture of the ventricular free wall contained by local pericardial adhesions or organized thrombus. Echocardiography identifies a narrow neck of the pseudoaneurysm and often spectral and color Doppler imaging shows flow through the communication between the LV and the pericardium.

### VENTRICULAR SEPTAL RUPTURE (VSR)

Post myocardial infarction VSRs are uncommon but associated with high mortality and usually occur in a large transmural, index infarct. Approximately 50 to 66% of postinfarction VSRs occur in anterior infarctions with the rest seen in inferior infarctions.<sup>18,19</sup> A VSR after an anterior MI most often occurs in the distal 1/3 of the septum whereas an inferior MI is associated with rupture of the basal inferior septum. Off-axis 2D and color Doppler imaging are useful, especially to demonstrate the RV exit site (Fig. 12-11). The size of the defect and the pressure difference between the ventricles determine the amount of shunting, which in turn influences mortality. Three-dimensional echocardiography can visualize the defect *en face* to demonstrate the precise location of the rupture and provide size measurements. This can be helpful in determining the suitability of percutaneous device versus surgical closure.<sup>20</sup>

### ACUTE MITRAL REGURGITATION (MR)

Acute mitral regurgitation (MR) in the setting of infarction is caused by papillary muscle infarction or rupture. It is usually associated with an inferior infarct as the posteromedial papillary muscle has a single blood supply from the posterior descending artery, whereas the anterolateral papillary muscle has dual blood supply from the left anterior descending artery and the left circumflex artery. Two-dimensional echocardiography demonstrates a flail segment of the mitral valve. The ruptured head of the papillary muscle or corresponding

**FIGURE 12-11** Post MI ventricular septal rupture. (A) Transthoracic echocardiographic off axis apical four-chamber view displaying the RV exit site of the VSR at the mid-septum. (B) Color Doppler displaying left to right shunting across the VSR in systole. RV = right ventricle, VSR = ventricular septal rupture.

chords may be seen moving randomly within the LV cavity (Fig. 12-12).

Color Doppler can underestimate the severity of acute MR. Due to rapid equalization of left atrial (LA) and LV pressures, coupled with tachycardia and the usually small LA size, the MR jet area can be of short duration and appear deceptively small. Assessment by vena contracta width remains

**FIGURE 12-12** Papillary muscle rupture. Transesophageal echocardiographic four-chamber view of a ruptured papillary muscle head in the left atrium (arrow).

reliable in this setting. Pulmonary venous systolic flow reversal is a feature which supports the presence of acute severe MR.<sup>21</sup> Assessment with TEE can provide a more definitive diagnosis.

### RIGHT VENTRICULAR INFARCTION

Echocardiography is a valuable diagnostic test for RV infarction. The most common features of RV infarction include inferior MI and hemodynamic compromise, often associated with jugular distension and absence of pulmonary edema. RV involvement is associated with higher mortality, arrhythmias, shock and mechanical complications.<sup>22</sup> Echocardiographic signs of RV infarction include RV dilatation and decreased RV free wall function. Impaired function is demonstrated by reduced tricuspid annular plane systolic excursion (TAPSE < 17 mm), and decreased tricuspid annular systolic velocity measured by Doppler tissue imaging ( $S'$  velocity < 9.5 cm/s).<sup>13,23</sup> Signs of elevated right atrial (RA) pressure include a dilated inferior vena cava (IVC) that does not collapse >50% on inspiration or bowing of the interatrial septum towards the left.

### Mitral Valve Disease

Echocardiography of the mitral valve (MV) includes evaluation of the valvular leaflets, mechanism and grading of severity of mitral stenosis (MS) and mitral regurgitation (MR), and assessment of the effects on the LA and LV. Specifically

this includes 2D imaging of leaflet thickness, mobility, coaptation geometry and area, LA size, LV size and function, spectral and color Doppler, valvular gradients, valvular area, and RV systolic pressure (RVSP).

## Mitral Regurgitation

### ETIOLOGY OF MR

MR can be classified into organic (primary) or functional (secondary). Organic MR is caused by intrinsic valvular disease whereas functional MR occurs as a result of regional or global left ventricular remodeling.

### ORGANIC (PRIMARY) MR

The most common cause of MR in the industrialized world is degenerative MV disease. The spectrum of conditions ranges from fibroelastic deficiency causing isolated prolapsed segments due to chordal rupture, to extensive myxomatous disease affecting all segments of the valvular leaflets. The former is most often seen in the older population whilst the latter in younger patients.

Mitral valve prolapse (MVP) is defined by displacement of the body of the leaflets by more than 2 mm behind the annular plane, measured in a long axis view (parasternal or apical views). Due to the saddle shape of the normal mitral annulus with its lowest points anteriorly and posteriorly, assessment in the apical four-chamber view which depicts the medial and lateral MV annulus is not recommended as this can lead to a false diagnosis of MVP.<sup>24</sup>

Flail leaflet is a common sequel of myxomatous disease and occurs due to ruptured chordae. The posterior leaflet (usually middle or P2 scallop) is predominantly affected, resulting in anteriorly directed MR. On echocardiography, the flail portion of the leaflet will exhibit excessive motion and the leaflet tip is displaced into the LA beyond the mitral annular plane (Fig. 12-13).

Other less common causes of primary MR include rheumatic heart disease, infective endocarditis, mitral valve cleft (in conjunction with a partial atrioventricular septal defect, or rarely in isolation), connective tissue diseases, and radiation induced heart disease. Of note, rheumatic mitral regurgitation is caused by commissural thickening, leaflet motion restriction, and loss of central coaptation. This is often accompanied by a degree of stenosis.

### ACUTE MR

Acute MR can be assessed by echocardiography and occurs due to disruption of the MV complex. Leaflet destruction or perforation occurs in infective endocarditis. Chordal rupture can be associated with endocarditis, but is more often seen in degenerative mitral valve disease. Papillary muscle dysfunction (rupture or ischemia) occurs with MI (usually the inferior territory). Due to the acute nature of the MR, the LV and LA sizes are often normal. LV systolic function is normal or hyperdynamic, except when the acute MR is due to myocardial ischemia.

### FUNCTIONAL (SECONDARY) MR

In functional (or secondary) MR, the mitral valve leaflets and subvalvular apparatus are structurally normal. The MR occurs as a result of LV remodeling from previous infarction or nonischemic cardiomyopathy. Regional or global LV dilatation and remodeling leads to displacement of the papillary muscles, stretching of chordae and subsequent leaflet tethering. The coaptation zone of the mitral valve leaflets is displaced apically and there is incomplete closure of the mitral valve. Dilatation of the mitral annulus also contributes to functional MR (Fig. 12-14).

Regional infarction (particularly of the inferoposterior territory) and subsequent local remodeling leads to unbalanced tethering forces that cause asymmetric closure of the valvular

**FIGURE 12-13** Flail anterior mitral valve leaflet. (A) Flail anterior mitral valve leaflet displayed on mid-esophageal TEE view with transducer angled at 0°. The leaflet tip is noted to extend into the LA cavity with a large coaptation gaps. (B) This results in severe posterolaterally directed MR.

**FIGURE 12-14** Incomplete closure of the mitral valve on apical four-chamber TTE. (A) There is global left ventricular dilation resulting in displaced papillary muscles. The mitral valve leaflets are pulled apically resulting in incomplete closure of the mitral valve. (B) Large central jet of mitral regurgitation.

leaflets. In such cases, the anterior leaflet tip may appear to prolapse relative to the tethered posterior leaflet, resulting in a posteriorly directed MR jet. In patients who develop diffuse LV dysfunction and global LV dilation either from ischemic or nonischemic causes, the papillary muscle displacement is more symmetric and the resultant MR is centrally directed.

Carpentier has developed a functional classification to reflect the pathological changes based on leaflet motion that caused MR: normal, excessive, restricted diastolic and restricted systolic motion.<sup>25</sup> (Table 12-1) Both TTE and TEE can be used to identify these patterns.

#### ECHOCARDIOGRAPHIC ASSESSMENT OF SEVERITY OF MR

The timing for intervention in MR is largely driven by symptoms and the impact of the volume load on LV size and function. Thus, accurate assessment of the severity of MR and the associated hemodynamic consequences is critical. Typical methods and supporting parameters are shown in Table 12-2.

Assessment of severity requires the integration of both qualitative and quantitative methods to minimize the effect of technical or measurement errors. For example, the severity of MR by color Doppler can be influenced by blood pressure, and MR can appear less severe during TEE compared to TTE, especially when lowered blood pressure is secondary to sedation or general anesthesia.

#### COLOR FLOW DOPPLER

Assessment of the regurgitant jet size and extent into the LA by color flow Doppler is the easiest and most common way to qualitatively assess the severity of MR. Generally speaking, an MR jet area >40% of the LA is consistent with severe MR.<sup>21</sup> However, this method is dependent on multiple hemodynamic and technical factors. For example, the driving blood pressure, machine settings such as gain or velocity scale, and regurgitant jet direction will all influence the appearance of the regurgitant jet area. When it comes to regurgitant jet direction, if MR jets are directed towards the wall of the

LA (ie, eccentric MR jets), then jet energy (velocity) is lost and eccentric MR jets would appear smaller on screen when compared to central MR jets despite similar regurgitant volumes.<sup>26</sup> Color flow should be used to diagnose presence of MR, but quantitative measures should be utilized when more than a small central MR jet is present to avoid this problem.

### VENA CONTRACTA WIDTH

The vena contracta is the region of the jet as it exits the regurgitant orifice. When quantified it is an indirect measure of the effective regurgitant orifice area (EROA) and this measurement is less subject to the factors affecting display of the color jet area. The VC is typically measured at the narrowest portion of the MR jet just beyond the coaptation line (Fig. 12-15). When measured as a linear dimension, it is assumed that the regurgitant orifice area is circular; however

**FIGURE 12-15** Vena contracta measurement in MR. The vena contracta is measured at the narrowest portion of the MR jet just beyond the coaptation line (red double-headed arrow). A measurement greater than 7 mm is consistent with severe MR.

VC has been found to often be elliptical in functional MR. A VC of >7 mm is consistent with severe MR. Intermediate values (3 to 7 mm) need confirmation by other quantitative methods.

### FLOW CONVERGENCE/PROXIMAL ISOVELOCITY SURFACE AREA

Quantitative parameters that assess MR severity include EROA, regurgitant volume (R Vol) and regurgitant fraction. These can be calculated by the proximal isovelocity surface area (PISA) method with echocardiography.

This method relies on the fact that the regurgitant flow at the regurgitant orifice is equal to the product of the cross-sectional area ( $CSA = 2\pi r^2$ ) of the flow and the peak velocity of the flow (peak MR vel). By adjusting the Nyquist limit (the velocity at which the signal is aliased) towards the direction of the regurgitant jet, a flow convergence zone in the LV with radius  $r$  can be depicted and measured.

Assuming that the flow converges onto the regurgitant orifice in an axis-symmetric fashion, the flow of this zone can be identified as  $2\pi r^2 \times$  aliasing velocity ( $V_a$ ) and will also be equal to the flow through the valve. This can be expressed as the product of the EROA and the peak velocity of the MR CW Doppler profile. Rearranging this continuity of flow relation yields:

$$EROA = (2\pi r^2 \times V_a) / \text{peak MR vel}$$

Since stroke volume is quantified as the product of the cross-sectional area and the velocity time integral of the CW MR velocity profile ( $VTI_{MR}$ ), the regurgitant volume (R Vol) is expressed as

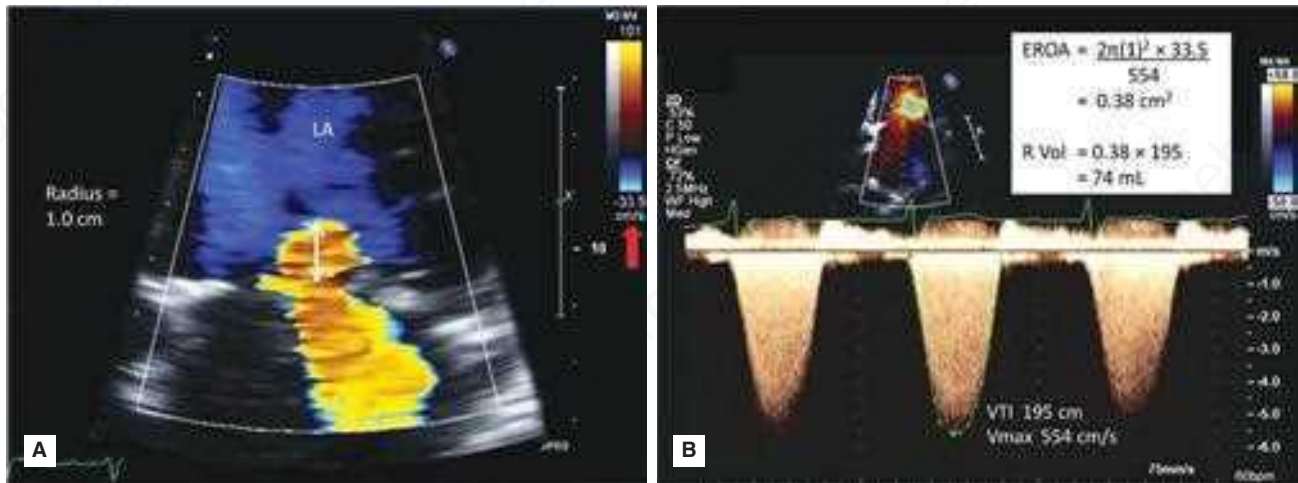

$$R \text{ Vol (cc)} = EROA \text{ (cm}^2\text{)} \times VTI_{MR} \text{ (cm)}$$

Qualitatively, the presence of flow convergence on TTE at a Nyquist limit of 50 to 60 cm/s should alert the surgeon to the presence of significant MR and prompt an assessment by quantitative method. The two-dimensional isovelocity surface area (2D PISA) approach is performed in either the four- or three-chamber view (Fig. 12-16).

### OTHER ECHOCARDIOGRAPHIC METHODS TO QUANTIFY MR

The regurgitant fraction can be calculated from stroke volume calculations if there is no aortic regurgitation present. The regurgitant fraction is the ratio of the volume of MR to the mitral inflow stroke volume. The volume of MR is the difference between the mitral inflow stroke volume and the aortic outflow stroke volume. The stroke volumes are calculated as the product of cross-sectional area (CSA) and velocity time integral (VTI) of flow. Thus, the volume of MR is the difference between (1) the product of the cross-sectional area of the mitral annulus and the VTI at the mitral annulus and (2) the product of the cross-sectional area of the left ventricular outflow tract (LVOT) and the VTI at the LVOT.

Direct measurement of the EROA by 3D planimetry of the vena contracta is feasible, does not require geometric or flow assumptions, and may improve the accuracy of MR grading when compared to the 2D PISA method.<sup>27</sup> However, due to technical limitations such as spatial resolution, 3D

**FIGURE 12-16** PISA method to quantify the severity of MR. (A) Measurement of the radius of the flow convergence zone (*double-headed arrow*). The Nyquist limit baseline is shifted in the direction of the MR jet (*red arrow*). (B) The maximum velocity and VTI of the MR jet is measured from the continuous wave Doppler jet profile.

color Doppler to date is used only in TEE and mainly for research applications.

#### OTHER SUPPORTIVE PARAMETERS

Adjunctive parameters help consolidate determination of the severity of MR when there is discrepancy between the quantified degree of MR and the clinical context.

Systolic reversal of flow in pulmonary veins as assessed by pulse wave Doppler is a reliable marker of severe MR. Blunting alone of systolic flow can accompany mitral regurgitation of increasing severity, but this phenomenon also occurs in atrial fibrillation, increasing age and diastolic dysfunction or other causes of elevated left atrial pressure. Therefore blunting of the pulmonary venous systolic flow lacks specificity for severe MR.

MR of increasing severity leads to increased transmitral forward flow in early diastole, reflected by an elevated E velocity. In the absence of mitral stenosis (MS), a peak E velocity of  $>1.5$  m/s is suggestive of severe MR, whereas the presence of a dominant A wave excludes it. This feature however lacks specificity since anything that raises LA pressure can lead to increased E velocity.

Severe MR produces a dense CW Doppler signal intensity. The CW display of MR velocity can demonstrate a “cut-off” sign, appearing more triangular than parabolic (reflecting the effect of the MR on LA pressure). It may be difficult to capture the full envelope of the MR jet in eccentrically directed MR despite the relatively dense velocity signal.

#### ECHOCARDIOGRAPHIC QUANTIFICATION OF SEVERE MR

The quantification of severity in functional MR can be difficult. In patients with *functional* MR, adverse outcomes are associated with a smaller calculated EROA compared to *organic* MR. Functional MR will progress due to associated progressive LV systolic dysfunction from the underlying myopathic process and adverse remodeling. There is also

an underestimation of EROA by the 2D echocardiography derived flow convergence method due to the fact that the regurgitant orifice may not be circular. Hence, the threshold to define severe functional MR is lower than that used for organic MR. An EROA  $\geq 40$  mm<sup>2</sup> or R Vol  $\geq 60$  mL indicates severe organic MR while an EROA  $\geq 20$  mm<sup>2</sup> or R Vol  $\geq 30$  mL identifies patients at risk of increased cardiovascular events with functional MR (Table 12-3).<sup>28</sup>

#### HEMODYNAMIC CONSEQUENCES AND PROGNOSTIC FACTORS OF SEVERE MR

In order to maintain forward stroke volume in chronic significant MR, the LV end diastolic volume increases in response to volume overload. This, in turn, leads to an increased LVEF.

#### TABLE 12-3: Echocardiographic Signs of Severe MR

- Central jet of MR  $> 40\%$  LA or holosystolic eccentric jet
- ERO  $\geq 0.4$  cm<sup>2</sup> (organic MR),  $\geq 0.2$  cm<sup>2</sup> (functional MR)
- Vena contracta  $\geq 0.7$  cm
- Regurgitant volume  $\geq 60$  mL (organic MR),  $\geq 30$  mL (functional MR)
- Regurgitant fraction  $\geq 50\%$
- Systolic flow reversal of the pulmonary veins
- Peak E velocity  $> 1.5$  m/s (in absence of mitral stenosis)
- Moderate-to-severe LA enlargement
- LV enlargement (LVESD  $> 40$  mm)
- Pulmonary hypertension

(Data from Lancellotti P, Tribouilloy C, Hagendorff A, et al: Recommendations for the echocardiographic assessment of native valvular regurgitation: an executive summary from the European Association of Cardiovascular Imaging, *Eur Heart J Cardiovasc Imaging* 2013 Jul;14(7):611-644; Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2014 Jun 10;63(22):e57-e185.)

A “normal” LVEF in MR is approximately 70%. Over time, as LV contractility declines, the LV end systolic volume also increases, leading to a reduction in LVEF. Once the LVEF declines below 60%, or when the LV end systolic dimension is  $>40$  mm, this suggests the onset of LV dysfunction, even though the LVEF is still in the normal range. LA dilation also occurs with MR of significant severity (except in acute MR), and therefore the presence of LA dilation suggests chronicity.

In primary MR, negative prognostic features include presence of symptoms, onset of LV dysfunction, pulmonary hypertension (pulmonary artery systolic pressure  $>50$  mm Hg) and onset of new atrial fibrillation.<sup>29,30</sup> Thus these findings are triggers for mitral valve surgery in the 2014 American Heart Association (AHA)/American College of Cardiology (ACC) guidelines (Fig. 12-17).

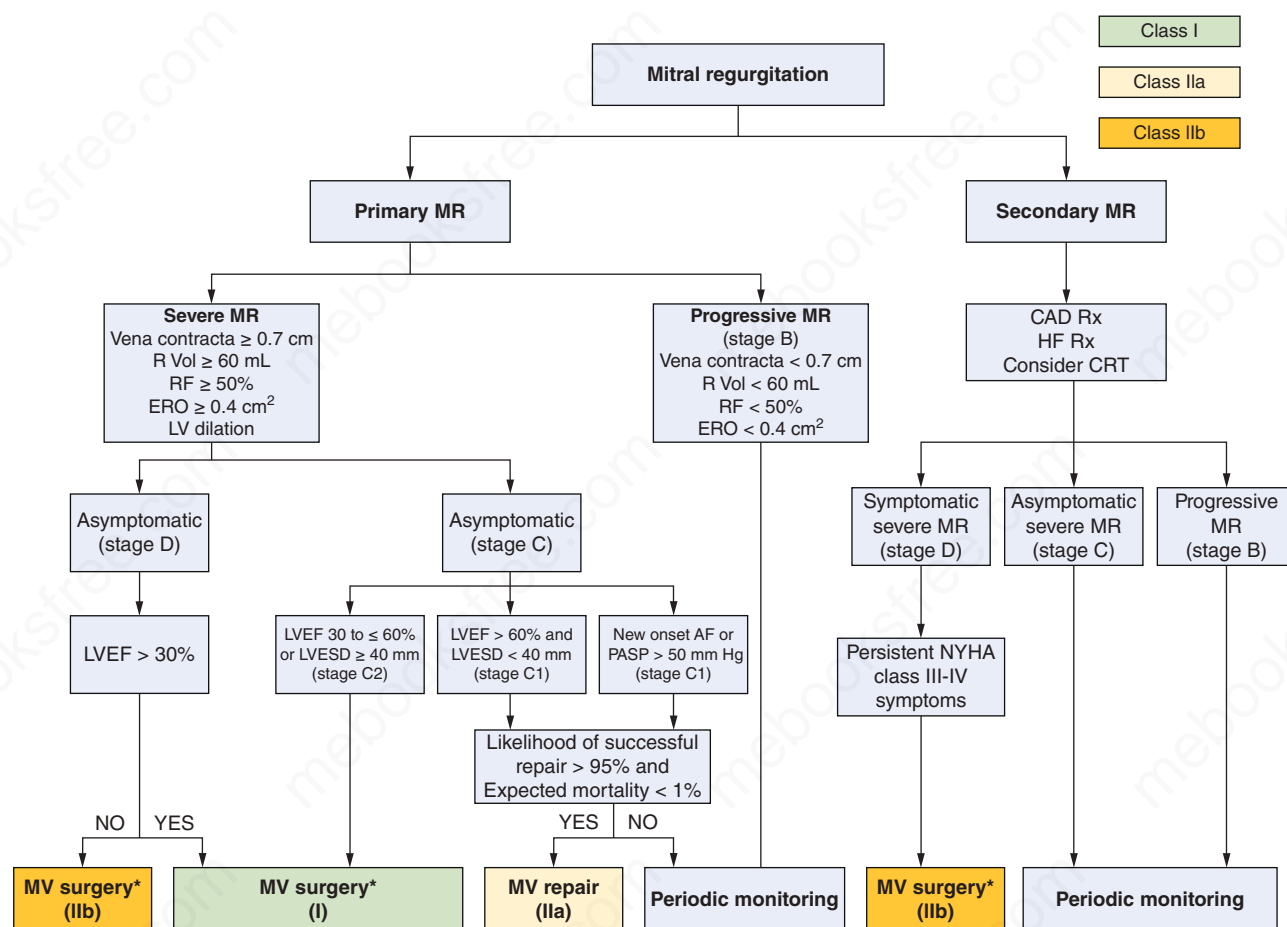

Mitral valve surgery is a Class I recommendation for chronic severe primary MR and LV dysfunction: LVEF  $> 30\%$  in symptomatic patients, and LVEF 30 to 60% +/- left ventricular end-systolic diameter (LVESD)  $\geq 40$  mm in asymptomatic patients. In asymptomatic nonrheumatic MR, a resting pulmonary artery systolic pressure (PASP) of

$>50$  mm Hg or new onset atrial fibrillation (AF) is a Class IIa indication for mitral valve repair.

### TEE IN MITRAL REGURGITATION

TTE alone is often helpful in determining the etiology of MR. TEE enables a more detailed and precise anatomic assessment of the mitral valve and should be utilized in more complex lesions or when further anatomic information is required about the mitral valve complex to assist in surgical planning. The proximity of the TEE probe to the mitral valve and the higher imaging frequency result in much improved resolution, which provides a more accurate and higher quality assessment of the vena contracta and PISA. Interrogation of flow in all four pulmonary veins is generally feasible with TEE.

TEE is also particularly useful in infective endocarditis where other potential infected structures can be fully assessed. Three-dimensional echocardiography is widely used as it displays the *en face* “surgeon’s view” of the mitral valve and enables direct visualization of mitral valve pathology.

\*Mitral valve repair is preferred over MVR when possible.

**FIGURE 12-17** AHA algorithm for MR. (Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2014 Jun 10;63(22):e57-e185.)

## EXERCISE ECHOCARDIOGRAPHY IN MITRAL REGURGITATION

Exercise echocardiography may prove helpful when symptoms or degree of LV and LA enlargement are out of proportion to the magnitude of MR on a resting TTE. Worsening MR severity, marked increase in pulmonary arterial pressure (PASP > 60 mm Hg during exercise), impaired exercise ability and symptoms during exercise echocardiography identify patients who may benefit from early surgery.<sup>28</sup>

## Mitral Stenosis

The majority of cases of mitral stenosis (MS) are due to rheumatic heart disease. Other less common causes include functional stenosis from severe mitral annular calcification, LA myxoma, congenital mitral stenosis (parachute mitral valve), drug induced valvulopathy, and systemic lupus erythematosus (SLE).

## ECHOCARDIOGRAPHIC FEATURES

Rheumatic MS has classic appearances on echocardiography. Thickening of leaflet tips with relative sparing of the mid-portion and fusion of the commissures leads to a doming or “hockey stick” appearance of the length of the anterior leaflet in diastole, which is best seen in the parasternal long axis view. The posterior leaflet is also thickened and restricted in motion. Commissural thickening and fusion is best appreciated in the short axis view. The subvalvular apparatus, mainly the chordae tendinae, are also thickened and may demonstrate calcification and fusion (Fig. 12-18).

Significant mitral annular calcification is seen in the elderly population. When the annular calcification is bulky enough to reduce the annular area or it extends onto the mitral valve leaflets reducing their excursion, increased diastolic gradients, particular during atrial contraction, are noted across the mitral valve. In these cases, the reduced orifice is most often at the base of the mitral leaflets as opposed to the leaflet tips,

**FIGURE 12-18** Mitral stenosis. (A) On parasternal long axis TTE, doming of the anterior mitral valve leaflet results in a “hockey stick deformity” with calcified leaflet tips, causing mitral stenosis. The left atrium is dilated. (B) Planimetry of the mitral valve orifice is performed in the parasternal short axis view. (C) Continuous wave Doppler spectral pattern showing the peak and mean gradients across the stenotic mitral valve. A mean gradient of 16 mm Hg is consistent with severe mitral stenosis.

and the pressure half-time method used to calculate valve area for rheumatic MS cannot be reliably applied.

### ASSESSMENT OF SEVERITY OF MITRAL STENOSIS

**Anatomic Assessment.** The normal MV area (MVA) in adults is 4 to 5 cm<sup>2</sup>. The 2014 AHA/ACC guidelines for valvular heart disease define a MVA of ≤1.5 cm<sup>2</sup> as severe MS and <1 cm<sup>2</sup> as very severe MS.<sup>31</sup> This area can be measured directly from echocardiographic images by planimetry in the short axis view. Care must be taken to ensure that the planimetry is performed at the level of the leaflet tips where the orifice is narrowest during the time point where this orifice is the largest in early diastole. Three-dimensional (3D) echocardiography permits proper alignment of the leaflet tips to ensure the most accurate measurement of the MVA.<sup>32</sup>

**Doppler Assessment.** The mean transmitral gradient is the single-most important factor in describing the severity of MS (mild < 5 mm Hg, moderate 5 to 10 mm Hg, severe >10 mm Hg).<sup>33</sup>

The mean and peak gradients are easily obtained from the mitral inflow CW Doppler signal. However, these measurements are also influenced by heart rate, loading conditions, and stroke volume. With tachycardia, there is reduced diastolic filling time, which leads to an elevation in mean gradient.

The most common Doppler method to calculate MVA is the pressure half-time in milliseconds (PHT), which is the time required for the transmitral pressure gradient to decay to half its value. It has a linear relationship with the MVA; the more severe the MS, the longer the pressure half-time:

$$\text{MVA (cm}^2\text{)} = 220/\text{PHT (ms)}$$

The constant of 220 is the net compliance constant and is derived empirically in a group of patients with mitral stenosis. Although easy to obtain, PHT measurements can be unreliable in tachycardia or atrial fibrillation (average of 5 beats recommended). PHT is also significantly affected by decreased LV compliance, which results in more rapid equilibration of

LA and LV pressures in diastole, leading to a shorter PHT and overestimation of the MVA if the constant of 220 is utilized. For this reason, MVA by PHT can be less reliable in patients with advancing age, hypertension, diabetes, and aortic stenosis. Also in the hours immediately following balloon mitral valvuloplasty, the net compliance constant is not accurately represented by the constant of 220.

MVA by the continuity method can be measured in the absence of MR or aortic regurgitation (AR):

$$\text{MVA} = \text{SV}_{\text{LVOT}}/\text{VTI}_{\text{MS}}$$

The PISA method, which requires an angle correction to account for the funnel shape of the accelerating mitral valve inflow in MS, is seldom used in clinical practice.

**Transesophageal Echocardiography in Mitral Stenosis.** A high-quality TTE is often sufficient for the diagnosis and quantification of mitral stenosis. TEE however has incremental value for assessment of associated left atrial body or appendage thrombus, or if TTE images of the valve are suboptimal.

**Severe MS.** Severe MS is defined by a series of echocardiographic variables. These include: a mitral valve area < 1.5 cm<sup>2</sup>, a mean gradient > 10 mm Hg, a diastolic pressure half time ≥ 150 ms and an RV systolic pressure > 50 mm Hg.

**Mitral Stenosis Valve Morphology Score.** Percutaneous mitral balloon valvuloplasty (PMBV) is considered first-line therapy when intervention is indicated in mitral stenosis. Mitral valve surgery is generally reserved for patients who are unsuitable candidates for or fail PMBV. Features favoring surgical interventions include moderate-to-severe MR, extensive leaflet and subvalvular thickening, fibrosis and calcification.

The valvular morphology or Wilkins' score is most commonly used in TTE to assess four components of the mitral valve and the summed score describes suitability for PMBV (Table 12-4).<sup>34</sup> A Wilkins' score of >8 and/or presence of moderate MR suggests that the valve will have a low probability of PMBV success and a surgical approach is advisable.

**TABLE 12-4: Wilkins' Score to Assess Suitability for Percutaneous Mitral Balloon Valvuloplasty**

Grade	Leaflet mobility	Subvalvular thickening	Leaflet thickening	Leaflet calcification
1	Highly mobile, only restricted leaflet tips	Minimal thickening just below the MV leaflets	Leaflet thickness 4 to 5 mm	Single area of increased echo brightness
2	Leaflet mid and base have normal mobility	Thickening up to 1/3 of chordal length	Mid-leaflets normal, thickening margins 5 to 8 mm	Scattered areas of brightness confined to leaflet margins
3	Valve continues to move forward in diastole, mainly from the base	Thickening extending to distal 1/3 of chords	Entire leaflet thickening 5 to 8 mm	Brightness extending into midportions of leaflets
4	No or minimal forward movement of the leaflets in diastole	Extensive thickening of all chordal structures	Thickening of all leaflet tissue 8 to 10 mm	Extensive brightness throughout much of the tissue

(Adapted with permission from Wilkins GT, Weyman AE, Abascal VM, et al: Percutaneous balloon dilatation of the mitral valve: an analysis of echocardiographic variables related to outcome and the mechanism of dilatation, *Br Heart J* 1988 Oct;60(4):299-308.)

**Stress Echocardiography in Mitral Stenosis.** The 2014 AHA/ACC guidelines recommend exercise testing with Doppler to evaluate the response of the mean mitral gradient and pulmonary artery pressure in patients with MS when there is a discrepancy between resting Doppler echocardiographic findings and clinical symptoms or signs.<sup>31</sup> Intervention can be considered if there is a rise in right ventricular systolic pressure to >60 to 70 mm Hg with exercise.

## Aortic Valve Disease

### AORTIC STENOSIS

Echocardiographic imaging of the stenotic aortic valve includes assessment of the valvular leaflet morphology, motion and thickness, description of the presence and location of calcification, measurement of the aortic root and ascending aorta, as well as quantification of LV function and wall thickness. This is followed by Doppler assessment of the severity of stenosis and the presence or absence of concomitant aortic regurgitation.

**Etiology.** The most common causes of aortic stenosis (AS) in the developed world are degenerative calcification of a trileaflet valve, or accelerated calcification of a bicuspid valve. Rheumatic AS is more prevalent in the developing world.

A bicuspid aortic valve affects approximately one percent of the population. The most common form involves fusion of the right and left coronary cusps (70–86%) with commissures observed in a horizontal position. This is followed by fusion of the right and noncoronary cusps (~12%) with commissures seen in the vertical orientation.<sup>35</sup> Fusion of the left and noncoronary cusps is seen rarely. The diagnosis of bicuspid valve is made in the short axis view in systole where an elliptical orifice formed by two unequally sized leaflets is present. However, when a raphe (fusion line of two leaflets) is present, the diastolic echocardiographic image may mimic the presence of a third leaflet. In the long axis view, the bicuspid aortic valve demonstrates an asymmetric closure line, systolic doming and, often, diastolic prolapse of the valvular leaflets. Since aortopathy is associated with bicuspid aortic valve, assessment of the aortic root and ascending aorta dimensions is necessary. Unicuspid and quadricuspid valves are rare causes of AS. Unicuspid valves usually have a posteriorly positioned commissure.<sup>36</sup>

Rheumatic AS results in commissural fusion and a narrowed triangular systolic orifice. Calcification is most prominent along the edges of the cusps. Aortic regurgitation and mitral involvement are common associations with rheumatic AS.

**Subvalvular and Supravalvular Obstruction.** Subvalvular and supravalvular AS are identified by 2D echocardiography and further characterized by Doppler velocity. Subvalvular obstruction may be fixed or dynamic. The former is seen in the form of a congenital discrete membrane or muscle band in the LVOT and the peak velocity typically occurs in mid-systole. A common cause of dynamic obstruction is

hypertrophic obstructive cardiomyopathy, where the obstruction usually occurs later in systole. In such cases, the CW Doppler systolic velocity profile appears late peaking or “dagger” shaped. Supravalvular obstruction is rare and typically a congenital condition. It is seen in adults as a recurrent or persistent discrete constriction at the superior aspect of the sinuses of Valsalva, or as a diffuse narrowing of the ascending aorta.<sup>37</sup>

**Assessment of Severity of Aortic Stenosis by Echocardiography.** Doppler methods to assess the hemodynamic severity of aortic stenosis include the maximum transvalvular velocity ( $V_{max}$ ) and calculation of the peak and mean pressure gradients. The aortic valve area (AVA) is typically calculated by the continuity equation.<sup>33</sup>

**Maximum Velocity and Gradients.** The maximum transvalvular velocity is measured using CW Doppler. The velocities across the aortic valve are assessed from multiple transducer positions including apical, suprasternal, and right parasternal locations to ensure that the highest velocity is recorded. Velocities from three beats are averaged in sinus rhythm and at least five beats in irregular rhythms. Postextra systolic beats are not measured. In more severe obstruction, the maximum velocity occurs later in systole and the CW Doppler profile assumes a more rounded shape, reflecting a higher gradient throughout systole.

The peak instantaneous gradient is calculated using the simplified Bernoulli equation:

$$\Delta P = 4(V_{max})^2$$

The mean gradient is typically calculated using a measurement program on the echocardiography machine, which averages the instantaneous gradients over the ejection period.

**Aortic Valve Area (AVA).** A normal AVA is 3 to 4 cm<sup>2</sup> and one definition of severe AS is an AVA less than 1 cm<sup>2</sup>. The AVA can be indexed to BSA, with a value  $\leq 0.6$  cm<sup>2</sup>/m<sup>2</sup> considered severe AS in children, adolescents, and small adults (BSA < 1.5 m<sup>2</sup>, BMI < 22).<sup>33</sup> Indexing to BSA is less applicable to obese patients.

The AVA is calculated based on the concept of continuity of flow: the stroke volume (SV) ejected through the LVOT is equal to the SV that passes through the stenotic aortic valve (Fig. 12-19).

Stroke volume is the product of the VTI of the Doppler-derived flow velocity profile and the CSA of the structure at the level the velocity profile is obtained:

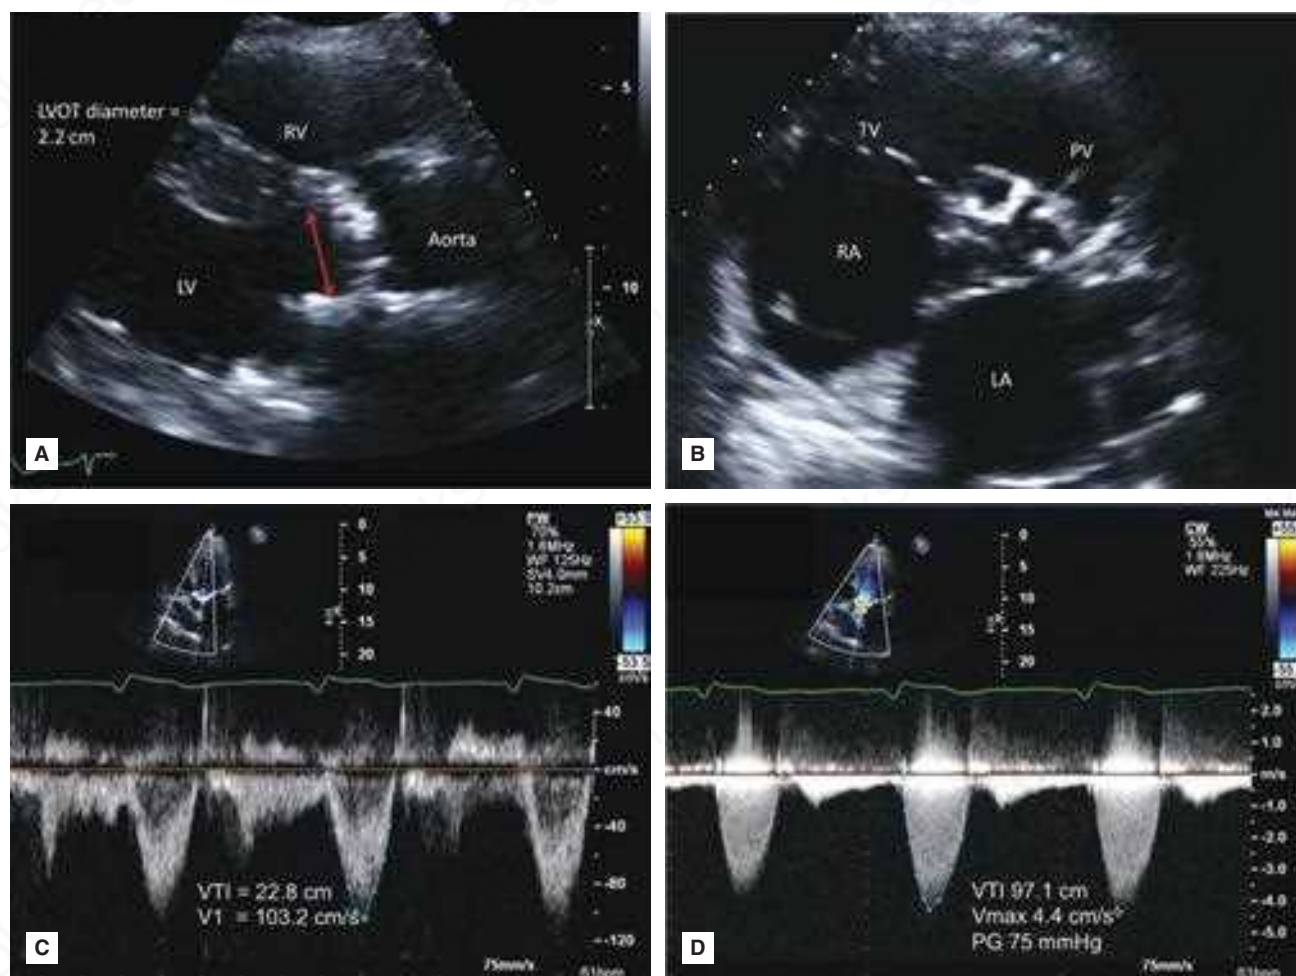

$$SV = CSA \times VTI$$

Continuity of flow is represented by

$$SV_{AV} = SV_{LVOT} \text{ or } CSA_{AV} \times VTI_{AV} = CSA_{LVOT} \times VTI_{LVOT}$$

Solving for the AVA ( $CSA_{AV}$ ) yields:

$$AVA = (CSA_{LVOT} \times VTI_{LVOT}) / VTI_{AV}$$

**FIGURE 12-19** Aortic stenosis. (A) Measurement of the LVOT diameter (arrow) is usually performed in the parasternal long axis TTE view. (B) Morphology of the aortic valve is determined in the parasternal short axis TTE view. This image shows a calcified trileaflet aortic valve with severe stenosis. (C) Pulse wave Doppler profile with the cursor placed in the LVOT in the apical five-chamber view to obtain the VTI. (D) Continuous wave Doppler profile across the aortic valve reveals a maximum velocity of 4.4 m/s, consistent with severe stenosis. Calculation of the aortic valve area:  $CSA_{LVOT} = \pi(2.2/2)^2 = 3.8 \text{ cm}^2$ .  $AVA = 3.8 \times 22.8/97.1 = 0.89 \text{ cm}^2$ .

The CSA of the LVOT is assumed to be circular and calculated using the equation for area of a circle:

$$CSA_{LVOT} = \pi(D/2)^2$$

where D is diameter of the LVOT measured in early systole. Of note, often the peak velocity is substituted for the VTI.

Accurate measurement of the LVOT diameter is of utmost importance. Since this parameter is squared for the calculation of the  $CSA_{LVOT}$ , deviations in measurement lead to significant errors in the AVA. For example, an under- or over-estimation of a 2-cm LVOT diameter by 5% (1 mm) will result in a 10% error in the LVOT area and AVA. Other potential errors include inaccurate measurement of LVOT or peak AV flow velocity profile when obtained at a nonparallel intercept angle, and failure to interrogate maximum AV velocity from multiple windows to obtain the highest velocity.

One approach that reduces potential sources of error related to inaccurate measurement of the LVOT diameter

is to remove the CSA from the equation. The dimensionless index expresses the size of the valvular effective orifice area as a proportion of the  $CSA_{LVOT}$ . This index can be calculated using a peak velocity ratio<sup>33</sup> or VTI ratio:

$$\text{Dimensionless index} = V_{LVOT}/V_{AV} \quad \text{or} \quad VTI_{LVOT}/VTI_{AV}$$

A dimensionless index of  $\leq 0.25$  indicates severe stenosis, corresponding to a valvular area 25% of the normal.<sup>38</sup>

AVA by planimetry is not routinely performed as it can be technically challenging to identify the minimum orifice area at the valvular tips, particularly when extensive calcification is present. Moreover, it is the effective orifice area rather than the anatomic orifice area that is the primary predictor of outcome in severe AS. However, during intra-operative TEE when it may be difficult to obtain accurate LVOT and AV velocities, planimetry can be used as a measure of stenosis.<sup>39</sup>

The 2014 AHA/ACC guidelines classify symptomatic severe AS into three groups: severe high-gradient AS, low

Severe high gradient AS (classical AS)	<ul style="list-style-type: none"> <li>• <math>AVA \leq 1 \text{ cm}^2</math> (or <math>AVA_i &lt; 0.6 \text{ cm}^2/\text{m}^2</math>) but may be larger with mixed AS/AR</li> <li>• Or aortic <math>V_{\text{max}} \geq 4 \text{ m/s}</math></li> <li>• Or mean gradient <math>\geq 40 \text{ mm Hg}</math></li> </ul>
Low flow low gradient AS with reduced LVEF (LVEF < 50%)	<ul style="list-style-type: none"> <li>• <math>AVA \leq 1 \text{ cm}^2</math> with resting aortic <math>V_{\text{max}} &lt; 4 \text{ m/s}</math> or resting mean gradient <math>&lt; 40 \text{ mm Hg}</math></li> <li>• Or with dobutamine inotropic stimulation to increase stroke volume, the resultant is <math>AVA \leq 1 \text{ cm}^2</math> with <math>V_{\text{max}} \geq 4 \text{ m/s}</math></li> </ul>
Low gradient AS with normal LVEF (paradoxical low flow AS)	<ul style="list-style-type: none"> <li>• <math>AVA \leq 1 \text{ cm}^2</math> with <math>V_{\text{max}} &lt; 4 \text{ m/s}</math> or mean gradient <math>&lt; 40 \text{ mm Hg}</math></li> <li>• Indexed <math>AVA \leq 0.6 \text{ cm}^2/\text{m}^2</math> and</li> <li>• Stroke volume index <math>&lt; 35 \text{ mL}/\text{m}^2</math></li> <li>• Measured when patient is normotensive (systolic BP <math>&lt; 140 \text{ mm Hg}</math>)</li> </ul>

flow low gradient (LFLG) severe AS with reduced LVEF, and low-gradient severe AS with normal LVEF (or paradoxical low flow AS).<sup>31</sup> Echocardiographic definitions for each class are shown in Table 12-5.

**Identification of Severe Aortic Stenosis by Echocardiography.** The traditionally well-accepted definition of severe AS is based on the natural history of AS without surgical intervention. Prognosis was shown to be poor with  $V_{\text{max}} > 4 \text{ m/s}$ , which corresponds to a mean gradient of  $> 40 \text{ mm Hg}$ .<sup>40</sup> The prognosis of patients was also poorer when  $AVA < 1 \text{ cm}^2$ .<sup>41</sup> These patients are classified as severe high-gradient AS.

However, a proportion of patients with severe AS have a low velocity and pressure gradient, that is,  $V_{\text{max}} < 4 \text{ m/s}$  and mean gradient  $< 40 \text{ mm Hg}$ , despite a calculated AVA of  $< 1 \text{ cm}^2$ . This typically occurs in the setting of decreased LVEF and SV. It is estimated that 5 to 10% of patients with severe AS have LFLG severe AS related to a decrease in LVEF. These patients typically have a dilated LV with markedly decreased LV systolic function due to concurrent ischemic heart disease, other cardiomyopathy and/or secondary to chronic pressure overload from the AS.<sup>42</sup> It is important to ascertain that the calculated low AVA is due to true severe AS, as opposed to pseudo-AS as the former benefits from AVR. In both situations, there is low flow due to the low LVEF, resulting in low  $V_{\text{max}}$  and low mean transvalvular gradient. In the latter condition, the aortic valve is only mildly or moderately stenotic; however the “weak” LV is unable to generate high enough flow to allow full excursion of the valve leaflets. Therefore, the AVA appears erroneously low. As discussed above, when there is a discrepancy between velocity/gradient and valvular area, it is important to make sure the proper LVOT measurement was used in the AVA calculation.

Low dose dobutamine combined with echocardiography is useful in distinguishing true severe LFLG AS with reduced

LVEF from pseudo-severe AS.<sup>43</sup> Patients with pseudo-severe AS will demonstrate an increase in AVA with only a modest increase in transaortic velocity or gradient as transaortic stroke volume increases with the dobutamine infusion. In contrast, patients with true severe AS will have a fixed valve area even with an increase in LV contractility and transaortic flow rate. Severe AS on low dose dobutamine stress echocardiography is defined as a maximum velocity of  $\geq 4.0 \text{ m/s}$  with a valve area of  $\leq 1.0 \text{ cm}^2$  at any point during the test protocol.<sup>33</sup>

Dobutamine stress echo also identifies a subgroup of patients who have a “lack of contractile reserve” by failing to show a 20% increase in stroke volume with dobutamine. This subgroup of patients has a poor prognosis with either medical or surgical therapy.<sup>44</sup>

**Low Gradient AS with Normal LVEF.** Low gradient AS with normal LVEF (also known as paradoxical LFLG AS) was first described in 2007.<sup>45</sup> These patients have severe AS defined by an indexed  $AVA \leq 0.6 \text{ cm}^2$ , but paradoxically lower than expected transvalvular gradients due to low stroke volume despite preserved LVEF ( $> 50\%$ ). This entity is found in approximately 10 to 25% of patients with severe AS.<sup>42</sup> They consist primarily of elderly women with more pronounced concentric LV hypertrophy resulting in a small LV cavity size and reduced stroke volume ( $< 35 \text{ mL}/\text{m}^2$ ). The LV end diastolic diameter is generally  $< 47 \text{ mm}$ , and end diastolic volume indexed for BSA  $< 55 \text{ mL}/\text{m}^2$ .<sup>46</sup> Such patients often have signs of diastolic dysfunction with restrictive physiology and decrease in LV compliance and filling.

Identification of this entity is important as patients with symptomatic low-gradient AS with normal LVEF have a poorer prognosis compared with patients with high-gradient severe AS if treated medically rather than surgically.<sup>47</sup> Before this diagnosis is considered, it is important to exclude errors in the component measurements used to calculate aortic valve area (LVOT size, or LVOT and aortic flows).

**Hemodynamic Effect on LV.** Echocardiography is useful in assessing the LV response to chronic pressure overload that results in LV hypertrophy. LV systolic function and volumes can be estimated by 2D and 3D echocardiography. Diastolic dysfunction often accompanies LV hypertrophy and is particularly pronounced in low-gradient AS with normal LVEF. Mitral  $E/e' > 15$ , MV E wave deceleration time  $< 150 \text{ ms}$  and a transmitral E/A ratio  $> 2.5$  suggests a restrictive filling pattern.<sup>48</sup> Estimation of pulmonary systolic pressure is obtained from the peak tricuspid regurgitation (TR) velocity using the simplified Bernoulli equation.

**Diagnostic Pitfalls with Echocardiography.** Maximum velocity and transvalvular gradients are dependent on LV function and flow. Hence, conditions affecting flow can influence the values of these parameters. For instance, when there is coexisting significant AR, the maximum transvalvular velocity and mean gradient will be higher for a given valvular area because of the high transaortic systolic flow rate.

In the presence of severe MR, transaortic flow rate may be low resulting in a low gradient even when severe AS is present. Valvular area calculations, however, remain accurate.

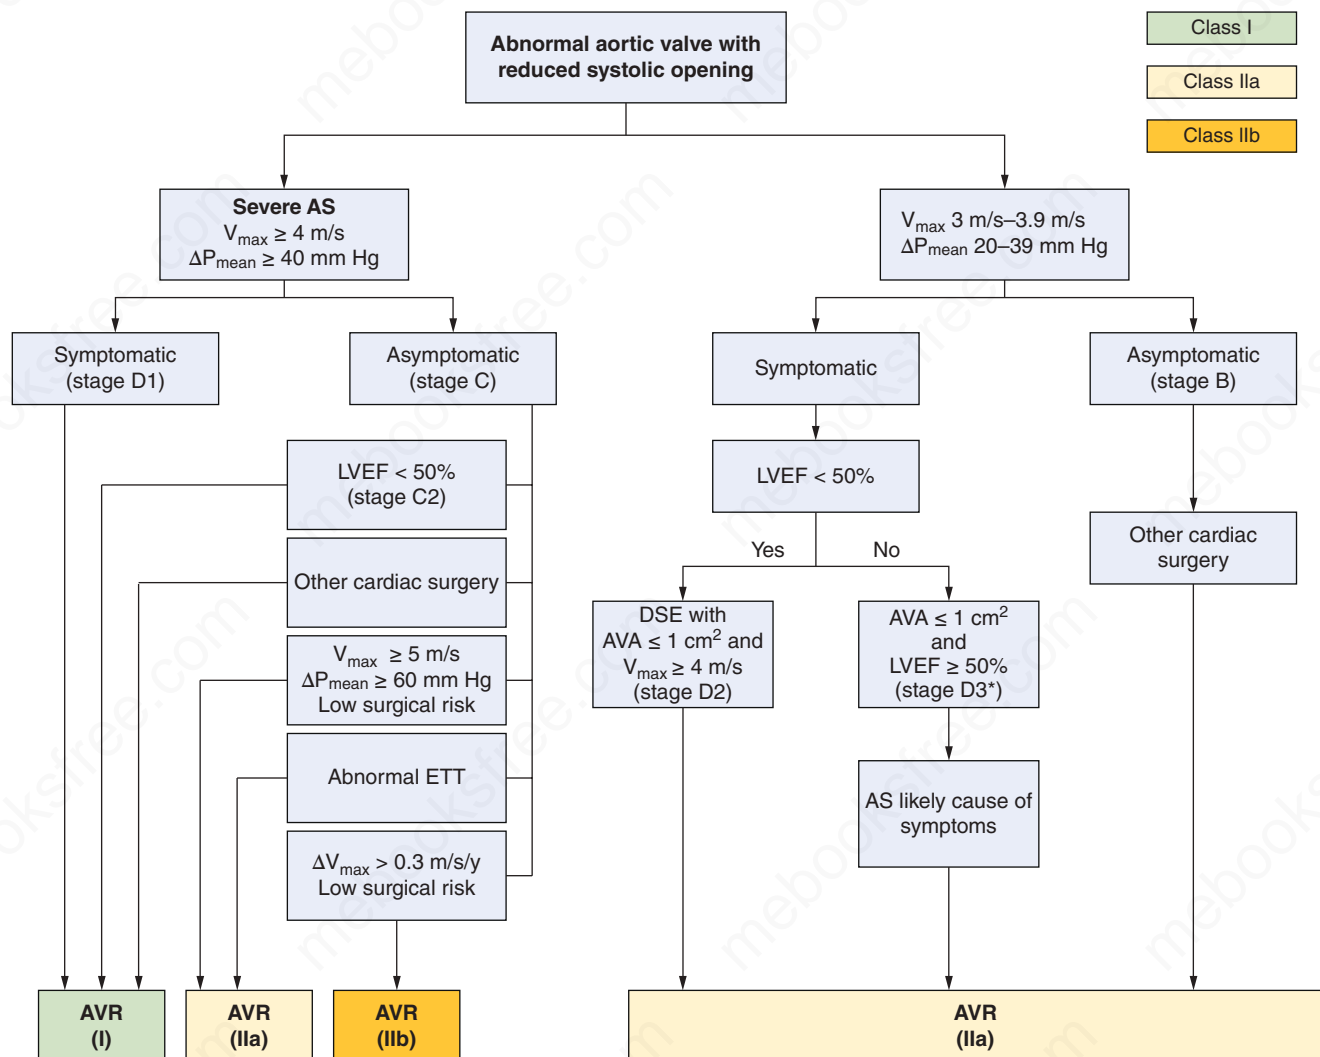

**Use of TEE.** TEE allows high-fidelity assessment of the geometry and the height of valvular leaflets relative to one another. This level of detail is not well seen on TTE. The  $CSA_{L_{VOT}}$  can also be obtained via 3D multi-planar reconstruction to reduce errors when using the continuity equation to calculate the AVA. TEE is also superior to TTE in obtaining precise measurements of the aortic root and ascending aorta, thus supporting surgical planning for aortic valve repair and guidance in the use of transcatheter or transcatheter AVR.

The 2014 AHA/ACC guidelines employ multiple echocardiographic parameters discussed above as part of the algorithm to determine the timing for an aortic valve replacement for severe AS (Fig. 12-20).

## AORTIC REGURGITATION

Echocardiography provides diagnostic information about the mechanism of aortic regurgitation (AR), assessment of severity of AR, hemodynamic effect of resultant volume overload on the LV, and the morphology and dimensions of the aortic root.

**Etiology of Aortic Regurgitation by Echocardiography.** Echocardiography can differentiate whether AR occurs as a result of leaflet abnormality, or aortic root dilatation that prevents complete leaflet coaptation. Specifically, echocardiography can identify leaflet abnormalities such as bicuspid aortic valve, degenerative leaflet calcifications, infective endocarditis, and rheumatic thickening. Likewise, dilation of the aortic annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta can be easily quantified with echocardiography. Some causes of aortic dilation include long-standing hypertension, Marfan's syndrome, connective tissue disorders, and aortitis.

\*AVR should be considered with stage D3 AS only if valve obstruction is the most likely cause of symptoms, stroke volume index is  $< 35 \text{ mL/m}^2$ , indexed AVA is  $\leq 0.6 \text{ cm}^2/\text{m}^2$ , and data are recorded when the patient is normotensive (systolic BP  $< 140 \text{ mm Hg}$ ).

**FIGURE 12-20** AHA/ACC guidelines: Algorithm for management of AS. (Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2014 Jun 10;63(22):e57-e185.)

The echocardiographic description of bicuspid aortic valve was discussed earlier under aortic stenosis. Since aortopathy is associated with bicuspid aortic valve, assessment of the aortic root and ascending aorta dimensions are important.

In degenerative calcific AR, the central portions of the cusps are calcified and there is no commissural fusion. In rheumatic AR, in contrast, there is commissural fusion, and the calcification and diffuse thickening of the leaflets at the leaflet free edges result in leaflet retraction and central AR.

**Echocardiographic Assessment of AR Severity.** Assessing the severity of AR requires integration of qualitative and quantitative echocardiographic measures, similar to the assessment of MR (Table 12-6).<sup>21</sup>

Color flow imaging is the easiest method to provide a visual estimate of the degree of AR. However, this method is subject to many limitations. Color jet size and length are influenced by the aortic to LV diastolic pressure gradient and LV compliance. Thus, it can poorly correlate with the severity of AR. Jets directed towards the anterior mitral valve leaflet or septum may appear narrow. Jet area and size are often overestimated in the apical views, and for this reason, they are best assessed in the parasternal long axis views due to better axial resolution. The ratio of the proximal jet width (measured from the long axis view) to the diameter of the LV outflow tract of  $>65\%$  is consistent with severe AR<sup>49</sup> (Fig. 12-21).

The vena contracta width is the narrowest flow diameter at the level of the aortic valve. This is measured in the parasternal long axis view and provides an indirect measure of the EROA. A vena contracta of 6 mm at a Nyquist limit of  $-60$  cm/s correlates with severe AR.<sup>50</sup>

The EROA is an ideal parameter for the assessment and follow up of AR. As discussed for MR, this requires assessment of the flow convergence zone. It is very challenging to derive EROA due to difficulty obtaining high-quality images of the flow convergence zone. Where feasible, the apical five-chamber view is recommended for central regurgitant jets, whereas in eccentric jets, the parasternal long axis view is used. An EROA  $\geq 30$  mm<sup>2</sup> or regurgitant volume  $\geq 60$  mL

**FIGURE 12-21** Aortic regurgitation. Color Doppler parasternal long axis TTE view displays aortic regurgitant jet that fills the entire left ventricular outflow tract, consistent with severe aortic regurgitation.

indicates severe AR.<sup>31</sup> Measurement of this parameter is less common than for MR.

Brief aortic diastolic flow reversal is observed in the aorta in normal studies as measured by pulse wave Doppler in the proximal descending aorta (just distal to the origin of the subclavian artery). In severe AR, there is holodiastolic flow with an end diastolic velocity typically  $>20$  cm/s.<sup>51</sup>

The density of the CW jet in comparison to the antegrade flow provides an estimate of the volume of regurgitation; however, it can be difficult to distinguish moderate from severe regurgitation based on CW jet density alone. CW Doppler of the AR jet is best obtained from the five-chamber view. Eccentrically directed jets may be better obtained from the right parasternal window.

The rate of deceleration of the diastolic regurgitant velocity and the PHT reflect the rate of equalization of aortic and LV diastolic pressure. In severe acute AR, there is rapid equalization resulting in a short PHT. A PHT  $< 200$  ms is consistent with severe AR, whereas  $>500$  ms is consistent with mild AR. However, this parameter is influenced by chamber compliance and pressure. The PHT can be shortened by elevated LV diastolic pressure, or lengthened and normalized with chronic LV adaptations to the severe AR.

**Hemodynamic Effects on the LV.** The LV dilates in response to the chronic volume overload of AR and assumes a more spherical shape. LV mass increases, although the increase in wall thickness is modest. Deterioration of LV systolic function is a late and possibly irreversible finding. However, patients with severe LV dysfunction (LVEF  $\leq 35\%$ ) and severe AR still experience a mortality benefit from AVR.<sup>52</sup>

In the 2014 AHA/ACC guidelines, aortic valve replacement is indicated when LV systolic dysfunction (LVEF  $< 50\%$ ) is present (Class I) and is reasonable with severe LV dilation (LVESD  $> 50$  mm or indexed LVESD indexed  $> 25$  mm/m<sup>2</sup>) with normal LV systolic function (LVEF  $\geq 50\%$ ) (Class IIa).

**TABLE 12-6: Echocardiographic Signs of Severe AR**

**Qualitative**

- Holodiastolic flow reversal in descending aorta (end-diastolic velocity  $> 20$  cm/s)
- Large central jet (jet width to LVOT diameter ratio  $> 65\%$ )
- Dense CW signal of AR jet
- Left ventricular dilatation

**Semi-Quantitative**

- VC width  $> 6$  mm
- Pressure half-time  $< 200$  ms

**Quantitative**

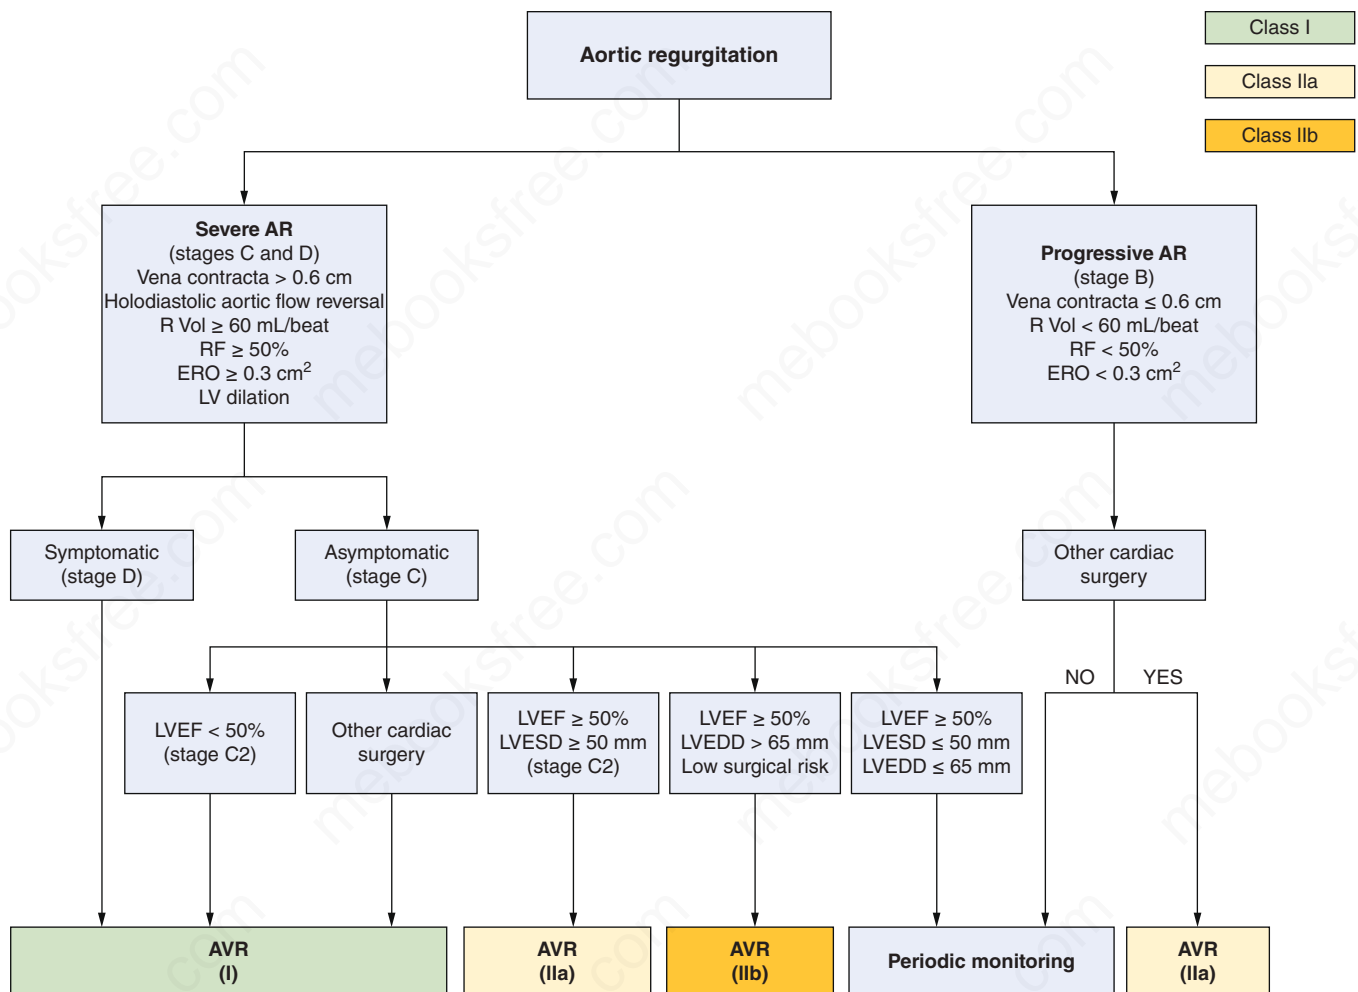

- EROA  $\geq 30$  mm<sup>2</sup>
- Regurgitant Vol  $\geq 60$  mL

**Acute AR.** The most common causes of acute AR are infective endocarditis and aortic dissection. The specificity and sensitivity of TTE for the diagnosis of aortic dissection are only 80% and 60% respectively, whereas TEE has a specificity and sensitivity of 95 to 100% and 98 to 100%.<sup>53</sup> Infective endocarditis causes aortic regurgitation via leaflet perforation, destruction, and malcoaptation due to mechanical effects of vegetations on the leaflet tips.

The primary difference in acute and chronic AR on echocardiography is the LV. In chronic AR, the LV has had time to remodel and dilate. Sudden volume overload in acute AR is poorly tolerated by the normally sized LV and this leads to a rapid rise in LV diastolic pressure and pulmonary edema. Due to the rapid equalization of aortic and LV diastolic pressures, the CW velocity profile of the acute AR jet demonstrates a steep slope with a short pressure half-time of <200 ms and pulse wave Doppler of the descending aorta demonstrates no end diastolic velocity. Markedly elevated LV diastolic pressures are indicated by short deceleration time on the mitral inflow and premature closure of the mitral valve on M-mode echocardiography.

**TEE in AR.** TEE is utilized for assessing the aortic root and ascending aorta dimensions when aortic dissection is suspected and for obtaining precise measurements in the surgical planning phase of aortic valve repair. A magnified view of the aortic valve can provide a cleaner vena contracta measurement than on TTE. Other Doppler assessments are better obtained from TTE due to difficulty obtaining TEE views where the ultrasound beam is parallel to the jet direction. But in the operating room, transgastric TEE can come close to being “on axis” in the LVOT. Also 3D TEE datasets can be manipulated in near real time to obtain perfect alignment and some systems allow reassessment of Doppler information in postanalysis. Also TEE is particularly useful in infective endocarditis to identify vegetations and abscess formation not seen as well on TEE.

**Timing of AVR for AR Based on Echocardiographic Parameters.** The 2014 AHA/ACC valvular heart disease guidelines utilize echocardiographic parameters in the algorithm for the timing of aortic valve replacement for severe AR. The algorithm is shown in Fig. 12-22.

**FIGURE 12-22** AR algorithm. (Reproduced with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2014 Jun 10;63(22):e57-e185.)

## Tricuspid Valve Disorders

### TRICUSPID REGURGITATION

Echocardiographic assessment of TR provides information on valvular morphology, severity of TR, hemodynamic effects on right-sided chambers and significance of left-sided disease. This requires a combination of 2D and Doppler methods to assess leaflet structure and function including thickness, coaptation geometry, gradients, annular dilation, presence of masses, RV size and function, and RV systolic pressure (RVSP).

**Functional TR.** The most common cause of TR is functional, where the leaflets are structurally normal and regurgitation is caused by incomplete leaflet coaptation due to annular dilatation and leaflet tethering. Any condition that causes RV dilatation and systolic dysfunction can lead to functional TR. The most common causes are left-sided heart disease particularly mitral and aortic valve diseases. Other etiologies include atrioopathy related to atrial fibrillation and pulmonary conditions causing pulmonary hypertension. Normal tricuspid valve annulus diameter measured in diastole in the four-chamber view is  $28 \pm 5$  mm. A diastolic annulus  $> 34$  mm is a marker of significant TR. Severe annular dilatation ( $>40$  mm or  $>21$  mm/m<sup>2</sup>) indicates an increased risk of persistent or progressive TR after isolated mitral valve surgery.<sup>54</sup> Thus, efforts are now focused on identifying patients early who will benefit from tricuspid valve (TV) interventions.

**Primary TR.** *Primary* disorders of the tricuspid apparatus are much less common. In rheumatic disease, the leaflets and papillary muscles are thickened, shortened and retracted. Tricuspid valve prolapse most often involves the anterior and septal leaflets and is almost always associated with mitral valve prolapse. A flail leaflet is caused by ruptured chordae, degenerative disease, infective endocarditis, trauma, or it can be iatrogenic from central lines, intravalvular pacemaker leads or during endomyocardial biopsies. Intracardiac device leads can also interfere with coaptation if there is impingement of the valvular leaflets.<sup>55</sup> With Ebstein's anomaly, the tricuspid valve leaflets are malformed: in the most common form, the anterior leaflet is the largest leaflet and the posterior and septal leaflets are vestigial and arise posteriorly and apically. Carcinoid disease affects the tricuspid and pulmonary valves. These leaflets appear short, thickened, and fibrotic with restricted motion. In severe cases of carcinoid disease, the leaflets are nonmobile, resulting in wide-open regurgitation.

**Assessment of Severity by Echocardiography.** The standards for determining the severity of TR are less robust than for MR with limited studies to validate quantitative measures for TR. The European Association of Echocardiography/American Society of Echocardiography (EAE/ASE) guidelines recommend an integrative approach: evaluating size and function of right-sided chambers, septal motion, and various Doppler parameters (Table 12-7).<sup>21,28</sup>

The following parameters are consistent with severe TR: (1) a jet area  $> 10$  cm<sup>2</sup> (caveat being that the severity

**TABLE 12-7: Echocardiographic Signs of Severe TR**

- Vena contracta width  $> 0.7$  cm
- CW jet density and contour: dense, triangular with early peak ("cut-off" sign)
- EROA  $\geq 40$  mm<sup>2</sup>
- Regurgitant volume  $\geq 45$  mL
- Central jet area  $> 10$  cm<sup>2</sup>
- Hepatic vein flow: systolic flow reversal
- Tricuspid inflow: E wave dominant ( $\geq 1$  cm/s)
- Dilated RV, RA and IVC with decreased respirophasic variation
- Interventricular septal flattening in diastole (RV volume overload)

of eccentrically directed regurgitant jets may be underestimated); (2) a vena contracta of  $\geq 7$  mm;<sup>56</sup> (3) EROA  $\geq 40$  mm<sup>2</sup> or regurgitant volume of  $\geq 45$  mL<sup>57</sup> (although the flow convergence method is rarely used in clinical practice); (4) continuous wave Doppler of the TR jet is dense and complete, and can appear truncated with a triangular contour due to an early peak velocity (cut-off sign); and (5) systolic flow reversal in the hepatic veins (sensitivity of 80%).<sup>6</sup>

**Hemodynamic Consequences of TR: Echocardiographic Assessment.** Chronic significant TR causes volume overload of the right-sided chambers, which subsequently leads to RV dilatation and failure, and elevated PASP. With RV volume overload, the interventricular septum demonstrates paradoxical motion and in the short axis view, appears flat in diastole. When pulmonary hypertension ensues, the septum also appears flat in systole as a sign of RV pressure overload. Chronic back pressure causes the interatrial septum to bow to the left, and there is right atrial (RA), IVC and hepatic vein dilatation indicating elevated RA pressure.

Impaired RV function has a negative impact on survival outcomes after tricuspid valve surgery<sup>7</sup> and intervention should ideally be performed before RV dysfunction occurs.<sup>58</sup> The assessment of RV function can be challenging due to its complex shape. Specifically, there is no single 2D imaging plane in which the inflow, apical and outflow views of the RV can be imaged simultaneously. Normal RV function can be defined by many echocardiographic parameters as defined by the ASE guidelines: TAPSE  $> 17$  mm, fractional area change  $>35\%$ , tricuspid valve annular velocity (S')  $>9.5$  cm/s.<sup>13,23</sup>

Estimation of RVSP is obtained from the TR jet peak velocity using the simplified Bernoulli equation (pressure =  $4 \times \text{velocity}^2$ ). The velocity of the TR jet itself is not equal to the severity of TR, but rather it is related to the peak systolic gradient between the RV and RA. The RVSP is then estimated as the sum of this pressure gradient determination plus the RA pressure. In wide-open TR, the TR jet may appear less turbulent, with a low jet velocity ( $<2$  m/s) due to rapid equalization of RA and RV pressures. In this scenario the simplified Bernoulli method may underestimate RVSP.

**Important Echocardiographic Parameters for Timing of TV Surgery.** Severe TR is associated with poor prognosis independent of LV and RV function, RV size and age.<sup>59</sup> TR is most often seen in left-sided disease, particularly mitral or aortic pathologies. The 2014 AHA/ACC guidelines recommend tricuspid valve surgery for patients with severe TR undergoing left-sided valve surgery (Class I).<sup>31</sup> Mild or moderate degrees of TR can progress in up to 25% of patients if left untreated at the time of left-sided valve surgery. Thus, tricuspid valve repair can be beneficial for patients with at least mild functional TR when undergoing left-sided valve surgery, if there is: (1) tricuspid annular dilatation (>40 mm diameter or 21 mm/m<sup>2</sup> indexed to body surface area), (2) prior evidence of right-heart failure (Class IIa); or (3) pulmonary hypertension present (Class IIb).<sup>31</sup> The risk factors for progression of TR include dilated tricuspid annulus (>40 mm diastolic diameter or 21 mm/m<sup>2</sup>), degree of RV dysfunction, pulmonary artery hypertension, AF, intra-annular RV pacemaker, or implantable cardioverter-defibrillator leads. Reoperation for severe isolated tricuspid regurgitation after left-sided valve surgery is associated with significant perioperative mortality.

**TEE in TR.** TEE is seldom required in the preoperative assessment of TR but is useful in infective endocarditis and when assessing for interference of intracardiac device leads on the valve leaflet function. Transgastric views can demonstrate the tricuspid valve in short axis, which is a view not readily seen on TTE, and a transgastric 120° view provides a highly reliable tricuspid annulus measurement for assessing the need for tricuspid repair. Also Doppler analysis of the flow direction in the anterior hepatic vein provides very precise data about the presence of systolic reversal of hepatic vein flow, an important indicator of severe TR.

## Prosthetic Valves

Echocardiography with Doppler is the method of choice for the noninvasive evaluation of prosthetic function. Echocardiographic assessment of prosthetic valves includes 2D imaging of the valve, its leaflets and its overall seating, assessment of valvular hemodynamics including transvalvular velocities and gradients, identification and quantification of valvular stenosis or regurgitation; and evaluation of cardiac chamber sizes, left ventricular systolic function and pulmonary artery pressures.

The basic Doppler principles applied to native valves to assess gradients and calculate for effective orifice area (EOA) are also used for prosthetic valves. Different models and sizes of prosthetic valves have different gradients and EOA.<sup>60</sup> The expected ranges of normal gradients and EOA for different types of valves in different valvular positions have been reported and are available in guidelines and other documents.<sup>60</sup>

Peak instantaneous pressure gradient is calculated by the simplified Bernoulli equation as previously described (see the Aortic Stenosis section). The EOA of the prosthetic aortic valve is calculated from the continuity equation, similar to

native stenotic aortic valves. For prosthetic aortic valves, it is also reasonable to use the dimensionless velocity index (DVI) to assess for stenosis. The DVI is the ratio of the velocity in the LVOT measured by pulse wave (PW) Doppler to the velocity through the aortic prosthesis measured by CW Doppler. A DVI <0.25 suggests significant valve obstruction if accompanied by an acceleration time > 100 ms (which is the time from transvalvular flow onset to maximum velocity).<sup>60</sup>

The continuity equation can also be applied (in the absence of significant MR or AR) for the mitral valve but is not as frequently used. When applied it is:

$$\text{MV area} = \text{CSA}_{\text{MVannulus}} \times \frac{\text{VTI}_{\text{MVannulus}}}{\text{VTI}_{\text{MV}}}$$

The PHT technique used to quantify the area of native stenotic mitral valves can be used to monitor prosthetic mitral valve function. Prolongation of the PHT when compared to baseline is a reliable indication of obstruction. DVI is increased in mitral prosthetic stenosis or regurgitation. In this scenario, the PHT can help differentiate between the two. A PHT of >200 ms is most consistent with stenosis, whereas a PHT < 130 ms, especially with an elevated peak E wave velocity, suggests regurgitation.<sup>60</sup>

A small degree of regurgitation occurs with virtually all types of mechanical prostheses and can be detected by color Doppler. These jets are normally brief and of low intensity with little penetration into the LA.<sup>61</sup> These “washing jets” are thought to prevent thrombus formation on the edges of the occluders and also reduce friction that might impede rapid valve opening.

## PROSTHETIC VALVULAR DYSFUNCTION

The main causes of prosthetic valvular dysfunction requiring surgery are prosthetic valve obstruction manifested by moderate-to-severe stenosis, degeneration manifested by moderate-to-severe central valvular regurgitation, or significant paravalvular regurgitation. Obstructions are most commonly caused by thrombosis, vegetation, pannus or fibrous ingrowth. Degeneration most commonly is due to aging of bioprosthetic leaflets or effects of endocarditis while paravalvular leaks most often are associated with infection.

## PROSTHETIC VALVULAR OBSTRUCTION

Almost all prosthetic valves have an EOA that is smaller than the native orifice area. Comparison with the baseline postoperative echocardiogram or with established normal values for valves of that specific type and size is particularly helpful for detection of significant prosthetic valvular obstruction.<sup>60</sup>

Mechanical valvular obstruction or stenosis occurs as a result of thrombus deposition or pannus formation, which interferes with normal leaflet occluder motion. Obstruction may not be obvious on 2D TTE imaging, but is suspected when there is a significant increase in pressure gradient. TEE is the primary means to confirm prosthetic valvular obstruction and identify its causes, particularly for the mitral valve (Fig. 12-23). It can be difficult to differentiate a thrombus

**FIGURE 12-23** Mechanical mitral prosthetic valve obstruction. TEE mid-esophageal long axis view of a thrombosed bileaflet mitral prosthesis. Only one leaflet opens in diastole (*arrow*). The other leaflet is obstructed by thrombus, that is also seen on the left atrial wall (\*). LA = left atrium.

from a pannus on echocardiography. However, a thrombus is usually larger, has a “softer” ultrasound appearance similar to myocardium and may demonstrate mobile elements. Large thrombi (>1 cm in length or 0.8 cm<sup>2</sup> in area) have a 2.4-fold higher rate of complications per 1 cm<sup>2</sup> increase in size.<sup>62</sup> Pannus formation is more common in aortic prostheses.<sup>60</sup> For a bioprosthetic valve, fibrosis and calcification of leaflets are the most common causes for obstruction.

Patient prosthesis mismatch (PPM) occurs when the EOA of the prosthesis is too small for the patient’s body size and stroke volume requirements, resulting in abnormally high gradients. Most studies have focused on the aortic prosthesis. PPM is considered mild (and therefore not clinically significant) if the indexed EOA of the aortic prosthesis is >0.85 cm<sup>2</sup>/m<sup>2</sup>, moderate if >0.65 to ≤0.85 cm<sup>2</sup>/m<sup>2</sup>, and severe if ≤0.65 cm<sup>2</sup>/m<sup>2</sup>.<sup>63</sup>

### PROSTHETIC VALVE PATHOLOGIC REGURGITATION

Pathological regurgitation of a mechanical prosthetic valve is typically due to a paravalvular leak. Paravalvular regurgitation that occurs soon after surgery is usually due to technical factors or infective endocarditis. Late paravalvular regurgitation is almost always due to infective endocarditis, causing suture dehiscence. Significant dehiscence can result in rocking or independent motion of the prosthesis. Occasionally thrombus or pannus formation limits normal occluder closure resulting in significant central valvular regurgitation.

For bioprostheses, pathologic central regurgitation usually occurs as a result of leaflet degeneration and/or calcification. The causes of paravalvular regurgitation are similar to that of mechanical prostheses.

Detection of regurgitation by TTE is challenging for mitral and tricuspid valves due to acoustic shadowing and reverberation artifacts from the prostheses that can obscure

**FIGURE 12-24** Mitral paravalvular leak. Mid-esophageal TEE of a mechanical bileaflet mitral prosthesis at transducer angle of 60°. Two physiological washing jets are seen at the periphery of the discs. A large paravalvular leak is noted outside the lateral aspect of the sewing ring. LA = left atrium, LV = left ventricle.

evidence of the Doppler regurgitation signal in the atria. Localization of paravalvular regurgitation may be difficult and can only be diagnosed if the flow is visualized around the outside of the sewing ring. Multiplanar TEE is particularly helpful in these situations (Fig. 12-24). Real-time 3D TEE with color Doppler can facilitate the location and quantify the extent of prosthetic regurgitation by visualizing the regurgitant orifice area *en face* from the perspective of the chamber receiving the regurgitation.

Indications for surgical intervention of significant prosthetic valve regurgitation are the same as indications for native regurgitation of the aortic or mitral valve. Specifically, this includes echocardiographic evidence of LV dysfunction including low LVEF or progressive LV dilation.<sup>31</sup>

For a discussion of echocardiographic imaging of infective endocarditis of prosthetic valves, see the section on Infective Endocarditis below.

### TTE VERSUS TEE IMAGING OF THE PROSTHETIC VALVES

TTE detects prosthetic valve dysfunction through quantitation of the severity of stenosis and regurgitation by Doppler techniques. TTE also allows assessment of LV size and systolic function, LA size, right heart function and estimation of pulmonary pressures. However, with its better image quality and structure resolution, TEE is superior to determine the actual mechanism of prosthetic valvular dysfunction in addition to providing the same information that TTE is capable of. But in the presence of multiple mechanical prostheses, either method may be limited by echo shadowing from one of the devices, and a combination of both may provide the most complete information. In the operating room this may mean combining TEE with epicardial views.

## Infective Endocarditis

Echocardiography plays a pivotal role in the diagnosis of infective endocarditis (IE), identifying underlying predisposing conditions, detecting complications, characterizing the hemodynamic severity of valvular lesions, and assessing ventricular function and pulmonary pressures.

The hallmark of IE on echocardiography is the identification of new vegetations. New or worsening valvular regurgitation, abscess and new partial dehiscence of a prosthetic valve are also important echocardiographic features.<sup>64</sup> A vegetation is defined echocardiographically as a mass that exhibits a motion pattern that is independent of the structure it is attached to, such as a valve or implanted intracardiac device. The sensitivity of TTE for the detection of vegetations ranges from 50 to 90%, depending on the quality of images, the location of the lesion, and the size of the lesion. TEE has far superior sensitivity at 90 to 100%.<sup>31</sup> Identification of vegetations may be difficult in the presence of preexisting lesions (degenerative calcified valves, mitral valve prolapse, prosthetic valves), if the vegetations are small or already embolized.

### COMPLICATIONS IDENTIFIED BY ECHOCARDIOGRAPHY

Valvular regurgitation is the most common complication of native valve endocarditis. It can arise from multiple mechanisms: coaptation failure from vegetation interference, leaflet destruction and perforation, or flail leaflet from ruptured chords.

Paravalvular abscess generally affects the aortic valve around the aortic root and can spread to the intervalvular fibrosa and anterior leaflet of the mitral valve. On echocardiography, an abscess is seen as a nonhomogeneous paravalvular thickening often with lucent spaces within it. The abscess can drain into a cardiac cavity and it may appear on echocardiography as a pseudoaneurysm (Fig. 12-25). With color Doppler, the pulsatile flow can be recorded into and out of this echo-free space. Fistula formation is more rare and visualized as a communication between two neighboring cavities through a perforation. The pattern and timing of the flow in the fistula with color Doppler is a function of the relative pressures between the two cavities. Spread of infection into the pericardial space can result in purulent pericarditis. It is difficult using echocardiography to distinguish purulent pericarditis from a sterile inflammatory pericardial effusion; so, the diagnosis is generally made based on clinical findings.

Systemic embolization of the vegetation or portions of the vegetation are a frequent and life-threatening complication. Echocardiographic features of the vegetation that correlate with embolization include large size (>10 mm for left sided lesions and 20 mm for right sided lesions) and excessive mobility especially when associated with the anterior leaflet of the mitral valve.<sup>65,66</sup> Worse prognosis is seen in vegetations >15 mm, increasing vegetation size despite antibiotic therapy, multiple sites of involvement, and extension to extra-valvular structures.<sup>67</sup>

**FIGURE 12-25** Prosthetic valve pseudoaneurysm. TEE mid-esophageal long axis view showing a dehiscent mechanical aortic valve (*white arrow*) with pseudoaneurysm formation (*star*) as a complication of an aortic root abscess. There is communication between the LVOT and the pseudoaneurysm (*red arrow*). LA = left atrium, LV = left ventricle.

### PROSTHETIC VALVE ENDOCARDITIS (PVE)

PVE has a lower incidence of vegetations (especially mechanical prostheses) and a higher incidence of annular abscesses and other paravalvular complications. Infection usually involves the region between the sewing ring and the annulus in PVE, leading to abscess formation that can progress to dehiscence, pseudoaneurysms, and fistulae. Echocardiographic features of valve dehiscence include paravalvular regurgitation, and excessive rocking motion of the valve. In bioprosthetic PVE, vegetations can also be seen on the leaflets, which can lead to perforation. Infrequently, large vegetations can cause prosthetic valve obstruction.

TTE and TEE have complementary roles in PVE. TEE is superior for detecting annular abscesses, and smaller vegetations. However, owing to acoustic shadowing from the valve, the anterior portion of the aortic valve and the LV side of the MV prosthesis are not as well seen on TEE and can be better assessed on TTE.<sup>68</sup> Assessment of hemodynamic severity of regurgitation is most often better assessed by TTE. Assessment of Doppler-derived aortic valve pressure gradients is typically better with TTE due to better alignment of the Doppler interrogation with flow.

The 2014 AHA/ACC guidelines for the management of valvular heart disease recommend early surgery during initial hospitalization for valve dysfunction causing heart failure, left-sided IE due to *Staphylococcus aureus*, fungal or highly resistant organism, heart block, annular or aortic abscess, and destructive penetrating lesions (Class I, level of evidence C).

Surgery is recommended in relapsing PVE without other source for portal of infection (Class I, Level of evidence B). Early surgery may be considered in mobile vegetations with a dimension larger than 10 mm (Class IIb, Level of evidence B). Early surgery is reasonable in patients with recurrent emboli and persistent vegetations despite appropriate antibiotic therapy (Class IIa, Level of evidence B).<sup>31</sup>

## Diseases of the Aorta

The thoracic aorta can be visualized almost in its entirety by echocardiography. TTE routinely assesses the aortic root and proximal ascending aorta in the parasternal view whereas the aortic arch and its three major branches are seen in the suprasternal view. TEE can depict all portions of the thoracic aorta with high resolution except for a small “blind spot”. This blind spot is in the distal ascending aorta just before the innominate artery, and is due to interposition of the right bronchus and trachea between the heart and esophagus. The descending aorta is easily seen from the left subclavian artery to the celiac trunk either in its short or long axis.

### AORTIC ANEURYSMS

Aortic root and ascending aorta aneurysms are well seen on echocardiography with reproducible and accurate measurements. Arch and descending aorta aneurysms, however, are better quantified by CT or magnetic resonance imaging (MRI). Since treatment guidelines are based on size, it must be understood that measurements by echocardiography are slightly smaller when compared to CT and MRI. The reason for this is that with echocardiography the measurements of the aorta are typically inner edge to inner edge (internal diameter) while with CT and MRI the outer edge to outer edge (external diameter) is measured.<sup>69</sup> Sinus of Valsalva aneurysms typically affect the right sinus. These are seen protruding into the right atrium in the short axis view and appear like a mobile, “windsock” structure.

### ACUTE AORTIC SYNDROMES

The diagnosis of acute aortic syndromes requires speed and accuracy due to the high mortality of these conditions and thus the need for rapid triage to appropriate treatment. TEE has similar diagnostic accuracy to CT and MRI.<sup>70</sup> Additional advantages are absence of radiation, the ability to be performed on unstable patients at the bedside without needing transfer to the imaging equipment, and no need for intravenous contrast whose use is a relative contraindication for patients with renal dysfunction. However, sedation and a fasting state are typically required. Although TEE is the technique of choice, TTE can be utilized initially in the immediate setting to not only diagnose the presence of dissection, but also to assess LV function, the presence of AR and pericardial effusion. A negative TTE does not exclude dissection and another imaging modality must be utilized if clinical suspicion is high. The specificity and sensitivity of TTE for the diagnosis of aortic root dissection are only 80% and 60%

respectively, whereas TEE has a specificity and sensitivity of 95 to 100% and 98 to 100%.<sup>53</sup>

Dissection typically occurs in the setting of aortic dilation. The diagnosis on echocardiography is made by identification of an intimal flap, which divides the aorta into true and false lumens. The true lumen is usually smaller than the false lumen, expands in systole and reveals systolic antegrade flow by Doppler. The false lumen is filled with slow moving blood and *in situ* thrombosis can be present. The points of entry and exit can often be identified by color Doppler.

Reverberation artifacts in a dilated ascending aorta are common and reported to be present in 44 to 55% of studies.<sup>71</sup> While these can be mistaken for a dissection flap they exhibit different characteristics. A dissection flap has independent mobility (low amplitude, high frequency), whereas an artifact moves in parallel motion with the aortic wall (higher amplitude, lower frequency). M-mode echo is often used to display these motion characteristics. Color flow imaging is useful in demonstrating separation of flow by the dissection flap, whereas flow will move through an artifact.

Intramural hematoma occurs as a result of hemorrhage within the medial layer of the aortic wall, with no communication between the media and true lumen. On echocardiographic cross-sectional views this appears as a crescent thickening of the aortic wall. The inner margin is smooth and displacement of intimal calcification due to accumulation of blood within the aortic wall can be seen. In contrast, a penetrating aortic ulcer has a crater-like distortion of the aortic wall, which is often associated with extensive atheroma.<sup>72</sup> A thrombus, represented by soft irregular echoes, often fills the ulceration.

### COMPLICATIONS OF AORTIC DISSECTION DETECTED BY ECHOCARDIOGRAPHY

Aortic regurgitation (AR) is a common complication in aortic dissection, occurring in approximately 40 to 76% of patients.<sup>73</sup> Multiple mechanisms account for this and they can be diagnosed by TEE. These include dilation of the aortic root and annulus, disruption of the valvular cusps or annulus, loss of support of the cusps due to extension of the dissection into the aortic root, or prolapse of the intimal flap through the aortic valve leaflets into the LVOT<sup>73</sup> (Fig. 12-26). Identification of the mechanism of AR helps in determining if the aortic valve can be spared at the time of dissection repair.

Pericardial tamponade is observed in <20% of patients with ascending aorta dissection and associated with doubling of mortality.<sup>74</sup> Presence of a pericardial effusion suggests rupture of the aorta has occurred and is associated with poor prognosis. However, the effusion may be secondary solely to inflammation. Determining etiology of the pericardial effusion by echocardiography is often not possible.

During TEE depiction of dissection, the origins of the coronary arteries and extra-aortic arch vessels should be demonstrated to determine the extent of the dissection and whether these vessels are supplied by the true or false lumen. The ostia of the coronary arteries are best seen in a short view of the aortic sinuses of Valsalva. The right coronary artery

**FIGURE 12-26** Aortic root dissection. Aortic root and ascending aorta dissection depicted in this TEE mid-esophageal long axis view. Two dissection flaps are seen: one flap in the aortic root prolapses across the aortic valve in diastole (*arrow*). The ascending aorta is dilated.

is most frequently involved and the presence of a new LV inferior wall motion abnormality can be used as indirect or supporting evidence of this occurrence. On TEE, the origins of the left subclavian and left common carotid arteries are usually easily visualized in an upper esophageal view either in a short axis view or an off-axis view of the aortic arch. However, the origin of the innominate artery is more challenging to visualize on TEE and the suprasternal view of the aortic arch on TTE may be superior for depicting it.

### COARCTATION OF AORTA

Coarctation of the aorta is diagnosed on TTE from the suprasternal view. A discrete narrowing of the proximal descending aorta is seen, corresponding with increased turbulence and high velocities detected by Doppler imaging in region of coarctation. In the presence of a hemodynamically significant coarctation, the Doppler display of blood flow in the abdominal aorta persists into diastole in contrast to the normal flow limited to systole.

## Pericardial Disease

### CARDIAC TAMPONADE

Transthoracic echocardiography is the best diagnostic modality to demonstrate the presence of a pericardial effusion and its hemodynamic significance. In most cases of cardiac tamponade, a moderate-to-large size effusion is present. However, tamponade can occur even in small effusions that have accumulated rapidly in the setting of a normal or noncompliant pericardium. In this situation there is a rapid acute rise in intrapericardial pressure. The sizes of pericardial effusions are typically quantified subjectively: small effusions are generally 50 to 100 mL, moderate 100 to 500 mL, and large greater than 500 mL.

Echocardiographic signs of cardiac tamponade include imaging signs of increased pericardial pressure and Doppler signs of exaggerated respiratory variation in intracardiac flows. Inversion of the RA free wall during ventricular systole (atrial diastole) that persists for greater than one-third of the cardiac cycle is nearly 100% sensitive and is specific for tamponade.<sup>75</sup> Inversion of the RV outflow tract or free wall of the RV in early diastole occurs next; however, this sign may be delayed or absent in the presence of pulmonary hypertension or RV hypertrophy. RV collapse is more specific but less sensitive than RA inversion (Fig. 12-27). With hemodynamically more severe tamponade the duration of diastolic RV wall collapse increases and the sensitivity of this feature increases. Left atrial collapse is a less common but an accurate sign for tamponade. Left ventricular collapse is rare since a higher pericardial pressure is required to distort the thicker LV walls but it can be observed in regional tamponade, which can occur with perioperative or postoperative bleeding.

As the intrapericardial pressure rises during the development of cardiac tamponade, exaggerated respiratory variation in the early mitral and tricuspid inflow (E wave) velocity is noted by pulse wave Doppler. During inspiration, the tricuspid E wave peak velocity increases >60% and the mitral E wave peak velocity decreases by 30%, whereas in expiration, the mitral E velocity increases >30%.<sup>76</sup> These findings reflect the influence of intrathoracic pressure on intracardiac filling as intrapericardial pressure rises. This variation in flow will be reversed during positive pressure ventilation.<sup>77</sup> Dilated inferior vena cava and hepatic veins typically indicate elevated right atrial pressures.

Regional cardiac tamponade, that is tamponade of only a portion of the heart but resulting in systemic hemodynamic affects, is most often noted after cardiac surgery, pericardiectomy, or myocardial infarction. A localized effusion or hematoma that compresses selective cardiac chambers may be

**FIGURE 12-27** Cardiac tamponade. TTE parasternal long axis view of a pericardial effusion (star). The anterior portion of the effusion is causing diastolic right ventricular compression (*arrow*) consistent with tamponade.

difficult to visualize on TTE and typically requires a TEE. The Doppler alterations in intracardiac flow may be noted on the TTE in this setting but with a reduced frequency compared to tamponade due to circumferential effusions. Cardiac tamponade seen in the postoperative period can be early (<24 hours), or late (>5 to 7 days). Early tamponade is typically related to surgical bleeding. In this situation, the right-sided chambers, particularly the RA, are usually compressed; however a posterior hematoma may compress the left atrium or LV.<sup>77</sup>

### CONSTRUCTIVE PERICARDITIS

In the United States and Europe, the most common causes for constrictive pericarditis are postcardiac surgery, idiopathic or secondary to nonspecific viral pericarditis. Other causes include tuberculous pericarditis, radiation pericarditis, and collagen vascular disease.<sup>78</sup>

Typical echocardiographic features include septal motion abnormalities, biatrial enlargement, and alterations in early diastolic mitral inflow. There are two types of septal wall motion abnormalities noted in constrictive pericarditis. The first is called the septal bounce. It is a subtle, early diastolic flutter that is noted on every cardiac cycle. This sign reflects an exaggeration in the difference in timing of passive filling of the right and left ventricles that occurs due to ventricular interdependence. The second septal wall motion abnormality is a brisk movement of the interventricular septum towards the LV in inspiration, followed by a brisk rebound back towards the RV in expiration. This occurs due to an exaggeration in the diastolic ventricular pressure differences induced with respiration. Moderate biatrial enlargement reflects the chronicity of the increase in atrial pressures. A restrictive transmitral pulse wave Doppler filling pattern is observed which is characterized by high early diastolic E velocity, reduced atrial A wave (E/A ratio > 2.5), and short E wave deceleration time (<160 ms).<sup>48,76</sup> This pattern reflects the increase in LA pressure and the reduced filling (due to early equilibration of LA and LV diastolic pressure) from pericardial constraint. Pulse wave Doppler shows a decrease >25% in the mitral inflow velocity and a >40% increase in tricuspid inflow velocity with the first beat of inspiration.<sup>76,4</sup> This variation in flow reflects the fact that the intracardiac pressures are isolated from the intrathoracic pressures due to the thickened pericardium. Thus, as intrathoracic pressure decreases with inspiration, the LA and LV diastolic pressures do not also decrease to the same magnitude and thus flow into the left heart from the pulmonary circulation is reduced. This pattern will be reversed for patients on positive pressure ventilation. The mitral annular motion and velocity assessed by tissue Doppler is normal or elevated (>7 cm/s). In contrast to normal subjects, the lateral annular velocity is lower than septal annular velocity, reflecting tethering of the lateral free wall to the thickened pericardium. The inferior vena cava and hepatic veins are usually dilated indicating elevated right atrial pressure. Prominent diastolic flow reversal in the hepatic veins is a classic finding in pericardial constriction. Some of

the Doppler signs of constrictive pericarditis can be difficult to differentiate from those noted with restrictive cardiomyopathy since that process is also associated with elevated LA pressure and early diastolic pressure equilibration (restrictive filling). However, in restrictive cardiomyopathy the respiratory variation in the Doppler pattern is not present.<sup>79</sup>

### Perioperative ECHO Guidance

The cardiac surgeon should develop a pattern of close communication with the echocardiographer, especially in the intraoperative setting. It is important to integrate imaging information into cardiac surgical practice and be willing to change the plan based on the ultrasound data. The surgeon can enhance outcomes by developing and communicating expectations for ultrasound data specific to the operation being performed. Based on data, the echocardiographer should be expected to make predictions which can help the surgeon to choose appropriate surgical techniques to optimize outcomes.<sup>83</sup> Examples of specific data elements and predictions are listed in Table 12-8.

In demanding operations such as aortic and mitral valve repair, communication between surgeon and echocardiographer is ideally a two-way street. The intraoperative

**TABLE 12-8: Perioperative ECHO Guidance**

Operation	Expected measurements	Echo-based predictions
Mitral repair	Mechanism of MR Leaflet heights Distance from Cx coronary to P1 annulus Coaptation depth potential Quantitation of tethering LA size LV size Mitral inflow gradient MR quantitation Assessment of AL to LVOT	Ring or band size SAM potential Size of prosthesis if repair fails Potential for Cx coronary damage
Mitral replacement	Same as Mitral repair	Potential for Strut SAM
Aortic repair	Mechanism of AI Annulus diameter Diameter of Sinuses of Valsalva Diameter of sinotubular junction Quantitation of aortic regurgitation Quantitation of AV systolic gradient	Potential to shorten A2 and create MR
Tricuspid repair	Mechanism of TR Annulus dimensions	Ring or band size

echocardiographer can use 3D images to enhance communication in terms of structure and function, and can base predictions on precise 3D TEE measurements. The surgeon can provide feedback to the imaging physician by using a head camera or field camera to share the anatomy and the performed operation.

The, modern cardiac surgeon should prepare himself or herself not only to understand ultrasound data, but also to acquire the skill to generate high-quality ultrasound images via an epicardial ultrasound probe in cases where TEE is not possible. Creating a culture of shared information promotes steep and continuous learning curves on both sides of the ether screen, supports the introduction of new technologies and devices, and can only improve patient outcomes.

# Extracorporeal Circulation

John W. Hammon • Michael H. Hines

Cardiopulmonary bypass (CPB) for support during cardiac surgery is unique because blood exposed to foreign, non-endothelial cell surfaces is collected and continuously recirculated throughout the body. This contact with synthetic surfaces within the perfusion circuit, as well as open tissue surfaces within the wound, triggers a defense reaction that involves at least five plasma protein systems and five types of circulating blood cells. This inflammatory response to CPB initiates a powerful thrombotic stimulus and the production, release, and circulation of vasoactive and cytotoxic substances that affect every organ and tissue within the body. Because of this, open-heart surgery (OHS) using CPB is essentially not possible without anticoagulation, usually with heparin; thus the inflammatory response to CPB involves the consequences of exposing *heparinized* blood to foreign surfaces, not lined with endothelial cells.

Although the inflammatory response has been well characterized, the development of a nonthrombogenic artificial surface that would allow heparin-free circulatory support has not yet occurred. This chapter summarizes the application of extracorporeal circulation in adult cardiac surgery, and is divided into three sections. The first section describes the components and operation of perfusion systems and related special topics. The issues of thrombosis and bleeding are addressed in the second section, whereas the humoral response to CPB, including the reaction of blood elements and the inflammatory response are presented later in this chapter. The final section deals with organ damage as a consequence of extracorporeal perfusion (ECP).

## PERFUSION SYSTEMS

During CPB for cardiac surgery, blood is typically drained by gravity into the venous reservoir of the heart-lung machine via cannulas placed in the superior vena cava (SVC) and inferior vena cava (IVC) or a single cannula placed in the right atrium. Specialized cannulas can also be placed into the lower IVC through a femoral approach. Blood from the reservoir is then pumped through a hollow fiber oxygenator,

and after appropriate gas exchange takes place, into the systemic arterial system through a cannula placed in the distal ascending aorta, the femoral artery, or the axillary artery (Fig. 13-1). This basic ECP system can be adapted to provide partial or total circulatory and respiratory support or partial support for the left or right heart or for the lungs separately.

The complete heart-lung machine includes many additional components (Fig. 13-2).<sup>1</sup> Most manufacturers consolidate a *hollow-fiber oxygenator*, *venous reservoir*, and *heat exchanger* into a single unit. A *microfilter-bubble trap* is added to the arterial outflow. Depending on the operation, various suction systems can be used to return blood from the surgical field, cardiac chambers, and/or the aorta, directly back into the cardiotomy reservoir, through a *microfilter* and then into the venous reservoir. Increasing evidence of the potential harmful effects of returning fat and lipid particles from the field into directly into the circulation, have increasingly led surgeons to preferentially use a *cell saver system* to collect and wash shed blood within the surgical field, and return the blood to the patient or circuit as packed red cells. In addition to adjusting pump flow, partially occluding *clamps* on venous and arterial lines allow additional regulation of venous drainage and flow. Access ports for sampling and *sensors* for monitoring pressures, temperatures, oxygen saturation, blood gases, and pH are included within most CPB systems. A separate pump and circuit for the administration of *cardioplegic* solutions at controlled composition, rate, and temperature is usually included in the system. An ultrafilter can be easily added within the circuit for the removal of excess fluid, electrolytes, and some inflammatory mediators, or simply for hemoconcentration.

## Venous Cannulation and Drainage

### PRINCIPLES OF VENOUS DRAINAGE

Venous blood usually enters the circuit by gravity or siphonage into a venous reservoir placed 40 to 70 cm below the level of the heart. The amount of drainage is determined by central venous pressure, the height differential and any resistance within the system (cannulas, tubing, and connectors).

**FIGURE 13-1** Basic cardiopulmonary bypass circuit with membrane oxygenator and centrifugal pump.

Successful drainage is dependent on a continuous column of blood or fluid and the absence of air within the system. Central venous pressure is determined by intravascular volume and venous compliance, which is influenced by medications, sympathetic tone, and anesthesia. Inadequate blood volume or excessive siphon pressure may cause compliant venous or atrial walls to collapse against cannular intake openings to produce “chattering” or “fluttering.” This phenomenon is corrected by adding volume to the system (circuit and/or patient), or partially occluding the venous line near the inlet to decrease the negative pressure.

### VENOUS CANNULAS AND CANNULATION

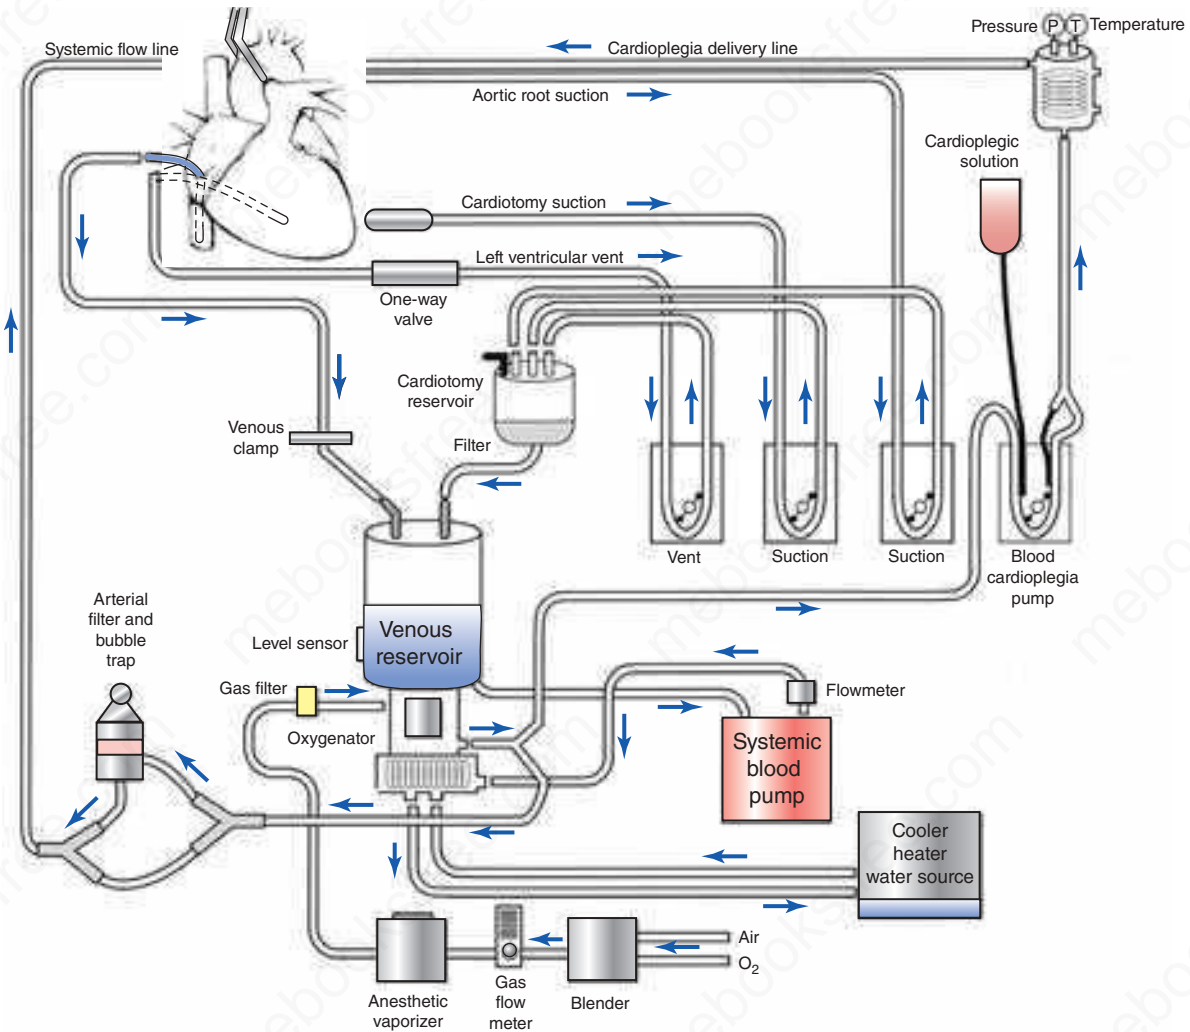

Most venous cannulas are made out of flexible plastic, which may be stiffened with wire reinforcement to prevent kinking. Cannula tips may be straight or angled and often are constructed of thin, rigid plastic or metal. Cannula sizes are selected based on patient size and weight, anticipated flow rate, and an index of catheter flow characteristics and resistance (provided by the manufacturer), as well as size of the vessel to be cannulated. For an average adult with 60-cm negative siphon pressure, a 30-French cannula in the SVC, and 34 French in the IVC or a single 42-French cavoatrial catheter almost always provides excellent venous drainage. Thin metal tipped right angle cannulas allow placement of smaller diameter cannulas with equal flow characteristics, and assist with insertion directly into the vena cavae. Catheters are typically inserted through purse-string guarded incisions in the right atrial appendage, lateral atrial wall, or directly in the SVC and IVC.

Three basic approaches for central venous cannulation are used: bicaval, single atrial, or cavoatrial (“two-stage”) (Fig. 13-3). *Bicaval cannulation* and caval tourniquets are

necessary to prevent bleeding into the field, and air entry into the system when the right heart is entered during CPB. Because of coronary sinus return, caval tourniquets should not be tightened without decompressing the right atrium if the heart is not still ejecting. Bicaval cannulation without caval snares is sometimes preferred to facilitate venous return during exposure of the left atrium and mitral valve.

*Single venous cannulation* is adequate for most aortic valve and coronary artery surgery; however, usually a cavoatrial cannula (“two-stage”) is employed (Fig. 13-3B). Introduced via the right atrial appendage, the narrowed distal end is guided into the IVC, leaving the wider proximal portion with multiple side holes to rest within the mid-right atrium. This tends to provide better venous drainage than a single cannula; however, proper positioning is critical.<sup>2</sup> Care must be taken with both a single and two-stage cannula as elevation of the heart may kink the superior cavoatrial junction, decreasing venous return, and potentially, and more importantly, impeding venous outflow from the cerebral circulation.

Venous cannulation can also be accomplished via the femoral or iliac veins through an open or percutaneous technique. This technique is frequently employed in emergency situations, where central venous cannulation may be difficult (as in complex redo sternotomies<sup>3</sup>) or for cardiopulmonary support when a thoracotomy is the approach of choice, as in descending aortic procedures, or redo mitral valve operations. It is also valuable in the support of critically ill or unstable patients prior to the induction of anesthesia, and for applications of CPB that do not require a chest incision. Adequate venous drainage requires the use of larger cannulas (up to 28 French), with the drainage ports either within the intrahepatic IVC or in the right atrium. Transesophageal echocardiography (TEE) can be particularly helpful in assuring proper placement of these cannulas. Specially designed

**FIGURE 13-2** Diagram of a typical cardiopulmonary bypass circuit with vent, field suction, aortic root suction, and cardioplegic system. Blood is drained from a single “two-stage” catheter into the venous reservoir, which is part of the membrane oxygenator/heat exchanger unit. Venous blood exits the unit and is pumped through the heat exchanger and then the oxygenator. Arterialized blood exits the oxygenator and passes through a filter/bubble trap to the aortic cannula, which is usually placed in the ascending aorta. Blood aspirated from vents and suction systems enters a separate cardiotomy reservoir, which contains a microfilter, before entering the venous reservoir. The cardioplegic system is fed by a spur from the arterial line to which the cardioplegic solution is added and is pumped through a separate heat exchanger into the antegrade or retrograde catheters. Oxygenator gases and water for the heat exchanger are supplied by independent sources.

commercially manufactured long, ultrathin, wire-reinforced catheters are available for this purpose. With recent advances in minimally invasive thoracic surgery, longer two stage canulas which can be inserted percutaneously via the femoral veins and guided superiorly into the SVC and RA have been developed and are now readily available.

#### PERSISTENT LEFT SUPERIOR VENA CAVA

A persistent left SVC (PLSVC) is present in 0.3 to 0.5% of the general population and usually drains into the coronary sinus; however, in about 10% of cases it drains into the left atrium.<sup>4</sup> Although more common in association with other congenital defects, it can be seen as an isolated anomaly, and should be suspected when the (left) innominate vein is small

or absent, or when a large coronary sinus (or the PLSVC itself) is seen on baseline TEE.<sup>5</sup>

A PLSVC may complicate the delivery of retrograde cardioplegia or entry into the right heart.<sup>6</sup> If an adequate-sized innominate vein is present (30% of patients), the PLSVC can simply be occluded during CPB, assuming the ostium of the coronary sinus is present, and the coronary venous drainage is not dependent on the PLSVC.<sup>7</sup> If the right SVC is absent (approximately 20% of patients with PLSVC), the left cava cannot be occluded and should be drained. With a normal right SVC (RSVC), but an innominate vein that is absent (40% of patients) or small (about 33%), occlusion of the PLSVC may cause venous hypertension and possible cerebral injury. Although division of the innominate vein during redo-sternotomy or complex surgery such as transplantation

**FIGURE 13-3** Placement of venous cannulas. (A) Cannulation of both cavae from incisions in the right atrium. (B) Cannulation using the “two-stage cannula.” Blood in the right atrium is captured by vents in the expanded shoulder several inches from the narrower IVC catheter tip.

has been shown to be safe, occlusion of the PLSVC during CPB relies on drainage of the cerebral venous return by the contralateral system, and so special attention must be paid to assure adequate RSVC cannula size, and prevent any kinking of the RSVC. In circumstances in which retrograde cardioplegia is required (severe aortic insufficiency) in the presence of a PLSVC, the retrograde cardioplegia cannula can be directly inserted into the coronary sinus and secured with a pursestring around the orifice of the coronary sinus, and with temporary snaring of the PLSVC, successful retrograde cardioplegia can be delivered.

#### AUGMENTED OR ASSISTED VENOUS RETURN

Negative pressure can be applied to the venous line to provide assisted venous drainage (AVD) using either a roller or a centrifugal pump system,<sup>8</sup> or by applying a regulated vacuum to a closed hard-shell venous reservoir (vacuum-assisted venous drainage, VAVD).<sup>9</sup> This may permit use of smaller diameter catheters<sup>10</sup> and may be helpful when long, peripheral catheters are used. However augmented negative pressure in the venous line increases the risk of aspirating gross or microscopic air and causing cerebral injury,<sup>11,12</sup> hemolysis, or aspiration of air into the blood phase of hollow fiber oxygenators. Conversely, positive pressure in the venous reservoir can cause air to enter the venous lines and the right heart.<sup>13</sup> These potential complications require special safety monitors and devices and adherence to detailed protocols when using AVD techniques.<sup>13,14</sup>

#### COMPLICATIONS ASSOCIATED WITH VENOUS CANNULATION AND DRAINAGE

Atrial arrhythmias, bleeding from atrial or vena caval tears, air embolization, venous injury, or obstruction owing to catheter

malposition, reversing arterial and venous lines, and unexpected decannulation can all occur during the conduct of cannulation for CPB. Encircling the vena cavae for snaring may lacerate branches or nearby vessels (eg, right pulmonary artery), or injure the vena cava itself. All of these injuries are more likely in the presence of previous surgery, and need to be recognized and corrected early to assure the proper conduct of CPB and minimize additional complications. During cannulation for minimally invasive procedures where placement is more “blind” than with direct open cannulation techniques, the use of ultrasound and TEE may help guide placement of the various cannulas and potentially prevent very serious complications.

Either before or after CPB, cannulas still in place may compromise venous return to the right atrium. The venous cannulas in the SVC or the superior caval tape may displace or compromise central venous or pulmonary arterial monitoring catheters. Conversely, monitoring catheters may compromise the function of caval tapes, allowing air to enter the venous lines between the cannulas and the catheters or sheaths.

During the conduct of the operation itself, any intracardiac catheter may be trapped by sutures, which may impede removal before or after the wound is closed. Any connection between the atmosphere and cannula intake ports may entrain air to produce an air lock or gaseous microembolism. AVD increases the risk of air entrapment.<sup>15</sup> Finally, improperly placed pursestring sutures may obstruct a cava when tied, particularly in the SVC.<sup>16</sup>

#### CAUSES OF LOW VENOUS RETURN

Low venous pressure, hypovolemia, drug- or anesthetic-induced venous dilatation, inadequate differential height between the heart and the reservoir, inadequate cannula size,

cannula obstruction or kinking, “air-lock,” and excessive flow resistance in the drainage system are all possible causes of impaired or inadequate venous return. These can usually be prevented or quickly corrected through close attention to detail, keeping the venous lines visible within the field when possible, and perhaps most importantly, frequent and detailed communication between surgeon and perfusionist. In addition to contributing to inadequate antegrade flow from the pump, partial obstruction of the venous line may lead to right ventricular distention and impair contractility off CPB.

## Arterial Cannulation

### ARTERIAL CANNULAS

The tip of the arterial cannula is usually the narrowest part of the perfusion system and may produce high pressure differentials, jets, turbulence, and cavitation at the required flows for CPB, particularly if the arterial catheters are small. Most arterial catheters are rated by a performance index, which relates external diameter, flow, and pressure differential.<sup>17</sup> High-velocity jets may damage the aortic wall, dislodge atheroemboli, produce dissections, disturb flow to nearby vessels, and cause cavitation and hemolysis. Pressure differences that exceed 100 mm Hg cause excessive hemolysis and protein denaturation.<sup>18</sup> Weinstein<sup>19</sup> attributed a predominance of left-sided stroke after cardiac surgery to the “sand-blasting” effect of end-hole aortic cannulas directing debris into the left carotid artery. Available aortic catheters with only side ports<sup>20</sup> are designed to minimize jet effects and better distribute arch vessel perfusion and pressure<sup>21</sup> and may be associated with fewer strokes.<sup>19</sup>

Recently a dual-stream aortic perfusion catheter has been developed that features an inflatable horizontal streaming baffle that is designed to protect the arch vessels from atherosclerotic and other emboli and permits selective cerebral hypothermia.<sup>22</sup> Another novel aortic cannula features a side port that deploys a 120- $\mu$ m mesh filter to remove particulate emboli beyond the ascending aorta.<sup>23</sup> Although this catheter may increase the pressure gradient by 50%,<sup>24</sup> it has been shown to remove an average of eight emboli in 99% of 243 patients studied, and reduce the incidence of cerebral injuries below an expected rate.<sup>25</sup>

### CONNECTION TO THE PATIENT

Anatomical sites available for arterial inflow include the proximal aorta, innominate artery and distal arch, femoral, external iliac, axillary, and subclavian arteries. Cannulation can be direct by arterial puncture within a pursestring, through a side graft anastomosed to an arterial vessel, or percutaneous, although usually only in emergency situations. The choice is influenced by the planned operation<sup>26</sup> and distribution of atherosclerotic disease.<sup>27</sup>

### ATHEROSCLEROSIS OF THE ASCENDING AORTA

Dislodgement of atheromatous debris from the aortic wall from manipulation,<sup>28</sup> cross-clamping, or the sand-blasting effect of the cannula jet is a major cause of perioperative

stroke<sup>29</sup> as well as a risk factor for aortic dissection<sup>30</sup> and postoperative renal dysfunction.<sup>31</sup> Simple palpation has been shown to be sensitive and accurate for detecting severe atherosclerosis than epiaortic ultrasonic scanning.<sup>28,32</sup> Although some have advocated for its use, even TEE views of the middle and distal ascending aorta are often inadequate.<sup>32,33</sup> Epiaortic scanning is now the preferred method of screening in all patients with a history of transient ischemic attack, stroke, severe peripheral vascular disease, palpable calcification in the ascending aorta, calcified aortic knob on chest radiograph, age older than 50 to 60 years, or TEE findings of moderate aortic atherosclerosis.<sup>28</sup> A calcified aorta (“porcelain aorta”), which occurs in 1.2 to 4.3% of patients,<sup>34</sup> is another indication for relocation of the aortic cannula.<sup>35</sup> Alternative sites include the distal aortic arch<sup>34</sup> along with the innominate, axillary-subclavian, or femoral arteries.

### ASCENDING AORTIC CANNULATION

The distal ascending aorta is the most common cannulation site because of easy access, and few complications. The cannula is usually placed through a small stab wound within one or two concentric pursestring sutures that are then snared to secure the cannula and provide hemostasis. Risk of dissection may be reduced by avoiding cannulation into the hypertensive aorta, and many surgeons choose to transiently reduce the systemic pressure below 100 mm Hg. The observation of pulsatile back bleeding into the cannula confirms that the tip is within the lumen of the aorta, and then the cannula should be positioned to direct flow to the mid-transverse aorta. The use of a long catheter with the tip placed beyond the left subclavian artery has also been reported.<sup>36</sup> Proper cannula placement is critical<sup>21</sup> and is confirmed by noting pulsatile pressure in the aortic line monitor and equivalent pressure in the radial artery. The cannula must be properly secured in place to prevent inadvertent dislodgement during the conduct of the operation.

Complications include difficult insertion; bleeding; tearing of the aortic wall; intramural or malposition of the cannula tip (in or against the aortic wall, toward the valve, or in an arch vessel)<sup>37</sup>; atheromatous emboli; failure to remove all air from the arterial line after connection; injury to the aortic back wall; high line pressure, indicating obstruction to flow; inadequate or excessive cerebral perfusion<sup>38</sup>; inadvertent decannulation; and aortic dissection.<sup>39</sup> It is essential to monitor aortic line and radial artery pressures and carefully observe the aorta for possible cannula-related complications particularly during the initiation of CPB as well as during the placement of aortic clamps. Asymmetric cooling of the face or neck may suggest a problem with cerebral perfusion. Late bleeding and infected or noninfected false aneurysms are delayed complications of aortic cannulation.

Aortic dissection occurs in 0.01 to 0.09% of aortic cannulations<sup>30,40</sup> and is more common in patients with aortic root disease. Early signs of aortic dissection include discoloration beneath the adventia near the cannulation site, an increase in arterial line pressure, or a sharp reduction in return to the venous reservoir. TEE may be helpful in confirming the

diagnosis,<sup>41</sup> but prompt action is necessary to limit the dissection and maintain perfusion. The cannula must be promptly transferred to a peripheral artery or uninvolved distal aorta. Blood pressure should be controlled pharmacologically and perfusion cooling to temperatures less than 20°C initiated. During hypothermic circulatory arrest, the aorta is opened at the original site of cannulation and repaired by direct suture, patch, or circumferential graft.<sup>40</sup> When recognized early, survival rates range from 66 to 85%, but when undiscovered until late during or after the operation, survival is approximately 50%.

### CANNULATION OF THE FEMORAL OR ILIAC ARTERY

These vessels are usually the first alternative to aortic cannulation, but may be the primary choice for rapid initiation of CPB for severe bleeding, cardiac arrest, acute intraoperative dissection, or severe shock. It is also a common first choice for limited access cardiac surgery, as well as in selected reoperative patients.<sup>3</sup> Femoral or iliac cannulation limits cannula size but the retrograde distribution of blood flow is similar to antegrade flow.<sup>42</sup> Percutaneous cannulation kits are available for emergency femoral access, and many surgeons also use these long wire reinforced peripheral arterial cannulas with an open Seldinger technique, inserting the cannula through a pursestring in the femoral or iliac vessel by direct cutdown. This may reduce some of the complications of open insertion of large short cannulas, and simplifies cannula removal and arterial repair. Femoral cannulation may be associated with many complications,<sup>3</sup> including tears, dissection, late stenosis or thrombosis, bleeding, lymphatic collection or drainage, groin infection, and cerebral and coronary atheroembolism. In patients with prior aortic dissections, retrograde femoral perfusion may create a malperfusion situation; thus, some surgeons recommend alternative cannulation sites for these patients.<sup>43</sup> Ischemic complications of the distal leg may occur during prolonged (3- to 6-hour) retrograde perfusions,<sup>44,45</sup> unless perfusion is provided to the distal vessel. This may be provided by a small Y catheter in the distal vessel<sup>45</sup> or a side graft sutured to the artery.<sup>46</sup>

Retrograde arterial dissection is the most serious complication of femoral or iliac arterial cannulation and may extend to the aortic root or cause retroperitoneal hemorrhage with an incidence of around 1% or less,<sup>47</sup> and is associated with a mortality of about 50%. This complication is more common in patients greater than 40 years, and in those with significantly diseased arteries. The diagnosis is similar to an aortic cannula dissection and may be confirmed by TEE of the descending thoracic aorta.<sup>41</sup> Antegrade perfusion in the true lumen must be immediately resumed by either the heart itself or cannulation in the distal aorta or axillary-subclavian artery. It is not always necessary to repair the dissected ascending aorta unless it progresses proximally to involve the aortic root.<sup>47</sup>

### OTHER SITES FOR ARTERIAL CANNULATION

The axillary-subclavian artery has been increasingly used for cannulation.<sup>48,49</sup> Advantages include freedom from

atherosclerosis, antegrade flow into the arch vessels, and protection of the arm and hand by collateral flow. Because of these advantages and the dangers of retrograde perfusion in patients with aortic dissection, some surgeons prefer this cannulation site over femoral access for these patients.<sup>49</sup> Brachial plexus injury and axillary artery thrombosis are reported complications.<sup>48</sup> The axillary artery is approached through a subclavicular incision, whereas the intrathoracic subclavian artery may be cannulated through a thoracotomy.<sup>50</sup>

Occasionally the innominate artery may be cannulated through a pursestring suture without obstructing flow to the right carotid artery by using a 7- or 8-French cannula.<sup>26</sup> The ascending aorta can also be cannulated by passing a cannula through the aortic valve from the left ventricular apex.<sup>51</sup> Coselli and Crawford<sup>52</sup> also describe retrograde perfusion through a graft sewn to the abdominal aorta.

### Venous Reservoir

The venous reservoir serves as volume reservoir during CPB and particularly with the body exsanguination of deep hypothermic circulatory arrest. It is placed immediately before the arterial pump when a membrane oxygenator is used (see Fig. 13-1). This reservoir serves as a high-capacitance (ie, low-pressure) receiving chamber for venous return, facilitates gravity drainage, is a venous bubble trap, provides access for drugs, fluids, or blood, and increases the storage capacity for the perfusion system. As much as 1 to 3 L of blood may be translocated from patient to circuit when full CPB is initiated. The venous reservoir also provides several seconds of reaction time if venous return is suddenly decreased or interrupted.

Reservoirs may be rigid (hard) plastic canisters ("open" types) or soft, collapsible plastic bags ("closed" types). The rigid canisters facilitate volume measurements and management of venous air, often have larger capacity, are easier to prime, permit suction for VAVD, and may be less expensive. Some hard-shell venous reservoirs incorporate macrofilters and microfilters and can serve as cardiotomy reservoirs to receive vented blood.

Disadvantages include the use of silicon antifoam compounds, which may produce microemboli,<sup>53</sup> and increased activation of blood elements.<sup>54</sup> Soft bag reservoirs eliminate the blood-gas interface and by collapsing reduce the risk of pumping massive air emboli if venous return is suddenly interrupted.

Interest in miniaturization of the circuit has peaked over recent years in an effort to reduce priming volumes and the need for transfusion with its associated consequences as discussed later in this chapter. A variety of these devices are now available. However as with all "advances", there are associated disadvantages, primarily the loss of a safety margin of circuit blood volume for continued perfusion should there be a sudden interruption in venous return.

### Oxygenators

*Membrane oxygenators* imitate the natural lung by interspersing a thin membrane of microporous polypropylene or

polymethylpentene (0.3- to 0.8- $\mu\text{m}$  pores), or silicone rubber between the gas and blood phases. Compared with previously used bubble oxygenators, membrane oxygenators are safer, produce less particulate and gaseous microemboli,<sup>55</sup> are less reactive to blood elements, and allow superior control of blood gases.<sup>56</sup> With microporous membranes, plasma-filled pores prevent gas entering blood, but facilitate transfer of both oxygen and  $\text{CO}_2$ . Because oxygen is poorly diffusible in plasma, blood must be spread as a thin film (approximately 100  $\mu\text{m}$ ) over a large area with high differential gas pressures between compartments to achieve oxygenation. Areas of turbulence and secondary flow enhance diffusion of oxygen within blood and thereby improve oxyhemoglobin saturation.<sup>57</sup> Carbon dioxide is highly diffusible in plasma and easily exits the blood compartment despite small differential pressures across the membrane.

The most popular design uses sheaves of hollow fibers (120-200  $\mu\text{m}$ ) connected to inlet and outlet manifolds within a hard-shell jacket (Fig. 13-4). The most efficient configuration creates turbulence by passing blood between fibers and oxygen within fibers. Arterial  $\text{PCO}_2$  is controlled by gas flow rate, and  $\text{PO}_2$  is controlled by the fraction of inspired oxygen ( $\text{FIO}_2$ ) produced by an air-oxygen blender. Modern membrane oxygenators add up to 470 mL of  $\text{O}_2$  and remove up to 350 mL  $\text{CO}_2$  per minute at 1 to 7 L of flow with priming volumes of 220 to 560 mL and resistances of 12 to 15 mm Hg per liter blood flow. Most units combine a venous reservoir, heat exchanger, and hollow fiber membrane oxygenator into one compact unit.

**FIGURE 13-4** Diagram of a hollow fiber membrane oxygenator and heat exchanger unit. Blood enters the heat exchanger first and flows over water-cooled or water-warmed coils and then enters the oxygenator to pass between woven strands of hollow fibers. Oxygen enters one end of the bundles of hollow fibers and exits at the opposite end. The hollow fiber bundles are potted at each end to separate the blood and gas compartments. Oxygen and carbon dioxide diffuse in opposite directions across the aggregate large surface of the hollow fibers.

Oxygen and  $\text{CO}_2$  diffuse across thin silicone membranes, which are made into envelopes and wound around a spool to produce a spiral coil oxygenator. Gas passes through the envelope and blood passes between the coil windings. Because of protein leakage that frequently occurs with hollow fiber membranes after 8 to 12 hours of use, these spiral coil silicone membranes have been preferred for the prolonged perfusions (days) used in long-term respiratory and cardiac support of extracorporeal membrane oxygenation or “ECMO” systems. More recently, however, the development of polymethylpentene oxygenators have combined the benefit of efficient small surface area hollow fiber oxygenators without the detrimental plasma leakage seen with polypropylene, and have allowed these membranes to be used with both CPB and ECMO.

Other membranes feature a very thin (0.05  $\mu\text{m}$ ), solid membrane on the blood side of a highly porous support matrix. This membrane reduces the risk of gas emboli and plasma leakage during prolonged CPB, but may impair transfer of volatile anesthetics.<sup>58</sup>

Flow regulators, flow meters, gas blender, oxygen analyzer, gas filter, and moisture trap are parts of the oxygenator gas supply system used to control the ventilating gases within membrane oxygenators. Often an anesthetic vaporizer is added, but care must be taken to prevent volatile anesthetic liquids from destroying plastic components of the perfusion circuit.

*Bubble oxygenators* are obsolete in the United States, but may still be used elsewhere for short-term CPB because of low cost and efficiency. Because each bubble presents a new foreign surface to which blood elements react, bubble oxygenators cause progressive injury to blood elements and entrain more gaseous microemboli.<sup>59</sup> In bubble oxygenators, venous blood drains directly into a chamber into which oxygen is infused through a diffusion plate (sparger). The sparger produces thousands of small (approximately 36  $\mu\text{m}$ ) oxygen bubbles within blood. Gas exchange occurs across a thin film at the blood-gas interface around each bubble. Carbon dioxide diffuses into the bubble and oxygen diffuses outward into blood. Small bubbles improve oxygen exchange by effectively increasing the surface area of the gas-blood interface,<sup>60</sup> but are difficult to remove. Large bubbles facilitate  $\text{CO}_2$  removal. Bubbles and blood are separated by settling, filtration, and defoaming surfactants in a reservoir. Bubble oxygenators add 350 to 400 mL oxygen to blood and remove 300 to 330 mL  $\text{CO}_2$  per minute at flow rates from 1 to 7 L/min.<sup>56</sup> Priming volumes are less than 500 mL. Commercial bubble oxygenators incorporate a reservoir and heat exchanger within the same unit and are placed upstream to the arterial pump.

Oxygenator malfunction requiring change during CPB occurs in 0.02 to 0.26% of cases,<sup>61-63</sup> but the incidence varies between membrane oxygenator designs.<sup>64</sup> Development of abnormal resistant areas in the blood path is the most common cause,<sup>63</sup> but other problems include leaks, loss of gas supply, rupture of connections, failure of the blender, and deteriorating gas exchange. Blood gases need to be monitored to ensure adequate  $\text{CO}_2$  removal and oxygenation. Heparin coating may reduce development of abnormally high resistance areas.<sup>62</sup>

## Heat Exchangers

Heat exchangers control body temperature by heating or cooling blood passing through the perfusion circuit. Hypothermia is frequently used during cardiac surgery to reduce oxygen demand or facilitate operative exposure with brief periods of circulatory arrest. Because gases are more soluble in cold than in warm blood, rapid rewarming of cold blood within the circuit or the body may cause formation of bubble emboli.<sup>65</sup> Most membrane oxygenator units incorporate a heat exchanger upstream to the oxygenator to minimize this potential problem. Blood should not be heated above 40°C to prevent denaturation of plasma proteins, and the temperature gradient between the body and the perfusion circuit remains within 10°C to prevent bubble emboli. The heat exchanger may be supplied by hot and cold tap water, but separate heater/cooler units with convenient temperature-regulating controls are preferred. Leakage of water into the blood path can cause hemolysis and malfunction of heater/cooler units may occur.<sup>61</sup>

Separate heat exchangers are needed for cardioplegia. The simplest system uses bags of precooled cardioplegia solution; however, commonly cardioplegia fluid is circulated through a dedicated heat exchanger or tubing coils placed in an ice or warm water bath.

## Pumps

Most heart-lung machines use two types of pumps, although roller pumps can be used exclusively (Table 13-1). Centrifugal pumps are usually used for the primary perfusion circuit for safety reasons and for a possible reduction in injury to blood elements, although this remains controversial and unproven.<sup>66</sup>

Centrifugal pumps (Fig. 13-5) consist of a vaned impeller or nested, smooth plastic cones, which when rotated rapidly, propel blood by centrifugal force.<sup>67</sup> An arterial flowmeter is required to determine forward blood flow, which varies with the speed of rotation and the afterload of the arterial line. Unless a check valve is used,<sup>68</sup> the arterial line must be clamped to prevent backward flow when the pump is off. Centrifugal blood pumps generate up to 900 mm Hg of forward pressure, but only 400 to 500 mm Hg of negative pressure and, therefore, less cavitation and fewer gaseous microemboli. They can pump small amounts of air, but become “deprimed” if more than 30 to 50 mL of air enters the blood chamber. Centrifugal pumps are probably superior for temporary extracorporeal cardiac assist devices and left heart bypass, and for generating pump-augmented venous return.

Roller pumps consist of a length of 1/4- to 5/8-inch (internal diameter) polyvinyl, silicone, or latex tubing, which is compressed by two rollers 180° apart, inside a circular raceway. Forward flow is generated by roller compression and flow rate depends upon the diameter of the tubing, rate of rotation (RPM), the length of the compression raceway, and completeness of compression or “occlusion.” Compression is adjusted before use to be barely nonocclusive against a standing column of fluid that produces 45 to 75 mm Hg back pressure.<sup>69</sup>

**TABLE 13-1: Roller Versus Centrifugal Pump**

	Roller pump	Centrifugal pump
Description	Nearly occlusive Afterload independent	Nonocclusive Afterload sensitive
Advantages	Low prime volume  Low cost  No potential for backflow  Shallow sine-wave pulse	Portable, position insensitive  Safe positive and negative pressure  Adapts to venous return  Superior for right or left heart bypass  Preferred for long-term bypass  Protects against massive air embolism
Disadvantages	Excessive positive and negative pressure  Spallation  Tubing rupture  Potential for massive air embolism  Necessary occlusion adjustments  Requires close supervision	Large priming volume  Requires flowmeter  Potential passive backward flow  Higher cost

Hemolysis and tubing wear are minimal at this degree of compression.<sup>69</sup> Flow rate is determined from calibration curves for each pump for different tubing sizes and rates of rotation. Roller pumps are inexpensive, reliable, safe, insensitive to after-load, and have small priming volumes, but can produce high negative pressures and microparticles shed from compressed tubing (spallation).<sup>70</sup> Roller pumps are vulnerable to careless operation that results in propelling air; inaccurate flow calibration; backflow when not in use if rollers are not sufficiently occlusive; excessive pressure with rupture of connections if arterial inflow is obstructed; tears in tubing; and changing roller compression settings during operation. In general roller pumps rather than centrifugal pumps are used for sucker systems and for delivering cardioplegic solutions.

Centrifugal pumps produce pulseless blood flow and standard roller pumps produce a sine wave pulse around 5 mm Hg. The arterial cannula dampens the pulse of pulsatile pumps, and it is difficult to generate pulse pressures above 20 mm Hg within the body during full CPB.<sup>71</sup> To date no one has conclusively demonstrated the need for pulsatile perfusion during short- or long-term CPB or circulatory assistance.<sup>72</sup>

Complications that may occur during operation of either type of pump include loss of electricity; loss of the ability to control pump speed, which produces “runaway pump” or

**FIGURE 13-5** Diagrams of blood pumps. (A) Roller pump with two rollers, 180° apart. The compression of the rollers against the raceway is adjustable and is set to be barely nonocclusive. Blood is propelled in the direction of rotation. (B) The impeller pump uses vanes mounted on a rotating central shaft. (C) The centrifugal pump uses three rapidly rotated, concentric cones to propel blood forward by centrifugal force.

“pump creep” when turned off; loss of the flow meter or RPM indicator; rupture of tubing in the roller pump raceway; and reversal of flow by improper tubing in the raceway. A means to manually provide pumping in case of electrical failure should always be available.

## Filters and Bubble Traps

### MICROEMBOLI

During clinical cardiac surgery with CPB the wound and the perfusion circuit generate gaseous and biologic and non-biologic particulate microemboli (<500  $\mu\text{m}$  diameter).<sup>23,73,74</sup> Microemboli produce much of the morbidity associated with cardiac operations using CPB (see section “Organ Damage” later in this chapter). Gaseous emboli contain oxygen or nitrogen and may enter the perfusate from multiple sources and pass through other components of the system.<sup>12,15</sup> Potential sources of gas entry include stopcocks, sampling and injection sites,<sup>74</sup> priming solutions, priming procedures, intravenous fluids, vents, the cardiomy reservoir, tears or breaks in the perfusion circuit, loose pursestring sutures (especially during augmented venous return),<sup>12</sup> rapid warming of cold blood,<sup>65</sup> cavitation, oxygenators, venous reservoirs with low perfusate levels,<sup>15</sup> and the heart and great vessels. Bubble oxygenators produce many gaseous emboli; membrane oxygenators produce very few.<sup>55,56</sup> Aside from technical errors (open stopcocks, empty venous reservoir, air in the heart) the cardiomy reservoir is the largest source of gaseous emboli in membrane oxygenator perfusion systems.

Blood produces a large number of particulate emboli related to thrombus formation (clots), fibrin, platelet and platelet-leukocyte aggregation, hemolyzed red cells, cellular debris, and generation of chylomicrons, fat particles, and denatured proteins.<sup>75</sup> Stored donor blood is also an important source of blood-generated particles.<sup>76</sup> Other biologic emboli include atherosclerotic debris and cholesterol crystals and calcium particles dislodged by cannulation, manipulation for exposure, or the surgery itself. Both biologic and nonbiologic particulate emboli are aspirated from the wound. Bits of muscle, bone, and fat are mixed with suture material, talc, glue, and dust and aspirated into the cardiomy reservoir.<sup>76,77</sup> Materials used in manufacturing, spalled material, and dust may also enter the perfusate from the perfusion circuit<sup>76</sup> if it

is not first rinsed by recirculating saline through a prebypass microfilter, which is discarded.

In vivo microemboli larger than 100  $\mu\text{m}$  are detected by transcranial Doppler ultrasound,<sup>78</sup> fluorescein angiography,<sup>55</sup> TEE, and retinal inspection. In the circuit, microemboli are monitored by arterial line ultrasound<sup>79</sup> or monitoring screen filtration pressure. Microfilter weights and examination, histology of autopsy tissues, and electron particle size counters of blood samples<sup>76</sup> verify microemboli beyond the circuit.

### PREVENTION AND CONTROL OF MICROEMBOLI

Table 13-2 outlines sources of microemboli. Major methods include using a membrane oxygenator and cardiomy reservoir filter; minimizing and washing blood aspirated from the field<sup>80</sup>; and preventing air entry into the circuit and using left ventricular vents when the heart is opened.<sup>81,82</sup>

The brain receives 14% of the cardiac output and is the most sensitive organ for microembolic injury.<sup>83</sup> Strategies to selectively reduce microembolism to the brain include reducing PaCO<sub>2</sub> to cause cerebral vasoconstriction<sup>84</sup>; hypothermia<sup>85</sup>;

**TABLE 13-2: Major Sources of Microemboli**

Gas	Foreign	Blood
Bubble oxygenators	Atherosclerotic debris	Fibrin
Air entry into the circuit	Fat, fat droplets	Free fat
Residual air in the heart	Fibrin clot	Aggregated chylomicrons
Loose purse-string sutures	Cholesterol crystals	Denatured proteins
Cardiomy reservoir	Calcium particles	Platelet aggregates
Rapid rewarming	Muscle fragments	Platelet-leukocyte aggregates
Cavitation	Tubing debris, dust	Hemolyzed red cells
	Bone wax, talc	Transfused blood
	Silicone antifoam	
	Glue, Surgicel	
	Cotton sponge fiber	

placing aortic cannulas downstream to the cerebral vessel<sup>36,74</sup>; and using special aortic cannulas with<sup>22,23,30</sup> or without<sup>19</sup> special baffles or screens designed to prevent cannula-produced cerebral atherosclerotic emboli.

Two types of blood microfilters are available for use within the perfusion circuit: depth and screen.<sup>86,87</sup> Depth filters consist of packed fibers or porous foam, have no defined pore size, present a large, tortuous, wetted surface, and remove microemboli by impaction and absorption. Screen filters are usually made of woven polyester or nylon thread, have a defined pore size, and filter by interception. Screen filters vary in pore size and configuration and block most air emboli; however, as pore size decreases, resistance increases. As compared with no filter, studies indicate that all commercial filters effectively remove gaseous and particulate emboli.<sup>88,89</sup> Most investigations find that the Dacron wool depth filter is most effective, particularly in removing microscopic and macroscopic air. Pressure differences across filters vary between 24 and 36 mm Hg at 5 L/min flow. Filters cause slight hemolysis and tend to trap some platelets; nylon filters may also activate complement.<sup>86</sup>

The need for microfilters in the cardiotomy suction reservoir is universally accepted,<sup>77</sup> and most commercial units contain an integrated micropore filter. The need for a filter in the cardioplegia delivery system, however, remains debatable,<sup>90</sup> and although almost always used, the requirement of an arterial line filter is unsettled.<sup>87</sup> In vitro studies demonstrate that an arterial filter reduces circulating microemboli<sup>89</sup> and clinical studies are confirmatory.<sup>89</sup> However, these filters do not remove all microemboli generated by the extracorporeal circuit.<sup>12,74,77</sup> When bubble oxygenators are used, studies show equivocal or modest reductions in microemboli<sup>55,91</sup> and neurologic outcome markers.<sup>91</sup> In contrast, membrane oxygenators produce far fewer microemboli and when used without an arterial filter, the numbers of microemboli are similar to those found with bubble oxygenators plus arterial line filters.<sup>87</sup>

Although the efficacy of arterial line microfilters remains unsettled, their use is almost universal<sup>92</sup>; and although they are effective bubble traps, they do increase cost, occasionally obstruct during use, are difficult to de-air during priming, and require a small bypass line and valved purge line to remove any air.

Other sources of biologic microemboli may be more important. Cerebral microemboli are most numerous during aortic cannulation,<sup>93,94</sup> application and release of aortic clamps,<sup>94</sup> and at the beginning of cardiac ejection after open heart procedures.<sup>95</sup> Furthermore, as compared with perfusion microemboli, surgically induced emboli are more likely to cause postoperative neurologic deficits.<sup>96</sup>

### LEUKOCYTE-DEPLETING FILTERS

Leukocyte-depleting filters are discussed later in this chapter and have been recently reviewed.<sup>97</sup> These filters reduce circulating leukocyte counts in most studies,<sup>98</sup> but fail to produce convincing evidence of clinical benefit.<sup>99</sup>

## Tubing and Connectors

The various components of the heart-lung machine are connected by polyvinyl tubing and fluted polycarbonate connectors. Medical grade polyvinyl chloride (PVC) tubing is universally used because it is flexible, compatible with blood, inert, nontoxic, smooth, nonwetable, tough, transparent, resistant to kinking and collapse, and can be heat sterilized. To reduce priming volume, tubing connections should be short. To reduce turbulence, cavitation, and stagnant areas, the flow path should be smooth and uniform without areas of constriction or expansion. Wide tubing improves rheology, but also increases priming volume. In practice 1/2- to 5/8-inch (internal diameter) tubing is used for most adults, but until a compact, integrated, complete heart-lung machine can be designed and produced as a unit, the flow path will produce some turbulence. Loose tubing connections can be sources of air intake or blood leakage and so all connections must be secure. For convenience and safety, most tubing and connectors are prepackaged and disposable.

## Heparin-Coated Circuits

Heparin can be bound to blood surfaces of all components of the extracorporeal circuit by ionic or covalent bonds. The Duraflo II heparin coating ionically attaches heparin to a quaternary ammonium carrier (alkylbenzyl dimethylammonium chloride), which binds to plastic surfaces (Edwards Lifesciences, Irvine, CA). Covalent attachment is produced by first depositing a polyethylenimine polymer spacer onto the plastic surface, to which heparin fragments bind (Carmeda Bioactive Surface, Medtronic, Inc., Minneapolis, MN). Ionic-bound heparin slowly leaches, but this is irrelevant in clinical cardiac surgery. The use of heparin-coated circuits during CPB has spawned an enormous literature<sup>100-102</sup> and remains controversial largely because studies are contaminated by patient selection, reduced doses of systemic heparin, and washing or discarding field-aspirated blood.<sup>102</sup> To date, there is no irrefutable and credible evidence that heparin-coated perfusion circuits reduce the need for systemic heparin or reduce bleeding or thrombotic problems associated with CPB. Although the majority of studies indicate that heparin coatings reduce concentrations of C3a and C5b-9,<sup>103</sup> the inflammatory response to CPB is not reduced and the evidence for clinical benefit is not convincing.<sup>104</sup>

Other more recently developed and available surface modifications and coatings<sup>101</sup> include a phosphorylcholine coating,<sup>105</sup> surface-modifying additives,<sup>106</sup> and a trillium biopassive surface<sup>107</sup> as well as other proprietary substances. While many in vitro and even in vivo studies imply multiple benefits from these coatings by reductions in various inflammatory mediators and in the stimulation of the coagulation cascade, there have been no blinded randomized trials demonstrating any measurable benefit in patient outcomes. Clearly additional investigation in this area is desirable.

## Cardiotomy Reservoir and Field Suction

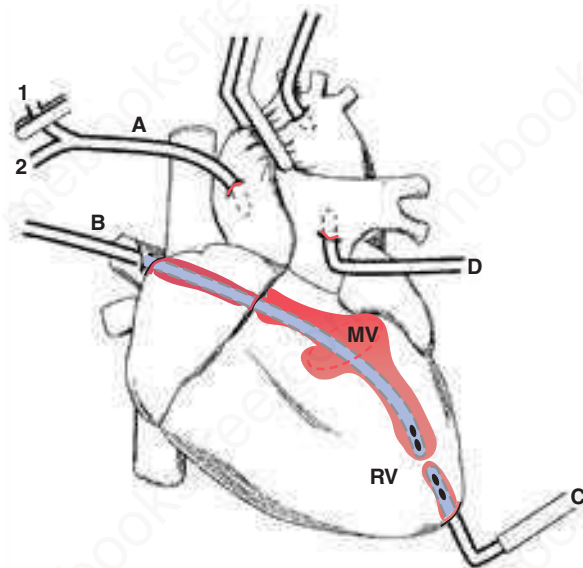

Blood aspirated from the surgical wound may be directed to the cardiotomy reservoir for defoaming, filtration, and storage before it is added directly to the perfusate. A sponge impregnated with a surfactant removes bubbles by reducing surface tension at the blood interface and macro, micro, or combined filters remove particulate emboli. Negative pressure is generated by either a roller pump or vacuum applied to the rigid outer shell of the reservoir. The degree of negative pressure and blood level must be monitored to avoid excessive suction or introducing air into the perfusate.

The cardiotomy suction and reservoir are major sources of hemolysis, particulate and gaseous microemboli, fat globules, cellular aggregates, platelet injury and loss, thrombin generation, and fibrinolysis.<sup>73,77,108</sup> Air aspirated with wound blood contributes to blood activation and destruction and is difficult to remove because of the high proportion of nitrogen, which is poorly soluble in blood. High suction volumes and admixture of air are particularly destructive of platelets and red cells.<sup>108</sup> Commercial reservoirs are designed to minimize air entrainment and excessive injury to blood elements. Air and microemboli removal are also facilitated by allowing aspirated blood to settle within the reservoir before it is added to the perfusate.

An alternative method for recovering field-aspirated blood is to dilute the blood with saline and then remove the saline to return only packed red cells to the perfusate. Two types of centrifugal cell washers automate the process. Intermittent centrifugation (eg, Haemonetics Cell Saver, Meomonetics Corp., Braintree, MA) removes air, thrombin, and many biologic and nonbiologic microemboli from the aspirate at the cost of discarding plasma. Continuous centrifugation (eg, Fresenius/Terumo CATS, Elkton, MD) in addition removes fat and activated leukocytes.<sup>109</sup> A third alternative is to discard all field-aspirated blood, although most surgeons would find this practice unacceptable if it increased allogeneic blood transfusion. Increasingly, field-aspirated blood is recognized as a major contributor to the thrombotic, bleeding, and inflammatory complications of CPB.

## Venting the Heart

If the heart is unable to contract, distention of either ventricle is detrimental to subsequent contractility.<sup>110</sup> Right ventricular distention during cardiac arrest or ventricular fibrillation is rarely a problem, but left ventricular distention can be insidious in that blood can enter the flaccid, thick-walled chamber from multiple sources during this period. During CPB, blood escaping atrial or venous cannulas and from the coronary sinus and thebesian veins may pass through the unopened right heart into the pulmonary circulation. This blood plus bronchial arterial and venous blood, blood regurgitating through the aortic valve, and blood from undiagnosed abnormal sources (patent foramen ovale, patent ductus, etc.) may distend the left ventricle unless a vent catheter is used (Fig. 13-6). During CPB bronchial blood and noncoronary

**FIGURE 13-6** Diagram shows locations used to vent (decompress the heart). (A) Aortic root vent, which can also be used to administer cardioplegic solution after the ascending aorta is clamped. (B) A catheter placed in the right superior pulmonary vein/left atrial junction can be passed through the mitral valve into the left ventricle. (C) Direct venting of the left ventricle at the apex. (D) Venting the main pulmonary artery, which decompresses the left atrium because pulmonary veins lack valves.

collateral flow average approximately  $140 \pm 182$  and  $48 \pm 74$  mL/min, respectively.<sup>111</sup>

There are several methods for venting the left heart during cardiac arrest. Although it was used commonly in the past, few surgeons in the modern era vent the left ventricular apex directly because of inconvenience and myocardial injury. Most often a multihole, soft-tip catheter (8-10 French) is inserted into the junction of the right superior pulmonary vein and left atrium (see Fig. 13-6) or left atrial appendage and may or may not be passed into the left ventricle. Others prefer to place a small suction catheter into the pulmonary artery.<sup>112</sup> The ventricle can also be vented by passing a catheter retrograde across the aortic valve when working on the mitral valve. Vent catheters are drained to the cardiotomy reservoir by a roller pump, vacuum source, or gravity drainage,<sup>113</sup> but must be carefully monitored for malfunction. If connected to a roller pump, the system should be carefully tested before use to ensure proper operation. Although inspection and palpation may detect ventricular distention, TEE monitoring or direct measurements of left atrial or pulmonary arterial pressures are more reliable. The heart is no longer vented for most myocardial revascularization operations, but the ventricle must be protected from distention.<sup>114</sup> If the heart cannot remain decompressed during distal anastomoses, a vent should be inserted. Often the cardioplegia line inserted into the aortic root is used for venting when not used for cardioplegia.<sup>115</sup>

The most common and serious complication of left heart venting is residual air when the heart is filled and begins

to contract. De-airing maneuvers and TEE are important methods for ensuring removal of all residual air. In addition, many surgeons aspirate the ascending aorta via a small metal or plastic cannula to detect and remove any escaping air as the heart begins to eject.<sup>116</sup> Bleeding, atrial perforation, mitral valve injury, and direct injury to the myocardium are other complications associated with left ventricular vents.

## Cardioplegia Delivery Systems

Cardioplegic solutions contain 8 to 20 mEq/L potassium, magnesium, and often other components that are infused into the aortic root proximal to the aortic cross clamp, or retrograde into the coronary sinus to arrest the heart in diastole. The carrier may be crystalloid or blood and is infused at temperatures around 4 or 37°C, depending upon surgeon's preference. Normothermic cardioplegia must be delivered almost continuously to keep the heart arrested while cold cardioplegia may be infused intermittently. Cardioplegic solutions are delivered through a separate perfusion system that includes a reservoir, heat exchanger, roller pump, bubble trap, and perhaps microfilter (see Fig. 13-2). Temperature and infusion pressure are monitored. The system may be completely independent of the main perfusion circuit or it may branch from the arterial line. The system also may be configured to vent the aortic root when not delivering cardioplegia.

Antegrade cardioplegia is delivered through a small cannula in the aortic root or via cannulas directly into the coronary ostia when the aortic valve is exposed. Retrograde cardioplegia is delivered through a cuffed catheter inserted into the coronary sinus.<sup>117</sup> Proper placement of the retrograde catheter is critical, but not difficult, and is verified by palpation, TEE, color of the aspirated blood, or pressure waveform of a catheter pressure sensor.<sup>118</sup> Complications of retrograde cardioplegia include rupture or perforation of the sinus, hematoma, and rupture of the catheter cuff.<sup>119</sup>

## Hemoconcentrators (Hemofiltration/ Ultrafiltration)

Hemoconcentrators, like oxygenators, contain one of several available semipermeable membranes (typically hollow fibers) that transfer water, electrolytes (eg, potassium), and molecules up to 20 kDa out of the blood compartment.<sup>120</sup> Hemoconcentrators may be connected to either venous or arterial lines or a reservoir in the main perfusion circuit, but require high pressure in the blood compartment to effect fluid removal. Thus a roller pump is needed unless connected to the arterial line. Suction may or may not be applied to the air side of the membrane to facilitate filtration. Up to 180 mL/min of fluid can be removed at flows of 500 mL/min.<sup>121</sup> Hemoconcentrators conserve platelets and most plasma proteins as compared with centrifugal cell washers, and may allow greater control of potassium

concentrations than diuretics.<sup>122</sup> Aside from cost, disadvantages are few and adverse effects are rare.<sup>121</sup>

## Perfusion Monitors and Safety Devices

Table 13-3 lists monitors and safety devices that are commonly used during CPB. *Pressure in the arterial line* between pump and arterial line filter is monitored continuously to instantly detect any increased resistance to arterial inflow into the patient. This pressure should be higher than radial arterial pressure because of resistance of the filter (if used) and cannula. The arterial pressure monitor may be connected to an audible alarm or the pump switch to alert the perfusionist to dangerous increases in the arterial line pressure.

An *arterial line flowmeter* is essential for centrifugal pumps and may be desirable to confirm flow calculations with roller pumps as well.

In-line devices are available to continuously measure *blood gases, hemoglobin/hematocrit, and some electrolytes*.<sup>123</sup> Placed within the venous line, these devices permit continuous assessment of oxygen supply and demand.<sup>124</sup> In the arterial line the devices offer better control of blood gases.<sup>125</sup> The need for these devices is unproved and because reliability is still uncertain, use may distract operative personnel and spawn unnecessary laboratory measurements.<sup>126</sup> The use of

automated analyzers by the perfusion team in the operating room is an alternative if frequent measurement of blood gases, hematocrit, and electrolytes is desirable.<sup>123</sup>

The *flow and concentration of oxygen* entering the oxygenator should be monitored.<sup>127</sup> Some teams also monitor exit gases to indirectly estimate metabolic activity and depth of anesthesia.<sup>127</sup> Some manufacturers recommend monitoring the *pressure gradient across membrane oxygenators*, which may be an early indication of oxygenator failure, although it is a rare event.<sup>62-64</sup>

*Temperatures* of the water entering heat exchangers must be monitored and carefully controlled to prevent blood protein denaturation and gaseous microemboli.<sup>65</sup> During operations using deep hypothermia, changes in venous line temperatures reflect rates of temperature change in the patient, and monitoring arterial inflow temperature helps prevent brain hyperthermia during rewarming.

A *low-level sensor* with alarms on the venous reservoir and a bubble detector on the arterial line are additional safety devices sometimes used. A *one-way valve* is recommended in the purge line between an arterial filter/bubble trap and cardiectomy reservoir to prevent air embolism. Ultrasound transducers imbedded in the arterial perfusion tubing distal to the filter are now available to monitor low-level air entry into the circulation. Valves in the venous and vent lines protect against retrograde air entry into the circulation or in the arterial line to prevent inadvertent exsanguination.<sup>68</sup>

*Automatic data collection systems* are available for preoperative calculations and to process and store data during CPB.<sup>128</sup> Computer systems for operating CPB are in development.<sup>129</sup>

## CONDUCT OF CARDIOPULMONARY BYPASS

### The Perfusion Team

Although the surgeon is directly responsible for the outcome of the operation, he or she needs a close working relationship with both the anesthesiologist and the perfusionist. These three principals must communicate freely, often, and candidly. Their overlapping and independent responsibilities relevant to CPB are best defined by written policies that include protocols for various types of operations and emergencies and by periodic multidisciplinary conferences. This teamwork is not unlike the communication advocated for the cockpit crew of commercial and military aircraft.

The surgeon determines the planned operation, target perfusion temperatures, methods of cardioplegia, cannulations, and anticipated special procedures. During operation the surgeon communicates the procedural steps involved in connecting and disconnecting the patient to CPB and interacts with the other principals to coordinate perfusion management with surgical exposure and working conditions. The perfusionist is responsible for setting up and priming the heart-lung machine, performing safety checks, operating the heart-lung machine, monitoring the conduct of bypass, monitoring

anticoagulation, adding prescribed drugs, and maintaining a written perfusion record.

The anesthesiologist monitors the operative field, anesthetic state and ventilation of the patient, the patient's physiology, and conduct of perfusion. A vigilant anesthesiologist is the safety officer and often "troubleshooter" of these complex procedures and along with the surgeon is in the best position to anticipate, detect, and correct deviations from desired conditions. In addition the anesthesiologist provides TEE observations before, during, and immediately after bypass.

### Assembly of Heart-Lung Machine

The perfusionist is responsible for setting up and preparing the heart-lung machine and all associated components necessary for the proposed operation. Most perfusionists use commercial, sterile, preprepared customized tubing packs that are connected to the various components that constitute the heart-lung machine. This dry assembly takes about 10 to 15 minutes, and a dry system can be kept in standby for up to 7 days. Once the system is primed with fluid, which takes about 15 minutes, it should be used within 8 hours to prevent malfunction of the oxygenator. After assembly, the perfusionist conducts a safety inspection and completes a written prebypass checklist.

### PRIMING

Traditional adult ECP circuits require 1.5 to 2.0 L of balanced electrolyte solution such as lactated Ringer's solution, Normosol-A, or Plasma-Lyte. Before connections are made to the patient, the prime is recirculated through a micropore filter to remove any residual particulate matter or air. In the average-sized adult, the priming volume represents approximately 30 to 35% of the patient's blood volume and reduces the hematocrit to about two-thirds of the preoperative value. In smaller patients or in the presence of preoperative anemia, banked blood may be added to the prime volume to raise the hematocrit to a predetermined minimum (eg, 25% or more), to achieve an acceptable resultant hemotocrit once CPB has been initiated. There is no consensus regarding the optimal hematocrit during CPB; most perfusates have hematocrits between 20% and 25% when used with moderate hypothermia (25-32°C). Dilution reduces perfusate viscosity, which is not a problem during clinical CPB, but also reduces oxygen-carrying capacity; mixed venous oxygen saturations less than 60% usually prompt either transfusion or increased pump flow.<sup>124</sup> Sometimes 12.5 to 50 g of mannitol is added to stimulate diuresis and possibly minimize postoperative renal dysfunction.

Efforts to avoid the use of autologous blood include reducing the priming requirement of the machine by using smaller diameter and shorter tubing lengths and operating the machine with minimal perfusate in the venous and cardiectomy reservoirs. This latter practice increases the risk of air embolism, the risk of which can be reduced by using collapsible reservoirs and reservoir level sensors that stop

**FIGURE 13-7** Typical miniature closed cardiopulmonary bypass circuit that uses coated surfaces to reduce coagulation and inflammation and removes the venous reservoir and excess tubing to reduce hemodilution.

the pump. In recent years, smaller, more compact circuits have been designed to reduce the prime volume and subsequent hemodilution, reducing transfusion requirements and platelet consumption.<sup>130</sup> Many of these circuits have totally removed the venous reservoir and used a variety of coated surfaces in an attempt to reduce hemodilution, avoid points of stasis and minimize activation of inflammation and coagulation cascades. A typical such mini-circuit is pictured in Fig. 13-7.

Autologous blood prime is another technique to minimize hemodilution, which displaces and then removes crystalloid prime by draining blood volume from the patient into the circuit just before beginning CPB.<sup>131</sup> This method reduces perfusate volume, but phenylephrine may be required to maintain stable hemodynamics.<sup>131</sup> The method reduces transfusions and does not affect clinical outcome.

The use of colloids (albumin, gelatins, dextrans, and hetastarches) in the priming volume is controversial.<sup>132</sup> Although their use clearly minimizes the decrease in colloid osmotic pressure<sup>133</sup> and may reduce the amount of fluid entering the extracellular space, any impact on clinical outcome remains unproved. Prospective clinical studies have failed to document significant clinical benefits with albumin,<sup>133</sup> which is expensive and may have adverse effects.<sup>134</sup> Hetastarch may contribute to postoperative bleeding.<sup>135</sup> McKnight et al. found no influence of prime composition on postoperative nitrogen balance.<sup>136</sup> Because of possible adverse effects, including neurologic deficits, the addition of glucose and/or lactate to the prime is generally avoided.<sup>137,138</sup>

## Anticoagulation and Reversal

Porcine heparin (300-400 units/kg IV) is administered before arterial or venous cannulas are inserted, and CPB is not started until anticoagulation is confirmed by either an activated clotting time (ACT) or the Hepcon test. Although widely used, bovine heparin is more antigenic in inducing antiplatelet IgG antibodies than is porcine heparin.<sup>139</sup> Although the distribution of intravenously administered heparin has been shown to be extremely rapid,<sup>140</sup> in general, the anticoagulation effect is measured about 3 minutes after heparin administration. However, groups differ in the minimum ACT that is considered safe for CPB. The generally accepted minimum for ACT before initiation of CPB is greater than or equal to 400 seconds; however, many groups recommend 480 seconds<sup>141</sup> because heparin only partially inhibits thrombin formation during CPB. More recently, in an attempt to reduce surgical bleeding, some centers have advocated accepting lower ACTs in the 300 range. Although early unpublished results may suggest that this can be done safely, it is still not generally accepted. Outside the United States, where aprotinin is still available, it is important to measure ACT with kaolin as opposed to celite, because celite may artifactually and erroneously increase the ACT. Failure to achieve a satisfactory ACT may result from either inadequate heparin dosage or low concentrations of antithrombin. If a total of 500 units/kg of heparin fails to adequately prolong ACT, antithrombin III should be administered to the patient either as fresh-frozen plasma or as recombinant antithrombin III when available<sup>142</sup> to increase antithrombin concentrations to overcome "heparin resistance." Antithrombin III is a necessary cofactor that binds circulating thrombin; heparin accelerates this reaction a thousandfold. See Thrombosis and Bleeding for management of patients with suspected or proved heparin-induced antiplatelet IgG antibodies and alternative anticoagulants to heparin.

During CPB, ACT or the Hepcon test is measured every 30 minutes. If ACT goes below the target level, more heparin is given. As a general rule, one-third of the initial total heparin bolus required for adequate anticoagulation is given every hour even when the ACT is within the normal range. The Hepcon test titrates the heparin concentration and is more reproducible than ACT, but ACT provides satisfactory monitoring of anticoagulation. Although excessively high concentrations of heparin (ACT > 1000 seconds) may cause remote bleeding away from operative sites, low concentrations increase circulating thrombin concentrations and risk clotting within the ECP circuit.

After the patient has successfully weaned from CPB and remains stable, 1 mg of protamine is given for each 100 units of heparin given in the initial bolus dose, but not to exceed 3 mg/kg. The heparin-protamine complex activates complement and may cause acute hypotension, which may be attenuated by the administration of calcium (2 mg/1 mg protamine). Once the administration of protamine has begun, it is generally recommended that the use of cardiotomy suction into the reservoir is discontinued because

of the risk of generating clot within the circuit and losing the potential for emergency support should the patient become unstable. Rarely, protamine may cause an anaphylactic reaction in patients with antibodies to protamine insulin.<sup>143</sup> This severe reaction may require urgently placing the patient back on CPB, although it may also be treating with resuscitation using epinephrine and immediate discontinuation of the protamine infusion. Neutralization of heparin is usually confirmed by an ACT or Hepcon test and more protamine (50 mg) is given if either test remains prolonged or bleeding is a problem. *Heparin rebound* is a term used to describe a delayed heparin effect because of release of tissue heparin after protamine is cleared from the circulation, particularly from heparin deposited in adipose tissues, and seen more often in obese patients. Although protamine is a mild anticoagulant at higher doses, one or two supplemental 25- to 50-mg doses can be given empirically if heparin rebound is suspected, or if the ACT remains elevated. It is also noted that the ACT can be elevated in the presence of significant thrombocytopenia, despite the full reversal of heparin. As a rule, the heart-lung machine should be available for unexpected decompensation and the need for urgent return to CPB until the wound is closed, the drapes are removed, and at many centers until the patient leaves the operating room.

### Initiation of Cardiopulmonary Bypass

Once the appropriate cannulation has occurred and adequate anticoagulation has been confirmed, CPB is initiated at the surgeon's request with concurrence of the anesthesiologist and perfusionist. As the venous return enters the machine, the perfusionist progressively increases arterial flow while monitoring the patient's blood pressure and volume levels in all reservoirs. Six observations are critical:

1. The venous drainage is adequate for the desired flow
2. The pressure in the arterial line is acceptable
3. The arterial blood is adequately oxygenated
4. The systemic arterial pressure is acceptable
5. The systemic venous pressure is acceptable
6. The heart is adequately decompressed

Once full stable CPB is established for at least 2 minutes, lung ventilation is discontinued, perfusion cooling may begin, and the aorta may be clamped for arresting the heart. Just as is seen with initiation of dialysis, it is not uncommon to see some vasodilation and early hypotension as the patient is first exposed to the artificial surfaces, particularly the oxygenator. This can usually be managed by the perfusionist with increased flows until the vasodilation resolves, although occasionally vasopressors such as neosynephrine may be transiently required.

### Cardioplegia

Antegrade blood or crystalloid cardioplegia is administered directly into the aortic root at 60 to 100 mm Hg pressure proximal to the aortic cross-clamp by a dedicated cardioplegia

roller pump (see Fig. 13-2). Blood entering the right atrium from the coronary sinus is captured by the right atrial or unsnared caval catheters. If the caval snares are tightened, the right atrium should be vented to prevent right ventricular distention. Many surgeons choose to monitor myocardial temperature and administer cardioplegia to cool the myocardium to a specific temperature range. Others deliver a specific amount of cardioplegia, or monitor the electrical activity to determine the delivered volume. With appropriate delivery of antegrade cardioplegia, the heart should usually arrest within 30 to 60 seconds, and failure to do so may indicate problems with delivery of the solution or unrecognized aortic regurgitation. Some surgeons monitor myocardial temperature or pH via direct needle sensors.<sup>144</sup>

The usual flow of retrograde cardioplegia is 200 to 400 mL/min at coronary sinus pressures between 30 and 50 mm Hg.<sup>145</sup> Higher pressures may injure the coronary venous system<sup>119</sup>; low pressures usually indicate inadequate delivery owing to malposition of the catheter or leakage around the catheter cuff, but may also indicate a tear in the coronary sinus. Induction of electrical arrest is slower (2-4 minutes) than with antegrade delivery, and retrograde cardioplegia may provide incomplete protection of the right ventricle.<sup>117</sup>

### Key Determinants of Safe Perfusion

The following offers rational guidelines for management of CPB, which uses manipulation of temperature, hematocrit, pressure, and flow rate to adequately support cellular metabolism during nonphysiologic conditions.

#### BLOOD FLOW RATE

Under normal circumstances, basal cardiac output is determined by oxygen consumption, which is approximately 250 mL/min. It is impractical to measure oxygen consumption while on CPB, so a generally accepted flow rate at 35 to 37°C with a hematocrit of 25% is approximately 2.4 L/min/m<sup>2</sup> in deeply anesthetized and muscle-relaxed patients. Hemodilution reduces blood oxygen content from approximately 20 to 10 to 12 mL/dL; consequently, flow rate must increase over resting normal cardiac output or oxygen demand must decrease. The resistance of venous catheters, turbulence, and loss of physiologic controls of the vasculature may also effect venous return and limit maximum pump flow.

Hypothermia reduces oxygen consumption by a factor of 0.5 for every 10°C decrease in temperature. However, at both normothermia and hypothermia maximal oxygen consumption falls with decreasing flow as described in the following equation:

$$VO_2 = 0.44 (Q - 62.7) + 71.6.$$

This relationship at various temperatures is depicted in Figure 13-8. For this reason Kirklin and Barratt-Boyes<sup>146</sup> recommend that flows be reduced only to levels that permit at least 85% of maximal oxygen consumption. At 30°C this flow rate in adults is approximately 1.8 L/min/m<sup>2</sup>; at 25°C, 1.6 L/min/m<sup>2</sup>; and at 18°C, 1.0 L/min/m<sup>2</sup>.

**FIGURE 13-8** Nomogram relating oxygen consumption to perfusion flow rate and temperature. The small xs indicate clinical flow rates used by Kirklin and Barratt-Boyes. (Reproduced with permission from Kirklin JW, Barratt Boyes BG: *Cardiac Surgery*, 3rd ed. New York: Churchill Livingstone; 2003.)

As long as mean arterial pressure remains above 50 to 60 mm Hg (ie, above the autoregulatory range), cerebral blood flow is preserved even if systemic flow is less than normal. However, there is a hierarchal reduction of flow to other organs as total systemic flow is progressively reduced. First skeletal muscle flow falls, then abdominal viscera and bowel, and finally renal blood flow.

### PULSATILE FLOW

Theoretical benefits of pulsatile blood flow include increased transmission of energy to the microcirculation, which reduces critical capillary closing pressure, augments lymph flow, and improves tissue perfusion and cellular metabolism. Theoretically, pulsatile flow reduces vasoconstrictive reflexes and neuroendocrine responses and may increase oxygen consumption, reduce acidosis, and improve organ perfusion. However, despite extensive investigation no one has convincingly demonstrated a benefit of pulsatile blood flow over nonpulsatile blood flow for short- or long-term CPB.<sup>71,147</sup> Two studies reported the association of pulsatile flow with lower rates of mortality, myocardial infarction, and low cardiac output syndrome,<sup>148</sup> but others failed to detect clinical benefits.<sup>149</sup>

Pulsatile CPB can reproduce the normal pulse pressure within the body, but is expensive, complicated, and requires a large-diameter aortic cannula. Higher nozzle velocities increase trauma to blood elements,<sup>150</sup> and pulsations may damage micromembrane oxygenators.<sup>151</sup> Thus for clinical CPB, nonpulsatile blood flow is an acceptable, nonphysiologic compromise with few disadvantages.

### ARTERIAL PRESSURE

Systemic arterial blood pressure is a function of flow rate, blood viscosity (hematocrit), and vascular tone. Perfusion of the brain is normally protected by autoregulation, but

autoregulation appears to be lost somewhere between 55 and 60 mm Hg during CPB at moderate hypothermia and a hematocrit of 24%.<sup>84,152</sup> Cerebral blood flow may still be adequate at lower arterial pressures,<sup>153</sup> but the only prospective randomized study found a lower combined major morbidity/mortality rate when mean arterial pressure was maintained near 70 mm Hg (average  $69 \pm 7$ ) rather than below 60 (average 52).<sup>154</sup> In older patients, who may have vascular disease<sup>155</sup> and/or hypertension, mean arterial blood pressure is generally maintained between 70 and 80 mm Hg at 37°C. Higher pressures are undesirable because collateral blood flow to the heart and lungs increases blood in the operative field.

Hypotension during CPB may be the result of low pump flow, aortic dissection, measurement error, or vasodilatation. Phenylephrine is most often used to elevate blood pressure, but arginine vasopressin (0.05–0.1 unit/min) has more recently been introduced. If anesthesia is adequate, hypertension can be treated with nitroprusside, an arterial dilator, or nitroglycerin, which predominantly dilates veins and pulmonary vessels.

### HEMATOCRIT

The ideal hematocrit during CPB remains controversial. Low hematocrits reduce blood viscosity and hemolysis, reduce oxygen-carrying capacity, and reduce the need for autologous blood transfusion. In general, viscosity remains stable when percent hematocrit and blood temperature (in degrees Celsius) are equal (ie, viscosity is constant at hematocrit 37%, temperature 37°C, or at hematocrit 20%, temperature 20°C). Hypothermia reduces oxygen consumption and permits perfusion at 26 to 28°C with hematocrits between 18% and 22%, but at higher temperatures limits on pump flow may not satisfy oxygen demand.<sup>156,157</sup> Hill<sup>158</sup> found that hematocrit during CPB did not affect either hospital mortality or neurologic outcome, but DeFoe observed<sup>159</sup> increasing hospital mortality with hematocrits below 23% during CPB; thus the issue remains unresolved.<sup>160</sup> However, higher hematocrits (25–30%) during CPB appear justified<sup>157</sup> in view of the increasing safety of autologous blood transfusion, improved neurologic outcomes with higher hematocrits in infant cardiac surgery,<sup>161</sup> and more frequent operations near normothermia in older sicker patients.

### TEMPERATURE

The ideal temperature for uncomplicated adult cardiac surgery is also an unsettled question.<sup>157</sup> Until recently, nearly all operations reduced body temperature to 25 to 30°C during CPB to protect the brain, support hypothermic cardioplegia, permit perfusion at lower flows and hematocrits, and increase the safe duration of circulatory arrest in case of emergency. Hypothermia, however, interferes with enzyme and organ function, aggravates bleeding, increases systemic vascular resistance, delays cardiac recovery, lengthens duration of bypass, increases the risk of cerebral hyperthermia, and is associated with higher levels of depression and anxiety postoperatively.<sup>162</sup> Because the embolic risk of cerebral injury

often is greater than perfusion risk, perfusion at higher temperatures (33–35°C), or “tepid” CPB, is recommended, in part because detrimental high blood temperatures are avoided during rewarming.<sup>163</sup> Increasingly, efforts are made to avoid cerebral hyperthermia during and after operation, and one study suggests improved neuropsychometric outcomes if patients are rewarmed to only 34°C.<sup>164</sup>

### PH/PCO<sub>2</sub> MANAGEMENT

There are two strategies for managing pH/PCO<sub>2</sub> during hypothermia: pH stat and alpha stat. During deep hypothermia and circulatory arrest (see the following) there is increasing evidence that pH-stat management may produce better neurologic outcomes during pediatric cardiac surgery.<sup>161</sup> Alpha stat may be better in adults.<sup>165</sup> pH stat maintains temperature-corrected pH 7.40 at all temperatures and requires the addition of CO<sub>2</sub> as the patient is cooled. Alpha stat allows the pH to increase during cooling so that blood becomes alkalotic. Cerebral blood flow is higher, and pressure is passive and uncoupled from cerebral oxygen demand with pH stat. With alpha stat, cerebral blood flow is lower, autoregulated, and coupled to cerebral oxygen demand.<sup>166</sup>

### ARTERIAL PaO<sub>2</sub>

PaO<sub>2</sub> should probably be kept above 150 mm Hg to assure complete arterial saturation. Whether or not high levels (ie, >200 mm Hg) are detrimental has not yet been determined.

### GLUCOSE

Although Hill<sup>158</sup> found no relationship between blood glucose concentrations during CPB and adverse neurologic outcome, others have been concerned that hyperglycemia (>180 mg/dL) aggravates neurologic injury<sup>138</sup> and other morbidity/mortality,<sup>167</sup> and recently many studies have documented the importance of tight glucose control in the prevention of infection, neurologic injury, renal and cardiac complications, as well as a reduction in ICU length of stay and overall mortality.<sup>168</sup>

## Patient Monitors

Systemic arterial pressure is typically monitored by radial, brachial, or femoral arterial catheter. Central venous pressure is routinely monitored by a jugular venous catheter. Routine use of a Swan-Ganz pulmonary arterial catheter is controversial and not necessary for uncomplicated operations in low-risk patients.<sup>169</sup> During CPB the pulmonary artery catheter should be withdrawn into the main pulmonary artery to prevent lung perforation and suture ensnarement.

### TRANSESOPHAGEAL ECHOCARDIOGRAPHY

A comprehensive TEE examination<sup>170</sup> is an important monitor during most applications of CPB<sup>171</sup> to assess catheter and vent insertion and location<sup>117,172,173</sup>; severity of regional atherosclerosis<sup>33</sup>; myocardial injury, infarction, dilatation, contractility, thrombi, and residual air; undiagnosed anatomic

abnormalities<sup>170</sup>; valve function after repair or replacement; diagnosis of dissection<sup>41,174</sup>; and adequacy of de-airing at the end of CPB.<sup>175</sup>

### TEMPERATURE

Bladder or rectal temperature is usually used to estimate temperature of the main body mass, but does not reflect brain temperature.<sup>176</sup> Esophageal and pulmonary artery temperatures may be affected by local cooling associated with cardioplegia. The jugular venous bulb temperature is considered the best surrogate for brain temperature, but is more cumbersome to obtain.<sup>177</sup> Nasopharyngeal or tympanic membrane temperatures are more commonly used, but tend to underestimate jugular venous bulb temperature during rewarming by 3 to 5°C.<sup>178</sup> During rewarming, arterial line temperature correlates best with jugular venous bulb temperature.<sup>179</sup>

### NEUROPHYSIOLOGIC MONITORING

Neurophysiologic monitoring during CPB is becoming more commonly used in both adult and pediatric perfusion, particularly in preparation for deep hypothermic circulatory arrest. However, its full efficacy and impact on outcomes has not yet been fully established as a necessary component of CPB, and remains under investigation. Techniques being investigated include jugular venous bulb temperature and saturation, transcranial Doppler ultrasound, near-infrared transcranial reflectance spectroscopy (NIRS), and the raw or processed electroencephalogram (EEG).<sup>180</sup>

### ADEQUACY OF PERFUSION

During CPB oxygen consumption (VO<sub>2</sub>) equals pump flow rate multiplied by the difference in arterial (CaO<sub>2</sub>) and venous oxygen content (CVO<sub>2</sub>). For a given temperature, maintaining VO<sub>2</sub> at 85% predicted maximum during CPB assures adequate oxygen delivery (see Fig. 13-8).<sup>146</sup> Oxygen delivery (DO<sub>2</sub>) equals pump flow multiplied by CaO<sub>2</sub> and should be greater than 250 mL/min/m<sup>2</sup> during normothermic perfusion.<sup>156</sup> Mixed venous oxygen saturation (SVO<sub>2</sub>) assesses the relationship between DO<sub>2</sub> and VO<sub>2</sub>; values less than 60% indicate inadequate oxygen delivery. Because of differences in regional vascular tone, higher SVO<sub>2</sub> does not assure adequate oxygen delivery to all vascular beds.<sup>181</sup> Metabolic acidosis (base deficit) or elevated lactic acid levels may indicate inadequate perfusion, even in the face of “normal” SVO<sub>2</sub> measurements.

### URINE OUTPUT

Urine output is usually monitored but varies with renal perfusion, temperature, composition of the pump prime, diuretics, absence of pulsatility, and hemoconcentration. Urine production is reassuring during CPB and oliguria requires investigation.

### GASTRIC TONOMETRY AND MUCOSAL FLOW

These Doppler and laser measurements gauge splanchnic perfusion but are rarely used clinically.

## Weaning from Cardiopulmonary Bypass

Before stopping CPB the patient is rewarmed to 34 to 36°C, the heart is defibrillated if necessary, and the lungs are reexpanded and ventilated. The cardiac rhythm is monitored, and hematocrit, blood gases, acid-base status, and plasma electrolytes are reviewed. If the heart has been opened, TEE is recommended for detection and removal of trapped air before the heart is allowed to eject. Caval catheters are adjusted to ensure unobstructed venous return to the heart. If the need for inotropic drugs is anticipated, these are started at low flow rates. Vent catheters are removed, although sometimes an aortic root vent is placed on gentle suction to remove undiscovered air.

Once preparations are completed, the surgeon, anesthesiologist, and perfusionist begin to wean the patient off CPB. The perfusionist gradually occludes the venous line to allow filling of the right heart and ejection through the lungs to the left side, while simultaneously reducing pump input as cardiac rate and rhythm, arterial pressure and pulse, and central venous pressure are monitored and adjusted. Initially blood volume within the pump is kept constant, but as pump flow approaches zero, volume is added or removed from the patient to produce arterial and venous pressures within the physiologic ranges. During weaning, cardiac filling and contractility is often monitored by TEE, and intra-cardiac repairs and regional myocardial contractility are assessed. Pulse oximetry saturation near 100%, end-tidal CO<sub>2</sub> greater than 25 mm Hg, and mixed venous oxygen saturation higher than 65% confirm satisfactory ventilation and circulation. When cardiac performance is satisfactory and stable, all catheters and cannulas are removed, protamine is given to reverse the heparin, and blood return from the surgical field is discontinued.

Once the patient is hemodynamically stable, as determined by surgeon and anesthesiologist, and after starting wound closure, the perfusate may be returned to the patient in several ways. The entire perfusate may be washed and returned as packed cells, excess fluid may be removed by a hemoconcentrator, or the perfusate, which still contains heparin, can be gradually pumped into the patient for hemoconcentration by the kidneys. Occasionally some of the perfusate must be bagged and given later. The heart-lung machine should not be completely disassembled until the chest is closed and the patient is ready to leave the operating room.

## SPECIAL TOPICS

### Special Applications of Extracorporeal Perfusion

Reoperations, surgery of the descending thoracic aorta, and minimally invasive procedures may be facilitated by surgical incisions other than midline sternotomy. These alternative incisions often require alternative methods for connecting the patient to the heart-lung machine. Some alternative applications of CPB are presented in the following.

### RIGHT THORACOTOMY

Anterolateral incisions through the fourth or fifth interspaces provide easy access to the cavae and right atrium, adequate access to the ascending aorta, as well as exposure to the left atrium and mitral valve, but no direct access to the left ventricle. Adequate exposure of the ascending aorta is available for cross-clamping, aortotomy, and administration of cardioplegia by retracting the right atrial appendage. De-airing the left ventricle (eg, after mitral valve repair) is more difficult. External pads facilitate defibrillation.

### LEFT THORACOTOMY

Lateral or posterolateral incisions in the left chest are used for a variety of operations. Venous return may be captured by cannulating the pulmonary artery via a stab wound in the right ventricle, or by retrograde cannulation of the left pulmonary artery or cannulation of the left iliac or femoral vein. With iliac or femoral cannulation, venous return may be augmented by threading the cannula into the right atrium using TEE guidance.<sup>182</sup> The descending thoracic aorta or left subclavian, iliac, or femoral arteries are accessible for arterial cannulation.

### LEFT HEART BYPASS

Left heart bypass uses the beating right heart to pump blood through the lungs to provide gas exchange.<sup>183</sup> An oxygenator is not used and intake cannulation sites are exposed through a left thoracotomy. The left superior pulmonary vein-left atrial junction is an excellent cannulation site for capturing blood. The left atrial appendage can also be used, but may be more friable and therefore more difficult with which to work. The apex of the left ventricle is infrequently used because of the potential for myocardial injury. The tip of the intake catheter must be free in the left atrium and careful technique is required to avoid air entry during cannulation and perfusion. The extracorporeal circuit typically consists only of tubing and a centrifugal pump and does not include a reservoir, heat exchanger, or bubble trap. This reduces the thrombin burden and may permit reduced or no heparin if anticoagulation poses an additional risk (eg, in acute head injury). Otherwise, full heparin doses are recommended. The reduced perfusion circuit precludes the ability to add or sequester fluid, adjust temperature, or intercept systemic air emboli. Intravenous volume expanders may be needed to maintain adequate flows; temperature usually can be maintained without a heat exchanger.<sup>184</sup>

*Full left heart bypass* may be employed for left-sided coronary artery surgery by draining all of the pulmonary venous return out of the left atrium and leaving no blood for left ventricular ejection. If the heart fibrillates, blood can still passively pass through the right heart and lungs, but often an elevated central venous pressure is required.<sup>185</sup>

*Partial left heart bypass* is identical in configuration and cannulation to full left heart bypass and is used to facilitate surgery on the descending thoracic aorta. This accomplishes two goals by providing perfusion to the lower body beyond

the aortic clamps, as well as allowing the perfusionist to remove preload as needed by increasing the flow, thereby controlling the perfusion pressure in the proximal aorta, preventing both hypotension, as well as hypertension and potential LV strain. The patient's left ventricle supplies blood to the aorta proximal to aortic clamps, and the circuit supplies blood to the distal body. Typically about two-thirds normal basal cardiac output (ie, 1.6 L/min/m<sup>2</sup>) is pumped to the lower body. Arterial pressure is monitored proximal (radial or brachial) and distal (right femoral, pedal) to the aortic clamps. Blood volume in the body and circuit is assessed by central venous pressure and TEE monitoring of chamber dimensions. Management is more complicated because of the single venous circulation and separated arterial circulations.<sup>183</sup>

### PARTIAL CARDIOPULMONARY BYPASS

Partial CPB with an oxygenator is also used to facilitate surgery of the descending thoracic aorta. After left thoracotomy, systemic venous and arterial cannulas are placed as described in the preceding. The perfusion circuit includes a reservoir, pump, oxygenator, heat exchanger, and bubble trap. The beating left ventricle supplies the upper body and heart, so lungs must be ventilated and upper body oxygen saturation should be independently monitored. Blood flow to the separate upper and lower circulations must be balanced as described for partial left heart bypass.

### FULL CARDIOPULMONARY BYPASS

Full CPB with peripheral cannulation is used when access to the chest is dangerous because of proximity of the heart, vital vessels (eg, mammary arterial graft), or pathologic condition (eg, ascending aortic mycotic aneurysm) abutting the anterior chest wall.<sup>3</sup> The patient is supine and a complete ECP circuit is prepared and primed. Venous cannulas may be inserted into the right atrium via the iliac or femoral vessels and/or the right jugular vein. The iliac, femoral, or axillary subclavian arteries may be used for arterial cannulation. Initiation of CPB decompresses the heart, but profound cooling is usually deferred to keep the heart beating and decompressed until the surgeon can insert a vent catheter, unless the conduct and complexity of the operation dictate deep hypothermic circulatory arrest (DHCA) prior to dividing the sternum.

### FEMORAL VEIN TO FEMORAL ARTERY BYPASS

Femoral vein to femoral artery bypass with full CPB is used to initiate bypass outside the operating room for emergency circulatory assistance,<sup>3</sup> supportive angioplasty,<sup>186</sup> intentional (aneurysm repair) or accidental hypothermia. Femoral vessel cannulation is occasionally used during other operations to facilitate control of bleeding (eg, cranial aneurysm, tumor invading the IVC) or ensure oxygenation (eg, lung transplantation, upper airway reconstruction).

### CANNULATION FOR MINIMALLY INVASIVE (LIMITED ACCESS) SURGERY

Off-pump coronary artery bypass (OP-CAB) describes construction of coronary arterial bypass grafts on the beating heart without CPB. Minimally invasive direct CAB (MID-CAB) refers to coronary arterial bypass grafting with or without CPB through small, strategically placed incisions. Peripheral cannulation sites, described above, may be used, but often central cannulation of the aorta, atrium, or central veins is accomplished using specially designed or smaller cannulas placed through the operative incision or through a separate small incisions in the chest wall.<sup>187</sup> Venous return may be augmented by applying negative pressure (see discussion of venous cannulation above); often soft tipped arterial catheters are used to minimize arterial wall trauma.<sup>20</sup>

The Port-Access System provides a means for full CPB, cardioplegia administration, and aortic cross-clamping without exposing the heart and can be used for both valvular and coronary arterial operations.<sup>173</sup> Through the right internal jugular vein separate transcatheter catheters are inserted into the coronary sinus for retrograde cardioplegia and the pulmonary artery for left heart venting. A multilumen catheter is inserted through the femoral artery and using TEE and/or fluoroscopy is positioned in the ascending aorta for arterial pump inflow, for balloon occlusion of the ascending aorta, and administration of antegrade cardioplegia into the aortic root. Venous return is captured by a femoral venous catheter advanced into the right atrium. The system allows placement of small skin incisions directly over the parts of the heart that require surgical attention.

Minimally invasive surgery using CPB is associated with potential complications that include perforation of vessels or cardiac chambers, aortic dissection, incomplete de-airing, systemic air embolism, and failure of the balloon aortic clamp. Because CO<sub>2</sub> is heavier than air and more soluble in blood, the surgical field is sometimes flooded with CO<sub>2</sub> at 5- to 10-L/min flow to displace air when the heart is open. The intra-aortic balloon occluder can leak, prolapse through the aortic valve, or move distally to occlude arch vessels. For safety the position of the occluding balloon is closely monitored by TEE, bilateral radial arterial pressures, and one of the following: transcranial Doppler ultrasound, cerebral near-infrared spectroscopy, or EEG.<sup>188</sup>

### Deep Hypothermic Circulatory Arrest

Deep hypothermic circulatory arrest is commonly used for operations involving the aortic arch, a heavily calcified or porcelain aorta, thoracoabdominal aneurysms, pulmonary thromboendarterectomy, selected uncommon cardiovascular and neurologic procedures,<sup>189</sup> and certain complex congenital heart procedures. The technology involves reducing body temperature to less than 20°C, arresting the circulation for a short period, and then rewarming to 37°C. Deep hypothermia reduces cerebral oxygen consumption (Fig. 13-9), and attenuates release of toxic neurotransmitters and reactive oxidants during ischemia and reperfusion.<sup>190</sup>

**FIGURE 13-9** Relation between cerebral oxygen consumption and nasopharyngeal temperature during CPB at 2 L/min/m<sup>2</sup>. (Data from Croughwell N, Smith LR, Quill T et al: The effect of temperature on cerebral metabolism and blood flow in adults during cardiopulmonary bypass, *J Thorac Cardiovasc Surg*. 1992 Mar;103(3):549-554.)

Because perfusion cooling produces differential temperatures within both the body and brain,<sup>176</sup> more than one temperature is customarily monitored. Bladder, pulmonary artery, esophageal, or rectal temperatures are used to estimate body temperature. Nasopharyngeal and tympanic membrane temperatures are imperfect surrogates for mean brain temperature. Most surgical teams cool to either EEG silence, jugular venous saturation greater than 95%, or for at least 30 minutes before stopping circulation at nasopharyngeal or tympanic membrane temperatures below 20°C. Caloric exchange is proportional to body mass, rate of perfusion, and temperature differences between patient and perfusate; however, rates of perfusion cooling and rewarming are restricted (see the section on heat exchangers). Perfusion cooling is usually supplemented by surface cooling using hypothermia blankets and/or packing the head in ice. Hyperthermia is avoided by keeping arterial inflow temperature below 37°C during rewarming, and by avoiding gradients greater than 10°C between the inflow blood temperature and the lowest monitored body temperature.

Changes in temperature affect acid-base balance, which must be monitored and managed during deep hypothermia. The pH-stat protocol (CO<sub>2</sub> is added to maintain temperature corrected blood pH at 7.4) may be preferred over the alpha-stat protocol, which allows cold blood to become alkalotic. Compared with alpha-stat, pH-stat increases the rate and uniformity of brain cooling,<sup>191,192</sup> slows the rate of brain oxygen consumption by 30 to 40% at 17°C,<sup>192</sup> and improves neurologic outcomes in animal models<sup>161,193</sup> and in infants,<sup>194</sup> but not necessarily in adults.<sup>195</sup> Hyperglycemia appears to increase brain injury and is avoided during deep hypothermia.<sup>196</sup> The value of high-dose corticosteroids or barbiturates remains unproved.

The safe duration of circulatory arrest during deep hypothermia is unknown. In adults arrest times as short as 25 minutes are associated with poor performance on neuropsychologic tests of fine motor function and memory.<sup>197</sup>

Ergin et al.<sup>198</sup> found duration of arrest was a predictor of temporary neurologic dysfunction, which correlated with long-term neuropsychologic deficits.<sup>199</sup> At 18°C, cerebral metabolism and oxygen consumption are 17 to 40% of normothermia<sup>200</sup> and abnormal encephalographic patterns and cerebrovascular responses can be detected after 30 minutes of circulatory arrest.<sup>200</sup> Most investigators,<sup>201</sup> but not all<sup>202</sup> report increased mortality and adverse neurologic outcomes after 40 to 65 minutes of circulatory arrest in adults. Most surgeons try to keep the period of arrest at less than 45 minutes and, if the operation allows, many perfuse for 10 to 15 minutes between serial arrest periods of 10 to 20 minutes. (For more details on DHCA, see Chapter 14.)

## Antegrade and Retrograde Cerebral Perfusion

*Antegrade cerebral perfusion* is used in lieu of DHCA or as a supplement. Once the body has been appropriately cooled as for DHCA, the cerebral vessels can be cannulated separately and perfused together by a single pump<sup>203</sup> or perfused collectively after a graft with a side branch is sewn to the top of the aortic arch from which the innominate, left carotid, and left subclavian arteries originate. Separate perfusion of separately cannulated vessels is rarely done. Perfusion is usually provided by a separate roller pump that receives blood from the arterial line. Line pressure is monitored and a microfilter may or may not be used. The cerebral vessels are collectively perfused with cold blood between 10 and 18°C and at approximate flows of 10 mL/kg/min; perfusion pressures are usually restricted to 30 to 70 mm Hg, though individual protocols vary widely.<sup>204</sup> The adequacy of cerebral perfusion can be assessed by monitoring jugular venous saturation or near-infrared spectroscopy. Selective antegrade cerebral perfusion risks dislodging atheromatous emboli or causing air embolism, cerebral edema, or injury from excessive perfusion pressure.

*Retrograde cerebral perfusion (RCP)* was initially introduced in 1980 as emergency treatment for massive air embolism.<sup>205</sup> Later, Ueda et al. introduced continuous RCP for cerebral protection as an adjunct to DHCA during aortic surgery.<sup>206</sup> During RCP and DHCA the SVC is perfused at pressures usually between 25 and 40 mm Hg, temperatures between 8 and 18°C, and flows between 250 and 400 mL/min from a sideport off the arterial line, which is clamped downstream from the sideport. Some surgeons advocate much higher pressures and flows to compensate for runoff and have not shown detrimental effects.<sup>207</sup> A snare is usually placed around the superior caval catheter cephalad to the azygous vein to reduce runoff. The IVC may or may not be occluded.<sup>208</sup>

Retrograde cerebral perfusion has been widely and safely used,<sup>207,209</sup> but its effectiveness in protecting the brain is not clear.<sup>210</sup> The method can wash out some particulate emboli entering from arteries, which is a major cause of brain injury after aortic surgery.<sup>211</sup> However, it is not clear how adequately and completely all regions of the brain are perfused.<sup>210</sup> Lin et al.<sup>209</sup> found cortical flows to be only 10% of control values.

RCP slows but does not arrest the decrease in cerebral oxygen saturation<sup>203,207</sup> and the decay in amplitude of somatosensory evoked potentials.<sup>212</sup> Other clinical and animal studies have suggested RCP provides some cerebral protection over DHCA alone.<sup>207,209</sup> A few studies report that antegrade cerebral perfusion provides better protection than the retrograde technique.<sup>203</sup>

## Complications and Risk Management

Life-threatening incidents can occur in 0.4 to 2.7% of operations with CPB and the incidence of serious injury or death is between 0.06% and 0.08% (Table 13-4).<sup>61,92</sup> Massive air embolism, aortic dissection, dislodgement of cannulas, and clotting within the circuit during perfusion are the principal causes of serious injury or death. Malfunctions of the heat exchanger, oxygenator, pumps, and electrical supply are the most common threatening incidents related to equipment. Others include premature takedown or clotting within the perfusion circuit.

### MASSIVE AIR EMBOLISM

The incidence of massive air embolism is between 0.003% and 0.007% with 50% of outcomes adverse.<sup>61,92</sup> Air can enter any component of the perfusion circuit at any time during an

operation if the integrity of the circuit is broken.<sup>213</sup> Stopcocks, connections, vent catheters, empty reservoirs, pursestring sutures, cardioplegia infusion catheters, and unremoved air in opened cardiac chambers are the most common sources of air emboli. Uncommon sources include oxygenator membrane leaks, residual air in the circuit after priming, reversal of flow in venous, vent or arterial lines, and unexpected inspiration by the patient during cannula removal.

Massive air embolism during perfusion is a catastrophe, and management guidelines are evolving.<sup>14,205,213</sup> Perfusion should stop immediately and clamps should be placed on both venous and arterial lines. Air in the circuit should be rapidly removed by recirculation and entrapment of all air in a reservoir or bubble trap. The patient should be immediately placed in steep Trendelenburg position and blood and air at the site of entry should be aspirated until no air is retrieved. TEE should be rapidly employed to search for air, but perfusion must resume promptly depending upon body temperature to prevent ischemic brain damage. Cooling to deep hypothermia should be considered to protect the brain and other organs while air is located and removed. As soon as possible, retrograde perfusion of the brain should be undertaken while the aortic arch is simultaneously aspirated with the patient in steep Trendelenburg position. Corticosteroids and/or barbiturates may be considered. Depending upon circumstances and availability, hyperbaric oxygen therapy may be helpful if patients can be treated within 5 hours of operation.<sup>214</sup>

**TABLE 13-4: Adverse Incidents Involving Cardiopulmonary Bypass**

	Incidence (events/1000)	Death or serious injury (%)*
Protamine reaction	1.3	10.5
Thrombosis during cardiopulmonary bypass	0.3-0.4	2.6-5.2
Aortic dissection	0.4-0.8	14.3-33.1
Dislodgment of cannula	0.2-1.6	4.2-7.1
Rupture of arterial connection	0.2-0.6	0-3.1
Gas embolism	0.2-1.3	0.2-8.7
Massive systemic gas embolism	0.03-0.07	50-52
Electrical power failure	0.2-1.8	0-0.6
Pump failure	0.4-0.9	0-3.5
Heater-cooler problems	0.5-3	0
Replace oxygenator during cardiopulmonary bypass	0.2-1.3	0-0.7
Other oxygenator problems	0.2-0.9	0
Urgent re setup after takedown	2.9	13
Early unplanned cessation of cardiopulmonary bypass	0.2	0-0.7

\*Percentage of incidents that resulted in death or serious injury. Data derived from references 94 and 151.

### RISK MANAGEMENT

Minimizing risks of ECP requires strict attention to personnel training, preparation and training for emergencies, equipment function, and record keeping.<sup>14</sup> All members of the operative team must be trained, certified, and recertified in their respective roles and participate in continuing education programs. A policy manual for the perfusion team and written protocols should be developed and continuously updated for various types of operations and emergencies. Emergency kits are prepared for out-of-operating-room (OR) crises. Adequate supplies are stocked in designated locations with sufficient inventory to support any operation or emergency for a specified period. An inventory of supplies is taken and recorded at regular intervals. Checklists are prepared and used for setting up the perfusion system and connecting to the patient. Equipment is inspected at regular intervals; worn, loose, or outdated parts are replaced; and preventive maintenance is provided and documented. New equipment is thoroughly checked before use and instructions are thoroughly digested by all user personnel. Safety alarms are optional; none replace the vigilance and attention of all OR personnel during an operation. Complete, signed written records are required for every perfusion; adverse events are recorded in a separate log and reviewed by the entire OR team. A continuous quality assurance program is desirable.<sup>215</sup>

During the procedure communication must be open among the surgeon, anesthetist, and perfusionist to

coordinate activities. Statements are verbally acknowledged. Distractive conversations are discouraged. The entire OR team is committed to a zero-error policy, which can only be achieved by discipline and attention to details.<sup>216</sup>

## THROMBOSIS AND BLEEDING

### Response of Humoral and Cellular Elements of Blood to Extracorporeal Circulation

Within the body the endothelial cell, the only surface in contact with circulating blood, simultaneously maintains the fluidity of blood and the integrity of the vascular system. This remarkable cell maintains a dynamic equilibrium by producing anticoagulants to maintain blood in a fluid state and generating procoagulant substances to enhance gel formation when perturbed. Blood proteins circulate as inert zymogens, which convert to active enzymes when stimulated. Likewise, blood cells remain quiescent until activated to express surface receptors and release proteins and enzymes involved in coagulation and inflammation. The continuous exposure of heparinized blood to the perfusion circuit and to cell tissues and fluid constituents of the wound during clinical cardiac surgery produces an intense thrombotic stimulus that involves both the tissue factor (TF) pathway (extrinsic coagulation pathway) in the wound and the contact and intrinsic coagulation pathways in the perfusion circuit. Thrombin is continuously generated and circulated despite massive doses of heparin in all applications of ECP.<sup>217</sup> This powerful enzyme along with TF from the wound and many other cytokines also activate an inflammatory reaction, which can damage tissues and ultimately produce cell death by necrosis or apoptosis.

### Initial Reactions in the Perfusion Circuit

When heparinized blood contacts any biomaterial, plasma proteins are instantly adsorbed (<1 second) onto the surface to form a *monolayer* of selected proteins.<sup>218</sup> Different biomaterials have different intrinsic surface activities for each plasma protein. The physical and chemical compositions of the *biomaterial surface* determine the intrinsic surface activity of the biomaterial. Thus intrinsic surface activity differs among biomaterial surfaces, plasma proteins, and different bulk concentrations of plasma proteins. The composition of the protein monolayer is specific for the biomaterial and various concentrations of proteins in the plasma, but the topography of the adsorbed protein layer may not be uniform across the surface of the biomaterial.<sup>219</sup> Thus it is not possible to predict the “thrombogenicity” of any biomaterial except by trial and error.

On most biomaterial surfaces fibrinogen is selectively adsorbed, but the adsorbed concentration of fibrinogen and

**FIGURE 13-10** Electron micrograph of a rabbit endothelial cell (E), the only known nonthrombogenic surface. Note the overlapping junctions with neighboring endothelial cells. Endothelial cells rest on the internal elastic lamina (I), which abut medial smooth muscle cells. The vessel lumen is at the top. (Reproduced with permission from Colman RW, Hirsh J, Marder VJ, et al: *Hemostasis and Thrombosis: Basic Principles and Clinical Practice*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 1987.)

other proteins may change over time.<sup>220</sup> The complexity of blood-biomaterial interactions is further compounded by the fact that adsorbed proteins often undergo limited conformational changes<sup>221</sup> that may expose “receptor” amino acid sequences that are recognized by specific blood cells or bulk plasma proteins.

Thus, heparinized blood does not directly contact biomaterial surfaces in ECP circuits, but contacts monolayers of densely packed, immobile plasma proteins arranged in undefined mosaics that differ between locations and possibly across time. All biomaterial surfaces, including heparin-coated surfaces, are *procoagulant*<sup>222</sup>; only the endothelial cell is truly nonthrombogenic (Fig. 13-10).

### Anticoagulation

ECP and CPB are not possible without anticoagulation; the large procoagulant surface quickly overwhelms natural circulating anticoagulants—antithrombin, proteins C and S, TF pathway inhibitor, and plasmin—to produce thrombin and thrombosis within the circuit. Thrombin is produced in ECP systems with small surface areas and high-velocity flow,<sup>223</sup> but thrombosis may not be apparent if other procoagulants (eg, addition of blood from wounds) are absent. Generation of thrombin varies widely between applications of extracorporeal technology, but this powerful and potentially dangerous enzyme is produced whenever blood contacts a nonendothelial cell surface (Fig. 13-11).

During CPB and OHS high concentrations of heparin (3-4 mg/kg, initial dose) are needed to maintain the fluidity of blood. Heparin has both advantages and

**FIGURE 13-11** Plasma thrombin-antithrombin (TAT) measurements of thrombin generation during CPB and clinical cardiac surgery of varying duration. (Data from Brister SJ, Ofosu FA, Buchanan MR: Thrombin generation during cardiac surgery: is heparin the ideal anticoagulant? *Thromb Haemost.* 1993 Aug 2;70(2):259-262.)

disadvantages; the most notable advantages are parenteral use, immediate onset of action, and rapid reversal by protamine or recombinant platelet factor 4.<sup>224</sup> Heparin does not directly inhibit coagulation, but acts by accelerating the actions of the natural protease, antithrombin.<sup>225</sup> Heparin-catalyzed antithrombin, however, does not inhibit thrombin bound to fibrin<sup>226</sup> or factor Xa bound to platelets within clots<sup>227</sup>; thus, heparin only partially inhibits thrombin in vivo. Antithrombin primarily binds thrombin; its action on factors Xa and IXa is much slower. Heparin inhibits coagulation at the end of the cascade after nearly all other coagulation proteins have been converted to active enzymes. In addition, heparin to varying degrees activates several blood constituents: platelets,<sup>228</sup> factor XII,<sup>229</sup> complement, neutrophils, and monocytes.<sup>230</sup> Thrombin concentrations cannot be measured in real time and only insensitive, indirect methods are available to regulate heparin anticoagulation in the operating room.<sup>231</sup>

Heparin is also associated with some clinical idiosyncrasies. In some patients recent, prolonged parenteral heparin may reduce antithrombin concentrations and produce *heparin resistance*.<sup>232</sup> Insufficient antithrombin may also occur because of insufficient synthesis or increased consumption in cachectic patients and patients with advanced liver or renal disease. The deficiency in antithrombin prevents heparin from prolonging ACTs to therapeutic levels. In these patients fresh-frozen plasma or recombinant antithrombin is needed to increase plasma antithrombin concentrations to inhibit thrombin. *Heparin rebound* is a delayed anticoagulant effect after protamine neutralization because of the rapid metabolism of protamine and delayed seepage of heparin into the circulation from lymphatic tissues and other deposits. Heparin is also associated with an allergic response

in some patients that produces heparin-induced thrombocytopenia (HIT) with or without thrombosis (HITT). Lastly, heparin only partially suppresses thrombin formation during CPB and all applications of extracorporeal perfusion and mechanical circulatory and respiratory assistance despite doses two to three times those used for other indications (see Fig. 13-11).<sup>217</sup>

Potential safe alternatives for heparin during ECP include low-molecular-weight heparin, recombinant hirudin (lepirudin), and the organic chemical, argatroban (Texas Biotechnology Corp.). All have important drawbacks and are approved for use in HIT and in patients with circulating IgG anti-heparin-PF4 complex antibodies (see the following). Low-molecular-weight heparins have long half-lives in plasma (4-8 hours), require antithrombin as a cofactor, primarily inhibit factor Xa, and are not reversible by protamine.<sup>233</sup> Recombinant hirudin (lepirudin) is a direct inhibitor of thrombin, is effective rapidly, does not have an effective antidote, is monitored by the partial thromboplastin time, is cleared by the kidney, and has a relatively short half-life in plasma (40 minutes).<sup>234</sup> This drug has been successfully used during CPB and OHS, but in many instances bleeding after bypass has been troublesome and substantial. A newer drug is a semisynthetic bivalent thrombin inhibitor composed of 12 amino acids from hirudin.<sup>235</sup> This drug, bivalirudin (angiomax), has a shorter half-life than hirudin and therefore may be safer. Argatroban is also a direct thrombin inhibitor with rapid onset of action and short plasma half-life (40-50 minutes).<sup>236</sup> Argatroban is metabolized in the liver and is without an antidote, but can be monitored with partial thromboplastin times or ACTs. At present there growing experience with the use of argatroban and bivalirudin as alternative anticoagulant when heparin cannot be used.<sup>237</sup>

### Heparin-Associated Thrombocytopenia, Heparin-Induced Thrombocytopenia, and Heparin-Induced Thrombocytopenia and Thrombosis

Heparin-associated thrombocytopenia (HAT) is a benign, nonimmune, 5 to 15% decrease in platelet count that occurs within a few hours to 3 days after heparin exposure. HIT and heparin-induced thrombocytopenia and thrombosis (HITT) are different manifestations of the same immune disease. Heparin binds to platelets in the absence of an antibody and releases small amounts of platelet factor 4 (as occurs in HAT). PF4 avidly binds heparin to form a heparin-PF4 (H-PF4) complex, which is antigenic in some people. In these individuals IgG antibodies to the *H-PF4 complex* are produced within 5 to 15 days after exposure to heparin and continue to circulate for approximately 3 to 6 months.<sup>238</sup> *IgG-anti-H-PF4 antibodies* plus *H-PF4 complexes* form *HIT complexes*, which unite IgG Fc terminals to platelet Fc receptors (Fig. 13-12). This binding strongly stimulates platelets to release more PF4.<sup>239</sup> A self-perpetuating, accelerating cascade of platelet activation, release,

**FIGURE 13-12** The generation of HIT complexes. Read each horizontal group of three left to right beginning at top left. See text for full explanation.

and aggregation ensues. Since platelet granules contain several procoagulatory proteins (eg, thrombin, fibronectin, factor V, fibrinogen, von Willebrand factor), release also activates coagulation proteins to generate thrombin.

The intensity of the immune reaction varies between patients, but also varies by the indications for heparin use. Patients who do not have conditions that activate platelets have a low incidence of HIT after administration of heparin, because few PF4 molecules are available to form H-PF4 complexes. Large doses of heparin are given and huge numbers of platelets are activated during CPB. Thus after CPB, 50% of patients have IgG anti-H-PF4 antibodies; 2% have immune heparin-induced thrombocytopenia; and approximately 1% develop HIT.<sup>240</sup> Because IgG antibodies are transient, a second heparin exposure 6 months after HIT is not likely to produce HIT or HITT,<sup>239</sup> but will stimulate production of new IgG antibodies to the H-PF4 complex. The danger is a second heparin exposure when IgG anti-H-PF4 antibodies are still circulating.

IgG anti-H-PF4 antibodies are detected in two ways. The serotonin release test detects the release of radioactive

serotonin from normal platelets washed by the patient's serum.<sup>241</sup> An enzyme immunoassay measures IgG anti-H-PF4 antibodies directly. Both assays are equally sensitive in patients with clinical HIT, but the enzyme immunoassay is more sensitive in detecting IgG anti-H-PF4 antibodies in patients without other evidence of the disease.<sup>242</sup>

The clinical presentation of HIT may be insidious. If the platelet count was originally normal, the earliest sign is an abrupt decrease of at least 50% in platelet count (to  $<150,000/\mu\text{L}$ ) in a patient who has had exposure to heparin within the past 5 to 15 days. This event is a preoperative stop sign for elective cardiac operations. After CPB, platelet counts less than  $80,000/\mu\text{L}$  should trigger an order to stop all heparin, including heparin flushes, and obtain daily platelet counts. The patient should be thoroughly examined for deep vein thrombosis, extremity ischemia, stroke, myocardial infarction, or any evidence of intravascular thrombosis using ultrasound and appropriate radiographic technology. Any evidence of vascular thrombosis should prompt a plasma sample for IgG anti-H-PF4 antibodies. A positive antibody test confirms the diagnosis of HIT in patients with

thrombocytopenia and HIT in those with either venous or arterial thrombosis or both. It is important to stress that HIT or HITT is a clinical diagnosis, and a positive antibody test is *not* required before stopping heparin.

Once the diagnosis of HIT or HITT is suspected, management must focus on prevention of further intravascular thrombosis. Bleeding is rarely the problem; intravascular thrombosis is. Neither heparin nor platelet transfusions should be given; platelet transfusions only add more PF4 if heparin and IgG anti-H-PF4 antibodies are still circulating. If heparin is proven absent from the circulation, platelet transfusions may be used very cautiously if the patient has significant nonsurgical bleeding. Surgical measures to reopen thrombosed large arteries are usually futile because the platelet-rich thrombus (white clot) often extends into small arteries and arterioles.

Modern management also includes full anticoagulation with recombinant hirudin (lepirudin), argatroban, or possibly bivalirudin to prevent further extension of thrombosis or development of clinical intravascular thrombosis. This may occur in 40 to 50% of patients with HIT who are treated only with heparin cessation.<sup>243</sup> At present there is little experience with argatroban in cardiac surgical patients with HITT, but the drug is a direct thrombin inhibitor, has attractive pharmacokinetics, and is approved for patients with HITT.<sup>244</sup> Full anticoagulation with hirudin or bivalirudin in fresh postoperative cardiac surgical patients is recommended, but the safety zone between bleeding and thrombosis is narrow. The patient must be carefully monitored for pericardial tamponade and signs of hidden bleeding. Hirudin is monitored by a PTT and the range used is similar to that with intravenous heparin. Dose must be reduced in patients with renal failure because the kidney clears the drug. Argatroban is sometimes a better choice, but it should be remembered that it is difficult to manage in the presence of liver disease because it is metabolized in that organ. In most patients oral anticoagulation with warfarin is started at the same time as intravenous hirudin.

Emergency or urgent OHS with CPB using hirudin is possible in patients with circulating IgG anti-HPF4 antibodies. The therapeutic level of drug should be between 3.5 and 4.5  $\mu\text{g}/\text{mL}$  during CPB.<sup>245</sup> Greinacher recommends bolus doses of 0.25 mg/kg IV and 0.2 mg/kg in the priming volume followed by an infusion of 0.5 mg/min until 15 minutes before stopping CPB. At that time 5 mg of hirudin is added to the perfusate to prevent clotting within the heart-lung machine. Bivalirudin has been compared to heparin and found to be comparable related to post op bleeding.<sup>246</sup>

## Coagulation and Extracorporeal Perfusion: Thrombin Generation

Generation of thrombin during CPB and other applications of extracorporeal circulatory technology is the cause of the thrombotic and bleeding complications associated with ECP. Theoretically, if thrombin formation could be completely

inhibited during ECP, the consumptive coagulopathy, which consumes coagulation proteins and platelets and causes bleeding complications, would not occur.

Thrombin generation and the fibrinolytic response primarily involve the extrinsic and intrinsic coagulation pathways, the contact and fibrinolytic plasma protein systems, and platelets, monocytes, and endothelial cells.

### CONTACT SYSTEM

The contact system includes four primary plasma proteins—factor XII, prekallikrein, high-molecular-weight kininogen (HMWK), and C-1 inhibitor and is activated during CPB and clinical cardiac surgery.<sup>247</sup> This system is involved in complement and neutrophil activation and the inflammatory response to ECP, but is not involved in thrombin formation *in vivo*.

### INTRINSIC COAGULATION PATHWAY

The intrinsic coagulation pathway probably does not generate thrombin *in vivo*, but does initiate thrombin formation when blood contacts nonendothelial cell surfaces such as perfusion circuits.<sup>248</sup>

### EXTRINSIC (TISSUE FACTOR) COAGULATION PATHWAY

The extrinsic coagulation pathway is the major coagulation pathway *in vivo* and is a major source of thrombin generation during CPB and clinical cardiac surgery.<sup>249,250</sup> Exposure of blood to TF by direct contact in the wound or by wound blood aspirated into the ECP circuit initiates the extrinsic coagulation pathway.<sup>251</sup> TF is a cell-bound glycoprotein that is constitutively expressed on the cellular surfaces of fat, muscle, bone, epicardium, adventia, injured endothelial cells, and many other cells except pericardium.<sup>252</sup> Plasma TF associated with wound monocytes is a second source of TF and may be an important source during CPB and clinical cardiac surgery.<sup>253</sup>

### COMMON COAGULATION PATHWAY

Factor Xa is the gateway protein of the common coagulation pathway. Factor Xa slowly cleaves prothrombin to  $\alpha$ -thrombin, the active enzyme, and a fragment, F1.2, and is the major pathway producing thrombin.<sup>251</sup> F1.2 is a useful marker of the reaction.

### THROMBIN

Thrombin is a powerful enzyme that accelerates its own formation by several feedback loops.<sup>254</sup> Thrombin is the major activator of factor XI and the exclusive activator of factor VIII in the intrinsic pathway. Thrombin is a secondary activator of factor VII, but once formed may be the most important activator in the wound.

Thrombin has both procoagulant and anticoagulant properties.<sup>254</sup> Thrombin is the enzyme that cleaves fibrinogen to fibrin and in the process creates two fragments, fibrinopeptides A and B. Thrombin activates platelets via the platelet

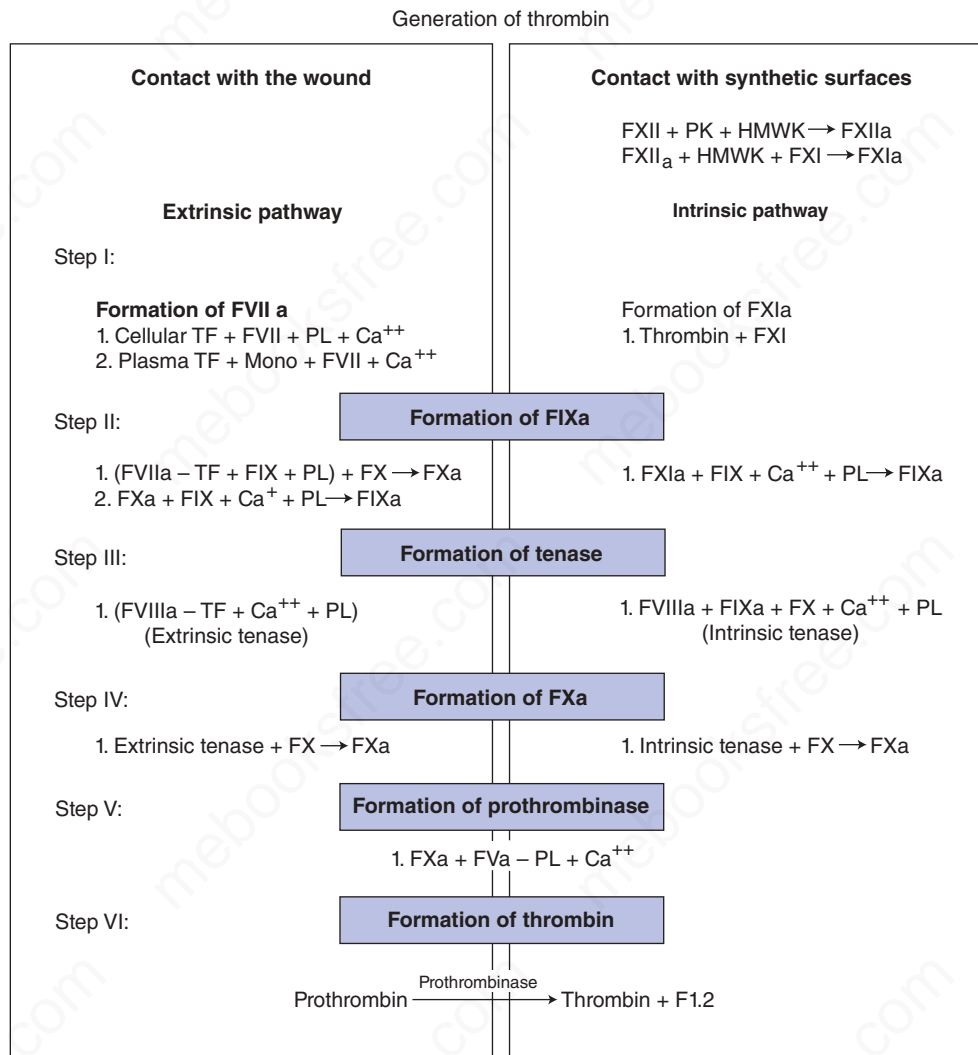

thrombin receptor and thus may be the major agonist for platelets both in the wound and in the perfusion circuit. Thrombin also activates factor XIII to cross-link fibrin to an insoluble form and attenuate fibrinolysis.

Thrombin also stimulates the production of anticoagulants. Surface glycosaminoglycans, such as heparan sulfate, inhibit thrombin and coagulation via antithrombin. Thrombin stimulates endothelial cells to produce tissue plasminogen activator, t-PA, which is the major enzyme that cleaves plasminogen to plasmin, and initiates fibrinolysis.

### THROMBIN GENERATION DURING EXTRACORPOREAL PERFUSION

All applications of ECP and exposure of blood to nonendothelial cell surfaces generate thrombin.<sup>217</sup> F1.2 is a protein fragment that is formed when prothrombin is cleaved to

thrombin; thus F1.2 is a measure of thrombin generation but not of thrombin activity. F1.2 and thrombin-antithrombin (TAT) complex increase progressively during clinical cardiac surgery with CPB, during applications of circulatory assist devices<sup>255</sup> and during extracorporeal life support (ECLS) (Fig. 13-13). The amount of thrombin produced seems to vary with the intensity of the stimuli for thrombin production and may vary with age, comorbid disease, and clinical health of the patient. Complex cardiac surgery that requires several hours of CPB produces more F1.2 than short procedures with minimal exposure of circulating blood to the wound.<sup>256</sup> Thrombin generation varies with the amount and type of anticoagulant used; surface area of the blood-biomaterial interface; duration of exposure to the surface; turbulence, stagnation, and cavitation within perfusion circuits; and to a lesser degree temperature and the “thromboresistant” characteristics of biomaterial surfaces.<sup>257</sup>

**FIGURE 13-13** Steps in the generation of thrombin in the wound and in the perfusion circuit via the extrinsic, intrinsic, and common coagulation pathways. PK, prekallikrein; HMWK, high-molecular-weight kininogen; Ca<sup>2+</sup>, calcium ion; PL, cellular phospholipid surface; TF, tissue factor; Mono, monocyte. Activated coagulation proteins are indicated by the suffix -a.

For many years blood contact with the biomaterials of the perfusion circuit was thought to be the major stimulus to thrombin formation during CPB and OHS. Increasing evidence indicates that the wound is the major source of thrombin generation during CPB and clinical cardiac surgery. This understanding has encouraged development of strategies to reduce the amounts of circulating thrombin during clinical cardiac surgery by either discarding wound blood<sup>258</sup> or exclusively salvaging red cells by centrifugation and washing in a cell saver. The reduced thrombin formation in the perfusion circuit has also supported strategies for reducing the systemic heparin dose during first-time coronary revascularization procedures using heparin-bonded circuits.<sup>259</sup> Although there is no good evidence that heparin-bonded circuits reduce thrombin generation, there is strong evidence that discarding wound plasma or limiting exposure of circulating blood to the wound (eg, less bleeding in the wound) does reduce the circulating thrombin burden.<sup>260</sup>

## Cellular Procoagulants and Anticoagulants

### PLATELETS

Platelets are activated by thrombin, contact with the surface of nonendothelial cells, heparin, and platelet-activating factor produced by a variety of cells during all applications of extracorporeal perfusion and/or recirculation of anticoagulated blood that has been exposed to a wound. Circulating thrombin and platelet contact with surface-adsorbed fibrinogen in the perfusion circuit are probably the earliest and strongest agonists. Circulating thrombin, although rapidly inhibited by antithrombin, is a powerful agonist and binds avidly to two specific thrombin receptors on platelets: PAR-1 and GPIb  $\alpha$ .<sup>261</sup> As CPB continues, complement, plasmin, hypothermia, epinephrine, and other agonists also activate platelets and contribute to their loss and dysfunction.

The initial platelet reaction to agonists is shape change. Circulating discoid platelets extend pseudopods, centralize granules, express GPIb and GPIIb/IIIa receptors,<sup>262</sup> and secrete soluble and bound P selectin receptors from alpha granules.<sup>263</sup> GPIIb/IIIa ( $\alpha_{IIb} \beta_3$ ) receptors almost instantaneously bind platelets to exposed binding sites on the  $\alpha$ - and  $\gamma$ -chains on surface-adsorbed fibrinogen (Fig. 13-14),<sup>264</sup> but the rough surfaces accumulate more platelets than smooth surfaces. Platelet adhesion and aggregate formation reduce the circulating platelet count, which is already reduced by dilution with pump priming solutions.

Plasma fibrinogen forms bridges between platelets expressing GPIIb/IIIa receptors to produce circulating platelet aggregates. Platelet bound P-selectin binds platelets to monocytes and neutrophils to form aggregates.<sup>265</sup> During ECP the circulating platelet pool is reduced by dilution, adhesion, aggregation, destruction, and consumption. The platelet mass consists of a reduced number of morphologically normal platelets, platelets with pseudopod formation, new and larger platelets released from megakaryocytes, partially and completely degranulated platelets. Most of the circulating platelets appear structurally normal, but bleeding times increase and remain prolonged for several hours after protamine.<sup>266</sup> The functional state of the circulating intact platelet during and early after CPB is reduced, but it is not clear whether this functional defect is intrinsic or extrinsic to the platelet. Flow cytometry studies of circulating intact platelets show little change in platelet membrane receptors.<sup>267</sup>

### MONOCYTES

In the wound with calcium present, monocytes associate with plasma TF to rapidly accelerate the conversion of factor VII to factor VIIa.<sup>268</sup> This association is specific for monocytes as the reaction is essentially nil for platelets, neutrophils, and lymphocytes—and does not occur if monocytes, plasma TF, or factor VII is not present. The major sources of TF in the

**FIGURE 13-14** Adhesion of activated platelets binding to surface-adsorbed fibrinogen via GPIIb/IIIa ( $\alpha_{IIb} \beta_3$ ) receptors. The same receptors bind plasma fibrinogen molecules to form platelet aggregates.

wound are the combination of monocytes, plasma TF, and cell-bound TF.

## Endothelial Cells

Endothelial cells, charged with maintaining the fluidity of circulating blood and the integrity of the vascular system, are activated during CPB and clinical cardiac surgery by thrombin, C5a, IL-1, and TNF- $\alpha$ .<sup>269</sup> Endothelial cells produce both procoagulants and anticoagulants. Procoagulant activities of endothelial cells include expression of TF and production of a host of procoagulant proteins.<sup>270</sup> Anticoagulant activities of endothelial cells include the production of tissue plasminogen activator (t-PA), heparin sulfate, TF inhibitor protein, prostacyclin, nitric oxide, and adenosine.<sup>271</sup>

## Fibrinolysis

Circulating thrombin activates endothelial cells to produce tissue plasminogen activator (t-PA), which binds avidly to fibrin.<sup>272</sup> Endothelial cells are the principal source of t-PA.<sup>273</sup> The combination of t-PA, fibrin, and plasminogen cleaves plasminogen to plasmin; plasmin cleaves fibrin. This reaction produces the protein fragment, D-dimer, which is a useful marker of fibrinolysis, and a marker of thrombin activity because fibrin is cleaved from fibrinogen by thrombin.<sup>274</sup>

Fibrinolysis is controlled by native protease inhibitors,  $\alpha$ 2-antiplasmin,  $\alpha$ 2-macroglobulin, and plasminogen activator inhibitor-1.<sup>274</sup> Alpha 2-antiplasmin rapidly inhibits unbound plasmin, preventing the enzyme from circulating, but poorly inhibits plasmin bound to fibrin.

## Consumptive Coagulopathy

Simultaneous and ongoing thrombin formation and fibrinolysis are by definition a consumptive coagulopathy<sup>275</sup> and is present in all applications of ECP. In the normal state the fluidity of blood and the integrity of the vascular system are established and maintained by an equilibrium between procoagulants favoring clot and anticoagulants favoring liquidity (Fig. 13-15A). Blood contact with ECP systems and the wound disrupts this equilibrium to produce a massive procoagulant stimulus that overwhelms natural anticoagulants; therefore, an exogenous anticoagulant, heparin, is required for nearly all applications of ECP (Fig. 13-15B). Exceptions are only possible in applications that produce a relatively weak procoagulant stimulus and a minimal thrombin burden that can be contained by natural anticoagulants. Surgeons must realize that any blood exposure to nonendothelial cell surfaces, including prosthetic heart valves, produces a procoagulant stimulus whether or not a clot is produced. Except for the healthy endothelial cell, no nonthrombogenic surface exists.

This concept of an equilibrium between procoagulants and anticoagulants is helpful in managing the thrombotic and bleeding complications associated with all applications of ECP. During ECP procoagulant stimuli, manifested by thrombin formation that is not measurable in real time, must

**FIGURE 13-15** (A) The balance between procoagulant and anticoagulant forces that produces an equilibrium allows blood to circulate. (B) During CPB and OHS (open heart surgery) the normal equilibrium is disturbed by changes in both procoagulants and anticoagulants. Imbalance of procoagulants risks thrombosis; an imbalance of anticoagulants risks bleeding.

be balanced by *either* increased anticoagulation or a reduction in the thrombin burden to maintain equilibrium. After ECP, anticoagulants must be inhibited to avoid excessive bleeding. During consumptive coagulopathy, coagulation proteins and platelets are consumed and may become too deficient to generate thrombin and fibrin-platelet clots. In cardiac surgical patients many additional variables affect the coagulation equilibrium and impact the availability of coagulation proteins and functional platelets. These variables include the quantity of blood in contact with the wound; surface area of the perfusion system; duration of perfusion; circulating anticoagulants; and to lesser degrees temperature and the rheology and biomaterials of the perfusion system. Patient factors also affect the coagulation equilibrium; these include age, infection, history or presence of cardiogenic shock, massive blood losses and transfusions, platelet coagulation deficiencies, fibrinolysis, liver disease, cachexia, reoperation, and hypothermia.

## Management of Bleeding

The cornerstone of bleeding management is meticulous surgical hemostasis during all phases of an operation. The surgical techniques, topical agents, and customary drugs used do not need reiteration for trained surgeons. Most cardiac surgical operations involving CPB are accompanied by net blood losses between 200 and 600 mL. Reoperations; complex procedures; prolonged (>3 hours) CPB; and patient factors listed above may be associated with excessive and ongoing blood losses. Most surgeons use an antifibrinolytic, such as

tranexamic acid or epsilon amino caproic acid, to reduce fibrinolysis in prolonged or complex operations. Problem patients who bleed excessively after heparin neutralization require an attempt to rebalance procoagulants and anticoagulants to near normal, pre-CPB concentrations.

The most useful tests in the operating room are an ACT or a protamine titration test to assess the presence of heparin; prothrombin time to uncover deficiency in the extrinsic coagulation pathway; and platelet count. If heparin is neutralized, the partial thromboplastin time may be measured to assess possible deficiency of coagulation proteins. Other tests such as measurements of fibrinogen, template bleeding time, and the thromboelastograph are controversial and/or difficult to obtain. Platelet counts below 80,000 to 100,000/ $\mu\text{L}$  should initiate platelet transfusions in bleeding patients, except those with IgG anti-H-PF4 antibodies, to add functioning platelets to the mass of partially dysfunctional platelets.

Measurements of F1.2 and D-dimer are two tests that can be very helpful and probably should be made available on an emergency basis in hospitals that perform complex procedures and offer mechanical circulatory and respiratory assistance. F1.2 measures thrombin formation by factor Xa, and if absent or low, there may be a deficiency in the concentrations of coagulation proteins; fresh-frozen plasma is needed. If F1.2 and D-dimer (a measurement of fibrinolytic activity) are both elevated, thrombin is being formed and an antifibrinolytic (tranexamic acid or epsilon amino caproic acid) is needed to neutralize plasmin. If both markers or F1.2 remain elevated

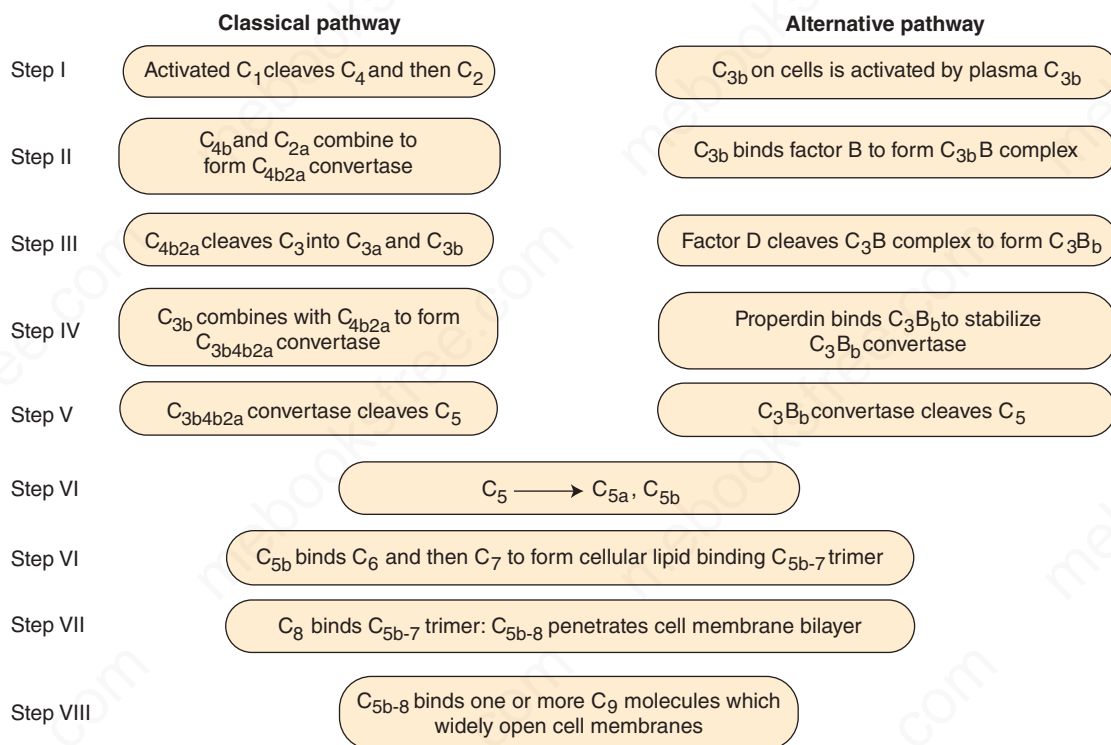

after the antifibrinolytic drug, this indicates continuing thrombin generation, and the cause (eg, infection usually) should be aggressively treated with antibiotics. Some thrombin is needed to stop bleeding, but excessive thrombin production feeds the consumptive coagulopathy. As with diffuse intravascular coagulopathy,<sup>275</sup> no guaranteed therapeutic recipe is known; success requires patience, persistence, and judicious use of platelets, antifibrinolytics, specific clotting factors, and replacement transfusions to rebalance the coagulation equilibrium at near normal concentrations of the constituents.

## THE INFLAMMATORY RESPONSE

### Primary Blood Constituents

#### COMPLEMENT

The complement system constitutes a group of more than 30 plasma proteins that interact to produce powerful vasoactive anaphylatoxins, C3a, C4a, and C5a, and the terminal complement cytotoxic complex, C5b-9.<sup>276</sup> Complement is activated by three pathways, but only the classical and alternative pathways are involved in CPB. Direct contact between heparinized blood and the synthetic surfaces of the ECP circuit activates the contact plasma proteins and the classical complement pathway. Activation of C1, possibly by activated factor XIIa, sequentially activates C2 and C4 to form C4b2a (classical C3 convertase) that cleaves C3 to form C3a and C3b (Fig. 13-16).

**FIGURE 13-16** Steps in activation of the classical and alternative complement pathways and formation of the membrane attack complex, C5b-9. (Data from Walport MJ: Complement. *NEJM* 2001; 344:1058; and Volkankis JE, Frank ME: *The Human Complement System in Health and Disease*. New York: Marcel Dekker; 1998.)

Generation of C3b activates the alternative pathway, which involves factors B and D in the formation of C3bBb, which is the alternative pathway C3 convertase that cleaves C3 to form C3a and C3b (see Fig. 13-16). Whereas the classical pathway proceeds in sequential steps, the alternative pathway contains a feedback loop that greatly amplifies cleavage of C3 by membrane-bound C3 convertase to membrane-bound C3b and C3a. During CPB complement is largely activated by the alternative pathway.<sup>277</sup>

The complement system is activated at three different times during CPB and cardiac surgery: during blood contact with nonendothelial cell surfaces<sup>278</sup> and wound exudate-containing tissue factor<sup>279</sup>; after protamine administration and formation of the protamine-heparin complex<sup>280</sup>; and after reperfusion of the ischemic, arrested heart.<sup>281</sup> CPB and myocardial reperfusion activate complement by both the classical and alternative pathways; the heparin-protamine complex activates complement by the classical pathway.

The two C3 convertases effectively merge the two complement pathways by producing C3b, which activates C5 to C5a and C5b (see Fig. 13-16). C3a and C5a are potent vasoactive anaphylatoxins. C5a, which avidly binds to neutrophils and therefore is difficult to detect in plasma, is the major agonist. C3b acts as an opsonin, which binds target cell hydroxyl groups and renders them susceptible to phagocytic cells expressing specific receptors for C3b.<sup>282,283</sup> C5b is the first component of the terminal pathway that ultimately leads to formation of the membrane attack complex, C5b-9. In prokaryotic cells like erythrocytes, C5b-9 creates transmembrane pores, which cause death by intracellular swelling after loss of the intracellular/interstitial osmotic gradient. In eukaryotic cells, deposits of C5b-9 may not be immediately lethal but may eventually cause injury mediated by release of arachidonic acid metabolites (thromboxane A2, leukotrienes) and oxygen free radicals by macrophages and neutrophils, respectively.<sup>284</sup>

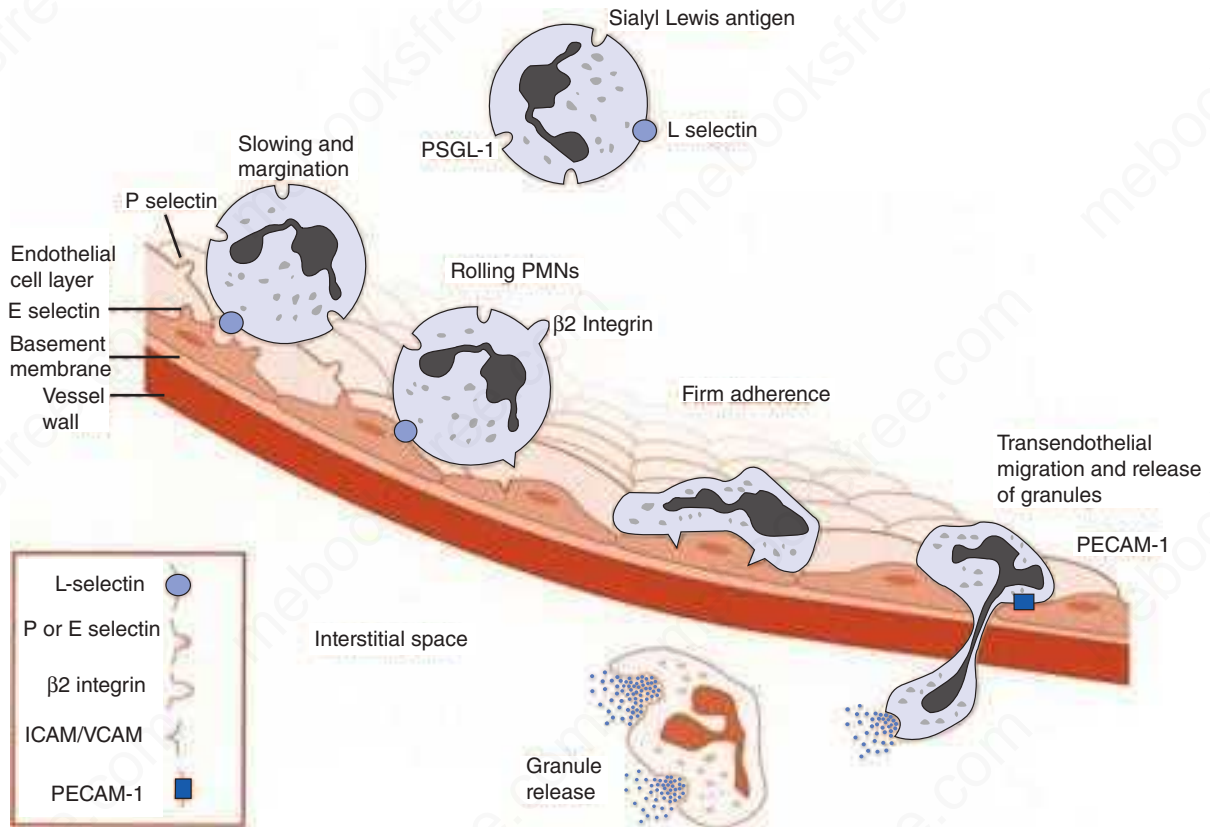

## NEUTROPHILS

Neutrophils are strongly activated during CPB (Fig. 13-17).<sup>285</sup> The principal agonists are kallikrein and C5a produced by the contact and complement systems. Neutrophils are recruited to localized areas of injury or inflammation by chemokines, complement proteins (C5a), IL-1 $\beta$ , TNF- $\alpha$ , and adhesion molecules. During CPB thrombin stimulates endothelial cell production of platelet activating factor (PAF).<sup>286</sup> Thrombin and PAF cause rapid expression of P-selectin by endothelial cells.<sup>287</sup> Regional vasoconstriction mediated by PAF reduces blood flow rates within local vascular beds to allow neutrophils to marginate near endothelial cell surfaces. P-selectin weakly binds to neutrophils<sup>288</sup>; selectin binding causes the slowly passing neutrophils to roll and eventually stop (Fig. 13-18).<sup>289</sup> Stronger adherence is produced by intracellular adhesion molecule-1 (ICAM-1) expressed on endothelial cells, which binds  $\beta$ 2 neutrophil integrins, principally CD11b/CD18. These adhesion molecules from the immunoglobulin superfamily completely stop neutrophils and the process of transmigration begins in response to chemoattractants and cytotoxins produced in the extravascular space.<sup>290</sup> This trafficking is strongly regulated by IL-8 produced by neutrophils, macrophages, and other cells.<sup>291</sup>

Using pseudopods and following the scent of complement proteins (C5a, C3b) and IL-8, neutrophils arrive at the scene of inflammation to begin the process of phagocytosis and release of cytotoxins. Organs and tissues experience periods of ischemia followed by reperfusion (lung, heart, brain) during CPB, and as a result express adhesion receptors and reactive oxidants, and are sources of neutrophil chemoattractants.<sup>292</sup> Neutrophils vary considerably among individuals in expression of adhesive receptors<sup>293</sup> and responsiveness to chemoattractants during CPB. The presence of diabetes, oxidative stress, and perhaps genetic factors (see the following) influences expression of cellular and soluble adhesive receptors and cytokines, which affect neutrophil adhesion and release

**FIGURE 13-17** Scanning electron micrographs of resting neutrophils (*left*) and 5 seconds after exposure to a chemoattractant. (Reproduced with permission from Baggiolini M: Chemokines and leukocyte traffic, *Nature* 1998 Apr 9;392(6676):565-568.)

**FIGURE 13-18** Mechanism of arrest and transmigration of neutrophils into the interstitial space. Neutrophils constitutively express L-selectin, which binds to endothelial cell glycoprotein ligands. Simultaneously, early response cytokines stimulate endothelial cells to rapidly express P-selectin and later E-selectin receptors, which weakly bind neutrophil PSGL-1 ligands. Marginated neutrophils, which are slowed by local vasoconstriction and reduced blood flow, lightly adhere to endothelial cells via selectin expression and begin to roll. Neutrophils activated by C5a, kallikrein, and early response cytokines express  $\beta 2$  CD11b and c receptors, which bind firmly to cytokine-activated endothelial cell intergrins, ICAM-1, and VCAM-1. Once arrested, L-selectins are shed and PECAM receptors on endothelial cell surfaces mediate neutrophil transmigration through endothelial cell junctions, led by chemoattractants into the interstitial space.

of granule contents. Neutrophils contain a potent arsenal of proteolytic and cytotoxic substances. Azurophilic granules contain lysozyme, myeloperoxidase, cationic proteins, elastase, and collagenases.<sup>294</sup> Activated neutrophils, in a “respiratory burst,” also produce cytotoxic reactive oxygen and nitrogen intermediates including superoxide anion, hydrogen peroxide, hydroxyl radicals, singlet oxygen molecules. Finally, neutrophils produce arachidonate metabolites, prostaglandins, leukotrienes, and platelet-activating factor. During CPB these vasoactive and cytotoxic substances are produced and released into the extracellular environment and circulation. Circulation of these substances mediates many of the manifestations of the “whole body inflammatory response” or “systemic inflammatory response syndrome” (SIRS) associated with CPB and clinical cardiac surgery.<sup>295</sup>

## MONOCYTES

Monocytes and macrophages (tissue monocytes) are relatively large, long-lived cells that are involved in both acute and chronic inflammation. Monocytes respond to chemical signals, are mobile, phagocytize microorganisms and cell

fragments, produce and secrete chemical mediators, participate in the immune response, and generate cytotoxins.<sup>296</sup> Monocytes are activated during CPB and have a major role in thrombin formation. Monocytes also produce and release many inflammatory mediators during acute inflammation, including proinflammatory cytokines, reactive oxygen and nitrogen intermediates, and prostaglandins.

## ENDOTHELIAL CELLS

Endothelial cells are activated during CPB and OHS by a variety of agonists.<sup>297</sup> The principal agonists for endothelial cell activation during CPB are thrombin, C5a, and the cytokines IL-1 $\beta$  and TNF- $\alpha$ . IL-1 $\beta$  and TNF- $\alpha$  induce the early expression of P-selectin and the later synthesis and expression of E-selectin, which are involved in the initial stages of neutrophil and monocyte adhesion. The two cytokines also induce expression of ICAM-1 and Vascular Cell Adhesion Molecule-1 (VCAM-1), which firmly bind neutrophils and monocytes to the endothelium and initiate leukocyte trafficking to the extravascular space (see Fig. 13-18). Experimentally ICAM-1 is upregulated during CPB in pulmonary vessels<sup>298</sup> and there

is evidence that selectins are upregulated during CPB and in myocardial ischemia-reperfusion sequences. IL-1 $\beta$  and TNF- $\alpha$  induce endothelial cell production of the chemotactic proteins IL-8 and MCP-1, and induce production of PGI<sub>2</sub> (prostacyclin) by the cyclooxygenase pathway and NO by NO synthase. These two vasodilators reduce shear stress and increase vascular permeability and therefore enhance leukocyte adhesion and transmigration.

### PLATELETS

Platelets are probably initially activated during CPB by thrombin, which is the most potent platelet agonist. Plasma epinephrine, PAF, vasopressin, from other cells, and internally generated thromboxane A<sub>2</sub> contribute to activation as CPB continues. Platelets possess several protease-activated receptors to most of these agonists and to collagen, which has an important role in adhesion and thrombus formation. Platelets contribute to the inflammatory response by synthesis and release of eicosanoids<sup>299</sup>; serotonin from dense granules; chemokines; and other proteins.<sup>300</sup> Platelets also produce and release acid hydrolases from membrane-bound lysosomes. Platelet-secreted cytokines may be particularly involved in the inflammatory response to CPB because of strong activation of platelets in both the wound and perfusion circuit.

## Other Mediators of Inflammation

### ANAPHYLATOXINS

The anaphylatoxins C3a, C4a, and C5a are bioactive protein fragments released by cleavage of complement proteins C3, C4, and C5. These fragments have potent proinflammatory and immuno-regulatory functions and contract smooth muscle cells, increase vascular permeability, serve as chemoattractants, and in the case of C5a, activate neutrophils and monocytes.<sup>301</sup> Anaphylatoxins contribute to increased

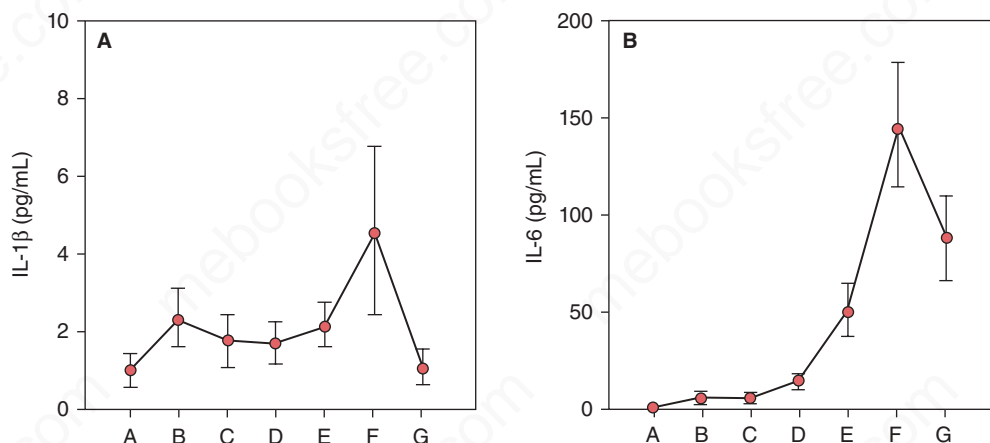

pulmonary vascular resistance, edema, and neutrophil sequestration and an increase in extravascular water during CPB. The duration of postoperative ventilation directly correlates with plasma C3a concentrations.<sup>302</sup> C3a and C5a are important mediators in ischemia/reperfusion injuries.

### CYTOKINES

Cytokines are small, cell-signaling peptides produced and released into blood or the extravascular environment by both blood and tissue cells. Cytokines stimulate specific receptors on other cells to initiate a response in that cell. All blood leukocytes and endothelium produce cytokines, but many tissue cells including fibroblasts, smooth muscle cells, and cardiac monocytes also produce cytokines.<sup>303</sup> IL-1 $\beta$  and TNF- $\alpha$  are early response cytokines that are produced by macrophages. These proteins stimulate surrounding cells to produce chemokines. The main anti-inflammatory cytokine observed during CPB is IL-10, which inhibits the production of chemokines from leukocytes.<sup>304</sup> Proinflammatory cytokines increase during and after cardiac surgery using CPB with peak concentrations occurring 12 to 24 hours after CPB<sup>305</sup> (Fig. 13-19). Some of the variation in measurements between studies also may be caused by patient factors such as age, left ventricular function, and genetic factors.<sup>306</sup>

### REACTIVE OXIDANTS

Neutrophils, monocytes, and macrophages produce reactive oxidants, which are cytotoxic inside the phagosome, but act as cytotoxic mediators of acute inflammation outside. Four enzymes generate a large menu of reactive oxidants: NADPH (nicotinamide adenine dinucleotide phosphate) oxidase, super-oxide dismutase, nitric oxide synthase, and myeloperoxidase.<sup>307</sup> The four products produced by these enzymes, O<sub>2</sub>, H<sub>2</sub>O<sub>2</sub>, NO, and HOCL, generate all reactive oxidants from nonenzymatic reactions with other molecules or ions.

**FIGURE 13-19** Changes in IL-1 $\beta$  (A) and IL-6 (B) in 30 patients who had elective first-time myocardial revascularization. Letters on x-axis represent the following events: (A) induction of anesthesia; (B) 5 minutes after heparin; (C) 10 minutes after starting CPB; (D) end of CPB; (E) 20 minutes after protamine; (F) 3 hours after CPB; (G) 24 hours after CPB. (Adapted with permission from Steinberg JB, Kapelanski DP, Olson JD, et al: Cytokine and complement levels in patients undergoing cardiopulmonary bypass, *J Thorac Cardiovasc Surg.* 1993 Dec;106(6):1008-1016.)

## ENDOTOXINS

Endotoxins, including lipopolysaccharides, and fragments of bacteria that are powerful agonists for complement, neutrophils, monocytes, and other leukocytes.<sup>308</sup> Endotoxins have been detected during CPB and after aortic cross-clamping.<sup>309</sup> Sources include contaminants within sterilized infusion solutions, the bypass circuit, and possibly the gastrointestinal tract owing to changes in microvascular intestinal perfusion, which may translocate bacteria.<sup>310</sup>

## METALLOPROTEINASES

CPB induces the synthesis and release of matrix metalloproteinases,<sup>311</sup> which are one of the four major classes of mammalian proteinases. These proteolytic enzymes have a major role in degradation of collagens and proteins in the pathogenesis of atherosclerosis and postinfarction left ventricular remodeling. The significance and possible injury produced by activation of these interstitial degradation enzymes over the long term remain to be determined.

## Control of the Acute Inflammatory Response to Cardiopulmonary Bypass

### OFF-PUMP CARDIAC SURGERY

Myocardial revascularization without either CPB or cardioplegia reduces the acute inflammatory response, but does not prevent it.<sup>312</sup> The response to surgical trauma, myocardial ischemia, manipulation of the heart, pericardial suction, heparin, protamine, other drugs, and anesthesia activates the extrinsic clotting system and produces an increase in the markers of acute inflammation, C3a, C5b-9, proinflammatory cytokines (TNF- $\alpha$ , IL-6, IL-9), neutrophil elastase, and reactive oxidants, but the magnitude of the response is significantly less than that observed with CPB.<sup>313</sup> Although it has not been shown that the attenuated acute inflammatory response directly reduces organ dysfunction, elderly patients,

and those with reduced renal and pulmonary function often tolerate off-pump surgery with less morbidity and mortality than patients treated with CPB.<sup>314</sup>

## PERFUSION TEMPERATURE

Release of mediators of inflammation is temperature sensitive. Normothermic CPB increases the release of cytokines and other cellular and soluble mediators of inflammation,<sup>312</sup> whereas hypothermia reduces production and release of these mediators until rewarming begins.<sup>315</sup> Perfusion at tepid temperatures between 32 and 34°C is a reasonable compromise for many operations requiring 1 to 2 hours of CPB.<sup>316</sup>

## PERFUSION CIRCUIT COATINGS

Ionic- or covalent-bonded heparin perfusion circuits are the most widely used surface coatings and are often combined with reduced doses of systemic heparin in first-time myocardial revascularization patients.<sup>317</sup> It is well established that heparin is an agonist for platelets, complement, factor XII, and leukocytes, but there is no reproducible evidence that heparin coating either produces a nonthrombogenic surface or reduces activation of the clotting cascade.<sup>318</sup> Clinical trials that have combined heparin-coated circuits with reduced systemic heparin and exclusion of field-aspirated blood from the perfusion circuit have demonstrated significant clinical benefits<sup>319</sup> (Fig. 13-20). New surface coatings are being developed or undergoing clinical studies.<sup>320</sup> In clinical trials these surface coatings significantly reduced platelet loss and granule release, and reduced markers of thrombin generation.<sup>320,321</sup> PMEA (poly-2-methylethylacrylate) is another manufactured surface coating designed to reduce surface adsorption of plasma proteins. Laboratory studies show reduced surface adsorption of fibrinogen and reduced bradykinin and thrombin generation in pigs.<sup>321</sup> Clinical studies show significant reductions in C3a, C4D, and neutrophil elastase, but ambivalent effects on IL-6 and platelets.<sup>322</sup>

**FIGURE 13-20** Changes in C5b-9 (TCC) terminal complement complex in heparin coated ( $n = 15$ ) and uncoated ( $n = 14$ ) perfusion circuits during myocardial revascularization. The two curves are significantly different by ANOVA ( $p = .004$ ). (Reproduced with permission from Videm V, Mollnes TE, Fosse E, et al: Heparin-coated cardiopulmonary bypass equipment. I. Biocompatibility markers and development of complications in a high-risk population, *J Thorac Cardiovasc Surg*. 1999 Apr;117(4):794-802.)

## MODIFIED ULTRAFILTRATION

Modified ultrafiltration to remove intravascular (and extravascular) water and inflammatory substances has produced improved results in adults and children.<sup>323,324</sup> Dialysis during CPB in adults may be beneficial in removing water, potassium, and protein wastes in patients with renal insufficiency.

## COMPLEMENT INHIBITORS

The sequential activation cascade with convergence of the classical and alternative pathways at C3 offers many opportunities for inhibition by recombinant proteins. Using a humanized, recombinant antibody to C5 (h5G1.1-scFv), Fitch et al. demonstrated that generation of C5b-9 was completely blocked in a dose-response manner (Fig. 13-21) and that neutrophil and monocyte CD11b/CD18 expression was attenuated in patients during and for several hours after clinical cardiac surgery using CPB.<sup>325</sup> Large-scale clinical trials

**FIGURE 13-21** Inhibition of C5b-9, complement terminal attack complex, with placebo (solid circles) and 2 µg/kg of h5G1.1-scFv (open circles) during clinical cardiac surgery with CPB. Letters on x-axis represent the following events: (A) before heparin; (B) 5 minutes after drug; (C) 5 minutes after cooling to 28°C; (D) after beginning rewarming; (E) 5 minutes after reaching 32°C; (F) 5 minutes after reaching 37°C; (G) 5 minutes after CPB; (H) 2 hours after CPB; (I) 12 hours after CPB; (J) 24 hours after CPB. HcG1.1-scFv completely inhibited formation of the C5b-9 terminal attack complex. (Data from Fitch JC, Rollins S, Matis L, et al: Pharmacology and biological efficacy of a recombinant, humanized, single-chain antibody C5 complement inhibitor in patients undergoing coronary artery bypass graft surgery with cardiopulmonary bypass, *Circulation*. 1999 Dec 21-28;100(25):2499-2506.)

that have followed have shown significant improvements in morbidity and mortality.<sup>326</sup>

Other complement recombinant protein inhibitors have been developed and are under active investigation because of the importance of this plasma protein system in CPB, ischemia/reperfusion, and injuries that summon the acute inflammatory response. Although any effective and safe inhibitor is welcome, C3 may be a better target for inhibition because both activation pathways are blocked at the point of convergence and because C3 concentrations in plasma are 15 times greater than C5.<sup>327</sup>

## GLUCOCORTICOIDS

Many investigators have used glucocorticoids to suppress the acute inflammatory response to CPB and clinical cardiac surgery, but beneficial effects in adult patients have been inconsistent.<sup>328</sup> Steroids reduce release of rapid-response cytokines, TNF-α, and IL-1β from macrophages, enhance release of IL-10, and suppress expression of endothelial cell selectins and neutrophil integrins.<sup>329</sup> Clinical results from a few randomized trials are conflicting: One study observed earlier extubation and reduced shivering,<sup>330</sup> but another found increased blood glucose levels and delayed extubation.<sup>331</sup> A recent large meta-analysis found that low-dose corticosteroids reduced atrial fibrillation incidence, and decreased ICU and hospital length of stay without increasing infectious complications.<sup>332</sup>

## ORGAN DAMAGE

Cardiopulmonary bypass can preempt normal reflex and chemoreceptor control of the circulation, initiate coagulation, activate blood cells, release circulating cell-signaling proteins, generate vasoactive and cytotoxic substances, and produce a variety of microemboli. Venous pressure can be elevated, plasma colloid osmotic pressure is reduced, flow is nonpulsatile, and temperature is manipulated. Tissues and organs may suffer from regional malperfusion that is independent of physiologic controls, and is caused by microemboli, increased interstitial water, and perfusion with a variable amount of cytotoxic substances. Reversible and irreversible cell injury may occur, but damage is diffusely distributed throughout the entire body as individual cells or small groups of cells are affected. Ischemia-reperfusion injury augments damage to the heart and on occasion to other organs. Amazingly, the body is able to withstand and for the most part repair the cellular damage, although some abnormalities may appear later. This section summarizes the reversible and permanent organ damage produced by CPB and complements the preceding two sections of this chapter and the chapter on ischemia and reperfusion (see Chapter 3).

## Mechanisms

Cardiac output during CPB is carefully monitored and synchronized with temperature and hemoglobin concentration

to ensure that the entire body is adequately supplied with oxygen (see earlier section on ECP systems). Excessive hemodilution reduces oxygen delivery,<sup>333</sup> and hemoglobin concentrations significantly below 8 g/L cause organ dysfunction at temperatures above 30°C.<sup>334</sup> However, regional hypoperfusion is not monitored; is independent of reflex and chemoreceptor controls; and is influenced by the inflammatory response, which produces circulating vasoactive substances. Regional perfusion is also influenced by acid-base relationships during cooling and may affect postoperative organ function. Alpha-stat management (pH increases during cooling) decreases cerebral perfusion during hypothermia; pH stat (pH 7.40 is maintained by adding CO<sub>2</sub>) improves organ perfusion but may increase embolic injury.<sup>335</sup> Temperature differences within the body and within organs produce regional temperature-perfusion mismatch,<sup>336</sup> which can precipitate regional hypoperfusion and acidosis caused by inadequate oxygen delivery.

The inflammatory response produces the cytotoxic compounds and activated neutrophils and monocytes that can and do destroy organ and tissue cells. These agents directly access the specialized cells of every organ by passing between endothelial cell junctions to reach the interstitial compartment. Reduced plasma colloid osmotic pressure, elevated venous pressure, and widened endothelial cell junctions<sup>337</sup> increase the volume of the interstitial space during CPB in proportion to the duration of bypass, magnitude of the dissection, transfusions, and other factors. In prolonged complicated perfusions the interstitial compartment may increase 18 to 33%,<sup>338</sup> but intracellular water does not increase during CPB.

Microemboli are defined as particles less than 500 μm in diameter. They enter the circulation during CPB from a variety of sources.<sup>339</sup> Table 13-2 summarizes sources of gas, foreign, and blood-generated microemboli, which are more fully discussed earlier. Air entry into the perfusion circuit produces the most dangerous gas emboli because nitrogen is poorly soluble in blood and is not a metabolite. Carbon dioxide is rapidly soluble in blood and is sometimes used to flood the surgical field to displace air. Foreign emboli, largely generated in the surgical wound, reach the circulation from the surgical field via the cardiomy reservoir. The cardiomy reservoir is the primary source of foreign emboli and the major source of blood-generated emboli, particularly fat emboli.<sup>340</sup> Extensive activation and physical damage to blood elements produce a wide variety of emboli, which tend to increase with the duration of perfusion.<sup>335</sup>

## Strategies for Reducing Microemboli

Although discussed in earlier sections, the principal methods for reducing circulating microemboli deserve emphasis and include the following: adequate anticoagulation; membrane oxygenator; washing blood aspirated from the surgical wound<sup>341</sup>; filtering the cardiomy reservoir; secure pursestring sutures around cannulas; strict control of all air entry sites within the perfusion circuit; removal of residual

**TABLE 13-5: Minimizing Microemboli**

Membrane oxygenator, centrifugal arterial pump
Cardiomy reservoir filter (≤40 μm)
Arterial line filter/bubble trap (≤40 μm)
Keep temperature differentials ≤8-10 °C
Prime with carbon dioxide flush; recirculate with saline and filter (5 μm)
Prevent air entry into the circuit
Snug purse-string sutures
Three-way stopcocks on all sampling ports
Meticulous syringe management
Adequate cardiomy reservoir volume (for debubbling)
Avoid excessive suction on vents
One-way valved purge lines for bubble traps
Use transesophageal echocardiography to locate trapped intracardiac air; de-air thoroughly
Wash blood aspirated from the surgical field
Prevent thrombus formation with adequate anticoagulation
Assess inflow cannulation site by epi-aortic ultrasound imaging
Cannulate distal aorta or axillary artery
Consider use of special aortic cannulas

air from the heart and great vessels; avoidance of atherosclerotic emboli; and selective filtration of cerebral vessels (Table 13-5).<sup>342,343</sup>

Many intraoperative strategies are available to reduce cerebral atherosclerotic embolization. These include routine epicardial echocardiography of the ascending aorta to detect both anterior and posterior atherosclerotic plaques and find sites free of atherosclerosis for placing the aortic cannula.<sup>344</sup> Recently, special catheters with or without baffles or screens have been developed to reduce the number of atherosclerotic emboli that reach the cerebral circulation.<sup>345</sup> In patients with moderate or severe ascending aortic atherosclerosis a single application of the aortic clamp as opposed to partial or multiple applications is strongly recommended and has been shown to reduce postoperative neuronal and neurocognitive deficits in a large clinical series.<sup>346</sup> Retrograde cardioplegia is preferred over antegrade cardioplegia in these patients to avoid a sandblasting effect of the cardioplegic solution.<sup>347</sup> No aortic clamp may be safe or even possible in some patients with severe atherosclerosis or porcelain aorta. If intracardiac surgery is required in these patients, deep hypothermia may be used with or without graft replacement of the ascending aorta. If only revascularization is needed, pedicled single or sequential arterial grafts,<sup>348</sup> T or Y grafts from a pedicled mammary artery,<sup>349</sup> or vein grafts anastomosed to arch vessels can be used.

In-depth or screen filters are essential for cardiomy reservoirs and are usually used in arterial lines. The efficacy of arterial line filters is controversial because screen filters with a pore size less than 20 microns cannot be used because of flow resistance across the filter. However, air and fat emboli can pass through filters although 20 micron screen filters more effectively trap microemboli than larger sizes.<sup>350</sup>

## Cardiac Injury

It is difficult to separate postoperative cardiac dysfunction from injury owing to CPB, ischemia/reperfusion, direct surgical trauma, the disease being treated, and maladjustment of preload and afterload to myocardial contractile function. The heart, like all organs and tissues, is subject to microemboli, protease and chemical cytotoxins, activated neutrophils and monocytes, and regional hypoperfusion during CPB before and after cardioplegia or fibrillatory arrest. However, the heart is protected from CPB for at least one half of the case when the aorta is cross-clamped. Some degree of myocardial “stunning” during the period coronary blood flow is interrupted is inevitable,<sup>351</sup> as is some degree of reperfusion injury after ischemia. Both myocardial edema and distention of the flaccid cardioplegic heart during aortic cross-clamping<sup>352</sup> reduce myocardial contractility. Lastly, if myocardial contractility is weak, excessive preload or high afterload during weaning from CPB increases ventricular end-diastolic volume, myocardial wall stress, and oxygen consumption. Thus postoperative performance of the heart depends upon many variables and not just the injuries produced by CPB.

## Neurologic Injury

The brain is the effector organ for all behavior, innate, and learned. It is the monarch of blood flow and will shut down all other vascular systems to preserve its own supply. Conversely, dysfunction in other organs can adversely affect brain function. It monitors other organ systems and is acutely sensitive and responsive to both the external and internal environment. Thus, even small injuries to the brain may produce symptomatic, functional losses that would not be detectable or important in other organs. Regional hypoperfusion, edema, microemboli, circulating cytotoxins or subtle changes in blood glucose, insulin, or calcium may result in changes in cognitive function, ranging from subtle to profound. A small 2-mm infarct may cause a disruption of behavioral patterns, physiologic and physical function changes can pass unnoticed, be accepted, and dismissed, or profoundly compromise the patient's quality of life. Move the lesion half a centimeter and the same volume lesion may result in a catastrophic stroke. Thus the brain is the most sensitive organ exposed to damage by CPB and also the organ that, with the heart, is most important to protect.

### ASSESSMENT

Routine assessment of neurologic injury that occurs in the setting of cardiac surgery is not done for most patients because of the priority of the cardiac lesion as well as costs in time and money. General neurologic examinations by members of the surgical team or individuals lacking specialized training are not adequate to rule out subtle neurologic injuries, and this is the principal reason that the incidence of stroke, or neurologic or neuropsychological injury varies widely in the surgical literature.<sup>353</sup>

The most obvious neurologic abnormalities are paresis, loss of vital brain functions such as speech, vision, comprehension, or coma. These are commonly lumped under the general heading of stroke. Disorders of awareness or consciousness can include coma, delirium, and confusion, but transitory episodes of delirium and confusion are often dismissed as caused by anesthesia or medications. More subtle losses are determined by comparison of preoperative and postoperative performances using a standard battery of neuropsychological tests prepared by a group of neuropsychologists. A neuropsychological examination is basically an extension of the neurologic examination with a much greater emphasis on higher cortical function. Dysfunction is objectively defined as a deviation from the expected, relative to a large population. For example, although performing at a 95 IQ level is in the normal range, it is low for a physician, and a search for a neurologic impairment would be triggered by such a poor performance. A 20% decline in two or more of these tests, compared with the patient's own baseline, suggests a neuropsychological deficit that should be followed until resolved or not resolved.<sup>354</sup> In studies involving long-term follow-up the inclusion of a control group of unoperated patients with the same disease and similar demographics helps define the causes of neuropsychological decline that occurs later than 3 to 6 months after surgery.<sup>355</sup>

Computed axial tomograms (CAT) or magnetic resonance imaging (MRI) scans are essential for the definitive diagnosis of stroke, delirium, or coma. Preoperative imaging is usually not necessary when new techniques such as diffusion-weighted MRI imaging, MRI spectroscopy, or MRI angiography are used to assess possible new lesions after operation.<sup>356</sup> Biochemical markers of neurologic injury after cardiac surgery are relatively nonspecific and inconclusive. Neuron-specific enolase (NSE) is an intracellular enzyme found in neurons, normal neuroendocrine cells, platelets, and erythrocytes.<sup>357</sup> S-100 is an acidic calcium-binding protein found in the brain.<sup>358</sup> The beta dimer resides in glial and Schwann cells. Both S-100 and NSE increase in spinal fluid with neuronal death and may correlate with stroke or spinal cord injury after CPB.<sup>359</sup> However, plasma levels are contaminated by aspiration of wound blood into the pump and hemolysis and are often elevated after prolonged CPB in patients without otherwise detectable neurologic injury.<sup>360</sup> Newer blood-borne biochemical markers such as Tau have been identified, but as of yet have not been shown to be diagnostic for subtle neurologic injury.

### POPULATIONS AT RISK

Advancing age increases the risk of stroke or cognitive impairment in the general population, and surgery, regardless of type, increases the risk still higher.<sup>361</sup> In 1986, Gardner and colleagues reported the risk of stroke during CABG surgery to be directly related to age.<sup>362</sup> A European study compared 321 elderly patients without surgery to 1218 patients who had noncardiac surgery and found a 26% incidence of cognitive dysfunction 1 week after operation and a 10% incidence at 3 months.<sup>363</sup> Between 1974 and 1990 the number of patients

**FIGURE 13-22** Effect of age by decade on neuropsychologic outcome after CABG. Abnormal neuropsychologic outcomes at 1 week and 1 month postoperative are more common with advancing age. Percentages of patients with deficits on two or more tests are shown ( $n = 374$ ). (Reproduced with permission from Hammon JW Jr, Stump DA, Kon ND, et al: Risk factors and solutions for the development of neurobehavioral changes after coronary artery bypass grafting, *Ann Thorac Surg* 1997 Jun;63(6):1613-1618.)

undergoing cardiac surgery over age 60 and over age 70 increased twofold and sevenfold, respectively<sup>364</sup> (Fig. 13-22). Genetic factors also influence the incidence of cognitive dysfunction after cardiac surgery.<sup>365</sup> The incidence of cognitive dysfunction at 1 week after cardiac surgery is approximately double that of noncardiac surgery.

As the age of cardiac surgical patients' increases, the number with multiple risk factors for neurologic injury also increases. Hypertension and diabetes occur in approximately 55% and 25% of cardiac surgical patients, respectively.<sup>366</sup> Fifteen percent have carotid stenosis of 50% or greater, and up to 13% have had a transient ischemic attack or prior stroke. The total number of MRI atherosclerotic lesions in the brachiocephalic vessels adds to the risk of stroke or cognitive dysfunction,<sup>367</sup> as does the severity of atherosclerosis in the ascending aorta as detected by epiaortic ultrasound scanning.<sup>368</sup> Palpable ascending aortic atherosclerotic plaques markedly increase the risk of right carotid arterial emboli as detected by Doppler ultrasound.<sup>369</sup> The incidence of severe aortic atherosclerosis is 1% in cardiac surgical patients less than 50 years old and is 10% in those aged 75 to 80.<sup>370</sup>

### MECHANISMS OF INJURY

The three major causes of neurologic dysfunction and injury during cardiac surgery are microemboli, hypoperfusion, and a generalized inflammatory reaction, which can occur in the same patient at the same time for different reasons. The vast majority of intraoperative strokes are caused by the embolization of atherosclerotic material from the aorta and brachiocephalic vessels. This occurs as a result of manipulation of the heart and major thoracic vasculature as well as dislodgement of atheromata from shearing forces directed at the walls of vessels from inflow CPB cannulae.<sup>371</sup> The use of a no-touch technique for CABG where patients with aortic atherosclerosis have no manipulation of the aorta and all arterial grafting have produced the best results in avoiding emboli.<sup>386</sup> Microemboli are distributed in proportion to blood flow<sup>20</sup>; thus reduced cerebral blood flow reduces microembolic injury but increases the risk of hypoperfusion.<sup>372</sup> During CPB both alpha-stat acid-base management and phenylephrine reduce cerebral injury in adults, probably by causing cerebral vessel

**FIGURE 13-23** Small capillary and arterial dilatations (SCADs) in cerebral vessels in a patient who expired 48 hours after CABG using cardiopulmonary bypass. (Alkaline phosphatase-stained celloidin section, 100  $\mu$ m thick;  $\times 100$ .)

vasoconstriction and reducing the number of microemboli.<sup>373</sup> Air, atherosclerotic debris, and fat are the major types of microemboli causing brain injury in clinical practice, and all cause neuronal necrosis by blocking cerebral vessels.<sup>374</sup> Massive air embolism causes a large ischemic injury, but gaseous cerebral microemboli may directly damage endothelium in addition to blocking blood flow.<sup>375</sup> The identification of unique small capillary arteriolar dilatations (SCADs) in the brain associated with fat emboli<sup>376</sup> (Fig. 13-23) raises the possibility that these emboli not only block small vessels, but also release cytotoxic free radicals, which may significantly increase the damage to lipid-rich neurons.

Anemia and elevated cerebral temperature increase cerebral blood flow but may cause inadequate oxygen delivery to the brain,<sup>377</sup> however, these conditions are easily avoided during clinical cardiac surgery. Although some investigators speculate that normothermic and/or hyperthermic CPB cause cerebral hypoperfusion,<sup>378</sup> experimental studies indicate that cerebral blood flow increases with temperature. Brain injuries associated with this practice are more likely due to increased cerebral microemboli, which produce larger lesions at higher cerebral temperatures.<sup>376</sup>

### NEUROPROTECTIVE STRATEGIES

Recommended conditions for protecting the brain during CPB include mild hypothermia (32-34°C) and hematocrit above 25%.<sup>161</sup> Temporary increases in cerebral venous pressure caused by SVC obstruction and excessive rewarming above blood temperatures of 37°C should be avoided.<sup>379</sup> A randomized study in which patients were mildly rewarmed to 35°C core temperature demonstrated improved neurocognitive outcomes over patients rewarmed to 37°C. Mean perfusion pressure (MPP) appears to have an effect on neurological outcome. Gold et al. randomized 248 patients to low (50-60 mm Hg) or high (80-100 mm Hg) MPP. The incidence of neurologic injury in the high pressure group was significantly reduced.<sup>380</sup> Either jugular venous bulb oxygen saturation or

near-infrared cerebral oximetry are recommended for monitoring cerebral perfusion in patients who may be at high risk for cerebral injury.<sup>381</sup>

Barbiturates reduce cerebral metabolism by decreasing spontaneous synaptic activity and provide a definite neuroprotective effect during clinical cardiac surgery using CPB.<sup>382</sup> Unfortunately, these agents delay emergence from anesthesia and prolong intensive care unit stays. NMDA (*N*-methyl-D-aspartate) antagonists, which are effective in animals, provide mild protection compared with control patients, but have a high incidence of neurologic side effects.<sup>383</sup> A small study demonstrated a neuroprotective effect of lidocaine, but this beneficial effect has not been reproduced.<sup>384</sup> Thus corticosteroids are the only drugs with potential neuroprotective effects that have significant evidence for a positive effect on outcomes.<sup>382</sup>

Off-pump myocardial revascularization theoretically avoids many of the causes of cerebral injury owing to CPB, but, as noted, many causes of neuronal injury are independent of CPB and related to atherosclerosis and air entry sites into the circulation. Nonrandomized measurements of carotid emboli by Doppler ultrasound indicate fewer emboli and slightly improved neurocognitive outcomes in high-risk patients who have off-pump surgery.<sup>385</sup> Clinical trials of off-pump versus on-pump patients have demonstrated a lower stroke rate in off-pump patients who were treated with all arterial grafting and a no-touch surgical technique.<sup>386</sup>

## PROGNOSIS

Patients with intraoperative stroke or those who develop stroke symptoms in the first week after surgery often improve in direct relation to the lesion size and location on imaging studies. Neuropsychologic deficits that are present after

3 months are almost always permanent.<sup>386</sup> Assessments after that time are confounded by development of new deficits, particularly in aged patients.<sup>387,388</sup>

The difficulty of separating intraoperative brain injury from that which occurs in the early or late postoperative period has been recently addressed by a reanalysis of data published earlier. The authors tracked specific neuropsychological deficits that persisted unchanged for 6 months (persistent deficits) and separated them from new deficits that appeared after surgery<sup>389</sup> (Fig. 13-24). Using this technique it is possible to accurately measure surgical brain injury and design techniques to eliminate this important cause of morbidity. Late follow-up studies should include a control group with similar risk factors but not having cardiac operations.<sup>390</sup> This technique demonstrated similar outcomes in surgical and nonsurgical controls at 3 years, putting to rest the previous fear that surgical patients had recurrent neurocognitive deficits and were thus at greater risk for poor long-term outcomes. In a recent study, a group of surgical patients who were evaluated with preoperative and postoperative neuropsychological studies had rigid control of cardiovascular risk factors.<sup>391</sup> They demonstrated no delayed or late cognitive decline offering hope that aggressive medical therapy can compliment skillful surgery in preventing neurological injury.

## Lung Injury

Patient factors and the separate effects of operation and CPB combine to compromise lung function early after operation. Chronic smoking and emphysema are the most common patient factors, but muscular weakness, chronic bronchitis, occult pneumonia, preoperative pulmonary edema, and unrelated respiratory disease are other contributors to

**FIGURE 13-24** Neurobehavioral deficits at 6 months after coronary artery bypass surgery. Note that an intraoperative strategy utilizing a single cross clamp results in fewer persistent neuropsychological deficits than multiple cross clamp or off pump coronary artery bypass (OPCAB). (Data from Hammon JW, Stump DA, Butterworth JF, et al: Coronary artery bypass grafting with single cross-clamp results in fewer persistent neuropsychological deficits than multiple clamp or off-pump coronary artery bypass grafting, *Ann Thorac Surg*. 2007 Oct;84(4):1174-1178.)

postoperative pulmonary dysfunction. Incisional pain, lack of movement, shallow respiratory sighs, increased work of breathing, reduced pulmonary compliance, weak cough, increased pulmonary arterial-venous shunting, and interstitial edema, to some degree, are consequences of anesthesia and any operation. CPB significantly adds to this injury.

During CPB the lungs are supplied by the bronchial arteries and pulmonary arterial blood flow may be absent or minimal. Whether or not alveolar cells suffer an ischemic/reperfusion injury is unclear, but the lungs are subject to many insults that combine to increase pulmonary capillary permeability and interstitial lung water. Hemodilution, reduced plasma oncotic pressure, and temporary elevation of left atrial or pulmonary venous pressure during CPB or during weaning from CPB increase extravascular lung water.<sup>392</sup> Microemboli and circulating cellular, vasoactive, and cytotoxic mediators of the inflammatory response reach the lung via bronchial arteries during CPB and with resumption of the pulmonary circulation during weaning.<sup>393,394</sup> These agents increase pulmonary capillary permeability, perivascular edema, and bronchial secretions, and perhaps cause observed changes in alveolar surfactant.<sup>395</sup> The combination of increased interstitial lung water and bronchial secretions, altered surfactant, patient factors, and the consequences of operation reduces pulmonary compliance and functional residual capacity and increases the work of breathing.<sup>396</sup> All of these changes combine to enhance regional atelectasis, increase susceptibility to infection, and increase the physiologic arterial-venous shunt, which reduces systemic arterial PaO<sub>2</sub>.

Postoperative respiratory care is based on restoring normal pulmonary capillary permeability and interstitial lung volume; preventing atelectasis; reinflating atelectatic segments; maintaining normal arterial blood gases; and preventing infection and facilitating removal of bronchial mucus. Improved postoperative respiratory care, an understanding of the mechanisms of lung injury during CPB, and efforts to reduced or control the causes of injury<sup>397</sup> have markedly reduced the incidence of pulmonary complications in recent years. (See Chapter 16 for a more detailed discussion of postoperative care.)

Acute respiratory distress syndrome (ARDS) is a rare complication of lung injury during CPB and is usually caused by intrabronchial bleeding from traumatic injury by the endotracheal tube or pulmonary artery catheter or to extravasation of blood into alveoli from acute increases in pulmonary venous pressure or severe pulmonary capillary toxic injury.<sup>398</sup>

## Renal Injury

As with other organs, the preoperative health of the kidneys is a major factor in the ability of that organ to withstand the microembolic, cellular, and regional malperfusion injuries caused by extracorporeal circulation. Risk factors include previous renal injury, increased age, and complex disease or cardiac operation.<sup>399</sup> The incidence of acute renal failure requiring dialysis after CPB is remarkably low, averaging 1%; however, the incidence increases to 5% with complex operations.

Some degree of renal injury is inevitable during CPB and post-perfusion proteinuria occurs in all patients.<sup>400</sup> Renal blood and plasma flow, creatinine clearance, free water clearance, and urine volume decrease without hemodilution.<sup>401</sup> Hemodilution attenuates most of these functional changes and also reduces the risk of hemoglobin precipitation in renal tubules if plasma-binding proteins become saturated with free hemoglobin during extracorporeal perfusion. Hemoglobin is toxic to renal tubules and precipitation can block both blood and urine flow to the tubules. Hemodilution dilutes plasma hemoglobin; improves flow to the outer renal cortex; improves total renal blood flow; increases creatinine, electrolyte, and water clearance; and increases glomerular filtration and urine volume.<sup>402</sup>

Perioperative periods of low cardiac output and/or hypotension added to the microembolic, cellular, and cytotoxic injuries of CPB and to any preoperative renal disease are the major cause of postoperative renal failure.<sup>403</sup> Low cardiac output reduces renal perfusion pressure and causes angiotensin II production and renin release, which further decrease renal blood flow. Kidneys, already compromised by preoperative disease and the CPB injury, are particularly sensitive to ischemic injury secondary to low cardiac output and hypotension. Thus perioperative management includes efforts to maximize cardiac output using dopamine or dobutamine if necessary, avoiding renal arterial vasoconstrictive drugs, providing adequate crystalloid infusions to maintain urine volume, and alkalinizing urine to minimize precipitation of tubular hemoglobin if excessive hemolysis has occurred.

If perioperative low cardiac output and hypotension do not occur, the normal kidney has sufficient functional reserve to provide adequate renal function during and after operation. The appearance of oliguric renal failure is ominous and usually requires dialysis, which is generally permanent if required for more than 2 weeks. Oliguric renal failure markedly increases morbidity and mortality by approximately eightfold.

## Injury to the Gastrointestinal Organs

### LIVER INJURY

Although subjected to microemboli, cytotoxins, and regional malperfusion during CPB, the enormous functional reserve and reparative processes of the normal liver nearly always overcome the injury without consequences. Often liver enzymes are mildly elevated, and 10 to 20% of patients are mildly jaundiced. Persistent and rising bilirubin 2 or more days after CPB may precede development of liver failure and is associated with increased morbidity and mortality.<sup>404</sup> Catastrophic liver failure, however, occurs in patients with overwhelming sepsis, oliguric renal failure, anesthetic or drug toxicity, or after a prolonged period of low cardiac output or an episode of hemorrhagic shock and multiple blood transfusions and is uniformly fatal. The liver usually is involved in patients who develop multiorgan failure and is often presaged by sudden hypoglycemia.

## PANCREATIC INJURY

Less than 1% of patients develop clinical pancreatitis after CPB, but approximately 30% develop a transitory, asymptomatic increase in plasma amylase and/or lipase.<sup>405</sup> A history of recurrent pancreatitis, perioperative circulatory shock or hypotension, excessively prolonged CPB, and continuous, high doses of inotropic agents are risk factors for developing postoperative pancreatitis.<sup>406</sup> Experimentally and clinically, high doses of calcium increase intracellular trypsinogen activation and histologic evidence of pancreatitis.<sup>407</sup> Fulminant pancreatitis is very rare, but is often fatal.

## STOMACH AND GUT INJURY

CPB at adequate flow rates does not decrease splanchnic blood flow.<sup>408</sup> Risk factors for gastrointestinal complications include advanced age, emergency surgery, prolonged CPB, postoperative low cardiac output or shock, prolonged vasopressor therapy, and elevated preoperative systemic venous pressure.<sup>409</sup>

CPB decreases gastric pH, which declines further after operation. Before the advent of H<sub>2</sub> blockers and regular use of antacids, duodenal and/or gastric erosion, ulcer, and bleeding were frequent complications after clinical cardiac surgery and were associated with mortality that approached 33 to 50%.<sup>410</sup> These complications are now uncommon.

Several days to 1 week after operation very elderly patients rarely may develop mesenteric vasculitis or severe mesenteric vasoconstriction in response to vasopressors that proceeds to small bowel ischemia and/or infarction. New onset abdominal pain with a silent, rigid abdomen and abrupt rise in white count may be the only signs of this catastrophic complication, which is frequently fatal. If suspected before infarction, infusion of papaverine or alternative vasodilators directly into the mesenteric arteries may prevent or limit subsequent infarction.

The role of CPB in the etiology of gastrointestinal complications is not completely known. If the complications listed in the preceding develop, an increase in the morbidity and mortality may be expected.<sup>411</sup>

# Transfusion Therapy and Blood Conservation

Andreas R. de Biasi • William J. DeBois  
• O. Wayne Isom • Arash Salemi

Concurrent with the development of cardiac surgery in the 1950s as a means of correcting congenital heart defects came the need for large-volume blood transfusions. In the 1960s and 1970s, the introduction of valve prostheses and direct grafting of coronary arteries also made the repair of acquired heart diseases a possibility. These landmarks, along with the early liberal use of allogeneic blood transfusion therapy, led to rapid growth of our field.

Historically, open-heart surgery has been associated with large transfusion requirements. Some reports suggest that up to 70% of this patient population requires blood transfusions, resulting in an average of 2 to 4 donor exposures per patient.<sup>1,2</sup> It has been reported that cardiac surgery consumes about 20% of the available blood supply in the United States, with similar figures observed worldwide.<sup>3</sup> These relatively high rates of transfusions are mostly attributable to cardiopulmonary-bypass-induced phenomena: coagulopathy, platelet dysfunction, and red cell hemolysis all occur to varying degrees as a result of the cardiopulmonary bypass (CPB) circuit.<sup>4-6</sup> Other mechanisms for bleeding include inherited and acquired disorders (including platelet dysfunctions, coagulation factor deficiencies, and derangements leading to excessive fibrinolysis) of numerous etiologies.<sup>7</sup> While common transfusion reactions such as urticaria and fever are easily managed and largely benign, rarer complications like transfusion-related acute lung injury (TRALI) pose serious risks to patients (eg, the mortality rate for TRALI in critically ill populations ranges from 35–58%<sup>8,9</sup>) and provide further impetus for the avoidance of blood product transfusions when at all possible.

Although life-threatening hemorrhage is an obvious absolute indication for blood products, many transfusions are also given to improve oxygen-carrying capacity and to avoid or reverse end-organ ischemia. Despite the potential benefits of transfusing blood to maintain end-organ oxygenation, there is a surprising lack of evidence to support the liberal use of blood transfusions in cardiac surgery. In fact, there is a growing literature base demonstrating that transfusions are associated with an increased risk of both morbidity and mortality.<sup>10-12</sup> For example, red blood cell (RBC) transfusions

have been associated with longer intensive care unit lengths of stay as well as with worse short- and long-term survival.<sup>13-15</sup> A large prospective study identified RBC transfusion as the strongest independent predictor of all-cause morbidity and mortality following isolated coronary artery bypass grafting (CABG) and that each unit of blood transfused posed an additive risk for adverse outcomes.<sup>16</sup>

Concerns over the negative consequences of blood transfusions are not new. As cardiac surgery grew as a discipline in the 1970s, investigators concomitantly noted an increasing incidence of transfusion-transmitted hepatitis; this public health concern first alerted patients and physicians to the concept of blood conservation. The emergence of the human immunodeficiency virus (HIV) a decade later further heightened interest in this area. Considering (1) the increased awareness of blood-borne infectious diseases, (2) the ever-present shortage of available blood donors, (3) the costs of blood products to both patients and institutions, (4) the needs of special populations like Jehovah's Witnesses, and (5) the inherent risks from transfusions, a greater effort was made to perform open-heart procedures without blood transfusions, even in high-risk patients. Additionally, randomized trials showing that lower hemoglobin thresholds were tolerated in both critically ill and cardiac surgical patients further contributed to decreasing transfusions and to the acceptance of some degree of anemia in our patients.<sup>17-19</sup>

As we will discuss, advances in preoperative screening and patient optimization; improvements in surgical techniques and shorter operative times; the use of perioperative pharmacologics and other technologies designed to curtail blood loss; and the aforementioned tolerance of lower hematocrits, especially on bypass, have allowed for extensive procedures to be routinely performed without significant blood loss and with fewer transfusions.

Comprehensive blood conservation programs that combine such elements (analogous to the use of care bundles in the critical care setting) are likely the most effective strategy in decreasing patients' exposure to allogeneic blood. In 1991, Ovrum and colleagues established the effectiveness of the simple "core" approach to blood conservation in a cohort

of 121 consecutive elective CABG patients—the authors achieved a transfusion rate of 4.1% and required only 0.06 RBC units per patient.<sup>20</sup> Later that year, the same group applied these principles to a larger group of 500 elective CABG patients, obtaining similar low rates of transfusion (2.4% of patients) and demonstrating that an impressive 96% of patients received no allogeneic blood products; the authors concluded their multimodal six-step blood conservation program was simple, safe, and cost effective.<sup>21</sup> More recently, Van der Linden and colleagues developed a blood conservation program that employed a standardized transfusion policy and algorithm-driven protocols aimed at minimizing perioperative blood loss.<sup>22</sup> Using this strategy, the group reported a 53% decrease in RBC utilization and a 46% decrease in the number of patients receiving any blood products, without a significant difference in postoperative hemoglobin; moreover, their strategy was also shown to be safe and cost effective.<sup>22</sup> It should be noted that the success of such multidisciplinary programs is not limited to large teaching institutions, as similar results have been shown in the community setting.<sup>23</sup>

## BLOOD CONSERVATION: PREOPERATIVE CONSIDERATIONS

### Identification of Patients at Risk of Bleeding or of Requiring Transfusion

An important first step in mitigating bleeding and transfusion requirements is to identify those patients most at risk for blood loss and/or for needing blood product replacement. Five factors have been identified that are consistently associated with increased rates of RBC transfusions in cardiac surgery: low preoperative hemoglobin and/or hematocrit, advanced patient age, female sex, renal insufficiency, and surgery urgency.<sup>24</sup> Additional risk factors include a personal and/or family history of any excessive bleeding or the presence of a documented bleeding disorder; preoperative antiplatelet or anticoagulation therapy (eg, aspirin, clopidogrel, warfarin); insulin-dependent diabetes mellitus; decreased left ventricular function; anticipated long CPB time; and type of surgery (with complex valvular and aortic surgeries conferring the greatest risks).<sup>25</sup> Current Society of Thoracic Surgery/Society of Cardiovascular Anesthesiologists (STS/SCA) blood conservation guidelines recommend obtaining preoperative hematocrits and platelet counts to aid risk prediction, as abnormalities in these variables are amenable to intervention; preoperative bleeding time may also be determined in high-risk patients, especially those on preoperative antiplatelet agents.<sup>26</sup> Of note, preoperative screening of the intrinsic coagulation system is not recommended unless there is a clinical history of a prior bleeding diathesis.<sup>26</sup>

Awareness of the above-listed risk factors is important as the recognition of specific risks should guide subsequent preoperative patient management with the intent of optimizing a given patient's risk profile. We will in turn discuss three

such preoperative management issues: medication cessation, increasing preoperative RBC mass, and preoperative autologous donation.

## Managing Medications Contributing to Bleeding and Transfusion Risks

The regular, preoperative use of antiplatelet medications like aspirin and clopidogrel have been associated with increased perioperative blood loss as well as with the need for blood products in cardiac surgery patients—as such, a thorough understanding of current guidelines pertaining to their use prior to cardiac surgery is requisite. With the advent of newer anticoagulants (eg, direct thrombin inhibitors, direct factor Xa inhibitors), insight into what to do about these drugs must be assimilated with knowledge of older, well-established guidelines on the cessation of traditional vitamin K antagonists. Table 14-1 lists some of the more commonly encountered of these drugs.

### ASPIRIN

Aspirin irreversibly inhibits cyclooxygenase-1 and -2, leading to decreased formation of thromboxane A<sub>2</sub> and ultimately to inhibited platelet aggregation. The ability of aspirin to irreversibly induce this qualitative platelet defect has led to its widespread use as a thromboprophylaxing agent in many cardiovascular disease states (eg, coronary artery disease, carotid artery stenosis, after prosthetic valve insertion, or CABG); as such, aspirin is a very frequently encountered drug in our patient population. Current guidelines state that it is reasonable to discontinue aspirin prior to cardiac surgery only in purely elective patients not having acute coronary syndromes.<sup>26</sup>

### ADENOSINE DIPHOSPHATE RECEPTOR INHIBITORS

These antiplatelet drugs (clopidogrel, prasugrel, ticagrelor, and ticlopidine) inhibit the P2Y<sub>12</sub> subtype of platelet adenosine diphosphate (ADP) receptors, thus causing irreversible platelet inhibition (of note, ticagrelor is an allosteric antagonist, making its ADP blockage reversible). Members of this class of drugs are frequently used in combination with other antiplatelet agents like aspirin as part of dual antiplatelet therapies for acute coronary syndromes and for thromboprophylaxis in those with stents and/or cerebrovascular disease. ADP receptor inhibitors are felt to confer greater bleeding and transfusion risks than aspirin; as such, guidelines recommend discontinuation of these agents as few as 3 days prior to cardiac surgery (with specific timing determined by a given drug's half-life of elimination).<sup>26</sup> Point-of-care (POC, discussed later) testing assessing platelet responsiveness to clopidogrel, specifically, may be used to identify those nonresponders who are candidates for early operative coronary revascularization and who may thus not require a preoperative cessation period.<sup>26</sup>

 **TABLE 14-1: Antiplatelet Agents and Anticoagulants**

Drug	Mechanism	Binding	Half-life
Aspirin	Acetylation of COX-1 and -2 enzymes, resulting in inhibition of TXA <sub>2</sub> formation, thereby inhibiting platelet aggregation.	Irreversible	15-20 min
<i>ADP Receptor Inhibitors</i>			
Clopidogrel (Plavix)	Inhibits the P2Y <sub>12</sub> subtype of platelet ADP receptors, thus preventing GP IIb/IIIa receptor complex activation, thereby reducing platelet activation and aggregation.	Irreversible	6 h
Prasugrel (Effient)	Inhibits the P2Y <sub>12</sub> subtype of platelet ADP receptors, thus preventing GP IIb/IIIa receptor complex activation, thereby reducing platelet activation and aggregation.	Irreversible	7 h
Ticagrelor (Brilinta)	Inhibits the P2Y <sub>12</sub> subtype of platelet ADP receptors, thus preventing GP IIb/IIIa receptor complex activation, thereby reducing platelet activation and aggregation.	Reversible	7 h
Ticlopidine (Ticlid)	Inhibits the P2Y <sub>12</sub> subtype of platelet ADP receptors, thus preventing GP IIb/IIIa receptor complex activation, thereby reducing platelet activation and aggregation.	Irreversible	13 h
<i>GP IIb/IIIa Inhibitors</i>			
Abciximab (ReoPro)	Monoclonal anti-GP-IIb/IIIa antibody, resulting in steric hindrance, thus inhibiting platelet aggregation.	Noncompetitive	30 min
Eptifibatide (Integrilin)	Cyclic heptapeptide inhibitor of GP IIb/IIIa receptor, thus interferes with platelet aggregation.	Reversible	2.5 h
Tirofiban (Aggrastat)	Non-peptide inhibitor of GP IIb/IIIa receptor, thus interferes with platelet aggregation.	Reversible	2 h
Unfractionated Heparin	Complexes with AT III, accelerating the thrombin-inactivating function of AT III by 1000- to 4000-fold.	Reversible	1.5 h
Warfarin	Inhibits hepatic synthesis of vitamin K-dependent coagulation factors (II, VII, IX, and X as well as proteins C and S).	Competitive	20-60 h
<i>Novel Oral Anticoagulants</i>			
Dabigatran (Pradaxa)	Direct thrombin inhibitor; inhibits coagulation via prevention of thrombin-mediated effects.	Reversible	12-17 h
Apixaban (Eliquis)	Direct factor Xa inhibitor, thus inhibits conversion of prothrombin to thrombin, thereby preventing platelet activation and fibrin formation.	Reversible	12 h
Edoxaban (Savaysa)	Direct factor Xa inhibitor, thus inhibits conversion of prothrombin to thrombin, thereby preventing platelet activation and fibrin formation.	Reversible	6-11 h
Rivaroxaban (Xarelto)	Direct factor Xa inhibitor, thus inhibits conversion of prothrombin to thrombin, thereby preventing platelet activation and fibrin formation.	Reversible	5-9 h

ADP, adenosine diphosphate; AT, antithrombin; COX, cyclooxygenase; GP, glycoprotein; TXA<sub>2</sub>, thromboxane A<sub>2</sub>.

### GLYCOPROTEIN IIb/IIIa INHIBITORS

Members of this drug class (eg, abciximab, eptifibatide, tirofiban) prevent platelet aggregation via inhibition of glycoprotein (GP) IIb/IIIa receptors on the surface of platelets; these agents are frequently used during percutaneous coronary interventions and in the treatment of acute coronary syndromes. Like the other previously mentioned high-intensity antiplatelet drugs, GP IIb/IIIa inhibitors are associated with increased bleeding after cardiac operations; as such, these medications should be stopped prior to surgery in order to decrease minor and major bleeding events.<sup>26</sup> Exact timing again depends on the half-life of each agent in question.

It should be noted that unfractionated heparin is the notable exception to the cessation recommendations pertaining to the high-intensity antithrombotic drugs outlined by the STS/SCA guidelines: unfractionated heparin is the only agent which can either be discontinued shortly before operation or not at all.<sup>26</sup>

### VITAMIN K ANTAGONISTS

Vitamin K antagonists are anticoagulants that reduce hepatic production of coagulation factors II, VII, IX, and X as well as of proteins C and S—all of which depend on vitamin K for their synthesis. Warfarin, the most widely encountered of

these drugs, is used both in the prophylaxis and treatment of thromboembolic disorders (eg, venous or pulmonary clots, prosthetic valve thrombosis); warfarin is similarly used in atrial fibrillation and can serve as an adjunct to reduce systemic embolic risks after myocardial infarction. According to recent guidelines produced by the European Association for Cardio-Thoracic Surgery, patients on warfarin prior to cardiac surgery should be managed in a similar manner to those undergoing major noncardiac surgery.<sup>27</sup> That is, warfarin should be discontinued 2 to 4 days before surgery and patients at higher risk of thrombosis should be bridged with intravenous heparin once the international normalized ratio becomes subtherapeutic.<sup>27</sup>

### NOVEL ORAL ANTICOAGULANTS: DIRECT THROMBIN INHIBITORS AND DIRECT FACTOR XA INHIBITORS

Although novel oral anticoagulants (NOACs) belonging to the direct thrombin inhibitor (eg, dabigatran) and direct factor Xa inhibitor (rivaroxaban, apixaban, edoxaban) classes are currently not indicated for patients with mechanical valves, their ease of use and their lack of a monitoring requirement (as compared to warfarin) have increased the popularity of these drugs for patients requiring long-term anticoagulation for nonvalvular reasons. Current guidelines regarding the perioperative use of NOACs recommend these drugs be discontinued 2 to 5 days prior to procedures with a high risk of bleeding, including major abdominal, cardiovascular, and thoracic operations.<sup>28,29</sup> Since the diminution of the anticoagulant effects of NOACs is predictable after their cessation, bridging is typically not required after NOACs are stopped.

The management of patients on NOACs requiring emergency surgery is complicated by the fact that these agents have no specific antidote. In this setting, surgery should be deferred for at least 12 hours if at all possible; given NOACs' short half-lives, this should allow for some mitigation of bleeding risk.<sup>30</sup> If delaying surgery is not possible, expert opinion suggests the use of oral activated charcoal or hemodialysis; prophylactic administration of fresh frozen plasma (FFP) or prothrombin complex concentrates (PCCs, discussed below) is not recommended in the absence of major bleeding.<sup>30</sup>

### HERBAL SUPPLEMENTS AND COMPLEMENTARY MEDICINE

The use of herbal supplements and complementary medicine has seemingly exploded in popularity recently and warrants mentioning since many of these naturopathic treatments can have profound hematologic effects. Herbs, such as thyme and rosemary have been shown to have a direct inhibitory effect on platelets.<sup>31</sup> Fish oil, an omega-3 polyunsaturated fatty acid, may affect platelet aggregation and/or vitamin K-dependent coagulation factors. Omega-3 fatty acids may lower thromboxane A<sub>2</sub> within platelets as well as decrease factor VII levels,<sup>32</sup> while garlic, ginger, and *Ginkgo biloba* have all been associated with platelet-dysfunction-induced bleeding.<sup>33</sup> Given the many possible antiplatelet and anticoagulant

effects of such alternative medicines, not to mention their myriad interactions (both known and unknown) with other drugs, it is therefore prudent to inquire about any supplements patients may be taking prior to cardiac surgery. It is our practice to have patients stop all such remedies 7 days prior to surgery.

### Increasing Preoperative Red Blood Cell Mass

Increasing RBC mass prior to surgery is another component of blood conservation, as decreased preoperative hemoglobin or hematocrit levels have been shown to be powerful predictors of the need for transfusion as well as significant risk factors for early and late mortality.<sup>25,34</sup> Such optimization necessitates diagnosing and treating preoperative anemia. Since iron-deficiency anemia is common in the cardiac surgery population, iron supplementation can restore hemoglobin concentrations to adequate levels (eg, 13 g/dL or above), thereby decreasing transfusion risk.

The use of recombinant human erythropoietin (EPO) has been studied as an additional means of improving RBC mass in anemic patients preparing to undergo cardiac surgery. A meta-analysis examining such preoperative EPO administration demonstrated that its use prior to cardiac surgery was associated with a significant reduction in the risk of exposure to allogeneic blood.<sup>35</sup> While there are some concerns that chronic EPO use may carry an increased risk of thrombotic complications, a recent randomized, blinded trial of preoperative high-dose EPO of short duration showed a 56% decrease in the relative risk of exposure to blood products in patients undergoing off-pump CABG following preoperative EPO versus those not given EPO; no adverse effects were observed.<sup>36</sup> The contemporary STS/SCA guidelines state that it is reasonable to use preoperative EPO and iron several days prior to cardiac surgery in patients with anemia, in those who refuse transfusion (eg, Jehovah's Witness), or in patients who are at high risk for postoperative anemia.<sup>26</sup>

### Preoperative Autologous Blood Donation

Preoperative autologous blood donation (PABD) remains an option at selected centers for minimizing patient exposures to allogeneic blood. Although this technique has been in practice since the 1960s, its use in cardiac surgery did not achieve widespread acceptance until the 1980s, when the rise of HIV led to increased interest in PABD as a way of reducing allogeneic transfusions. Unfortunately, the acuity of most cardiac operations precludes the routine use PABD as there must be sufficient time between donation and surgery to allow for the regeneration of the patient's RBC mass. In general, this time is a minimum of 2 weeks per unit of blood donated. What is more, patients must have enough reserve to tolerate the ensuing transient anemia, further limiting PABD's utility. PABD is only an option for the elective, stable preoperative patient;

additionally, there are numerous relative contraindications to PABD, including the presence of left main disease, critical aortic stenosis, congestive heart failure, severe coronary artery disease with ongoing ischemia, active endocarditis, and baseline anemia.

Most of the randomized studies evaluating PABD involve small sample sizes and level A evidence of its benefits are lacking<sup>37</sup>; nevertheless, a recent case-control study examining the technique showed a lower incidence of allogeneic transfusions among those patients who donated preoperatively compared to those who did not (but 20% of the donated blood products were discarded postoperatively).<sup>38</sup> As such, the most recent STS/STA guidelines do not directly endorse PABD; they mention PABD only in the context of EPO use, wherein the guidelines state EPO additionally may be considered to restore RBC volume in patients undergoing PABD.<sup>26</sup> For reasons of practicality and cost effectiveness, PABD has largely been supplanted by numerous perioperative blood conservation strategies, which we discuss in the next section.

## BLOOD CONSERVATION: PERIOPERATIVE STRATEGIES

### Cardiopulmonary Bypass Considerations

Numerous CPB techniques have been validated to reduce blood loss and to protect against transfusions during and after cardiac surgery. These strategies, which we discuss in turn, require coordination between the operating surgeon and perfusionist and constitute another vital component of any comprehensive blood conservation program.

#### ACUTE NORMOVOLEMIC HEMODILUTION

Acute normovolemic hemodilution (ANH) involves the removal of 1 to 2 units of whole blood (target hematocrit of 25–30%) from the patient immediately before, or during, surgery (but prior to CPB initiation) while simultaneously replacing it with crystalloid or colloid to maintain normovolemia. The theoretical basis for ANH (also known referred to as intraoperative autologous donation) is that this lowering of the hematocrit results in fewer RBCs being lost when the patient subsequently bleeds during the course of the operation. Moreover, the removed blood is spared the effects of hemodilution from CPB and is shielded from the inflammatory response of blood cells to the bypass circuit. The collected blood—rich in valuable components (eg, platelets, coagulation factors)—is then infused back to the patient after separation from CPB and heparin reversal.

The amount of blood that an individual patient is capable of donating via ANH depends strictly on the patient's own physiologic parameters, estimated blood volume (based on height-weight nomograms), and hematocrit. Figure 14-1 is our nomogram for allowable ANH blood drainage—this conservatively estimates the volume of blood that can be removed to achieve a hematocrit of 24% or greater (based on a 1000 mL CPB prime volume).

ANH is relatively contraindicated in patients with preoperative anemia, unstable angina, and those with ejection fractions less than 30%.<sup>37</sup> Additionally, evidence supporting its use is conflicting: a few prospective studies showed a significant decrease in allogeneic blood product use,<sup>39,40</sup> others showed no benefit from ANH,<sup>41,42</sup> while a meta-analysis and review found only a modest benefit.<sup>43</sup> Contemporary guidelines state that ANH may be considered as part of a multipronged approach to blood conservation in selected (ie, nonanemic) patients, but note that its usefulness is not well-established.<sup>26,44</sup>

#### RETROGRADE AUTOLOGOUS PRIMING

Low hematocrits during CPB were shown to have detrimental effects on end-organ function and cognitive outcomes.<sup>45-49</sup> In retrograde autologous priming (RAP), the CPB circuit is primed with the patient's own whole blood, thereby minimizing circuit-induced hemodilution (which results from crystalloid priming) and ideally reducing the subsequent need for allogeneic transfusions. Specifically, blood from the aorta is allowed to flow retrogradely through the arterial arm of the bypass circuit, displacing portions of the crystalloid prime. Once the desired prime volume is displaced, a similar procedure can be applied to the venous line (so-called venous antegrade priming) to remove additional crystalloid from the circuit.

RAP was shown to reduce hemodilution and allogeneic transfusions (as compared to conventional CPB priming) in a large, retrospective study<sup>50</sup> as well as in a recent meta-analysis<sup>51</sup>; however, the latter showed that RAP had no effect on clinical outcomes like ventilator hours or length of stay.<sup>51</sup> RAP is currently endorsed by several societal guidelines as a method of reducing allogeneic blood transfusions during on-pump cardiac surgery.<sup>26,44</sup>

#### MINI-CIRCUITS AND VACUUM-ASSISTED VENOUS DRAINAGE

Advances in CPB circuit design have further reduced the impact of priming-induced hemodilution as well as the inflammatory responses initiated by blood-material interactions—these improvements may lessen the need for subsequent transfusions. Minimizing circuit length decreases the priming volume while also reducing the surface area of foreign material to which blood is exposed. This latter point serves to decrease the contact-dependent systemic inflammatory response, thereby reducing transcapillary leak; minimizing blood-material interactions via smaller circuits can also decrease the sheering of blood cells.<sup>37</sup>

Newer, so-called mini-circuits are fully closed CPB systems that also eliminate blood-air contact, as these circuits often do not use a venous reservoir; mini-circuits typically have priming volumes of less than 500 mL. Compared to conventional CPB, mini-circuits have been shown to more stably maintain hemoglobin concentrations intraoperatively, to reduce postoperative transfusion requirements, and even to improve mortality after CABG.<sup>52-54</sup> One potential downside

to mini-circuits is that the introduction of air into the closed venous system risks creation of an air lock; additionally, the absence of a venous reservoir creates the potential for exsanguination after uncontrolled bleeding. Based on the results of nine randomized trials and a well-constructed meta-analysis, all of which suggested mini-circuits reduce postoperative bleeding and transfusions, the STS/STA guidelines now recommend the use of these systems for blood conservation.<sup>26</sup>

Many mini-circuits also incorporate vacuum-assisted venous drainage, as opposed to the gravity drainage used in conventional CPB systems. While mini-circuits using vacuum drainage may improve hemostasis and decrease blood requirements compared to regular circuits, there is some concern that the vacuum entrains air and that this can lead to increased systemic microemboli compared with gravity venous drainage. Therefore, current guidelines urge caution with respect to vacuum-assisted venous drainage but point out that this technology may provide some benefit, especially in pediatric patients.<sup>26</sup>

### MODIFIED ULTRAFILTRATION

Another method of limiting CPB-induced hemodilution involves modified ultrafiltration (UF), wherein water and low-molecular-weight substances are filtered out of the blood

at the conclusion of a case; the resultant protein-rich concentrated whole blood is then returned to the patient. Specifically, this technique uses a special UF device added to a typical bypass system; using the existing CPB cannulae, free water as well as detrimental, pump-induced inflammatory mediators are removed from the patient's blood at the conclusion of a pump run but prior to the patient leaving the operating theater. Compared with other intraoperative UF procedures (eg, conventional UF, which runs simultaneously with CPB, or zero balance UF, in which the removed free water is replaced with a crystalloid solution), modified UF has well-established benefits in terms of mitigating hemodilution as well as reducing postoperative bleeding and blood product usage.<sup>26</sup> As such, the current STS/STA guidelines recommend the use of modified UF for blood conservation and for reducing postoperative blood loss in adult cardiac surgeries requiring CPB.<sup>26</sup>

### AUTOTRANSFUSION OF CARDIOTOMY-SUCTIONED, CENTRIFUGED, OR RESIDUAL-CIRCUIT BLOOD

Salvaging extravascular blood (ie, shed blood from the operative field or residual blood in the bypass circuit) is another important element in blood conservation. Cell salvage

systems have been shown to decrease the incidence of RBC transfusions in cardiac surgery<sup>55</sup> and may be especially useful in off-pump CABG, where cardiomy suction is not available.<sup>37</sup>

Contemporary blood conservation guidelines therefore recommend intraoperative autotransfusions during CPB using blood directly from cardiomy suction and/or recycled blood that has been centrifuged to concentrate red cells.<sup>26,44</sup> Additionally, consensus suggests that reinfusion of residual blood in the CPB circuit at the conclusion of a procedure is a reasonable part of a blood management program.<sup>26</sup>

## Operative Techniques

Interest in minimally invasive techniques for cardiac surgery continues to grow. At their core, these advanced procedures are intended to lessen the extent of the surgical insult, which, in turn, can translate into reduced blood loss and the avoidance of transfusions. Operations performed without CPB, via transcatheter or endovascular approaches, or through mini-thoracotomies (MTs) are becoming increasingly prevalent in cardiac surgery and have been studied with respect to their ability to conserve blood.

### OFF-PUMP CABG

A number of well-designed studies have shown that patients undergoing off-pump CABG have reduced transfusion requirements as compared to patients undergoing CABG on CPB,<sup>56-58</sup> have fewer reoperations for bleeding,<sup>57</sup> and are less coagulopathic postoperatively.<sup>58</sup> As is the case with minicircuits, these benefits from off-pump surgery stem from the avoidance of CPB-induced hemodilution and inflammation. While the current STS/STA blood conservation guidelines recommend off-pump CABG as a reasonable means of blood conservation,<sup>26</sup> recent evidence suggesting that graft patency is reduced in off-pump CABG patients has tempered some of the earlier excitement surrounding this technique.<sup>56,59</sup>

### OTHER MINIMALLY INVASIVE APPROACHES

Numerous other minimally invasive surgical procedures have emerged over the last decade. These techniques are still evolving and many have not been subjected to rigorous, prospective study. Nevertheless, promising lines of evidence are beginning to emerge showing that several of these new cardiac operations may have the potential to curb blood loss and to reduce transfusion risks. For example, thoracic endovascular aortic repair (TEVAR) is increasingly being used to repair various descending aortic lesions and has been demonstrated to reduce transfusions and reoperations for bleeding as compared to open aortic surgery.<sup>60</sup> The use of TEVAR in selected patients was therefore added as a recommendation in the most recent STS/STA blood conservation guidelines.<sup>26</sup> Transcatheter aortic valve replacement (TAVR) allows for the replacement of stenotic aortic valves in high-risk patients using a sternum-sparing, endovascular approach. Although

TAVR has been associated with higher rates of vascular complications, major bleeding events occurred less often with this technique as compared to surgical aortic valve replacement (AVR).<sup>61</sup> Accordingly, the incidence of transfusions following TAVR was also shown to be less than with surgical AVR.<sup>62-64</sup>

Bleeding can also be minimized by forgoing full sternotomy in favor of smaller thoracic incisions. For instance, both the aortic and mitral valves can be approached via a small right anterior thoracotomy (ie, MT). AVR performed through MT has been shown to reduce blood loss as compared to sternotomy-based AVR<sup>65</sup>; similarly, mitral valve replacement (MVR) via MT was demonstrated to reduce RBC transfusion volumes as compared to MVR performed via traditional sternotomy.<sup>66</sup> Although current International Society for Minimally Invasive Cardiothoracic Surgery (ISMICS) guidelines do not go so far as to recommend such MT approaches outright, they point out that the ability of MTs to reduce allogeneic blood exposures should be considered when balancing the risks and benefits of these newer procedures.<sup>44</sup>

## Topical Hemostatic Agents

Surgical bleeding (ie, bleeding from suture lines or anastomoses) accounts for over half of all cases taken back to the operating room due to postoperative blood loss.<sup>67</sup> As a result, numerous topical hemostatic agents have been developed to reduce or prevent surgical bleeding when used as adjuncts to conventional suturing techniques. The limited efficacy of older topical agents such as oxidized cellulose and microfibrillar collagen has led to the introduction of newer products with novel applicator systems, some of which can directly activate the clotting cascade. We briefly describe some of the more commonly encountered of these products, although evidence-based comparisons between these agents are largely lacking. Table 14-2 comprehensively summarizes most of the currently available topical agents.

Fibrin sealants (Tisseel [Baxter Healthcare Corp., Deerfield, IL, USA], Beriplast [CSL Bering, King of Prussia, PA, USA], and Hemaseel [Haemacure Corp., Montreal, QB, Canada]) comprised of freeze-dried human fibrinogen, clotting proteins, fibronectin, and bovine thrombin or bovine aprotinin have been widely used in cardiac surgery; a systematic review on their use suggested that fibrin sealants are efficacious in decreasing the need for allogeneic transfusions.<sup>68</sup> However, these products are quite immunogenic and can lead to an unacceptably high incidence of anaphylaxis<sup>69</sup>; recent reports of myocardial injury secondary to acute coronary bypass graft thrombosis<sup>70</sup> and of mechanical aortic valve dysfunction<sup>71</sup> following the use of fibrin sealants have led some to further caution against using these agents in such procedures.

FloSeal (Baxter Healthcare Corp.) is a bovine-derived gelatin matrix cross-linked with a human-derived thrombin solution, which when applied, activates the clotting cascade and simultaneously forms a nondisplacing hemostatic plug. Unlike other fibrin sealants, FloSeal requires blood as a fibrinogen source; the product is biocompatible and reabsorbed in 6 to 8 weeks. Compared to a Gelfoam-thrombin control,

**TABLE 14-2: Topical Hemostatic Agents Recommended by the Society of Thoracic Surgeons/Society of Cardiovascular Anesthesiologists Blood Conservation Clinical Practice Guidelines.<sup>26</sup>**

Agent	Commercial name	Composition	Mechanism of action	Class of recommendation
Oxidized regenerated cellulose for wound compression	Surgicel, Oxycel	Oxidized cellulose	Accelerate clotting by platelet activation followed by swelling and wound compression. Some bacteriostatic properties.	Class IIb
Microfibrillar collagen	Avitene, Colgel, Helitene	Bovine collagen shredded into fibrils	Collagen activates platelets causing aggregation, clot formation, and wound sealing.	Class IIb
Combined compression and sealant topical agent	Recothrom or Thrombin JMI added to USP porcine Gelfoam, Costasis, FloSeal	Bovine fibrillar collagen or bovine gelatin combined with thrombin and mixed with autologous plasma	Activation of platelet-related clotting followed by swelling and wound compression. Recombinant thrombin has potential safety advantage. Combination of compression and sealant agents.	Class IIb
Fibrin sealants ("fibrin glue")	Tisseel, Beriplast, Hemaseel, Crosseal	Source of fibrinogen and thrombin mixed with antifibrinolytics combined at anastomotic sites	Fibrin matrix serves to seal the wound. Contains either aprotinin or tranexamic acid.	Class IIb
Synthetic cyanoacrylate polymers	Omnex	Polymers of 2 forms of cyanoacrylate monomers	Seals wounds without need for intact clotting mechanism.	Class IIb
Synthetic polymers of polyethylene glycol	CoSeal, DuraSeal	Polymers of polyethylene glycol cross link with local proteins	Polymers and proteins form matrix sealant.	Class IIb
Sealant mixture of bovine albumin and glutaraldehyde	BioGlue	Albumin and glutaraldehyde dispensed in 2-syringe system	Sealant created without need for intrinsic clotting system by denaturation of albumin. Safety concerns because of glutaraldehyde toxicity.	Class IIb
Large surface area polysaccharide hemospheres	Arista, HemoStase	Plant-based polysaccharides with a very large surface area	Rapidly dehydrate blood by concentrating serum proteins, platelets, and other blood elements on the surface of contact.	Class IIb
Chitin-based sealants	Celox, HemCon, Chitoseal	Naturally occurring polysaccharide polymer	Chitin forms clots in defibrinated or heparinized blood by a direct reaction with the cell membranes of erythrocytes. Probably induces local growth factors.	Class IIb
Antifibrinolytic agents in solution	Trasylol, tranexamic acid	Antifibrinolytic agents dissolved in saline	Limit wound-related generation of plasmin.	Class IIa

Reproduced with permission from Ferraris VA, Brown JR, et al: 2011 update to the Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists blood conservation clinical practice guidelines. Society of Thoracic Surgeons Blood Conservation Guideline Task Force, *Ann Thorac Surg*. 2011 Mar;91(3):944-982.

FloSeal proved more effective in stopping arterial suture line bleeding within 10 minutes in cardiac surgery patients, especially before protamine reversal.<sup>72</sup>

BioGlue (CryoLife Inc., Kennesaw, GA, USA) is a biologic glue approved initially for use in the repair of aortic dissections. This product consists of a glutaraldehyde solution and a separate bovine serum albumin solution that are mixed at the time of use via a dual-cartridge, single-nozzle dispenser.

The resultant flexible mechanical seal forms within 2 minutes, independent of the body's clotting mechanism. Both observational and randomized studies have demonstrated BioGlue significantly decreased anastomotic bleeding in cardiac, aortic, and peripheral vascular procedures as compared with a standard surgical control.<sup>73,74</sup>

Current STS/STA guidelines state that topical hemostatic agents may be considered to provide local hemostasis

at anastomotic sites as part of a multimodal blood management program.<sup>26</sup> As those guidelines point out, despite the widespread use of such products in cardiac surgery, no single topical preparation has emerged as a clear frontrunner, highlighting the need for randomized controlled trials of these agents.<sup>26</sup>

## Antifibrinolytic Agents

Antifibrinolytic prophylaxis has been well-studied in cardiac surgery and currently is centered around two drugs: the lysine analogs tranexamic acid (TA) and epsilon-aminocaproic acid (EACA). These agents bind to plasminogen and inhibit its binding to fibrin, thereby impairing fibrinolysis. A third antifibrinolytic drug, aprotinin, is a bovine-derived serine protease inhibitor of the fibrinolytic enzyme, plasmin. While aprotinin has long been confirmed to decrease bleeding rates and transfusion requirements as compared to placebo, aprotinin was removed from market in 2007 over concerns regarding renal toxicity<sup>75,76</sup> and because of higher mortality in aprotinin-treated patients in a randomized, prospective trial comparing that drug with TA and EACA.<sup>77</sup>

### TRANEXAMIC ACID

Although TA and EACA share similar mechanisms of action, the significant difference between the two agents is that TA is roughly 10 times more potent than EACA. Several meta-analyses have highlighted the benefits of TA in decreasing postoperative transfusion requirements,<sup>78,79</sup> the most recent of which demonstrated significant decreases in RBC transfusions and in repeat surgery rates for bleeding when comparing TA use with controls.<sup>80</sup> No sufficiently powered, randomized controlled trial exists, however, comparing the effects of TA administration versus placebo on transfusion requirements. Of note, concerns over TA's safety profile (seizure risk, in particular) as well as debates on dosing strategies for this drug continue. Nevertheless, the use of TA is a class I recommendation in the current STS/SCA blood conservation guidelines for reducing total blood loss and for decreasing the number of patients who require blood transfusions during cardiac procedures.<sup>26</sup>

### EPSILON-AMINOCAPROIC ACID

Introduced to cardiac surgery in 1962,<sup>81</sup> EACA remains the most commonly used antifibrinolytic agent in the United States. EACA has repeatedly been shown to result in decreased postoperative RBC blood loss and in transfusion rates similar to those observed for aprotinin (when compared to placebo).<sup>82-85</sup> Loading doses from 50 to 150 mg/kg followed by infusions from 25 to 30 mg/kg/h allow plasma EACA levels to be maintained at greater than 130 µg/mL, the minimum concentration needed to suppress plasmin activity.<sup>25</sup> Like TA, EACA is indicated for blood conservation by the contemporary STS/SCA guidelines.<sup>26</sup>

## POSTOPERATIVE CONCERNS AND MANAGEMENT

Blood conservation does not stop at the conclusion of the cardiac surgery; rather, through the coordinated efforts of both the surgical and intensivists teams, various postoperative strategies—transfusion triggers, POC testing, the use of novel blood products, etc.—can be employed to minimize further bleeding and to avoid unnecessary hemodilution and RBC transfusions. Perhaps the most central issue in this postoperative blood conservation paradigm concerns the seemingly straightforward question of “when do we transfuse a patient?”

### Transfusion Triggers

The literature indicates that the anesthetized patient on full CPB at moderate hypothermia can safely tolerate a hematocrit as low as 15%, with the exception of patients at risk for decreased cerebral oxygen delivery—namely, those with a history of stroke, diabetes, or cerebrovascular disease.<sup>86</sup> These latter patients can tolerate a hematocrit as low as 18% when using moderate hypothermia.<sup>87</sup> Once the patient is warm and being weaned from CPB, these percentage points are raised by 2% each (17% and 20%, respectively) because the relative protective effects of hypothermia are no longer present. In our institution, once the patient is off CPB, our practice is to reinfuse all (or as much as possible) remaining blood in the CPB circuit to the patient and then to give all available cell salvage blood, including any blood remaining in the CPB circuit that was not initially given back to the patient; next, any blood collected from ANH, and finally, PABD blood if available. Then and only then, if the hematocrit remains unsatisfactorily low, does the patient receive allogeneic blood. Of course, the issue becomes: what does “unsatisfactorily low” mean?

Unfortunately, data to support postoperative transfusion decisions in cardiac surgery are sparse. Since a given patient's unique clinical situation (eg, volume status, hemodynamics, surgical extent, ongoing bleeding, and mixed venous oxygen saturation) is likely the most important factor in weighing his or her need for transfusion, it would be impossible to assign a single transfusion trigger that can universally be applied to all patients. However, based upon the results of numerous case series, several nonrandomized observational studies, a handful of prospective randomized clinical trials, and expert opinions, consensus now exists that helps guide us in the transfusion decision-making process.<sup>26,88</sup>

It is widely accepted (and as outlined by the current STS/SCA guidelines) that RBC transfusions to improve oxygen transport when a hemoglobin level is greater than 10 g/dL are almost never of benefit, whereas most patients with hemoglobin levels less than 7 g/dL do indeed stand to benefit from transfusion.<sup>26,88</sup> Two studies in particular formed much the basis for this understanding: in 1999, a multicenter randomized trial of Transfusion Requirements in Critical Care (TRICC) enrolled 838 critically ill patients and randomized them to either a restrictive (transfuse if hemoglobin < 7 g/dL)

or a liberal (transfuse if hemoglobin < 10 g/dL) transfusion strategy.<sup>89</sup> The 30-day mortality rates, though better in the restrictive strategy group, did not reach statistical significance; however, myocardial infarction and pulmonary edema occurred less frequently under the restrictive strategy.<sup>89</sup> A subgroup analysis, which looked at younger patients (age < 55) and patients who were less acutely ill (APACHE score < 20) showed significantly lower mortality rates with the restrictive strategy.<sup>89</sup> Patients with known, significant cardiac disease had comparable mortality rates regardless of the transfusion strategy used.<sup>89</sup>

A second, more recent randomized trial examined appropriate transfusion triggers in cardiac surgical procedures specifically: the Transfusion Requirements After Cardiac Surgery (TRACS) trial randomized 502 patients who had undergone cardiac surgical procedures with the use of CPB to restrictive (maintain hematocrit  $\geq$  24%) versus liberal (maintain hematocrit  $\geq$  30%) transfusion strategies.<sup>19</sup> The primary, composite end point of 30-day mortality and in-hospital major morbidity was comparable between both strategies.<sup>19</sup> In the restrictive strategy group, there was a 60% diminution in the number of transfused units.<sup>19</sup> Furthermore, RBC transfusions were again found to be an independent risk factor for mortality.<sup>19</sup>

The contemporary STS/SCA blood conservation guidelines therefore state RBC transfusion is reasonable when hemoglobin levels are below 6 g/dL, as they can be life-saving.<sup>26</sup> Moreover, transfusion is reasonable in most postoperative patients whose hemoglobin is less than 7 g/dL, even though little high level evidence supports this recommendation.<sup>26</sup>

## Point-of-Care Testing

Traditional laboratory-based testing of blood (eg, complete blood counts, coagulation profiles) helps guide rational transfusion practices. Yet, some of these assays may be limited by processing times that are quite long relative to the acuity of many postsurgical cardiac patients. Hence, various POC tests have been developed that seek to optimize and expedite patient management. The proposed advantages of POC testing include (1) the targeting of transfusion therapies according to specific coagulation abnormalities, (2) the rapid identification of patients who could benefit from pharmacologic therapy to decrease bleeding, and (3) the identification of a surgical source for excessive bleeding in the setting of normal test results.<sup>25</sup>

The use of thromboelastography (TEG) or rotational thromboelastometry (ROTEM) to assess whole-blood coagulation, platelet function, and fibrinolytic activity has gained popularity in cardiac surgery (Fig. 14-2).<sup>90</sup> However, as the recent ISMICS consensus statement points out, despite some evidence that TEG/thromboelastometry may reduce blood subcomponent transfusions, results have been largely heterogeneous and no benefits have been shown with respect to clinically relevant outcomes.<sup>44</sup> As such, evidence remains too premature to recommend POC technologies for routine use in blood conservation following cardiac surgery.

**FIGURE 14-2** Working principles of thromboelastography and rotational thromboelastometry.<sup>90</sup> Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) assess viscoelastic changes in clotting whole blood under low shear conditions after the addition of a specific coagulation activator to a sample of blood. The main end point of TEG and ROTEM is the determination of the blood's viscoelasticity, referred as amplitude (for TEG) and clot firmness (for ROTEM). Specifically, the viscoelastic (tensile) force between the blood-containing cup and the immersed pin results from the interaction between activated platelet glycoprotein IIb/IIIa receptors and polymerizing fibrin during endogenous thrombin generation and fibrin degradation by fibrinolysis. In TEG (A), the cup holding the blood sample is rotating, whereas the torsion wire is fixed. In ROTEM (B), the cup is fixed, whereas the pin is rotating. Changes in torque are detected electromechanically in TEG and optically in ROTEM. The computer-processed signal is then presented as a tracing. (C) Shows typical tracings from TEG (lower tracing) and ROTEM (upper tracing). The time course of viscoelastic changes is depicted as additional parameters that reflect the rate and stability of clot formation; the values of these parameters can then guide clinical decision-making. ## Novel Blood Products

Two newer, novel blood products—recombinant activated factor VII (rFVIIa) and PCCs—have garnered considerable

attention but their roles in cardiac surgery and blood conservation may not yet be widely understood by practicing surgeons. We therefore close this chapter with brief discussions of these two products.

### RECOMBINANT ACTIVATED FACTOR VII

Endogenous activated factor VII plays a central role in coagulation; rFVIIa is nearly identical to the endogenous form of this factor and works by both tissue-factor-dependent and—independent mechanisms to generate thrombin.<sup>91</sup> The rFVIIa is approved by the Food and Drug Administration for the management of bleeding in patients with hemophilias A and B and in patients with congenital factor VII deficiency. The off-label use of rFVIIa in cardiac surgery has surged in recent years, where it is used to treat refractory intraoperative and/or postoperative hemorrhage.

However, the results of studies examining the use of this novel agent in cardiac surgery (mainly nonrandomized studies, case reports, and small case series) have been mixed. As such, a randomized controlled clinical trial was recently undertaken to assess the dose-escalating safety and efficacy of rFVIIa in postoperative cardiac surgical patients with refractory bleeding.<sup>92</sup> When used at either a low or high dose (40 or 80 µg/kg, respectively), rFVIIa was associated with significantly lower bleeding rates and allogeneic transfusions than was placebo.<sup>92</sup> The authors concluded that this therapy was effective for refractory bleeding but that the study was ultimately underpowered to speak to this blood product's safety profile.<sup>92</sup> A recent comprehensive review of 35 randomized clinical trials using rFVIIa for all off-label indications sought to address this question of safety and demonstrated a significantly higher incidence of arterial thrombotic events with rFVIIa versus placebo (5.5 vs 3.2%, respectively).<sup>93</sup>

Current blood conservation guidelines state that rFVIIa may be considered for the management of intractable non-surgical bleeding that is otherwise unresponsive to conventional hemostatic therapies.<sup>26,44</sup> Yet, the routine, prophylactic use of rFVIIa in cardiac surgery cannot be endorsed for reasons of cost, due limited data on its efficacy, and because of concerns for increased risk of serious adverse events with this blood product.

### PROTHROMBIN COMPLEX CONCENTRATES

PCCs are plasma-derived concentrates of vitamin K-dependent coagulation factors (II, VII, IX, X, and proteins C and S); several PCC products are currently available. PCCs are useful for the rapid reversal of oral anticoagulants; in a randomized trial of cardiac surgical patients, PCC reversed oral anticoagulation safely, more quickly, and with decreased bleeding compared to reversal with FFP.<sup>94</sup> PCCs are also beginning to be studied for the treatment of post-CPB coagulopathy and early results suggest that PCC use may decrease subsequent FFP and platelet transfusion requirements<sup>95</sup>—though these promising preliminary results have yet to be validated in larger, randomized controlled clinical trials.

## KEY POINTS

- There is little evidence to support the routine, liberal use of blood transfusions in cardiac surgery.
- Comprehensive blood conservation programs are the most effective strategy in decreasing patients' exposures to allogeneic blood.
- Blood conservation should be approached in a multidisciplinary fashion using a team that includes members from surgery, anesthesiology, nursing, perfusion, blood banking, and quality improvement.
- Preoperative strategies for minimizing bleeding risks and transfusion requirements include: the identification of high-risk patients; appropriately stopping medications that contribute to coagulopathy; and increasing preoperative red cell mass with iron supplementation, erythropoietin, and/or PABD.
- The use of CPB techniques that reduce blood loss and protect against transfusions should be maximized—these include: ANH with the subsequent reinfusion of drained autologous blood, retrograde autologous priming, and the utilization of mini-circuits and modified UF.
- Antifibrinolytic drugs and topical hemostatic agents are important adjuncts to blood conservation.
- A patient's unique clinical situation, rather than rigid transfusion triggers, should guide postoperative blood utilization.
- The incorporation of new surgical techniques, novel agents and blood products, and evolving technologies into blood conservation programs must be based on evidence from well-designed clinical trials.

# Deep Hypothermic Circulatory Arrest

Bradley G. Leshnower • Edward P. Chen

Surgical therapy for aortic arch disease involves partial or complete replacement of the arch with great vessel reimplantation during a period of time when native cerebral blood flow is temporarily interrupted. In its original description, this interval of suspended cerebral perfusion required the cessation of blood flow to the entire body and was labeled hypothermic circulatory arrest (HCA). HCA employs the use of systemic hypothermia to protect the brain and visceral organs during the ischemic period, and provides a bloodless operative field to facilitate arch reconstruction. Since the initial report of the use of HCA for aortic arch replacement, cerebral protection, and circulation management techniques have evolved to enable safe, reproducible arch reconstruction with excellent neurologic outcomes.<sup>1</sup>

HCA traces its beginnings to the work of Bigelow who demonstrated a role for hypothermia in cardiac surgery in a canine model.<sup>2</sup> John Lewis used systemic hypothermia at 28°C combined with venous inflow occlusion to perform the first successful atrial septal defect repair. He subsequently described the use of profound systemic hypothermia (9°C) with one hour of circulatory arrest without any evidence of central nervous system injury to treat an adult with ovarian carcinoma.<sup>3,4</sup> Systemic hypothermia was temporarily abandoned with the arrival of the cardiopulmonary bypass machine, but was rediscovered and used in isolated reports of arch replacement in the 1960s.<sup>5,6</sup> However, it was the translational research of Dr. Randall Griepp, who applied lessons learned from his canine laboratory models to successfully repair aortic arch aneurysms using HCA, that ushered in the modern era of aortic arch surgery.<sup>1</sup>

## BASIC PRINCIPLES

For the purposes of clarity throughout this chapter, the use of HCA without adjunctive cerebral perfusion will be termed as “HCA alone”. The classification system in Table 15-1 will be used to describe varying degrees of hypothermia used for HCA Table 15-1. Deep hypothermic circulatory arrest (DHCA) and moderate hypothermic circulatory arrest (MHCA) are the two levels of HCA that will be primarily focused upon throughout the subsequent text.

## Cerebral Metabolism and Blood Flow

Comprehension of HCA mandates a fundamental understanding of cerebral metabolism and blood flow. The metabolic rate and energy requirements of the brain are approximately 7.5 times the metabolism of non-nervous system tissues. The brain depends upon the aerobic process of glycolysis for energy and is estimated to have only a 2-minute supply of glucose stored as glycogen in neurons at any time. The brain is intolerant of ischemia and in that setting quickly resorts to anaerobic metabolism for energy production. Once adenosine triphosphate (ATP) stores are depleted, basic cellular ionic pumps fail and calcium accumulates in the intracellular space. This leads to irreversible neuronal injury.<sup>7</sup>

In order to support the high cerebral metabolic rate, the body provides approximately 60 mg of glucose and 3.5 mL of oxygen per 100 mg of brain tissue per minute. This translates to a cerebral blood flow of 750 to 900 mL/min or 15% of resting cardiac output under normothermic conditions.<sup>7</sup> The autoregulatory capacity of the cerebral microcirculation ensures constant flow rates in normotensive individuals within a mean arterial blood pressure range of 60 to 140 mm Hg. This level of perfusion maintains a ratio of cerebral blood flow to metabolism of 20:1. However, several physiologic variables including temperature, pH, and hematocrit can modulate cerebral blood flow.<sup>8</sup>

Since oxygen is vital to brain metabolism, measurement of the cerebral metabolic rate for oxygen (CMRO<sub>2</sub>) provides important comparative information regarding the metabolic state of the brain. Hypothermia has been shown to exponentially reduce cerebral metabolism. Systemic hypothermia at 20°C reduces the CMRO<sub>2</sub> to 76% of its baseline, and deeper hypothermia to 15°C reduces CMRO<sub>2</sub> to 84% of baseline values (Table 15-2).<sup>9</sup> In contrast to the CMRO<sub>2</sub>, hypothermia reduces cerebral blood flow in a linear fashion. As the core body temperature decreases to 22°C, the cerebral microcirculation loses its ability to autoregulate and cerebral blood flow becomes dependent upon mean arterial pressure.<sup>10</sup> Loss of autoregulation translates into an uncoupling of cerebral blood flow and metabolism. This produces excess or “luxury” perfusion of the brain, and the ratio of cerebral blood flow to

**TABLE 15-1: Consensus on Hypothermia Classifications in Aortic Arch Surgery**

Category	Nasopharyngeal temperature
Profound hypothermia	≤14°C
Deep hypothermia	14.1-20°C
Moderate hypothermia	20.1-28°C
Mild hypothermia	28.1-34°C

metabolism increases to a ratio of 75:1. The significance of luxury perfusion is unclear. Potential beneficial effects of luxury perfusion include a quicker, more homogenous cooling of the brain; however, potential detrimental effects include the development of brain edema and exposure to an increased embolic load.<sup>8</sup>

The most clinically accessible method of assessing cerebral metabolism is the measurement of cerebral electrical activity, which can be monitored by electroencephalography (EEG). Systemic cooling diminishes cerebral electrical activity and electrocerebral or EEG silence indicates maximal cerebral metabolic suppression. Many aortic centers use complete EEG silence during the cooling period as a reliable and safe measure of adequate cerebral suppression, indicating that it is safe to initiate HCA.

## pH Management

As stated previously, cerebral blood flow is impacted by temperature and the acid-base status of the blood. Two different strategies are used during HCA to manage pH. Alpha-stat pH management maintains normal acidemia and blood gases in 37°C (normothermic) blood. This optimizes cellular enzyme activity and preserves cerebral autoregulation. In

**TABLE 15-2: Measurement of the Cerebral Metabolic Rate for Oxygen (CMRO<sub>2</sub>) Provides Important Comparative Information Regarding the Metabolic State of the Brain**

Temperature (°C)	Cerebral metabolic rate (% of base line)	Safe duration of HCA (min)
37	100	5
30	56 (52-60)	9 (8-10)
25	37 (33-42)	14 (12-15)
20	24 (21-29)	21 (17-24)
15	16 (13-20)	31 (25-38)
10	11 (8-4)	45 (36-62)

alpha-stat management, the pH is allowed to change as the blood temperature decreases, and the blood becomes more alkaline and hypocapnic. Such conditions cause a shift of the oxyhemoglobin dissociation curve to the left, which increases the affinity of hemoglobin for oxygen. The net effect is that in deep hypothermia, oxygen bound to hemoglobin is less available to be released to the tissues, and the fraction of oxygen dissolved in blood represents the major source of oxygen to the tissues.

The alternative strategy is pH-stat management, which maintains a normal pH at hypothermia by adding CO<sub>2</sub> to the blood during cooling. Supplementary CO<sub>2</sub> causes cerebral vasodilatation and eliminates the autoregulatory capacity of the cerebral microvasculature. This results in an increase in cerebral blood flow and an uncoupling of cerebral blood flow from cerebral metabolism. Due to the supplementary CO<sub>2</sub>, at deep hypothermia, the oxyhemoglobin dissociation curve is shifted to the right, which decreases the affinity of hemoglobin to oxygen and increases the delivery of oxygen to the tissues. Under pH-stat management, the blood becomes acidotic and hypercapnic when the blood temperature is rewarmed to 37°C.

Studies comparing the two strategies have been conducted in both large animals and humans. The majority of human studies contain small numbers of patients who underwent either adult cardiac or congenital heart procedures that did not utilize circulatory arrest. The adult studies are composed of patients undergoing coronary artery bypass grafting under moderate-to-mild levels of hypothermia (26-32°C). Conclusions from the adult studies indicate superior outcomes with alpha-stat management. The animal and pediatric studies contain data conducted under deep hypothermia with either low flow cardiopulmonary bypass or circulatory arrest. Outcomes in these studies were superior with pH-stat management.<sup>11</sup>

The mechanisms of intraoperative brain injury differ between adults and children. Adults are prone to suffer embolic injury secondary to risk factors for vasculopathy (eg, hypertension, atherosclerosis, diabetes mellitus). Children undergoing repair of complex congenital heart disease are more susceptible to global ischemic injury from prolonged periods of low flow or circulatory arrest. Therefore, alpha-stat management may be more optimal in adults, where the preservation of cerebral autoregulation enables the microvasculature to adjust to areas of stenoses and any disproportionate distribution of flow. Conversely, children may benefit from the global cerebral vasodilatation associated with pH-stat management to augment blood flow during prolonged low flow states.<sup>11-13</sup>

## Pathogenesis of Brain Injury During HCA

It is well recognized that there are two different types of brain injury observed in patients treated with HCA: (1) permanent neurologic dysfunction (PND) and (2) temporary neurologic dysfunction (TND). PND, commonly referred to as stroke, manifests clinically as a focal neurologic deficit

secondary to an embolism of particulate matter or air/gas bubbles causing vascular occlusion resulting in an ischemic cerebral infarct. Risk factors for PND in patients undergoing HCA include atheromatous disease involving both the ascending aortic and the site of arterial cannulation for cardiopulmonary bypass.<sup>14-16</sup> The axillary artery has been shown to provide the lowest risk of stroke in patients undergoing HCA operations.<sup>16</sup> Other neuroprotective strategies to reduce the risk of embolic stroke include the use of epiaortic ultrasound to guide the site of arterial cannulation and aortic cross clamping, and the addition of antegrade or retrograde cerebral perfusion (RCP).

TND is a reversible, diffuse subtle injury which is attributed to inadequate cerebral protection.<sup>17</sup> Patients with TND can experience confusion, agitation, delirium, prolonged obtundation, or parkinsonism without localizing signs in the immediate postoperative period. Brain imaging in this clinical setting with computed tomography or magnetic resonance imaging is negative. TND is the clinical manifestation of a global cerebral ischemic injury that results in necrotic and/or apoptotic neuronal cell death.

Necrotic cell death following HCA occurs due to a failure to meet minimum cerebral cellular metabolic and oxygen requirements. In this instance, cellular stores of ATP are exhausted and the cell converts to anaerobic metabolism. The lack of ATP also causes a failure of the  $\text{Na}^+/\text{K}^+$  pump which has a multitude of consequences including cellular swelling, depolarization of the cell membrane, opening of voltage sensitive  $\text{Ca}^{2+}$  channels and a massive influx of calcium into the cytoplasm. Accumulation of intracellular calcium activates proteases and lipases that disrupt the cellular membrane and results in cell lysis and death. Histologically, cellular necrosis is characterized by pyknotic nuclei, swollen eosinophilic cytoplasm, and the presence of an inflammatory reaction. Risk factors for neuronal cell necrosis following HCA include inadequate levels of hypothermia, the presence of electrocerebral activity at the time of circulatory arrest, and prolonged duration (>40 minutes) of HCA without cerebral perfusion.<sup>18-20</sup>

The second type of cell death observed in patients after HCA with inadequate cerebral protection is apoptosis. Apoptotic cell death is an energy-dependent process that occurs despite adequate stores of cellular energy. It represents a sublethal ischemic injury that results in the activation of specific genes, receptors and enzymes that break down the cell in a programmed manner.<sup>21</sup> Morphologically it is characterized by nuclear karyorrhexis, and margination of chromatin in the nucleus with minimal cytoplasmic or inflammatory changes. Apoptosis is a highly sophisticated and complex process that has not yet been fully characterized, and a detailed description is beyond the scope of this chapter. Fundamentally, it is a carefully regulated process that leads to the generation of caspases which initiate a proteolytic cascade in which one caspase activates other caspases and leads to rapid cell death.<sup>22</sup> Multiple animal models of DHCA have demonstrated apoptotic cell death beginning within hours of reperfusion and continuing as long as 72 hours after DHCA.<sup>23,24</sup>

Ischemia and hypoxia can initiate cell death through a third mechanism related to excessive neuronal stimulation and hyperactivity. Once the brain converts to anaerobic metabolism, lactate is produced. The inability of the neuronal cells to utilize lactate as an energy source, combined with the lack of blood flow during HCA, results in the accumulation of lactate and a drop in intracellular pH. The development of intracellular acidosis has a multitude of effects including the release of the potent excitatory neurotransmitters glutamate and aspartate, and failure of the neurotransmitter pumps. This results in the accumulation of glutamate in the intercellular space. Glutamate in increasing concentrations becomes neurotoxic and mediates the opening of calcium channels. The end result is an influx of calcium into the cytoplasm, which initiates a lethal biochemical cascade resulting in neuronal cell death. Excitotoxicity is the term applied to this type of neuronal cell death induced by excitatory amino acids. Excitotoxicity plays an important role in both necrotic and apoptotic ischemic neuronal cell death.<sup>18</sup> Metabolic rates differ throughout the different regions of the brain, and foci with high metabolic rates are more sensitive to ischemia. This concept has been termed "selective vulnerability" and, applies to neurons in the hippocampus, basal ganglia and cerebellum.<sup>25,26</sup> Patients with TND due to inadequate cerebral protection following HCA can often display poor cognition, altered short-term memory, and fine motor deficits. Neuropsychological tests in patients undergoing HCA have demonstrated memory and fine motor deficits consistent with subtle brain injury in patients following periods of DHCA > 25 minutes.<sup>27</sup> This type of subtle brain injury is likely due to necrotic or apoptotic neuronal cell death in the hippocampus, basal ganglia, and cerebellum. The impact of TND is not clinically insignificant and correlates with long-term memory and motor deficits following prolonged periods of DHCA.<sup>28</sup>

## DEEP HYPOTHERMIC CIRCULATORY ARREST

### Cooling

After the initiation of cardiopulmonary bypass, systemic hypothermia is achieved by cooling the blood passing through a heat exchanger connected to the perfusion circuit. A temperature gradient (arterial inflow to venous return) that does not exceed  $10^\circ\text{C}$  is maintained during the cooling period to prevent the formation of gaseous emboli. The duration of the cooling period required to equilibrate blood and tissue temperatures is highly variable and is dependent upon blood flow, temperature gradient (between perfusate and organs), and tissue-specific coefficients of temperature exchange. Patient-specific variables that impact cooling include occlusive vascular disease and body mass index.

There is no consensus regarding cooling strategies for HCA. Intraoperative monitoring of time, temperature, jugular venous bulb oxygen saturation, and electroencephalographic activity can assist in the evaluation of cerebral

metabolic suppression during the cooling period. Temperature is monitored in many different sites including the inflow and outflow lines of the perfusion circuit, and by probes inserted into the bladder, rectum, nasopharynx, and esophagus. If the cerebral protection strategy is HCA alone or in conjunction with RCP, then the cooling strategy should be based upon esophageal or nasopharyngeal temperatures, as these sites have been shown to closely approximate brain temperature.<sup>29</sup> However, if antegrade cerebral perfusion is used, bladder or rectal temperatures are more important, as visceral organ protection becomes the primary goal of hypothermia.

Generally accepted parameters that ensure sufficient cerebral metabolic suppression include cooling for a minimum of 30 minutes, a goal nasopharyngeal temperature of 18°C, a jugular venous saturation > 95%, and electrocerebral silence.<sup>30-32</sup> However, relying on such parameters alone as a measure of adequate metabolic suppression may not be completely adequate. In a study of 109 patients undergoing HCA, >50% of patients had not achieved electrocerebral silence at a nasopharyngeal temperature of 18°C, and approximately 25% of patients have not achieved electrocerebral silence after 30 minutes of cooling.<sup>33</sup> This emphasizes the need to thoroughly evaluate all available monitoring parameters prior to initiating HCA. If HCA alone is employed, topical cooling by packing the head in ice is advocated in order to minimize upward drift of intracranial temperatures during the ischemic period.<sup>31</sup>

## Rewarming

Cerebral reperfusion and rewarming following the period of HCA is a critical phase that can exacerbate neuronal injury if not conducted properly. Following HCA, reinitiating brain reperfusion with a short period of low-pressure cold blood flow prior to rewarming is recommended. In contrast to immediate rewarming, cold reperfusion has been associated with improved cerebral perfusion, a reduction in intracranial pressure, and a decrease in cerebral edema. This strategy attenuates the adverse effects of the impaired cerebral vascular autoregulation that occurs following DHCA, and results in a reduction in brain injury.<sup>34,35</sup> Experimental data have also suggested that reperfusion should also be carried out with a higher hematocrit and normoglycemia. A lower hematocrit in the reperfusate ( $\approx 20\%$ ) has been shown to increase the degree of histopathologic brain injury compared to a higher (30%) hematocrit.<sup>36</sup> In addition to an increased oxygen carrying capacity, a higher hematocrit is thought to be beneficial due to an increase in the buffer, redox and free-radical scavenging capacity. Hyperglycemia during reperfusion has been correlated with worsening intracellular acidosis, which prevents the return of normal cellular metabolism.<sup>37</sup>

Oxygen delivery to the brain is particularly important during the reperfusion period as there is a mismatch between cerebral metabolism and blood flow. Cerebral vascular resistance is increased for up to 8 hours following the period of

HCA. This results in a reduction in cerebral blood flow and an abnormally high extraction rate of oxygen and glucose from the blood in order to sustain cerebral metabolism.<sup>38</sup> It is during this period that secondary brain injury can occur with episodes of hypotension, hypoxemia, and anemia.<sup>31</sup> A gradient < 10°C must be maintained to prevent the formation of gas emboli, and the temperature of the perfusate should not exceed 36°C. Cerebral hyperthermia results in worse neurobehavioral outcomes and increased neuronal cell injury compared to mild hypothermia following DHCA.<sup>39</sup> The mechanisms behind this injury are poorly understood; however, it is likely multi-factorial and related to increases in the permeability of the blood-brain barrier and cellular metabolism in the setting of hyperthermia. The risk of this delayed neurologic injury is significant, and many high volume aortic centers advocate a period of permissive hypothermia in the intensive care unit following DHCA in an attempt to reduce this risk.<sup>18,40</sup>

## Safe Duration of DHCA

“DHCA alone” or DHCA without adjunctive cerebral perfusion represents the simplest, most convenient form of cerebral protection. It does not require complex perfusion strategies or neuromonitoring, and is the cerebral protection strategy of choice for surgeons who infrequently perform aortic arch reconstructions. The main concern surrounding the use of DHCA alone is the duration of the circulatory arrest period.

In an attempt to provide data regarding the safe interval of circulatory arrest at different temperatures, the Mount Sinai group measured arterial and venous blood gases at various time and temperature points in 37 adults undergoing HCA. This led to the calculation of the  $CMRO_2$  consumption at various temperatures. Using  $CMRO_2$ , the  $Q_{10}$  (a well-described physiologic variable describing the temperature-dependent decrease in cerebral metabolism), and the assumption that cerebral blood flow can be safely interrupted for 5 minutes at 37°C, a calculated safe duration of HCA was determined for a range of temperatures. Figure 15-1 demonstrates the relationship between  $CMRO_2$ , temperature, and the calculated safe duration of HCA.<sup>9,18</sup>

Although most high volume aortic centers have added adjunctive cerebral perfusion to HCA as their standard strategy of cerebral protection, some centers such as Dr. Elefteriades' group at Yale still maintain the use of DHCA alone. In a contemporary series of 394 patients undergoing elective and emergent proximal and distal thoracic aortic repairs involving arch pathology, these authors cooled to a mean bladder temperature of 19°C without the use of neuromonitoring prior to initiating HCA. This correlated to a cooling period of 30 to 35 minutes. Their overall mortality and stroke rates were 6.3% and 4.8%. The incidence of seizure and dialysis were 3.1% and 2.3%, respectively. The mean DHCA time was 31 minutes, and there was a trend toward an increased stroke risk in patients with a DHCA time exceeding 40 minutes.<sup>30</sup> In a series of 656 patients undergoing DHCA alone

**FIGURE 15-1** Limits of 'safe' duration of circulatory arrest.  $Q_{10}$  for the adult brain calculated from direct measurement of cerebral metabolic rate for oxygen (CMRO<sub>2</sub>) in 37 adult patients undergoing thoracic aortic operations with DHCA. The temperature-related reduction in the metabolic rate and the calculated 'safe' periods of arrest are shown. (Data from McCullough JN, Zhang N, Reich DL, et al: Cerebral metabolic suppression during hypothermic circulatory arrest in humans, *Ann Thorac Surg.* 1999 Jun;67(6):1895-1899.)

from Dr. Crawford's Houston group, circulatory arrest times > 40 minutes were also associated with an increased risk of stroke.<sup>41</sup>

Based upon these data above, when using DHCA alone for the repair of aortic pathology involving the arch, cooling for 30 minutes to achieve a bladder temperature of 18°C or an esophageal/nasopharyngeal temperature of 15°C will safely provide cerebral protection for 30 minutes of circulatory arrest. When the circulatory arrest period extends beyond this duration, adjunctive cerebral perfusion should be employed.

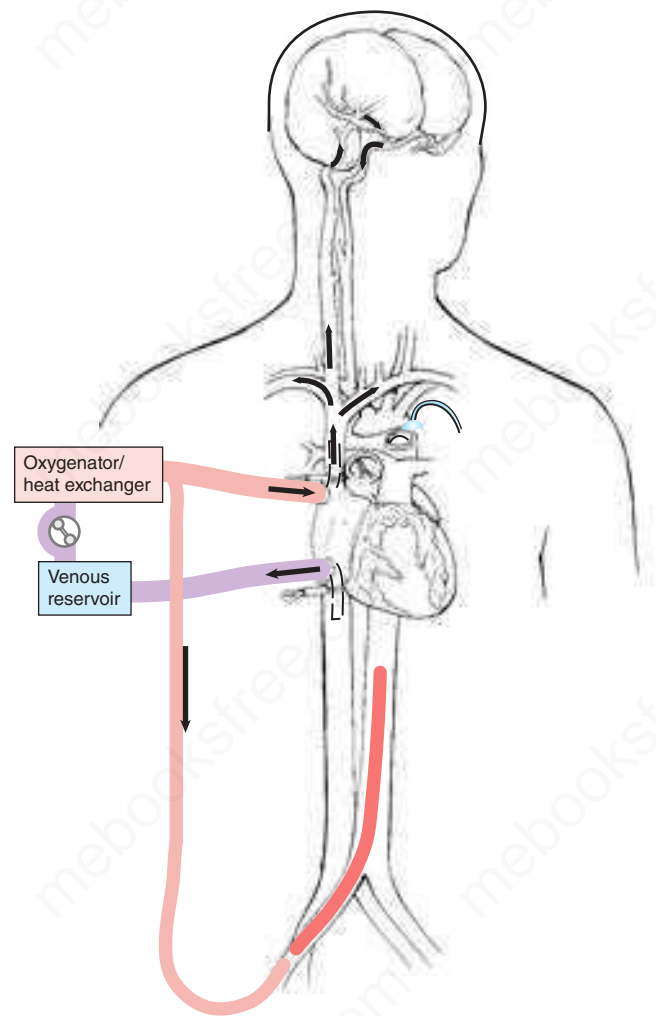

## Cerebral Perfusion

Although DCHA revolutionized aortic arch surgery, the incidence of brain injury following prolonged periods of DHCA alone was not insignificant. It was quickly recognized that complex aortic arch reconstructions requiring circulatory arrest times > 30 minutes were associated with increased rates of adverse neurologic outcomes and mortality.<sup>30,41,42</sup> The introduction of adjunctive cerebral perfusion as an additional method of cerebral protection had a transformative effect on the field and produced dramatic improvements in neurologic outcomes following arch reconstruction.

### RETROGRADE CEREBRAL PERFUSION

RCP was first described by Mills and Ochner in the treatment of a massive air embolus during cardiopulmonary bypass.<sup>43</sup> In 1990, Ueda was the first to report the use of RCP

as an adjunct to profound HCA in a series of eight patients undergoing aortic arch replacement.<sup>44</sup> RCP is performed by cannulating and snaring the superior vena cava, and infusing hypothermic arterial blood from the cardiopulmonary bypass circuit up the superior vena cava to perfuse the brain in a retrograde direction during the period of circulatory arrest (Fig. 15-2). Generally accepted flow rates are 300 to 500 mL/min to maintain a SVC pressure of 20 to 25 mm Hg. If performed properly, RCP will produce dark blood (suggesting cerebral oxygen extraction) flowing retrograde from the origins of the great vessels into the open aortic arch during HCA. The theoretical cerebral protection benefits of RCP are to (1) flush embolic material (gaseous and particulate) from the cerebral circulation; (2) maintain cerebral hypothermia by bathing the brain in cold blood; and (3) support cerebral metabolism by providing sufficient cerebral flow during the period of HCA.

**FIGURE 15-2** Schematic of retrograde cerebral perfusion (RCP). Arterial blood is perfused via the superior vena cava, with a target CVP of 25 mm Hg. Flow can be monitored through the open aortic arch. Balloon occlusion catheter can be employed to increase perfusion to body.

The proposed benefits of RCP have been extensively investigated using experimental models of HCA. RCP has been shown to significantly reduce intracranial temperatures in porcine and canine models of HCA. The maintenance of cooler temperatures resulted in a reduction of neurologic injury based upon histopathology examinations.<sup>45,46</sup> RCP has also been shown to be highly effective in washing out particulate emboli from the brain using microspheres in a porcine model.<sup>47</sup> However, despite a large number of experiments in various animal models, the data are inconclusive regarding the capacity of RCP to provide significant cerebral blood flow. Shunting of blood away from brain capillaries occurs during profound hypothermic RCP via large venoarterial connections.<sup>46,48-51</sup> Cerebral blood flow can be improved with higher retrograde perfusion pressures and occlusion of the inferior vena cava; however, there is an increase in cerebral edema with histologic evidence of cerebral injury.<sup>52</sup> Based upon human cadaver studies, the majority of internal jugular veins have competent venous valves. In these experiments, significant retrograde cerebral blood flow was observed in <30% of cadavers, and the azygous rather than the internal jugular vein, represented the predominant pathway of flow.<sup>53,54</sup> Despite the unconvincing results of the cerebral blood flow data, RCP has been shown to improve metabolic support during HCA, with improved oxygen delivery, increased levels of cerebral ATP, a reduction in lactate production, and improved brain tissue oxygenation.<sup>46,55,56</sup>

Although human studies have also failed to conclusively demonstrate significant cerebral capillary blood flow, the addition of RCP to HCA has markedly improved clinical outcomes following arch reconstruction.<sup>57,58</sup> In a series of 479 patients undergoing elective and emergent arch repair, Coselli compared outcomes using DHCA ( $n = 189$ ) versus DHCA + RCP ( $n = 290$ ). The addition of RCP significantly reduced mortality (DHCA + RCP 3.4% vs DHCA 14.8%,  $p < .001$ ) and stroke rates (DHCA + RCP 2.4% vs DHCA 6.5%,  $p < .05$ ).<sup>59</sup> In a series of 1107 arch repairs, Estrera compared outcomes using DHCA ( $n = 200$ ) versus DHCA + RCP ( $n = 900$ ). For the entire series, the mortality and stroke rates were 10.4% and 2.8%, respectively. In both univariate and multivariate analyses, the addition of RCP was protective against mortality ( $p < .001$ ) and stroke ( $p = .02$ ). However, the incidence of TND was 15.5% with relatively short mean RCP times of 26 minutes.<sup>60</sup> Although this is lower than the 25% incidence of TND associated with arch reconstruction using DHCA alone,<sup>28</sup> it still represents a significant incidence of inadequate cerebral protection. Other groups have also reported an incidence of TND ranging from 17 to 25% with the use of DHCA + RCP.<sup>61-63</sup>

### SELECTIVE ANTEGRADE CEREBRAL PERFUSION

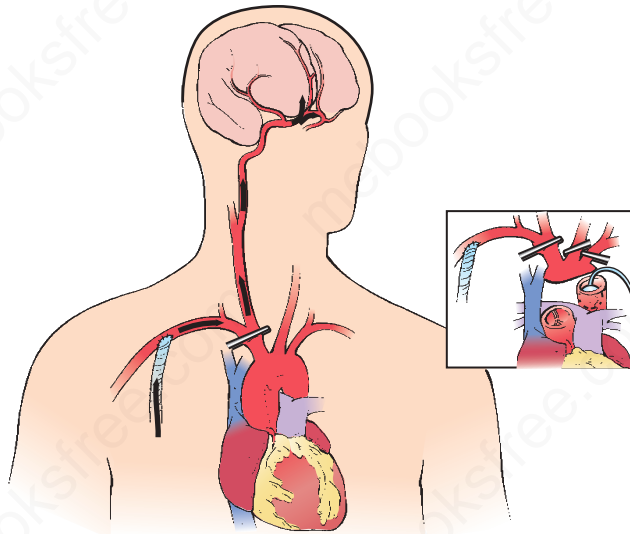

DeBakey and Cooley were the first to successfully describe the use of selective antegrade cerebral perfusion (SACP) in the surgical repair of an arch aneurysm in 1957.<sup>64</sup> In their initial report, cannulas were placed into the right femoral and bilateral carotid arteries, and a separate pump from the main

cardiopulmonary bypass machine was used to perfuse normothermic blood into the carotid arteries during the period of HCA. Despite its initial success, this method was considered complex and cumbersome, and was subsequently abandoned. SACP was later revisited in the late 1980s due to the recognition of the limitations of DHCA alone. In 1991, Bacht published a series of 54 patients undergoing open arch reconstruction in which SACP was combined with HCA for cerebral protection. The technique consisted of bilateral carotid artery cannulation and infusion of blood at temperatures of 6 to 12°C (“cold cerebroplegia”) at a rate of 250 to 350 mL/min during a mean period of 22 minutes of HCA conducted at a rectal temperature of 25 to 28°C. Hospital mortality was 13% and the incidence of stroke was 1.8%.<sup>65</sup> One year later, Kazui reported the results of 23 arch reconstructions performed with systemic hypothermia, SACP, and lower body perfusion alone via the femoral artery. The mortality rate was 8.7% and there were no strokes. The mean SACP perfusion time was 90 minutes.<sup>66</sup> These two initial series provided the foundation for the use of SACP as the predominant form of cerebral protection for extended aortic arch reconstructions in the modern era.

In contrast to RCP, experimental data have confirmed the ability of SACP to provide adequate cerebral blood flow to support brain metabolism during the period of HCA. Transcranial Doppler measurements of middle cerebral artery blood flow in patients undergoing arch reconstruction have clearly demonstrated the superiority of SACP compared to RCP in providing reliable cerebral perfusion.<sup>67</sup> In a porcine model of HCA, Filgueiras and colleagues demonstrated the maintenance of near normal cerebral metabolism with DHCA + SACP, based upon measurements of pH and levels of cerebral metabolites. Animals undergoing DHCA + RCP or DHCA alone demonstrated a significant drop in cerebral pH during the protocol.<sup>68</sup> In a separate study using the same model, these same investigators demonstrated preserved cell structure upon histopathologic analysis with DHCA + SACP compared to DHCA + RCP.<sup>69</sup> Hagl and colleagues showed in an acute porcine model that a strategy of DHCA + SACP compared to DHCA alone is associated with improved neurophysiologic recovery, lower intracranial pressure, less cerebral edema, and reduced tissue acidosis following the circulatory arrest period.<sup>70</sup>

It should be recognized that the utilization of SACP changes the paradigm of circulatory arrest. Circulatory arrest, as originally described, refers to the complete interruption of the circulation and the absence of perfusion to all organs. The addition of SACP changes this concept from total body circulatory arrest to lower body circulatory arrest, as the brain, arms, and the spinal cord (via collateral circulation) are perfused. Therefore the legs and the abdominal visceral are the sole ischemic organs during the circulatory arrest period with the use of SACP.

Numerous techniques have been described for the delivery of SACP. Bilateral SACP (bSACP) involves direct cannulation of the cervical left and right common carotid arteries or the introduction of perfusion cannulas into the ostia of the

**FIGURE 15-3** Schematic of right axillary artery cannulation for antegrade cerebral perfusion (ACP). Insert shows open aortic arch and ACP with occlusion of arch vessels to ensure perfusion of Circle of Willis.

innominate and left carotid arteries via the open arch at the time of HCA. The disadvantages of this latter method include the risk of introducing air or atherosclerotic emboli and cluttering the operative field with additional cannulas. At Emory, the preferred method of cerebral perfusion is unilateral SACP (uSACP) via right axillary artery cannulation. An 8-mm graft is sewn end to side to the right axillary artery prior to sternotomy and used as the arterial inflow line to initiate cardiopulmonary bypass. At the time of HCA, blood flow is decreased to 10 mL/kg/min and the base of the innominate and left common carotid arteries are occluded with vascular clamps (Fig. 15-3). Left carotid occlusion is performed to pressurize the extra cranial circulation and collateral system and minimize steal. This enables blood to flow via the right common carotid and right vertebral arteries to perfuse the brain and spinal cord. Flows are adjusted to maintain cerebral perfusion pressures of 50 to 60 mm Hg.<sup>71</sup> Critics of this technique argue that uSACP provides insufficient cerebral blood flow to the left cerebral hemisphere. However, both animal and clinical data have demonstrated that there is no significant difference in cerebral blood flow between uSACP and bSACP, with and without an intact circle of Willis.<sup>72-74</sup> Furthermore, data from a large, contemporary, propensity-matched analysis of 1097 patients undergoing arch replacement with HCA and SACP demonstrated no difference in morbidity and mortality between uSACP and bSACP. Interestingly, there was a trend toward a higher incidence of stroke in the bSACP group that was attributed to great vessel manipulation.<sup>77</sup>

### MODERATE HYPOTHERMIA

The implementation of SACP as an adjunct to hypothermia for cerebral protection has led to a departure from the use of deep hypothermia, to the use of moderate levels of hypothermia

at the time of lower body ischemia. The rationale behind this strategy is based upon the concept that SACP has transformed total body circulatory arrest into lower body circulatory arrest. Since cerebral perfusion is maintained with cold blood throughout the period of circulatory arrest, the primary purpose of systemic hypothermia is to provide protection to the visceral organs, skeletal muscle, and spinal cord via metabolic suppression. The metabolic rate of the visceral organs and skeletal muscle is significantly less than the brain; therefore, the visceral organs require a reduced degree of hypothermia for optimal protection and are more tolerant of ischemia. As stated in the preceding sections, colder temperatures clearly correlate with a greater reduction in metabolism. However, the induction of deep hypothermia is not a benign process. It requires prolonged cardiopulmonary bypass times for cooling and rewarming which can have detrimental effects on the lungs, liver, and kidneys. Deep hypothermia has been associated with vascular endothelial dysfunction, bleeding complications, and an increased systemic inflammatory response.<sup>75-78</sup>

The impact of MHCA has been examined in several retrospective studies. Minatoya and colleagues evaluated the outcomes of 229 patients who received arch reconstruction with HCA + bSACP at three different temperatures: 20°C (n = 81), 25°C (n = 81), and 28°C (n = 67). Eighty-one percent of all patients received total arch replacement. There were no significant differences between the three groups with regard to the incidence of mortality, PND, or TND.<sup>79</sup> These authors published a subsequent review of 1007 patients undergoing elective and emergent arch reconstruction (73% total arch) comparing DHCA (<25°C)/bSACP versus MHCA (>25°C)/bSACP. Their overall mortality was 4.7% with PND and TND rates of 3.5% and 6.7%, respectively, with no differences observed between the two strategies.<sup>80</sup> Pacini and colleagues examined the impact of moderate hypothermia on visceral organ protection in 334 patients undergoing elective arch reconstruction with a strategy of either DHCA (<25°C)/bSACP or MHCA (>25°C)/bSACP. Overall in-hospital mortality was 4.6% and the incidence of PND and TND were 5.9% and 7.9%, respectively. The incidence of dialysis-dependent renal failure was 6.9% and there were no cases of liver failure. There was no difference in mortality, PND, TND, dialysis-dependent renal failure, or liver dysfunction between the two strategies. In a multivariate analysis of their results, cardiopulmonary bypass time > 180 minutes and deep hypothermia were predictive risk factors for renal and/or liver dysfunction.<sup>81</sup>

MHCA/SACP currently represents the preferred circulation management strategy for many high-volume aortic centers worldwide. At Emory, MHCA with uSACP is the standard cerebral protection method for elective and emergent hemiarch and total arch replacements. Hemiarch replacement is routinely conducted at temperatures of 28 to 29°C with mortality rates in elective and emergent cases of 4.3% and 7.7%, respectively. There is a low incidence of PND (elective 1.9%, emergent 4.6%), TND (elective 3.8%, emergent 6.2%), and dialysis-dependent renal failure (elective 2.4%, emergent 9.2%) with this technique. Mean circulatory

arrest times are 23 minutes in elective cases and 33 minutes in emergent cases.<sup>82</sup> Total arch replacement is conducted at temperatures of 25 to 26°C for both emergent and elective cases. A recent review of 145 consecutive patients undergoing total arch replacement at Emory demonstrated an operative mortality of 9.7%. The incidence of PND, TND, and dialysis-dependent renal failure were 2.8%, 5.6%, and 2.8%, respectively. The mean duration of circulatory arrest for these patients was 55 minutes.<sup>83</sup> Other high volume aortic centers have reported similar outcomes confirming MHCA/SACP as a safe and effective strategy for circulation management in aortic arch surgery.<sup>81,84-86</sup>

### COMPARISONS OF CEREBRAL PROTECTION STRATEGIES

Currently there is no consensus amongst aortic surgeons regarding the optimal method of cerebral protection during arch reconstruction. Instead, high-volume aortic centers employ a variety of different techniques using varying degrees of hypothermia with or without adjunctive cerebral perfusion. Often the method of cerebral protection is based upon the institutional bias rather than outcome data. Contemporary cerebral protection strategies are composed of multiple variables: arterial cannulation site, temperature at HCA, antegrade versus RCP, and unilateral versus bSACP. The majority of comparisons of cerebral protection strategies in the literature are essentially retrospective reviews of changes in circulation management strategies at a single institution over time. These comparisons are valuable, but limited by their retrospective nature, lack of randomization, and differences in several important variables including the extent of arch reconstruction, the temperature at HCA, antegrade versus RCP, and the percentage of emergent cases. Nevertheless, several lessons may be learned from a review of the existing literature.

Hagl reviewed the neurologic outcomes from the Mount Sinai experience of 717 patients undergoing arch replacement with different methods of cerebral protection: (1) DHCA (n = 588); (2) DHCA/RCP (n = 43); and (3) DHCA/SACP (n = 86). All patients were cooled to esophageal temperatures of 10 to 13°C. The overall incidence of PND and TND were 5.7% and 30%. In the 156 patients with HCA times > 40 minutes, there was no difference in the incidence of PND; however, DHCA/SACP significantly reduced the incidence of TND compared to the other strategies.<sup>87</sup> A recent retrospective review of the Japanese Adult Cardiovascular Surgery Database analyzed the outcomes of 8169 patients undergoing elective total arch replacement using either DHCA/RCP (n = 1141) or MHCA/SACP (n = 7038). The RCP group underwent HCA at 21.2°C compared to the SACP group who underwent HCA at 24.2°C. The duration of HCA was not reported in this study. In unmatched and propensity-matched analyses, there were no differences between the groups in mortality, PND, TND, or dialysis. However, it was clear that in this contemporary study, SACP was the preferred modality of cerebral perfusion amongst Japanese surgeons

for total arch replacements that required prolonged periods of HCA.<sup>88</sup> There is a single prospective trial comparing the impact of SACP versus RCP in the literature. Okita compared DHCA/RCP versus DHCA/SACP in 60 consecutive patients undergoing total arch replacement with a variety of different cannulation sites. RCP patients underwent HCA at 17.2°C and SACP patients underwent HCA at 22.1°C. There was no difference in mortality or stroke, but SACP significantly reduced the incidence of TND (SACP 13.3% vs RCP 33.3%,  $p = .05$ ).<sup>89</sup>

The remainder of the retrospective comparisons between SACP and RCP in the literature are limited by significant differences in the temperature at which HCA is conducted. In these studies, the majority of patients receiving SACP undergo circulatory arrest at moderate levels of systemic hypothermia, as opposed to DHCA with the use of RCP. Three recurring themes emerge from the existing analyses in the literature: (1) an adjunct form of cerebral protection (SACP or RCP) is superior to DHCA alone and (2) the method of cerebral perfusion (SACP or RCP) has no impact upon the incidence of PND, however, (3) SACP significantly reduces the incidence of TND. Furthermore, most experts agree that in patients undergoing extended/complex arch reconstructions requiring prolonged periods of HCA, SACP is superior to RCP in preventing TND and is associated with improved overall neurologic outcomes.<sup>40,90-92</sup> The thoracic aortic surgical community recognizes the need for a prospective randomized multi-institutional trial comparing cerebral protection strategies; however, the logistics remain complicated.

### Pharmacologic Adjuncts

Pharmacologic adjuncts that have been utilized to optimize cerebral protection during HCA include corticosteroids, barbiturates, and mannitol. Cardiopulmonary bypass and DHCA have been associated with a significant systemic inflammatory response, increased permeability of the blood-brain barrier and cerebral edema. Corticosteroids are a potent anti-inflammatory agent that have been shown to suppress the inflammatory response associated with DHCA. Experimental data have demonstrated that pretreatment with corticosteroids prior to cardiopulmonary bypass reduces the permeability of the blood-brain barrier, attenuates cerebral apoptosis and improves cerebral blood flow following DHCA.<sup>93,94</sup> At Emory our typical protocol includes the administration of 1 g of methylprednisolone following induction of anesthesia and a rapid taper of steroids over the first 72 hours of the postoperative period.

Barbiturates have been shown to reduce cerebral oxygen consumption, produce an isoelectric electroencephalogram, and minimize cerebral edema. Thiopental, the most commonly used barbiturate, is employed in several high-volume aortic centers for cerebral protection in cases requiring DHCA. The timing and dose of thiopental administration can impact its effectiveness. If administered prior to HCA, the cerebral energy state is reduced which may lead

to adverse outcomes; however, its effects are considered to be advantageous when thiopental is administered during HCA. Furthermore, there is also a dose-dependent effect of barbiturates. Although low-dose barbiturates minimize cerebral metabolism, higher doses are associated with negative inotropy and sedation which could prolong the time to extubation. A recent analysis of the currently existing data did not conclusively demonstrate a cerebral protection advantage with the use of barbiturates in patients undergoing DHCA.<sup>95,96</sup>

Mannitol is a potent osmotic diuretic that is an established agent for reducing cerebral edema. It also possesses free oxygen radical scavenger properties and may have an anti-apoptotic effect following cerebral ischemia.<sup>96</sup> The impact of these three pharmacologic agents upon postoperative mortality and adverse neurologic outcomes was recently evaluated in an analysis of the German Registry for Acute Aortic Dissection Type A. Based upon univariate and multivariate analyses, steroids were the only agent that provided additional cerebral protection by reducing the risk of new postoperative PND. Both mannitol and barbiturates were associated with a significant reduction in 30-day mortality based upon the univariate analysis, but only mannitol lowered mortality in the multivariate analysis. Neither agent conferred additional neuroprotection.<sup>96</sup> In summary, the use of steroids and mannitol is advantageous following DHCA, while the use of thiopental cannot be recommended based upon the available data.

# Myocardial Protection

M. Salik Jahania • Roberta A. Gottlieb  
• Robert M. Mentzer, Jr.

Myocardial protection in the operating room refers to strategies and methods used to attenuate or prevent perioperative infarction and/or postischemic ventricular dysfunction. In the setting of an acute myocardial infarction (MI) it refers to adjuvant therapy administered before, during or after reperfusion therapy. In transplantation it refers to the methods used to preserve the donor heart. Although the clinical situations are different, the goal of protection is the same, that is, to prevent or treat myocardial stunning and infarction. The underlying pathophysiology in all three settings is the same and relates to the etiology and consequences of ischemia/reperfusion (I/R) injury. After surgery the injury may manifest as low cardiac output, hypotension, and the need for postoperative inotropic support and ultimately mechanical circulatory support. I/R injury may be reversible (stunning) or irreversible (infarction) and is differentiated by electrocardiographic abnormalities (presence of a new Q-wave), elevations in the levels of specific plasma enzymes or proteins such as creatine kinase-MB and troponin I or T and/or the presence of regional or global echocardiographic wall motion abnormalities. Depending upon the criteria used, the incidence of postoperative MI in patients undergoing coronary artery bypass grafting (CABG) with cardiopulmonary bypass (CPB) ranges between 3% and 18%.<sup>1-4</sup> While the majority of these are non-Q wave infarctions, they still are independently associated with adverse outcomes and prolonged aortic cross-clamp time and duration of CPB. Despite advances in techniques and cardioprotective strategies, the incidence of severe ventricular dysfunction, heart failure and death postoperatively ranges between 1% and 15%. The higher mortality rates are generally associated with high-risk patients with minimal cardiac reserve. These complications have an enormous impact on both families and society. From an economic standpoint alone, procedures for cardiovascular diseases are costly.

According to Heart Disease and Stroke Statistics—2015 Update,<sup>5</sup> in 2010 an estimated 954,000 percutaneous interventions (PCIs), 397,000 CABG operations, 1,029,000 diagnostic cardiac catheterizations, 97,000 defibrillator implants and 370,000 pacemaker procedures were performed on inpatients in the United States. The estimated cost was

\$204.4 billion. Between 2013 and 2030, medical costs of coronary heart disease alone are projected to increase by 100%. Cardiovascular disease costs more than any other diagnostic group. Therefore, a reduction in perioperative complications associated with heart surgery would have a significant impact on resource utilization and overall operative costs.<sup>6-8</sup> Since I/R injury is a major cause of morbidity and mortality after heart surgery, the purpose of this chapter is to review its underlying mechanisms, review the history of myocardial protection, update the reader regarding the current protective techniques and discuss new strategies under investigation.

## ISCHEMIA/REPERFUSION INJURY

The etiology of perioperative myocardial necrosis and postischemic myocardial dysfunction after cardiac surgery is multifactorial. Myocardial necrosis and elevation of associated cardiac biomarkers may arise as a result of ischemia due to intrinsic coronary disease unrelated to revascularization, anesthetic factors, atrial cannulation, suturing of heart muscle, plaque rupture or platelet embolism, and graft spasm or thrombosis. Despite the considerable progress made to date, high-risk heart surgery patients including those with unstable angina, poor ventricular function, diabetes, repeat CABG, and advanced age continue to experience postoperative complications such as low cardiac output, perioperative MI and heart failure requiring prolonged intensive care. In many of these instances the complications are due to I/R injury and inadequate myocardial protection. Thus there is a compelling unmet need to develop better methods to protect the heart during surgery.

## Deleterious Sequelae of Ischemia/Reperfusion

Myocardial I/R injury manifests as postischemic “stunning”, which is reversible, and apoptosis and/or necrosis, which are irreversible. Myocardial stunning is an injury that lasts for hours to days despite the restoration of normal blood flow. Typically these patients require some type of temporary inotropic support in the immediate postoperative period in order

to maintain an adequate cardiac output. Stunned cardiomyocytes exhibit minimal ultrastructural damage that resolves within hours to days following relief of ischemia. Apoptosis, or programmed cell death, is a pattern of cell death that affects single cells. It is characterized by an intact cell membrane with blebbing, cell shrinkage, condensation of the nucleus and oligonucleosomal fragmentation of DNA. Externalization of phosphatidylserine on the outer leaflet of the plasma membrane serves as a cue for phagocytic removal of apoptotic cells by neighboring cells or professional phagocytes without inflammation. It is unclear whether apoptosis is initiated during ischemia and but manifests during reperfusion or whether it is a consequence of reperfusion, but the preponderance of evidence favors the latter.<sup>9,10</sup> Regardless, apoptotic cell death occurs in the infarct zone and continues to occur in the border zone subsequently. Prolonged ischemia results in necrotic cell death characterized by cell swelling, plasma membrane rupture, mitochondrial swelling and loss of cristae, and DNA degradation followed by an inflammatory response to the cellular debris. Dying cells may exhibit features of both apoptosis and necrosis, that is, both nuclear condensation and plasma membrane damage.<sup>11-14</sup>

### Long-term Consequences

While the end result of inadequate myocardial protection is usually apparent in the immediate postoperative period, for example, low cardiac output syndrome, the full impact may not be evident for months to years. Klatte and colleagues reported that the 6-month mortality was greater in patients with increased peak creatine kinase-myocardial band (CK-MB) enzyme ratios after CABG surgery.<sup>15</sup> The 6-month mortality rates were 3.4%, 5.8%, 7.8% and 20% for patients with peak CK-MB ratios that were <5, 5-10, 11-20, and >20-fold higher than the upper limits of normal (UNL), respectively. In another study, Costa and colleagues<sup>16</sup> reported that normal postoperative CK-MB levels were observed in only 38.1% of 496 patients who underwent CABG surgery. When the CK-MB levels were stratified, the incidence of death at 30 days was 0.0%, 0.5%, 5.4%, and 7.0% when the enzyme levels were normal, 1 to 3 times higher, 4 to 5 times higher, and >5-fold higher than ULN, respectively. The 1-year mortality for these groups was 1.1%, 0.5%, 5.4%, and 10.5%. The peak postoperative cardiac enzyme level correlated significantly with worse clinical outcome. Thus, while CK-MB elevations are often dismissed as inconsequential in the setting of multivessel CABG surgery, they occur frequently and are associated with significant increases in both repeat MI and death beyond the immediate perioperative period. Consistent with this is the report by Steuer<sup>17</sup> and associates in which they examined postoperative serum aspartate aminotransferase and CK-MB levels and their relationship to early and late cardiac-related death in 4911 consecutive patients who underwent CABG during a 6-year period. They reported that elevated enzyme levels on the first postoperative day greatly increased the risk of early cardiac death and were associated with a 40 to 50% increased risk in late mortality at 7 years.

In a retrospective analysis Brener et al showed that CK-MB elevation was common after both percutaneous and surgical revascularization.<sup>18</sup> The incidence of CK-MB elevation above the normal range was 90% for CABG surgery and 38% for percutaneous coronary intervention (PCI). In a small fraction of patients the elevations exceeded  $10 \times$  ULN (6% for CABG and 5% for PCI). At 3 years follow-up the cumulative mortality was 8% for CABG and 10% for PCI. Even relatively small CK-MB elevations after interventions were associated with increased mortality over time. Similar observations were made when troponin release was used as a biomarker of myocardial injury. Lehrke et al reported in a series of 204 patients that a serum troponin-T concentration of 0.46 mcg/L or more, 48 hours after surgery was associated with a 4.9-fold increase in long-term risk of death.<sup>19</sup>

Finally, in one of the largest studies to date Domanski et al<sup>20</sup> reviewed the relationship between peak postoperative levels of biomarkers of myocardial damage and early-, intermediate- and long-term mortality reported in previously reported and randomized clinical trials and registries. A total of 18,908 patients from seven studies were included for analysis. The follow-up ranged from 3 months to 5 years. The investigators reported that, in the aggregate, even modest elevations of troponin I at the 24-hour level were prognostically significant, and any CK-MB elevation after CABG was associated with increased mortality. In short, biomarkers of myocardial injury are frequently elevated after CABG surgery and are associated with decreased short-, medium-, and long-term survival.

### Intracellular Mechanisms Underlying Ischemia/Reperfusion Injury

The primary mediators of I/R injury include intracellular  $\text{Ca}^{2+}$  overload and oxidative stress induced by reactive oxygen species (ROS) generated at the onset of reperfusion<sup>21</sup> (Fig.16-1). The molecule nitric oxide (NO) also can interact with superoxide ( $\text{O}_2^-$ ) or peroxides to generate reactive nitrogen species that are capable of inducing injury as well.<sup>22</sup> In addition, metabolic alterations occurring during ischemia can contribute directly and indirectly to  $\text{Ca}^{2+}$  overload and ROS formation. For example, decreased cytosolic phosphorylation potential, that is,  $[\text{ATP}]/([\text{ADP}] \times [\text{P}_i])$ , results in less free energy from ATP hydrolysis than is necessary to drive the energy-dependent pumps (sarcolemmal calcium ion adenosine triphosphatase ( $\text{Ca}^{2+}$ -ATPase), the sarcolemmal  $\text{Ca}^{2+}$ -ATPase) that maintain intracellular calcium homeostasis.<sup>23</sup> With the onset of ischemia and the build-up of lactic acid, pH falls to as low as 6.6, resulting in proton efflux and sodium influx via the  $\text{Na}^+$ - $\text{H}^+$  exchanger. The driving forces for  $\text{Na}^+$ / $\text{H}^+$  exchange are the relative transmembrane  $\text{N}^+$  and  $\text{H}^+$  gradients. The activity of the exchanger is regulated by the interaction of the  $\text{H}^+$  with a sensor site on the exchanger protein; it can be additionally modulated by phosphorylation.<sup>24</sup> During reperfusion the accumulated intracellular  $\text{Na}^+$  competes with  $\text{Ca}^{2+}$  for sites on the  $\text{Na}^+$ / $\text{Ca}^{2+}$  exchanger, effectively causing the exchanger to run in reverse, thereby exacerbating

**FIGURE 16-1** Myocardial alterations associated with ischemia-reperfusion injury. PKC, protein kinase C;  $\text{Ca}^{2+}$ , calcium;  $[\text{Ca}^{2+}]_i$ , intracellular calcium concentration;  $[\text{Na}^+]_i$ , intracellular sodium concentration; GPCR, G-protein coupled receptor;  $G_s$ , stimulatory G proteins; PLC, phospholipase C;  $\text{IP}_3$ , inositol trisphosphate; DAG, diacylglycerol; NHE, sodium-hydrogen exchanger; NCX, sodium-calcium exchanger;  $\text{Na}^+$ , sodium; RP, reperfusion; NO, nitric oxide;  $\text{mK}_{\text{ATP}}$  channel, mitochondrial ATP-sensitive potassium channel; mPTP, mitochondrial permeability transition pore; ER, endoplasmic reticulum;  $[\text{Ca}^{2+}]_m$ , intramitochondrial calcium concentration.

intracellular calcium accumulation. The elevated intracellular  $\text{Ca}^{2+}$  leads to activation of calcium-dependent proteases and phospholipases, calpain-mediated damage to myofibrillar contractile elements, gap junction dysfunction, injury of the sarcoplasmic reticulum and opening of the mitochondrial permeability transition pore (mPTP). Opening of the pore in the inner mitochondrial membrane is associated with a collapse of the membrane, uncoupling of the electron transport chain, release of cytochrome c and other proapoptotic factors, swelling of the matrix and ultimately rupture of the outer mitochondrial membrane and cell death.<sup>25</sup>

The metabolic changes that occur during ischemia also deplete the endogenous antioxidant defense systems of cardiac myocytes. I/R damages mitochondrial complex I generating excessive ROS ( $\text{O}_2^-$  and  $\text{H}_2\text{O}_2$ ) and resulting in damage to cellular lipids, proteins and nucleic acids. Glutathione is a critical defense against oxidative stress, in which GSH (reduced glutathione) is used to repair oxidized protein thiols, generating GSSG (oxidized glutathione) system; GSH is regenerated by glutathione reductase which depends upon the nicotinamide adenine dinucleotide phosphate, reduced form: nicotinamide adenine dinucleotide phosphate (NADPH:NADP<sup>+</sup>) ratio. Depletion of glutathione impairs

the ability to detoxify ROS-mediated damage to proteins.<sup>26,27</sup> During ischemia NADPH levels drop thereby limiting the ability to regenerate reduced glutathione. Thus, the formation of ROS during reperfusion occurs at a time when the myocyte's endogenous defense mechanisms are depressed. The NADPH:NADP<sup>+</sup> ratio is a primary determinant of the redox state of the cell, and there is evidence that the redox state plays a key role in determining the bioactivity and the redox state of NO.<sup>22,28</sup> In addition, there are several reports that in the absence of normal levels of its cofactors, nitric oxide synthase (NOS), itself can generate the superoxide anion.<sup>29</sup> Although systolic intracellular calcium concentration,  $[\text{Ca}^{2+}]_i$ , may decrease to normal levels early in the reperfused stunned myocardium, transient increases in  $[\text{Ca}^{2+}]_i$  can result in sustained activation of protein kinase C (PKC) isoforms, calpain proteases and deoxyribonuclease II (DNase II).<sup>30</sup> Calpain-mediated proteolysis of contractile proteins has been implicated in the reduction of myofilament  $\text{Ca}^{2+}$  sensitivity observed in stunned myocardium.<sup>31</sup>

There is considerable evidence that ROS are involved in mediating myocardial stunning. Various spin-trap agents and chemical probes have demonstrated the rapid release of ROS into the vascular space during reperfusion after brief

ischemia *in vivo*.<sup>32</sup> While mitochondria are a major source of intracellular ROS in cardiac myocytes, they are not the only source of ROS during I/R.<sup>33,34</sup> It has been shown that antioxidants administered before the onset of ischemia attenuate myocardial stunning *in vitro* and *in vivo*. Antioxidants administered prior to or at the onset of reperfusion may show efficacy, although there are contradictory studies.<sup>21,35</sup> It has been shown that ROS can attack thiol residues of numerous proteins such as the sarcoplasmic reticulum Ca<sup>2+</sup> ATPase (SR Ca<sup>2+</sup>-ATPase), the ryanodine receptor, and contractile proteins, which may explain why myofibrils isolated from *in vivo* reperfused stunned, but not necrotic myocardium, exhibit reduced Ca<sup>2+</sup> sensitivity.<sup>36,37</sup> Prolonged ischemia resulting in irreversible injury is associated with more severe intracellular Ca<sup>2+</sup> overload and further depletion of endogenous antioxidants, conditions that both contribute to and are exacerbated during reperfusion by the production of ROS. Overproduction of ROS during reperfusion increases in [Ca<sup>2+</sup>]<sub>i</sub> through increased L-type Ca<sup>2+</sup> channel current.<sup>27,38,39</sup> Ca<sup>2+</sup> overload with I/R exacerbates mitochondrial ROS production.<sup>39,40</sup> Mitochondria can buffer small increases in intracellular Ca<sup>2+</sup> via the Ca uniporter, a process that is energetically favorable owing to the [Ca<sup>2+</sup>] gradient and the mitochondrial membrane potential. During reperfusion the increase in cytosolic Ca<sup>2+</sup> enhances mitochondrial Ca<sup>2+</sup> uptake. Since excess cytosolic Ca<sup>2+</sup> has been associated with the loss of myocyte viability, mitochondrial Ca<sup>2+</sup> buffering is initially cardioprotective.<sup>41</sup> However, continued mitochondrial Ca<sup>2+</sup> uptake in the face of decreased antioxidant reserves and ongoing oxidative stress ultimately triggers opening of the mitochondrial permeability transition pore, a large conductance channel that allows release of stored mitochondrial Ca<sup>2+</sup>, osmotic swelling of the mitochondria, collapse of mitochondrial membrane potential and cell death. The synergistic interactions between Ca<sup>2+</sup> overload and ROS formation during conditions of decreased antioxidant reserves also may explain why ROS scavengers are not very effective at reducing irreversible injury when administered at reperfusion.<sup>42</sup> It also possible that antioxidants employed in studies to date are not targeted to the sites where ROS are generated and mediate most of their damage. Specific mitochondrial antioxidants may be more effective.<sup>43-45</sup>

### Broadening the Spectrum of Ischemia/Reperfusion Injury

Historically myocardial I/R injury has been characterized as either reversible or irreversible, based on staining techniques, enzyme release and histology. There is now increasing evidence that the transition from reversible to irreversible injury occurs on a continuum rather than an all-or-none phenomenon. Apoptosis depends on the availability of ATP and precedes loss of membrane integrity; however, if ATP depletion occurs rapidly, the Na<sup>+</sup>/K<sup>+</sup>-ATPase will be unable to regulate cell volume, resulting in plasma membrane rupture and necrotic cell death before the enzymatic processes of apoptosis are complete.<sup>46,47</sup> Intracellular ROS and/or intracellular

calcium overload can initiate the apoptotic program through proapoptotic BH3-only proteins Bnip3 (activated by ROS) and Bid (proteolytically activated by calpain).<sup>48,49</sup> (Fig. 16-2) The BH3-only proteins trigger oligomerization of Bax or Bak directly or indirectly (through interaction with antiapoptotic Bcl-2 family members, Bcl-2, Bcl-x<sub>L</sub>, or Mcl-1), thus permeabilizing the outer mitochondrial membrane and allowing the release of cytochrome *c* into the cytosol.<sup>49-51</sup> Formation of a cytosolic complex comprising cytochrome *c*, apoptotic protease activating factor 1 (APAF-1), and caspase-9 leads to proteolytic activation of caspase 3 and subsequent cleavage of multiple targets and activation of endonucleases and poly(ADP)-ribose polymerase (PARP). Proteolytic activation of PARP results in rapid consumption of adenine nucleotides and culminates in cell death. In parallel, intracellular ROS and calcium overload trigger mPTP opening and mitochondrial swelling; the mitochondrial F<sub>0</sub>-F<sub>1</sub> ATP synthase runs in reverse hydrolyzing ATP in a futile effort to restore membrane potential across the inner mitochondrial membrane. ATP depletion compromises the ability to maintain ion and volume homeostasis via the Na<sup>+</sup>/K<sup>+</sup>-ATPase culminating in cell swelling, rupture of the plasma membrane and necrotic cell death. Myocardial damage can be further aggravated by the influx of macrophages and leukocytes, complement activation, and endothelial plugging by platelets and neutrophils.

Detection of apoptosis based on DNA fragmentation (TUNEL assay), the final event in apoptotic cell death underestimates the extent of apoptosis. Detection of externalized phosphatidylserine with annexin V conjugated to a fluorescent dye allows earlier recognition of apoptosis and has been used for *in vivo* imaging of apoptosis in the mouse heart; however, not all cells recognized by Annexin V are irreversibly committed to cell death.<sup>52-55</sup> Estimates of apoptosis in I/R injury are further confounded by the fact that the apoptotic remnants are efficiently cleared by neighboring cells or professional phagocytes. Thus the magnitude and significance of apoptosis in I/R injury has remained controversial. Genetic manipulations of mice have shown that disrupting the apoptotic machinery can result in a 60 to 70% reduction in infarct size. However, attempts to mitigate apoptosis with caspase inhibitors have not resulted in substantial reductions in infarct size, possibly because interruption of the late stages of apoptosis may simply result in necrosis. As a result, many investigators have turned their attention to interventions targeting the early events in apoptosis or preventing mPTP opening and necrotic cell death. Regardless of which stage is being addressed, current cardioprotection strategies are designed to reduce cellular and subcellular ROS formation and oxidative stress to enhance the heart's endogenous antioxidant defense mechanisms and prevent intracellular Ca<sup>2+</sup> overload.

### CARDIOPROTECTION: HISTORICAL PERSPECTIVES

In 1883, Ringer described the antagonistic effects of calcium and potassium ions on cardiac contraction. In 1929, Hooker reported the successful resuscitation of dogs with

**FIGURE 16-2** Mechanisms of cardiomyocyte cell death following ischemia-reperfusion injury. Bax, proapoptotic family of proteins; Bcl-2, antiapoptotic protein;  $\text{Ca}^{2+}$ , calcium; ROS, reactive oxygen species; Apaf, apoptotic protease-activating factor 1; PS, phosphatidylserine; SR, sarcoplasmic reticulum. Intracellular  $\text{Ca}^{2+}$  overload during ischemia and reperfusion and reactive oxygen species (ROS) formation during reperfusion are primary mediators of cell death via apoptosis and necrosis. The mechanisms of  $\text{Ca}^{2+}$  overload and ROS formation are described in detail in the text. In the intrinsic apoptosis pathway, BH3-only proapoptotic members of the Bcl-2 family are activated by calpain or caspase 8 (Bid) or ROS (Bnip3); they interact with Bax or Bak to form pores in the outer mitochondrial membrane allowing release of cytochrome *c*. This interaction is opposed by the antiapoptotic Bcl-2 family members including Bcl-2, Bcl- $x_L$ , and Mcl-1. In the cytosol, cytochrome *c* interacts with Apaf-1 and ATP or dATP to promote proteolytic activation of caspase 9 and the downstream executioner protease, caspase 3. Caspase 3 cleaves multiple targets, inactivating many cell survival pathways and activating endonucleases responsible for oligonucleosomal DNA fragmentation (DNA laddering). Cleavage of spectrin internal to the plasma membrane is permissive for phosphatidylserine redistribution to the external leaflet of the cell membrane, marking the dying cell for phagocytic removal by tissue macrophages or neighboring cells without an inflammatory response. In the necrotic death pathway,  $\text{Ca}^{2+}$  overload and ROS trigger opening of the mitochondrial permeability transition pore (mPTP), resulting in swelling of the matrix, disruption of the outer mitochondrial membrane, and rampant ATP hydrolysis by the ATP synthase running in reverse in a futile attempt to restore mitochondrial membrane potential. This energetic crisis leads to failure of the plasma membrane  $\text{Na}^+/\text{K}^+$  ATPase, loss of plasma membrane integrity, and cell rupture, triggering an inflammatory response.

potassium in which ventricular fibrillation was induced by electric shock.<sup>56,57</sup> In 1930, Wiggers reported that injections of potassium chloride were capable of abrogating ventricular fibrillation and arrested the heart in diastole. He also demonstrated that revival of the heart was possible using calcium chloride and massage.<sup>58</sup> The work by Wiggers led Beck, a thoracic surgeon, to successfully apply defibrillation therapy and save a human life using this method.<sup>59</sup> This resulted in a surge in basic and clinical research in the field of fibrillation and defibrillation with the principles applied to cardiac surgery.

With the advent of CPB, there was a need to refine techniques to protect the heart while creating a quiescent and

bloodless field for the unhurried repair of intracardiac defects. Over the next 50 years, a variety of cardioprotective methods and techniques were introduced (Table 16-1). One of the first methodologies evolved from the concept of shielding the heart from perioperative insult using hypothermia. Bigelow and colleagues suggested using hypothermia “as a form of anesthetic” to expand the scope of surgery. The technique “might permit surgeons to operate upon the ‘bloodless heart’ without recourse to extra corporal pumps and perhaps allow transplantation of organs.”<sup>60</sup> Five years later Melrose and colleagues reported another way to stop and restart the human heart reliably by injecting potassium citrate into the root of the aorta at both normal and reduced body temperatures.<sup>61</sup>

**TABLE 16-1: Evolution of Cardioprotective Methods and Techniques**

Reference	Year	Innovation
Bigelow WG <sup>60</sup>	1950	Studied the application of hypothermia to cardiac surgery in canines
Swan H <sup>75</sup>	1953	Showed that hypothermic arrest (26°C) in humans provided a bloodless field for operating
Melrose DG <sup>61</sup>	1955	Introduced the concept of reversible chemical cardiac arrest in canines
Lillehei CW <sup>76</sup>	1956	Heart was protected by retrograde coronary sinus infusion of oxygenated blood
Lam CR <sup>77</sup>	1957	One of the earliest known uses of the term “cardioplegia”
Gerbode F <sup>78</sup>	1958	Used potassium citrate to induce cardiac arrest in humans
McFarland JA <sup>79</sup>	1960	Challenged the safety of the Melrose technique; changed from potassium arrest to intermittent aortic occlusion or coronary artery perfusion for myocardial protection
Bretschneider HJ <sup>65</sup>	1964	Developed a sodium-poor, calcium-free, procaine-containing solution to arrest the heart
Sondergaard KT <sup>80,81</sup>	1964	Adopted Bretschneider’s solution for clinical use
Gay WA <sup>68</sup>	1973	Credited with revival of potassium-induced cardioplegia; demonstrated that potassium solution could arrest a canine heart for 60 minutes without cellular damage
Roe BB <sup>69</sup>	1973	Demonstrated that “the modalities of cardioplegia, hypothermia, and capillary washout” provided effective myocardial protection
Tyers WA <sup>62</sup>	1974	Demonstrated in preclinical studies that an infusion of cold blood to maintain myocardial temperature <4°C provided 90 minutes of protection
Hearse DJ <sup>66</sup>	1975	Emphasized preischemic infusions to negate ischemic injuries in rats; this formula became known as St. Thomas solution no. 1
Braimbridge MV <sup>67</sup>	1975	One of the first to use St. Thomas solution no. 1 clinically
Effler DB <sup>82</sup>	1976	Simple aortic clamping at room temperatures recommended
Solarzano J <sup>83</sup>	1978	Introduced concept of retrograde coronary sinus perfusion as adjunct to myocardial protection
Buckberg GD <sup>71</sup>	1979	Blood is an effective vehicle for infusing potassium into coronary arteries
Akins CW <sup>84</sup>	1984	Hypothermic fibrillatory arrest for coronary revascularization without cardioplegia
Murry CE <sup>85</sup>	1986	First to report that brief periods of ischemia (preconditioning) and reperfusion enable the heart to withstand longer periods of ischemia in a canine model
Lichtenstein SV <sup>86</sup>	1991	Reported warm antegrade and retrograde blood cardioplegia safe
Salerno TA <sup>87</sup>		
Ikonomidis JS <sup>88</sup>	1995	Combined normothermic continuous retrograde cardioplegia with intermittent antegrade infusions
Teoh LK <sup>89</sup>	2002	Introduced concept that intermittent cross-clamp fibrillation in CABG surgery patients confers cardioprotection via ischemic preconditioning and adenosine receptor activation
Quinn DW <sup>90</sup>	2006	Phase II human trial demonstrated efficacy of cardioprotective effects of systemic glucose-insulin-potassium (GIK) when administered perioperatively
Mentzer Jr RM <sup>1</sup>	2008	Phase III myocardial protection trial demonstrated proof of concept that perioperative MI can be reduced with an intravenous infusion of a pharmacologic agent in CABG surgery patients

Soon thereafter, the clinical application of potassium citrate arrest was adopted by many centers. Interest in using the Melrose technique waned, however, with subsequent reports that potassium citrate arrest was associated with myocardial injury and necrosis. Within a short time, many cardiac surgeons shifted from using potassium-induced arrest to normothermic cardiac ischemia, that is, normothermic heart surgery performed with the aorta occluded while the patient was on CPB, intermittent aortic occlusion or coronary artery perfusion. Experimental and clinical evidence showed, however, that normothermic cardiac ischemia was associated with metabolic acidosis, hypotension and low cardiac output.<sup>62-64</sup> As a consequence, there was a renewed interest in discovering ways to arrest the heart. Bretschneider published the principle of arresting the heart with a low-sodium, calcium-free solution.<sup>65</sup> It was Hearse and colleagues however who

studied the various components of cardioplegic solutions which led to the development and use of St. Thomas solution.<sup>66</sup> The components of this crystalloid solution were based on Ringer’s solution with its normal concentrations of sodium and calcium with the addition of potassium chloride (16 mmol/L) and magnesium chloride (16 mmol/L) to arrest the heart instantly. The latter component was shown by Hearse to provide an additional cardioprotective benefit. In 1975, Braimbridge and colleagues introduced this crystalloid solution into clinical practice at St. Thomas Hospital.<sup>67</sup> Gay and Ebert showed experimentally that lower concentrations of potassium chloride could achieve the same degree of chemical arrest and myocardial protection afforded by the Melrose solution without the associated myocardial necrosis reported earlier.<sup>67,68</sup> Shortly thereafter, Roe and colleagues reported an operative mortality of 5.4% for patients who

underwent cardiac surgery with potassium-induced arrest as the primary form of myocardial protection.<sup>69</sup> In 1977, Tyer and colleagues demonstrated that potassium cardioplegia provided satisfactory protection in over 100 consecutive cardiac patients.<sup>70</sup> By the 1980s, normothermic aortic occlusion had been replaced for the most part by cold blood cardioplegia to protect the heart during cardiac surgery. The major controversy at the time was not whether cardioplegic solutions should be used, but what was the ideal composition. The chief variants consisted of (1) the Bretschneider solution (containing primarily sodium, magnesium, and procaine); (2) the St. Thomas solution (consisting of potassium, magnesium, and procaine added to Ringer's solution); and, (3) potassium-enriched solutions containing no magnesium or procaine (Table 16-2). Coincident with this controversy, another variant of cardioplegia was introduced, that is, the use of potassium-enriched blood cardioplegia.<sup>71,72</sup> Theoretically blood cardioplegia would be a superior delivery vehicle based on its oxygenating and buffering capacity. Ironically, Melrose and colleagues had initially used blood as the vehicle to deliver high concentrations of potassium citrate more than 20 years earlier. While hypothermia and potassium infusions remain the cornerstone of myocardial protection today, a variety of cardioprotective techniques and solutions are used

which allow patients to undergo heart operations with excellent 30-day outcomes.<sup>73,74</sup>

## CARDIOPLEGIC TECHNIQUE

Cardioplegic surgery techniques utilize solutions containing a variety of chemical agents that are designed to arrest the heart rapidly in diastole, create a quiescent operating field and provide reliable protection against ischemia/reperfusion injury. While contemporary cardiac surgery in low-risk patients is relatively safe, patient characteristics have been changing over the past decade. In addition to coronary heart disease and poor ventricular function, patients are presenting with more comorbidities such as obesity, diabetes, renal dysfunction, peripheral vascular disease and emphysema. Despite ongoing improvements in cardioplegic techniques, low cardiac output syndrome (LCOS) still occurs after surgery and is a major factor associated with poor outcomes. In the absence of technical complications, the most common cause of postoperative LCOS is inadequate myocardial protection. For this reason, there is a real need to develop more effective strategies and novel additives to existing cardioplegic solutions. Currently there are two types of cardioplegic solutions that are used: *crystalloid cardioplegia* and *blood cardioplegia*. These

solutions are administered most frequently under hypothermic conditions.

## Crystalloid Cardioplegia

One of the first cardioplegic solutions used to protect the heart during surgery consisted of a cold crystalloid formulation. It was developed on the premise that its administration would protect the heart by reducing its metabolism and aid the surgeon by providing a bloodless field. Over the years a number of crystalloid cardioplegic solutions have been developed which contain different ingredients. The rationale for these ingredients has been based on the need to: (a) induce a rapid cardiac arrest using potassium or magnesium; (b) reduce energy demand and conserve ATP reserves using hypothermia; (c) maintain intracellular ionic and metabolic homeostasis; (d) lower myocardial oxygen consumption; (e) enhance anaerobic and aerobic energy production utilizing glucose and amino acids; (f) stabilize the pH using bicarbonate, phosphate, or histidine buffers; (g) stabilize cellular membranes by using steroids, oxygen free radical scavengers such as glutathione, calcium antagonists and/or procaine; (h) avoid intracellular calcium overload by providing a hypocalcemic environment and adding magnesium; and (i) prevent cellular edema by the addition of colloids such as mannitol to maintain normal oncotic pressures.

There are basically two types of crystalloid cardioplegic solutions: the intracellular type and the extracellular type.<sup>91</sup> Both types can be used as preservation solutions for organ transplantation. The intracellular types are characterized by absent or low concentrations of sodium and calcium. The extracellular types contain relatively higher concentrations of sodium, calcium and magnesium. Both types avoid concentrations of potassium >40 mmol/L (typical range is 10-40 mmol/L), contain bicarbonate for buffering and are osmotically balanced. Examples of various crystalloid cardioplegic solutions are shown in Table 16-2.

### OPERATIVE PROCEDURE

While the degree of core cooling varies from center to center, patients undergoing CPB are cooled to between 33 and 28°C. To initiate immediate chemical arrest after cross-clamping the aorta, the solution is infused through a cardioplegic catheter inserted into the aorta proximal to the cross-clamp. The catheter may or may not be accompanied by a separate vent cannula. The cold hyperkalemic crystalloid solution is then infused (antegrade) at a volume that generally does not exceed 1000 mL. One or more infusions of 300 to 500 mL of the cardioplegic solution may be administered if there is evidence of resumption of electrical heart activity or if a prolonged ischemic time is anticipated. If myocardial revascularization is being performed, the aortic cross-clamp can be removed after completing the distal anastomoses and the heart reperfused while the proximal anastomoses are completed using a partial occlusion clamp. Alternatively, the proximal grafts can be performed after the

distal grafts have been completed with the cross-clamp still in place (the single-clamp technique). Another approach is to perform the proximal aortic grafts first with a partial occlusion clamp and then cross-clamp the aorta and infuse the cardioplegic solution. When valve repair or replacement is being performed, the crystalloid cardioplegia can be administered directly into the coronary arteries via cannulation of the coronary ostia. Crystalloid cardioplegia also can be administered retrograde via a coronary sinus catheter with or without a self-inflating silicone cuff.

### OUTCOMES

Although there is a concern that crystalloid cardioplegia lacks blood components and therefore has a limited oxygen carrying capacity, this has not been shown to be clinically relevant. Likewise while there is preclinical evidence that hyperkalemic crystalloid cardioplegia may damage coronary vascular endothelium and impair the ability of endothelial cells to replicate and produce endothelial derived factors, this has not been shown to be of clinical significance.<sup>92,93</sup> In fact, there are numerous clinical studies which demonstrate that crystalloid cardioplegia is as effective as blood cardioplegia, particularly in centers where it is the primary form of protection.<sup>94,95</sup>

## Blood Cardioplegia

Cold blood cardioplegia, widely employed throughout the world, is the cardioplegic technique used most often in the United States. The rationale for using blood as a vehicle for hypothermic potassium-induced cardiac arrest is that it (a) provides an oxygenated environment and a method for intermittent reoxygenation of the heart during arrest; (b) limits hemodilution when large volumes of cardioplegic solution are used; (c) affords an excellent buffering capacity and osmotic properties; (d) allows for electrolyte composition and pH that are physiologic; (e) offers a number of endogenous antioxidants and free-radical scavengers; and (f) is less complex to prepare than other solutions.

Although there are a variety of formulations it is usually prepared by combining autologous blood, obtained from the extracorporeal circuit while the patient is on CPB, with a crystalloid cardioplegic solution that consists of citrate-phosphate-dextrose (CPD) buffered with tris-hydroxymethyl-aminomethane or bicarbonate and supplemented with potassium chloride. The CPD is used to lower the ionic calcium, and the buffer is used to maintain an alkaline pH at approximately 7.8. The final concentration of potassium used to arrest the heart is approximately 20 to 25 mEq/L. After the initial induction dose for rapid arrest, subsequent administrations may be intermittent or continuous and utilize a concentration of 8 to 10 mEq/L (the low concentration maintenance dose).<sup>96,97</sup> (Table 16-2)

Prior to administering blood cardioplegia, the temperature of the solution usually is lowered with a heat-exchanging coil to between 12 and 4°C. The ratio of blood to crystalloid varies among centers with the most common ratios being 8:1,

4:1, and 2:1; this in turn affects the final hematocrit of the blood cardioplegia infused. For example, if the hematocrit of the autologous blood obtained from the extracorporeal circuit is 30, these ratios would result in a blood cardioplegia with a hematocrit of approximately 27, 24, and 20, respectively.

The use of undiluted blood cardioplegia, or “miniplegia” (using a minimum amount of crystalloid additives), also has been reported to be effective. Petrucci et al studied the use of all-blood miniplegia in a clinically relevant swine preparation and compared miniplegia with crystalloid cardioplegia. They concluded that the use of all-blood miniplegia was effective or superior in the acutely ischemic heart.<sup>98</sup> Velez and colleagues used an acute ischemia/reperfusion canine preparation to test the hypothesis that an all-blood cardioplegia in 66:1 blood:crystalloid ratio would provide superior protection compared with a 4:1 blood cardioplegia delivered in a continuous retrograde fashion.<sup>99</sup> They found very little difference between the animal groups with respect to infarct size or postischemic recovery of function. This is consistent with the findings by Rousou and colleagues years earlier; that, it is the level of hypothermia that is important in blood cardioplegia not necessarily the hematocrit.<sup>100</sup>

With respect to efficacy, there are numerous preclinical studies and nonrandomized and randomized clinical trials that demonstrate cold blood cardioplegia is an effective way to provide excellent myocardial protection. Many of these same studies have suggested that cold blood cardioplegia is superior to cold crystalloid cardioplegia. It is important to note that other investigators have shown crystalloid cardioplegia to be as cardioprotective and cost-effective if not more so. Unfortunately, most contemporary clinical trials comparing the efficacy of blood cardioplegia with crystalloid cardioplegia have involved single-center studies, enrolled a limited number of patients, focused on a specific subset of patients and/or omitted details regarding clinical management. In 2006, Guru et al reported the results of a meta-analysis of 34 clinical trials that compared blood cardioplegia to crystalloid cardioplegia. A lower incidence of low cardiac output syndrome and CK-MB release was observed in patients administered blood cardioplegia; no difference, however, was observed in the incidence of perioperative MI or mortality.<sup>101</sup> Jacob et al (2008) analyzed clinical data from 15 randomized trials. Although eight of the trials reported statistically significant outcomes favoring blood cardioplegia, and five showed differences in enzyme release, the bulk of the evidence favoring one over the other was inconclusive.<sup>95</sup>

In 2014, Zeng performed a meta-analysis of 12 randomized control trials in which cold blood cardioplegia was compared to cold crystalloid cardioplegia.<sup>102</sup> The trials accounted for 2866 patients: 1357 received cold crystalloid cardioplegia; 1509 received cold blood cardioplegia. The analysis showed no significant differences in mortality risk, incidence of fibrillation or stroke. The incidence of perioperative MI was lower however in the patients receiving cold blood cardioplegia. Regardless, the authors concluded that both crystalloid and cold blood cardioplegia are safe and effective for revascularization. The limitations of the study include the inherent

problems associated with meta-analyses, and mortality was assessed only at the end of 30 days.

## Warm Blood Cardioplegia

The concept of using warm (normothermic) blood cardioplegia as a cardioprotective strategy dates back to the 1980s. Proponents held that warm blood cardioplegic solutions would provide nutrients and endogenous factors that were absent in crystalloid solutions, and that normothermia would avoid possible adverse consequences of hypothermia. In 1982, Rosenkranz and colleagues reported that warm induction with normothermic blood cardioplegia, followed by maintenance of arrest with multi-dose cold blood cardioplegia, resulted in better recovery of function in canines than a similar protocol using cold blood induction.<sup>103</sup> In 1986, Teoh and colleagues provided experimental evidence that a terminal infusion of warm blood cardioplegia before removing the cross-clamp (a “hot shot”) accelerated myocardial metabolic recovery.<sup>104</sup> This was followed by a report in 1991 by Lichtenstein and colleagues that normothermic blood cardioplegia in humans is an effective cardioprotective approach.<sup>86</sup> They compared the results of 121 consecutive patients undergoing CABG surgery who received antegrade normothermic blood cardioplegia to a historical group of 133 patients who received antegrade hypothermic blood cardioplegia. The operative mortality in the warm cardioplegic group was 0.9% compared with 2.2% for the historical controls. Despite these encouraging reports, there are concerns that for any given patient, it is difficult to determine how long a warm heart can tolerate an ischemic insult if the infusion is interrupted or flow rates are reduced owing to an obscured surgical field or maldistribution of the cardioplegic solution. Another concern is the report by Martin and colleagues that warm cardioplegia is associated with an increased incidence of neurologic deficits.<sup>52</sup> In a prospective, randomized study conducted in 1001 patients, the efficacy of continuous warm blood cardioplegia with systemic normothermia ( $\geq 35^{\circ}\text{C}$ ) versus intermittent cold oxygenated crystalloid cardioplegia and moderate systemic hypothermia ( $\leq 28^{\circ}\text{C}$ ) were compared. While operative mortalities were similar (1.0 vs 1.6%, respectively), the incidence of permanent neurologic deficits was threefold greater in the warm blood normothermic group (3.1 vs 1.0%). Thus in this study—warm blood cardioplegia offered no advantage over cold crystalloid cardioplegia in terms of myocardial protection and carried with it the risk of increased ischemic injury if the oxygen supply to the warm heart was interrupted.

In 2014, DeBryn and colleagues performed a retrospective review of a prospectively collated database to compare the relative efficacies of using either antegrade warm blood cardioplegia ( $32^{\circ}\text{C}$ ) or antegrade cold crystalloid cardioplegia ( $7^{\circ}\text{C}$ ).<sup>105</sup> The database included patient demographics, preoperative risk factors, operative technique, postoperative course and 30-day, in-hospital morbidity and mortality. The first 150 patients received cold crystalloid cardioplegia; the second group of 143 patients received cold blood cardioplegia.

Overall the investigators found the clinical outcome for the patients was comparable and concluded that while warm blood cardioplegia is safe; it did not confer superior protection. Thus it appears that appropriately designed protocols using intermittent antegrade warm blood cardioplegia provide clinically acceptable myocardial protection.<sup>106-108</sup>

## Tepid Blood Cardioplegia

Both cold blood (4-10°C) and warm blood cardioplegic solutions (37°C) have temperature-related advantages and disadvantages. As a consequence, a number of studies were performed in the 1990s to determine the optimal temperature. Hayashida and colleagues were one of the first groups to study the efficacy of tepid blood (29°C) cardioplegia.<sup>109</sup> In this study, 72 patients undergoing CABG were randomized to receive cold (8°C) antegrade or retrograde, tepid (29°C) antegrade or retrograde, or warm (37°C) antegrade or retrograde blood cardioplegia. While protection was adequate for all three, the tepid antegrade cardioplegia was the most effective in reducing anaerobic lactate acid release during the arrest period. These authors reported similar findings when the tepid solution was delivered continuously retrograde and intermittently antegrade.<sup>110</sup> In contrast, Baretta et al reported in anesthetized open-chest swine placed on CPB that tepid normokalemic continuous antegrade blood cardioplegia was associated with an increased incidence of intermittent fibrillation.<sup>111</sup> Subsequent to this report Mallid et al, in a retrospective chart review, analyzed the effects of cold blood and warm or tepid blood cardioplegia on early and late outcomes in 6064 patients who underwent CABG surgery. In the patients receiving warm or tepid blood cardioplegia (n = 4532), the systemic temperature was maintained between 32 and 37°C. The temperature of warm blood cardioplegia was 37°C. In the tepid cardioplegia cohort the systemic temperature was allowed to drift between 32 and 34°C; the temperature of the tepid cardioplegia ranged between 28 and 30°C. In the cold blood cardioplegia cohort (n = 1532) the systemic temperature was maintained between 25 and 32°C; the temperature of the blood cardioplegia ranged between 5 and 8°C. At 5 years, actuarial survival was 91.1% in the warm cardioplegia group and 89.9% in the cold blood cardioplegia group ( $p = .09$ ). While this study has all the limitations associated with a large retrospective chart review conducted over the course of a decade, the findings are consistent with the basic conclusion that current methods of cardioplegia all show similar degrees of efficacy. To date, most tepid blood cardioplegia studies have been single-center studies conducted in relatively small cohorts of patients. Whether tepid cardioplegia confers superior protection over other methods remains to be determined. For the most part, however, the current methods of cardioplegia all show similar efficacy.

## Methods of Delivery

In addition to a variety of formulations and temperatures, there are also many different ways of administering the

<b>Infusion types</b>
Antegrade Retrograde Combined retrograde/antegrade
<b>Infusion temperatures</b>
Cold Tepid Warm
<b>Infusion intervals</b>
Intermittent Continuous

**FIGURE 16-3** Methods for delivering cardioplegic solutions.

cardioplegic solutions (Fig. 16-3). As one might expect with so many options, the optimal delivery method also remains controversial. The various methods include intermittent antegrade, antegrade via the graft, continuous antegrade, continuous retrograde, intermittent retrograde, antegrade followed by retrograde and simultaneous antegrade and retrograde infusions. While all methods appear to be similarly efficacious, comparisons across trials are difficult because the studies also have differed with respect to: (1) the composition of the solution; (2) the temperature of the solution; (3) the duration of the infusion; and, (4) the infusion pressure. Additional factors that affect a surgeon's choice for delivery method include the type and complexity of the operation and the anticipated cross-clamp time.

## ANTEGRADE CARDIOPLEGIA

The most widely used method of delivering cardioplegic solutions is the antegrade method. It entails infusion of the solution into the aortic root while the ascending aorta is cross-clamped. After the initiation of CPB, chemical arrest can be achieved quickly with the infusion of the solution through a catheter inserted into the aorta proximal to the cross-clamp. The catheter may or may not be accompanied by a separate vent cannula to decompress the left ventricle between infusions. The induction dose usually has a higher concentration of potassium than subsequent maintenance doses. It is infused rapidly to ensure aortic valve closure usually at a rate of 250 to 300 mL/min (10 and 15 mL/kg body weight/min). If cardiac activity persists or recurs additional infusions may be necessary. For maintenance, infusions can be administered at 15 to 20 minute intervals or as needed. Concurrent external cooling can be achieved by suffusion with cold saline (4°C).

The typical aortic root perfusion pressure is maintained between 60 mm Hg and 80 mm Hg. Adjustments in rates of administration are made to accommodate patients with hypertrophied ventricles. Intermittent maintenance doses of 300 to 500 mL of low-dose cardioplegia are administered every 15 to 20 minutes or earlier if there is evidence of resumption of electrical activity. During CABG surgery, in order to minimize cold ischemia and aortic cross clamp

time, the heart can be reperfused earlier by removal of the aortic cross-clamp as soon as the distal anastomoses are completed; the proximal anastomoses are then performed using a partial occlusion clamp. Alternatively the proximal grafts can be performed after the distal grafts have been completed with the cross-clamp still in place (the single-clamp technique).

The administration of antegrade cardioplegia depends on a competent aortic valve and hence is liable to be ineffective and relatively contraindicated in patients with significant aortic valve incompetence. In such cases, antegrade cardioplegia can be administered directly into the coronary arteries via cannulation of the individual coronary ostium. This technique is used in cases requiring the opening of the ascending aorta such as in aortic valve replacement, ascending aortic aneurysm repair and aortic root replacement procedures. Coronary ostial infusion may be necessary for induction in patients with severe aortic incompetence in the presence of coronary sinus pacing leads. Potential complications include coronary dissection, unintentional selective delivery into left anterior descending or left circumflex artery due to a short left main coronary artery, and the late occurrence of coronary ostial stenosis.<sup>112</sup>

### RETROGRADE CARDIOPLEGIA

Retrograde cardioplegia entails placement of a coronary sinus catheter with or without a self-inflating silicone cuff and infusion of the cardioplegic solution either for induction or maintenance of cardioplegia. This approach originated with a concept developed by Pratt in 1898, who suggested that oxygenated blood could be supplied to the ischemic heart via the coronary venous system.<sup>113</sup> Sixty years later, Lillehei and colleagues used retrograde coronary sinus perfusion to protect the heart during aortic valve surgery.<sup>76</sup> Today, it is an accepted method for delivering a cardioplegic solution and is used frequently as an adjunct to antegrade cardioplegia. Placement of the catheter is often facilitated by the use of catheters that are precurved and the simultaneous use of transesophageal echocardiography to guide placement. Care must be taken to avoid rupture of the coronary sinus, an uncommon but real and potentially fatal complication. This can be prevented by infusing the solution at a rate that ensures that the coronary sinus perfusion pressure does not exceed 45 to 50 mm Hg. The retrograde approach can be used for continuous or intermittent delivery of blood or crystalloid cardioplegia as well. In situations where the native coronary arteries are severely stenotic or totally occluded, the antegrade approach may result in an uneven distribution in the myocardium. In this situation retrograde infusion or infusion via the vein grafts as they are completed can be complementary. While most routine on-pump cardiac procedures can be done with good outcomes using just the antegrade technique, patients with poor ventricular function, high-risk patients requiring long aortic cross clamp times and those with occlusive coronary disease may benefit from a dual approach, that is, both antegrade and retrograde techniques. Another advantage to the retrograde technique is that it may be effective in reducing the risk of embolization from saphenous vein grafts that could occur

during antegrade perfusion for reoperative coronary artery bypass surgery. The retrograde approach also has the theoretical advantage of ensuring a more homogeneous distribution of the cardioplegic solution to regions of the heart that are poorly collateralized.

Despite these advantages, retrograde cardioplegia is not without its limitations. There are experimental and clinical studies which suggest that cardioplegia administered via the coronary sinus results in a suboptimal distribution of cardioplegia to the right ventricle. This is due in part to the anterior region of the right ventricle being poorly drained by the coronary sinus, the marked variability in venous anatomy, the frequency of coronary sinus anomalies and the Thebesian veins draining directly into the cavities of the heart. As a consequence a number of studies have been performed to evaluate not only the safety and efficacy of the retrograde approach but also to compare its efficacy to a combined antegrade/retrograde approach.<sup>114-117</sup> While the findings have been mixed, most of results have shown that retrograde delivery of cardioplegic solutions is safe and effective during cardiac surgery. Taking a different approach, Bhaya et al compared the efficacy of an antegrade approach with an integrated antegrade/retrograde method in patients undergoing on pump heart surgery using three-dimensional transthoracic speckle tracking echocardiography.<sup>118</sup> Twenty-two patients were studied one day prior to surgery and 4 to 5 days after the operation. They found that the integrated approach conferred better protection in terms of maintenance of strain parameters in segments of the septum and free wall of the left ventricular free wall and septum. These findings support the general consensus that a combined approach allows for a more reliable homogeneous distribution of cardioplegic solutions. The combined approach may be most relevant when it is anticipated that the cross-clamp time will be long and/or when the coronary artery stenoses are particularly extensive and severe.

### CONTINUOUS CARDIOPLEGIA VERSUS INTERMITTENT CARDIOPLEGIA

To minimize the interruption of coronary flow during aortic cross-clamping, cardioplegia can be administered continuously using a retrograde coronary sinus catheter or cannulating the coronary ostia directly via an open aortic root. A continuous infusion, especially if it is oxygenated, has the theoretical advantage of minimizing ischemia particularly during periods of prolonged aortic cross-clamping. One of the first studies to test this assumption was by Louagie and colleagues.<sup>119</sup> Seventy patients undergoing CABG surgery were prospectively randomized to receive retrograde cold blood cardioplegia either intermittently ( $n = 35$ ) or in a continuous fashion ( $n = 35$ ). Hemodynamic measurements included right ventricular ejection fraction, cardiac output, left and right ventricular stroke work index and systemic and pulmonary vascular resistance. Coronary sinus blood samples were obtained before aortic cross-clamping and immediately after unclamping for the measurement of lactate and hypoxanthine levels; venous blood samples were collected at predetermined times to measure CK-MB and troponin levels.

Overall, they found a trend for better hemodynamics and a lower use of inotropic agents and significantly lower lactate and hypoxanthine levels in the patients who received continuous retrograde cardioplegia. On the other hand there were no differences in patient outcomes, and the CK-MB and troponin levels were comparable postoperatively. Given this was a single-center study, the surgery was performed by the same surgeon, and the relatively small sample size, it is difficult to extrapolate the findings to the general population of patients undergoing cardioplegic surgery with aortic cross-clamping. To date it remains unclear as to whether continuously administered cardioplegia is superior to intermittent cardioplegia. The major advantage of using intermittent cardioplegia is the ability to achieve and sustain a dry, quiescent operative field. Moreover, continuous cardioplegia still necessitates interruption of the surgical steps while the infusion is delivered.

### Current Status of Cardioplegic Technique

In summary, controversy persists as to whether blood cardioplegia or crystalloid cardioplegia is better, which temperature is ideal and what is the best method of delivery. A survey of practice patterns in the United Kingdom in 2004 showed that 56% of all cardioplegia on-pump surgery was performed with cold blood cardioplegia; whereas, warm blood cardioplegia was used in 14% of cases.<sup>120</sup> In the same survey, 14% of surgeons used crystalloid cardioplegia, 21% used retrograde cardioplegia and 16% did not use any cardioplegia, preferring to use cross-clamp fibrillation only. Based on these observations and experiences in the United States, it appears that most surgeons favor cold intermittent blood cardioplegia. Nevertheless a wide spectrum of variation exists among heart centers; there is no international consensus regarding the ideal cardioplegic solution or its use.<sup>120</sup> Awareness of the options allows the surgeon to utilize the best approach that meets the individual needs of the patient.

### Noncardioplegic Technique

Intermittent cross-clamping with fibrillation (ICCF) and systemic hypothermia with intermittent elective fibrillatory arrest are the most common forms of noncardioplegic heart surgery used today. The objective is to provide a relatively quiescent surgical field without having to arrest the heart with a cardioplegic solution.

#### Intermittent Aortic Cross-Clamping with Fibrillation

This technique is the earliest method developed to protect the heart during surgery and is still used at many centers. The patient is placed on CPB, the ascending aorta is cannulated and generally a dual-stage single-venous cannula is used. Often the patient is cooled to 30 to 32°C; this technique allows the surgeon to operate in a relatively quiet but not quiescent field during ventricular fibrillation. In the setting of CABG surgery, the aortic cross-clamp is removed intermittently after the

completion of each graft. The duration of fibrillation is determined by how long it takes to perform the distal anastomosis. After completion of the revascularization, the heart is defibrillated and the proximal anastomoses performed on the beating heart using an aortic partial occlusion clamp. This technique is particularly useful in patients with cold agglutinin disease, an autoimmune phenomenon in which antibody directly agglutinates human red cells at low temperatures. In these patients open heart operations with hypothermia carry the risk of red cell agglutination and may result in hemolysis, MI, renal insufficiency and cerebral damage.

As a result of increasing pressures to reduce cost and yet maintain acceptable levels of cardioprotection, there remains an interest in using this approach. There are a number of reports which indicate that satisfactory protection can be conferred using this technique. In 1992, Bonchek et al reported a large clinical series in which the advantages and safety of this technique were meticulously analyzed.<sup>121</sup> In this study, the authors reviewed the outcomes of the first 3000 patients at their institution who underwent primary CABG using ICCF. Preoperative risk factors, for example, age, gender, left ventricular dysfunction, preoperative use of the intra-aortic balloon pump (IABP), the urgency of operation and operative deaths were analyzed. In this series, 29% of the patients were older than 70 years of age, 27% were females, 9.7% had an ejection fraction of less than 0.30, 13% had an MI less than 1 week preoperatively and 31% had preinfarction angina in the hospital; only 26% underwent purely elective operations. Using the noncardioplegic cardioprotective technique, the authors reported an elective operative mortality rate of 0.5%, an urgent mortality rate of 1.7% and an emergency rate of 2.3%. Postoperatively, inotropic support was needed in only 6.6% of the patients, and only 1% required insertion of the IABP. It is important to note however that this was a retrospective, single-center institutional experience. The findings would have been enhanced if the analysis had included a similarly matched group of patients at the same institution in which cardioplegic arrest had been employed. Nevertheless the findings support the perspective that noncardioplegic strategies can provide satisfactory myocardial protection even in high-risk patients.

In 2002, Raco and colleagues reported their experience in 800 consecutive CABG operations performed by a single surgeon using ICCF in both elective and nonelective settings. The patients were divided into three cohorts: (1) elective; (2) urgent; and, (3) emergent. Among these cohorts the mean age, number of distal grafts and mortality among the three groups was comparable. The mortality rate in the elective, urgent and emergent groups was 0.6%, 3.1%, and 5.6%, respectively, and consistent with outcomes associated with cardioplegic surgery. Since this report reflects the experience of a single surgeon, there is the concern that the technique may not be generally applicable. Regardless, the findings do support the notion that ICCF is a safe technique for both elective and nonelective patients undergoing CABG surgery.<sup>122-124</sup> In 2003, Bonchek et al reported their experience in 8300 patients who underwent CABG surgery without cardioplegia. The unadjusted mortality rates in

elective, urgent and emergent patients was 0.9%, 1.5%, and 4.0%, respectively. The overall mortality of 1.7%, was considerably lower than the 3.27% predicted based on the Society of Thoracic Surgeons National Database model.<sup>125</sup> This experience represented the work of five surgeons, three of whom had not been trained in noncardioplegic surgery; it provides additional evidence that ICCF is an effective form of cardioprotection. Evidence that the cardioprotective effects of ischemic preconditioning (IPC) may contribute to the efficacy of ICCF in the human heart has resulted in an interest in using this method of protection especially in the United Kingdom. Results in animal studies indicate that the protective effect of ICCF is blocked by protein-kinase C inhibitors and  $K_{ATP}$  channel antagonists, both of which have been implicated in the signaling pathways involved in IPC.<sup>126</sup> Regardless of the mechanism underlying the protection, there are numerous reports which indicate that noncardioplegic strategies such as ICCF can provide satisfactory myocardial protection even in high-risk patients.<sup>127</sup>

### Systemic Hypothermia and Elective Fibrillatory Arrest

Elective fibrillatory arrest is another safe approach to protect the heart during noncardioplegic heart surgery. The use of systemic hypothermia (26–30°C) and maintenance of systemic perfusion pressure between 80 and 100 mm Hg are key elements. This approach is particularly applicable in the setting of the severely calcified “porcelain aorta,” where clamping the aorta may be associated with increased risk of stroke and aortic dissection. Under these circumstances the distal anastomoses are performed locally occluding the coronary artery using vascular clamps or sutures. The proximal anastomoses can be completed during short periods of hypothermic circulatory arrest. Alternatively the proximal anastomoses can be based entirely on an in situ internal thoracic artery. Using this approach one can avoid manipulation of the aorta altogether. Akins and colleagues, in 1984, reported a low incidence of perioperative MI and a low hospital mortality rate in 500 consecutive patients using this technique.<sup>84</sup> In 1987, Akins and Carroll assessed the late results of hypothermic fibrillatory arrest in 1000 consecutive patients undergoing nonemergent CABG surgery. They concluded that the technique is effective and yields excellent event-free survival. Potential disadvantages include (1) the surgical field may be obscured as a result of existing collateral circulation; (2) ventricular fibrillation may be associated with increased muscular tone and thus compromise the surgeon’s ability to position the heart for optimal exposure; (3) aortic valvular regurgitation may be exacerbated; and (4) it is generally not applicable for intracardiac procedures. An advantage with the technique is that it can be used when aortic occlusion or cardioplegic arrest is undesirable, for example, in the setting of a calcified ascending aorta. This approach can also be used in patients undergoing mitral valve surgery.<sup>128</sup> Imanaka et al, in 2003, published a retrospective observational study in which mitral valve surgery was performed in 27 patients with ischemic mitral regurgitation using perfused ventricular fibrillation.

Concomitant procedures included CABG in 23 patients and the Dor procedure in five patients. Surgery was performed using moderate hypothermia (~28°C) and fibrillatory arrest; flow rates on bypass were maintained at 2.4 L/min/m<sup>2</sup> and the perfusion pressure was 70 mm Hg. Among these select patients the mortality rate was 3.7%. The authors concluded that extended periods of ventricular fibrillation during hypothermic surgery can be well-tolerated without excessive morbidity and mortality and is appropriate in patients in whom aortic cross-clamping is unsuitable or the duration of cross-clamping is expected to be long.<sup>129</sup>

### Strategies for Cardioprotection under Investigation

There are currently a number of physiological processes and pharmacological agents known to confer protection against I/R injury in the experimental setting. Several clinical trials are underway to determine the relevance of these new approaches. The purpose of this section is to review the cardioprotective strategies that are being examined and hold promise for the future.

### Physiological Processes

#### ISCHEMIC PRECONDITIONING

“Preconditioning with ischemia is an endogenous adaptive phenomenon whereby the heart becomes more tolerant to a period of prolonged ischemia if first exposed to brief episodes of coronary artery occlusion. This adaptation to ischemia was first described by Murry and colleagues and is now referred to as ‘classic,’ ‘first window’ or ‘early phase’ ischemic preconditioning (IPC).<sup>85</sup> IPC is associated with a reduction in infarct size, apoptosis, and reperfusion-associated arrhythmias and has been demonstrated in every animal species studied to date. It lasts for as long as 1 to 2 hours after the preconditioning stimulus.<sup>130–132</sup> It is ineffective when the sustained ischemic insult lasts for more than 3 hours; thus, protection is conferred only when the sustained ischemia is followed by timely reperfusion. Subsequent studies have revealed that this endogenous defense mechanism manifests itself in several ways. After the acute phase of preconditioning disappears, a second phase of protection appears 24 hours later and is sustained for up to 72 hours. This is referred to as the ‘second window of protection,’ ‘late-phase’ preconditioning, or ‘delayed’ preconditioning. Late phase preconditioning protects against MI and stunning unlike classic IPC which only protects against infarction.”<sup>133,134</sup>

**Cellular Mechanisms Underlying IPC.** Reports of adaptation to ischemia led to major investigative efforts to elucidate the intracellular mechanism(s) underlying the heart’s endogenous defenses against I/R injury. The assumption was, and still is today, that a better understanding of these mechanism(s) would lead to the development of potent new therapeutic modalities that would be more effective in treating or preventing the deleterious consequences of I/R injury.

One of the earliest hypotheses was that the primary mediator of IPC was the activation of the adenosine  $A_1$  and/or  $A_3$  receptors on the cardiomyocyte.<sup>132,135</sup> Subsequent studies have shown that in addition to adenosine, there are multiple guanine nucleotide-binding (G) protein-coupled receptors that once activated can mimic the infarct-sparing effect of ischemic preconditioning. These include bradykinin, endothelin,  $\alpha_1$ -adrenergic, muscarinic, angiotensin II, and delta-opioid receptors (Fig. 16-4). The infusion of exogenous agents to

mimic ischemic preconditioning is referred to as pharmacologic preconditioning. Exactly which of these receptors is the most important in mediating endogenous preconditioning is unknown because there appear to be species differences and redundant signaling pathways. Regardless, it is now thought that these triggers of IPC result in activation of various tyrosine kinases, isoforms of PKC, p38 mitogen-activated protein kinases and extracellular signal-regulated kinases (ERKs)]. P38 mitogen-activated protein kinases

**FIGURE 16-4** Signaling pathways of ischemic preconditioning (IPC). IPC, ischemic preconditioning; MMP, matrix metalloproteinases; HB-EGF, heparin-binding epidermal growth factor; Pro, Pro-HB-EGF; PI3, phosphatidylinositol 3-kinase; PI<sub>4,5</sub>P<sub>2</sub>, phosphatidylinositol bisphosphate; PI<sub>3,4,5</sub>P<sub>3</sub>, phosphatidylinositol trisphosphate; MEK, mitogen activated protein kinase kinase; ERK, extracellular-signal regulated kinase; NO, nitric oxide; NOS, NO synthase; eNOS, endothelial NOS; GC, guanylyl cyclase; PKG, protein kinase G; ROS, reactive oxygen species; mK<sub>ATP</sub>, mitochondrial ATP-dependent potassium channel; p70S6K kinase; GSK-3β, glycogen synthase kinase; mPTP, mitochondrial permeability transition pore; PDK, phosphoinositide-dependent kinase. Numerous triggers (opioids, bradykinin, and adenosine) and intracellular signaling pathways are involved in the cardioprotection conferred by IPC. The signal transduction pathways are complex, interactive, and include the HB-EGF receptor, PI3K, Akt, ERK1/2, eNOS, PKG, the opening of the mK<sub>ATP</sub> channel, ROS production, PKC activation, p70 S6 kinase, and GSK-3β. Possible end effectors of IPC include the opening of the mK<sub>ATP</sub> channel and inhibition of the mitochondrial transition pore opening. If only a few mitochondria are affected, cytochrome c may be released and induce apoptosis and cause cell death at a later time. Recent evidence suggests a unique role for the adenosine A2b receptor when activated at the time of reperfusion. While the process of autophagy has been implicated in IPC-induced cardioprotection where and how this process interacts with the signaling pathways remains to be determined.

are a family of serine/threonine protein kinases that are responsive to various stress stimuli cytokines, include heat shock protein, and are involved in cell differentiation, apoptosis and autophagy. The ERK cascade couples signals from cell surface receptors to transcription factors which regulate gene expression.

Interestingly, IPC-induced cardioprotection appears to require repopulation of receptors and activation (or, in some instances, reactivation) of “pro-survival” kinases upon relief of sustained ischemia. In this regard, Hausenloy and Yellon introduced the term “Reperfusion Injury Salvage Kinase” (RISK) pathway to represent the PI3K-Akt and ERK1/2 prosurvival kinases activated at the time of reperfusion and proposed that manipulation and upregulation of the RISK pathway may represent another approach to myocardial protection.<sup>136</sup>

While the identity of the end effector(s) of IPC remain speculative, significant evidence has accumulated indicating that the cardiomyocyte mitochondria are key targets of conditioning-induced protection (Fig.16-4).<sup>137,138</sup> Specifically, inhibition of mPTP and the opening of the mitochondrial  $K_{ATP}$  ( $mK_{ATP}$ ) channels have been implicated as the effectors of IPC.<sup>139,140</sup> Under normal conditions the mitochondrial inner membrane is impermeable to most metabolites and ions, and the mPTP is closed. While the molecular structure of the pore has yet to be determined, it is characterized by the formation of a large conductance megachannel, which is regulated by cyclophilin D in the matrix.<sup>140a</sup> While early investigations implicated the voltage-dependent anion channel in the outer mitochondrial membrane and the adenine nucleotide translocator (ANT) in the inner membrane in addition to cyclophilin D, genetic studies have refuted that model. Mouse models in which all ANT isoforms were deleted still exhibited mPTP opening; this was also the case for deletion of voltage-dependent anion channel (VDAC) isoforms. However, deletion of cyclophilin D resulted in hearts that were much more resistant to I/R injury, and further studies revealed that although the threshold for mPTP opening was greatly increased, it was still possible to trigger pore opening. It was concluded that cyclophilin D plays an important regulatory role in mPTP opening, but the molecular composition of the pore remains uncertain. Under conditions of stress, the mPTP may open resulting in depolarization of the inner mitochondrial membrane and an influx of water and ions into the matrix due to its high oncotic pressure. Matrix swelling expands the highly folded inner membrane but ultimately ruptures the outer membrane resulting in release of cytochrome *c* and other proapoptotic factors. Even in the absence of outer membrane rupture, loss of mitochondrial membrane potential results in ATP hydrolysis by the  $F_0-F_1$  ATP synthase in a futile effort to restore membrane potential, thereby accelerating energy depletion.

An ATP-sensitive potassium channel in the mitochondrial inner membrane ( $mK_{ATP}$ ) has been implicated on the basis of pharmacologic effects of diazoxide and pinacidil (channel openers) and 5-hydroxydecanoate and glibenclamide (channel closers). Many pharmacologic studies have demonstrated

a protective role for the putative  $mK_{ATP}$  although its molecular composition also remains unknown. Garg and Hu have proposed that PKC activation enhances the import of plasma membrane  $K_{ATP}$  channels into mitochondria.<sup>141</sup> This was based on their observation that in COS-7 cells, Kir6.2 protein (a subunit of  $K_{ATP}$  channels) and channel activity increased in mitochondria after PMA treatment, and this increase was inhibited by the selective PKC inhibitor chelerythrine. Pharmacologically triggered opening of the  $mK_{ATP}$  channel has been shown to reduce calcium overload, mitochondrial ROS production, swelling, and to preserve ATP levels after ischemia/reperfusion.

While early-phase preconditioning shares many of the same signaling mechanisms with late-phase preconditioning, the most obvious difference between the two is the apparent requirement for protein synthesis in the latter. Late-phase IPC has been shown to be associated with the upregulation of various proteins including but not limited to heat-shock proteins, inducible NOS (iNOS), cyclooxygenase 2, hemoxygenase and manganese superoxide dismutase.<sup>142,143</sup> There are however conflicting reports on what specific proteins are upregulated during late-phase preconditioning, which may be due to species differences as well as stimulus-specific responses.

**Clinical Relevance of IPC.** There is evidence that ischemic preconditioning occurs in the human being. Investigators have reported that patients experiencing angina prior to an MI have a better in-hospital prognosis and a reduced incidence of cardiogenic shock, fewer and less severe episodes of congestive heart failure and smaller infarcts as assessed by cardiac enzyme release.<sup>144</sup> Moreover, follow-up studies suggest that patients who have had angina prior to an infarct have better long-term survival rates.<sup>145-147</sup> There are also a myriad of reports that patients who undergo PCIs have an enhanced tolerance to ischemia after the first balloon inflation provided that the first balloon inflation exceeds 60 to 90 seconds.<sup>131</sup> Chest pain severity, regional wall motion abnormalities, ST-segment elevation, QT dispersion, lactate production and CK-MB release all have been reported to be attenuated in this setting as well.<sup>148,149</sup>

In patients undergoing PCI, a preconditioning-like effect has been mimicked by the administration of a variety of pharmacologic agents that are known to induce preconditioning in animal studies. For example, the administration of adenosine prior to PCI has been reported to attenuate myocardial ischemic indices during the first balloon inflation.<sup>150</sup> Administration of other agents, such as bradykinin and nicorandil (a  $K_{ATP}$  channel opener), also have been reported to produce similar effects.<sup>151,152</sup> Conversely the administration of aminophylline (a nonselective adenosine receptor antagonist), glibenclamide (a  $K_{ATP}$  channel blocker), or naloxone (an opioid receptor blocker) reportedly abolish the effects of ischemic preconditioning during PCI.<sup>153,154</sup> Additional studies provide evidence of delayed pharmacologic preconditioning in the clinical setting. Leeser and colleagues reported that a 4-hour intravenous infusion of nitroglycerin (an NO donor)

24 hours prior to PCI decreased ST-segment, changed and reduced chest pain during the first balloon occlusion compared with patients treated with saline vehicle.<sup>155</sup> An earlier report by this same group indicated that delayed preconditioning with nitroglycerin decreased exercise-induced ST-segment changes and improved exercise tolerance. Thus there are observational studies that support the hypothesis that myocardial protection conferred by ischemic preconditioning and its possible mediators in animal studies is translatable to humans. It is important to note however that classic or early ischemic preconditioning observed in animals is associated with a reduction in infarct size, but not protection against stunning, and that many of the clinical studies are either retrospective in nature or have used surrogate markers of injury as end points.

With respect to a role for IPC during cardiac surgery, numerous small trials have been conducted.<sup>156</sup> One of the first studies was conducted by Yellon and colleagues in patients undergoing CABG surgery.<sup>157</sup> Patients were subjected to a protocol that involved two cycles of 3 minutes of global ischemia. The aorta was cross-clamped intermittently and the heart was paced at 90 beats per minute to induce ischemia. This was followed by 2 minutes of reperfusion before a 10-minute period of global ischemia and ventricular fibrillation. Myocardial biopsies were obtained during the 10-minute period of global ischemia, and ATP tissue content was measured. The results showed that the ATP levels in the biopsies obtained from patients subjected to the preconditioning-like protocol were higher. However, since ATP content is not a marker of necrosis, a follow-up study was performed, and troponin T serum levels were measured. In this study the investigators reported that troponin release was attenuated in the patients subjected to the preconditioning protocol. In 2002, Teoh and colleagues reported that IPC conferred myocardial protection beyond that provided by intermittent cross-clamp fibrillation in patients undergoing CABG.<sup>89</sup> While other investigators reported similar findings, most of these studies have involved small numbers of patients.

In 2008, Walsh et al reported the results of a meta-analysis of the available small trials to determine the effect of IPC on patient outcomes.<sup>156</sup> They identified 22 eligible trials encompassing 933 patients; there were 374 patients in the IPC cohort and 402 patients served as controls. Twenty of the trials followed a protocol that involved aortic cross-clamping, and two involved coronary artery occlusion. The primary endpoint was perioperative mortality; the secondary endpoints included incidence of postoperative ventricular arrhythmias and MIs, the need for postoperative inotropic support and stroke. While the results suggested IPC was associated with a reduction in the incidence of ventricular arrhythmias, inotropic requirements and admissions to the critical care units and the incidence of perioperative MI and death was the same between the two cohorts. The investigators were appropriately cautious in the interpretation of the data considering the many caveats including bias and heterogeneity in relation to the endpoints. Given the low mortality rate in both groups,

the study was markedly underpowered to discern an effect on the primary endpoint, that is, death.

Thus despite a number of surgical studies that suggest IPC is effective in the setting of aortic cross-clamping and the administration of cardioplegia, it is important to note that the total number of patients studied to date is relatively small, and the outcomes have been limited to surrogate markers of myocardial necrosis, viz., CK-MB levels and troponin release and not definitive endpoints such as perioperative MI and death. In addition to the inherent risk of neurological complications associated with manipulation of the ascending aorta, the absence of compelling clinical outcomes may explain why IPC has not been adopted as an adjuvant approach among the myocardial protection techniques employed to date. A more promising strategy may evolve however once a better understanding of the intracellular events and effectors that confer protection have been elucidated.

**Postconditioning.** The phenomenon of ischemic “postconditioning” (PostCond) was first reported by Zhao *et al* in the canine model.<sup>158</sup> The term refers to rapid intermittent interruptions of blood flow in the early phase of reperfusion, that is, relief of ischemia in a stuttered or staccato manner. While the cellular mechanisms underlying PostCond are poorly defined, they appear to involve many of the same signal transduction pathways that are involved in IPC including cell surface receptor signaling, prosurvival kinases, inhibition of mPTP and activation of the  $mK_{ATP}$  channel. Although the duration and frequency of ischemia/reperfusion cycles may differ across studies, for the most part the cycles that induce PostCond are measured in seconds in smaller species and slightly longer in larger animals and humans, justifying the name “stuttering reperfusion.” The reduction in infarct size appears to be comparable to that observed with IPC. Preclinical studies conducted in multiple models and species (including dog, rat, rabbit, mouse, and pig) have demonstrated a reduction in infarct size that ranges from 20 to 70%. The restoration of blood flow in a stuttering manner during early reperfusion is of major interest to clinicians since it holds particular promise for patients presenting with an acute MI. In the surgical setting PostCond could be applied in the operating room after release of the aortic cross-clamp.

Evidence that PostCond exists in humans was first reported in patients undergoing PCI. Patients receiving brief balloon inflations/deflations in the initial minutes of reperfusion during PCI exhibited smaller ST-segment changes and lower levels of total creatine kinase release compared with patients that were not subjected to stuttering reperfusion. In 2007, Darling et al conducted a retrospective chart review in patients undergoing emergent cardiac catheterization for ST segment elevation MI (STEMI).<sup>159</sup> The hypothesis was that outcome would be better in patients undergoing multiple balloon inflations after primary angioplasty. Patients were divided into two cohorts: those who, at the discretion of the interventional cardiologist, received one to three balloon inflations and those in whom four or more inflations were applied. In this retrospective analysis, peak CK release was less in patients requiring  $\geq 4$  inflations. In a separate study

by Lønborg et al, the cardioprotective effects of PostCond in patients treated with PCI was evaluated using magnetic resonance imaging (MRI).<sup>160</sup> These investigators reported that mechanical PostCond appeared to be independent of the size of myocardium at risk. The findings were consistent with the concept that stuttering reperfusion confers cardioprotection during percutaneous interventions.

In the context of heart surgery, Luo reported a beneficial effect of surgical PostCond in 24 patients undergoing repair for tetralogy of Fallot at the time of aortic declamping. The postconditioning protocol consisted of aortic re-clamping for 30 seconds and declamping for 30 seconds; the process was repeated twice. The intervention was reported to reduce perioperative troponin-T and CK-MB release and decreased the need for inotropic support after surgery.<sup>161</sup> A similar finding was reported by the same investigator in a study of adult patients undergoing valve surgery and children undergoing corrective surgery using cardioplegia. Thus there is evidence that a PostCond protocol may benefit patients undergoing heart surgery, albeit the majority of studies suggesting a beneficial effect have been conducted in the setting of percutaneous interventions. While PostCond may offer more promise than IPC in terms of clinical application, it is important to note that both are invasive in nature. Ideally, the elucidation of the cellular mechanisms underlying ischemic conditioning will lead to pharmacological approaches that would obviate the need for invasive approaches.

**Remote Ischemic Preconditioning.** Remote ischemic preconditioning (RIPC) is a phenomenon whereby brief ischemia of one organ or tissue confers protection on a distant naive organ or tissue against a sustained ischemia-reperfusion injury. RIPC was first described by Przyklenk and colleagues in 1993.<sup>162</sup> In the original study the investigators questioned whether IPC protected only heart cells exposed to brief coronary artery occlusions or was it possible that repetitive or stuttering occlusions in a remote naive vascular bed could reduce infarct size in the area subjected to prolonged ischemia. They used a canine preparation in which a branch of the circumflex coronary artery was subjected to four episodes of 5-minute occlusion and reperfusion; this was followed by 1-hour occlusion of the left anterior descending (LAD) coronary artery. After 4.5 hours of reflow, infarct size in the distribution of the LAD was measured. Indeed a marked reduction in infarct size was observed. Since then numerous other investigators have confirmed these findings, and the phenomenon has been observed in various species and with different organs. Brief occlusions of the renal and mesenteric arteries and brief restriction of blood flow to the skeletal muscle of the lower limb have also been reported to reduce myocardial infarct size.<sup>163</sup> As a consequence, RIPC is also referred to as inter-organ preconditioning.

Not surprisingly, multiple mechanisms trigger RIPC is signaled through neuronal signaling and multiple secreted factors (such as adenosine, bradykinin and calcitonin gene-related peptide) followed by activation of multiple kinases including p38 mitogen-activated phosphokinase (p38 MAPK), extracellular signal-regulated kinase 1/2 (ERK1/2)

and c-Jun N-terminal kinase (JNK). One way by which the remote preconditioning signal may be conveyed to the target organ is through exosomes. These membrane-bound nanoparticles contain proteins, mitochondrial RNAs (mRNAs) and microRNAs which are taken up by target cells and elicit a response.<sup>164</sup> As with many other cardioprotective interventions, lack of a clear understanding of the molecular basis of the phenomenon has not dampened the enthusiasm for applying the approach clinically.

One of the first studies involving surgery was conducted in 17 children undergoing congenital heart surgery with CPB.<sup>165</sup> Brief intermittent lower limb ischemia attenuated troponin release and the need for postoperative inotropic support. Hausenloy et al reported a similar finding in 57 patients undergoing CABG.<sup>166</sup> Patients were randomized to RIPC or no treatment; all patients also received cardioprotection by either intermittent cross-clamping or cardioplegia. Perioperative troponin-T release was reduced by 43% in the RIPC group. In another study involving 23 adult patients undergoing on-pump CABG surgery and cold blood cardioplegia, RIPC was associated with a 42% reduction in total troponin-T release.<sup>167</sup> In this study, RIPC was induced by three 5-minute cycles of right forearm ischemia by inflating a blood pressure cuff on the upper arm to 200 mm Hg with an intervening 5-minute reperfusion period; the control group had a deflated cuff placed on the upper arm for 30 minutes.

In 2013, Thielmann et al reported the results of a prospective single-center double-blind randomized controlled study in 329 CABG patients. Patients underwent surgery preceded by RIPC (n = 162) or not (n = 167). Patient demographics and perioperative data were comparable between the two groups. Postoperative troponin I levels were significantly lower in the RIPC group. At 4-year follow-up, all-cause mortality and major adverse cardiac and cerebrovascular events were less frequent; however, this did not reach significance because the study was underpowered, given the low mortality rate. This is one of the first studies to examine the clinical benefit of RIPC beyond the biochemical markers of myocardial damage. The findings parallel other studies of patients undergoing PCI electively or for ST-segment-elevation MI.<sup>168,169</sup> Not all studies have shown that RIPC improves clinical outcomes after surgery. To examine the effects of RIPC combined with remote ischemic PostCond (RIPostCond), Hong and colleagues prospectively randomized 1280 CABG surgery patients to receive RIPC plus RIPostCond or no conditioning.<sup>170</sup> The protocol consisted of four cycles of 5-minute ischemia and 5-minute reperfusion administered to the upper limb prior to initiating CPB and repeated after CPB. The primary endpoints were a reduction in major adverse events including MI, stroke and death. Treatment had no effect on mortality or the incidence of cardiac or neurological complications. Of concern, the subgroup of off-pump patients that received RIPC plus RIPostCond had an increase in composite adverse events, notably increased RBC transfusions. The impact of the study was limited by the heterogeneity of procedures and the exclusion of patients with poor ventricular function; however it did raise concern regarding clinical efficacy of RIPC and RIPostCond.

Taken altogether, these RIPC studies led to the RIPHeart Study and the ERRICA trial.

In the RIPHeart Study, the objective was to assess the efficacy of remote ischemic preconditioning (RIPC) in reducing the composite endpoint of death, MI, stroke or acute renal failure in patients undergoing CABG surgery.<sup>170a</sup> Patients were randomized to undergo RIPC (n=692) induced by four 5 min cycles of transient upper limb ischemia/reperfusion or a control group (n=693) receiving four cycles of blood pressure cuff inflation/deflation in an imitation arm. In this study RIPC treatment had no effect on the composite endpoint or on any of the subgroup analyses. The incidence of postoperative MI was similar for the two groups, viz., 6.8% in the RIPC arm and 9.1% in the placebo group.

The ERICCA Trial<sup>170b</sup> was a multicenter, sham-controlled study in which the clinical relevance of RIPC. Patients undergoing on-pump CABG with blood cardioplegia were randomized to a RIPC group (n=801) or a control group (n=811). RIPC was induced with four 5-minute inflations and deflations of a standard blood-pressure cuff on the upper arm prior to surgery. The combined endpoint was death from cardiovascular causes assessed at 12 months. In this study, RIPC had no effect on the primary endpoint or any of the secondary end points of perioperative myocardial injury. As a consequence of these studies, for now, it appears that RIPC will not become a therapeutic modality in the routine practice of cardiac surgery.

**Conditioning by Stem Cells and Cell Products.** While stem cells have been explored for treatment of tissue loss after MI or in the setting of chronic heart failure, most studies have focused on endpoints months to years out, based on the expectation that stem cells function by regenerating tissue. However, recent work suggests they may be beneficial in the acute setting.<sup>171</sup> Marbán and colleagues used cardiosphere-derived cells (CDCs) delivered via intracoronary infusion 30 minutes after onset of reperfusion in a porcine model of MI. They found that the CDC infusion resulted in lower troponin I levels at 24 hours and decreased infarct size and microvascular obstruction at 48 hours. In isolated perfused rat hearts, an infusion of mesenchymal stem cells pre-stimulated with transforming growth factor alpha (TGF- $\alpha$ ) before ischemia resulted in improved functional recover and reduced inflammation and cell death.<sup>172</sup> A conditioned medium from human mesenchymal stem cells was shown to reduce infarct size and improve function in pigs subjected to MI.<sup>173</sup> The same group subsequently showed that the active component of the conditioned medium was exosomes.<sup>174</sup> Exosomes derived from an immortalized allogenic stem cell line offer a number of advantages for clinical development including standardization of the material, longer shelf life and availability for all patients without the need for histocompatibility matching. Thus cell therapy may be eclipsed by exosomes, and both approaches hold promise for intraoperative myocardial protection.

**Autophagy.** In the heart, adaptive autophagy is an endogenous protective response to cardiac stress. It plays an important

role in cardiovascular disease, neurodegeneration, and cancer. Studies are now underway to harness its cardioprotective potential and, based on this process, develop effective cardioprotective therapies to protect the heart against I/R injury. Autophagy is the process whereby a double-membrane structure called the autophagosome sequesters cytoplasmic components such as ubiquitinated protein aggregates or organelles including mitochondria, peroxisomes and endoplasmic reticulum. It is involved in degradation of long-lived proteins and the removal of excess or damaged organelles. The outer autophagosomal membrane fuses with a lysosomal membrane, resulting in degradation of the cargo by lysosomal hydrolases; the resulting macromolecules are exported to the cytosol for reuse<sup>175</sup> (Fig. 16-5).

One of the first studies to suggest autophagy is an adaptive process responsive to stress in the heart was the report by Decker et al in which they noted an increase in degenerating mitochondria and autophagosomes in rabbit hearts subjected to hypoxia and reoxygenation.<sup>176</sup> Reperfusion restored contractility, and the injured myocytes underwent a cellular repair process that involved a marked increase in lysosomal autophagy. They concluded that autophagy was part of a repair response to hypoxic stress in the heart. Upregulation of autophagy has been described in cell models of hypoxia/reoxygenation and models of I/R injury in rodents and pigs.<sup>177-185</sup> Hamacher-Brady et al showed that upregulation of autophagy in HL-1 myocytes protected against cell death induced by simulated ischemia reperfusion (sI/R) whereas inhibition of autophagy-enhanced cell death.<sup>177</sup> Dosenko et al also found that inhibition of autophagy exacerbated cell death during anoxia-reoxygenation.<sup>178</sup> Matsui et al showed that glucose deprivation increased the number of autophagosomes in neonatal cardiac myocytes, whereas inhibiting autophagy enhanced cell death.<sup>179</sup> In a porcine model of chronic myocardial ischemia and hibernating myocardium, Yan et al reported that cardiac myocytes with enhanced autophagy were not apoptotic; in contrast, apoptotic cells did not show features of autophagy.<sup>180</sup> Collectively these studies suggest that upregulation of autophagy promotes survival during I/R.

There is now direct evidence that autophagy plays an important role in mediating ischemic and pharmacologic preconditioning. Using HL-1 cells and adult rat cardiomyocytes, Yitzhaki et al showed that the adenosine preconditioning agent 2-chloro-N(6)-cyclopentyladenosine (CCPA) upregulated autophagy within 10 minutes of adenosine treatment and inhibition of autophagy resulted in significant loss of cytoprotection against hypoxia/reoxygenation injury. Autophagy was also shown to be important for delayed preconditioning in this cell-based model.<sup>181</sup> Multiple cardioprotective agents including CCPA, sulfaphenazole and chloramphenicol, as well as ischemic preconditioning, also upregulate autophagy in vivo.<sup>182-185</sup> Based on these findings, it appears that autophagy is an important mediator of protection in the heart.

**Autophagy in the Human Heart.** Delineating the role of impaired autophagy in heart patients is challenging because of the need to access tissue. One of the first studies to suggest

**FIGURE 16-5** Cellular process of autophagy. Adapted from Gottlieb RA, Finley KD, Mentzer Jr RM: Cardioprotection requires taking out the trash. *Basic Res Cardiol* 2009; 104:169-180. I/R, ischemia/reperfusion; ROS, reactive oxygen species; RNS, reactive nitrogen species; mTor, mammalian target of rapamycin; AMPK, AMP-activated protein kinase; LC3, light chain 3-phosphatidylethanolamine; Atg1, Atg4, Atg7, Atg12, Atg16L, autophagy regulating proteins; Vps34, a class III PI3 kinase involved in vesicular trafficking, nutrient signaling, and autophagy; PIP3, phosphatidylinositol 3,4,5-trisphosphate; 3MA, 3-methyladenine. Autophagy is a dynamic adaptive process in the setting of I/R injury. The process involves the synthesis of a cup-shaped pre-autophagosomal double-membrane structure which surrounds cytoplasmic material and closes to form an autophagosome. This process is regulated by the autophagy proteins Atg4, Atg7, LC3, and the complex of Atg12-Atg5-Atg16L. The process is activated by a number of stimuli including ROS or RNS. Induction by Beclin1 and Vps34 in conjunction with other Atg proteins results in the formation of an isolation membrane to which Atg proteins are recruited. Atg12-Atg5 and LC3 proteins are involved in the expansion of the membrane. This allows the phagophore to surround and engulf damaged organelles or protein aggregates which may accumulate as a result of I/R injury. The result is the formation an autophagosome. The green insert shows autophagosomes (green puncta). This photo was obtained in a cell expressing a fusion protein of green fluorescent protein (GFP) fused to the N-terminus of LC3; the GFP-LC3 was incorporated into the double-membrane structure of the phagophore. Wortmannin and 3 MA are agents that can inhibit the initiation phase of autophagy; bafilomycin and chloroquine can inhibit the degradation phase.

that autophagy is an adaptive process in the human heart was the report by Kassiotis et al.<sup>186</sup> Biopsies of the left ventricle were obtained from nine patients with idiopathic dilated cardiomyopathy at the time of implantation and removal of left ventricular assist devices. Autophagy-related mRNAs and proteins were downregulated after prolonged circulatory support leading the authors to conclude that autophagy is an adaptive mechanism in the human heart. Garcia et al studied 170 patients who had undergone elective CABG and preoperatively were in normal sinus rhythm.<sup>187</sup> Intraoperative right atrial biopsies revealed that autophagic vesicles and lipofuscin deposits and biochemical markers of impaired autophagic flux were more commonly observed in the biopsies of the

patients who developed postoperative atrial fibrillation suggesting that loss of normal autophagic activity may increase the risk of postoperative arrhythmias. Jahania et al reported the results from 19 patients in which atrial biopsies were collected just prior to the onset of CPB and again after removal of aortic cross-clamp and weaning from CPB. Ischemic stress was associated with a significant depletion of autophagy-related proteins suggestive of a coordinated engagement of the autophagy machinery.<sup>188</sup> Consistent with this, Singh et al examined mRNA and protein in samples taken from right atrial appendages before cardioplegic arrest and after reperfusion.<sup>189</sup> I/R was associated with upregulation of several autophagy-related genes and biochemical evidence of

increased autophagy, leading the authors to conclude that I/R affects gene expression and posttranslational regulation of autophagy in the human heart. In contrast, Gedik et al<sup>190</sup> failed to detect an association between autophagy and protection conferred by RIPC in patients undergoing CABG surgery. Analysis of autophagy proteins in left ventricular biopsies taken before initiation of CPB and at early reperfusion showed no consistent changes in key autophagy proteins either with I/R or between the placebo and RIPC cohorts, despite evidence of RIPC-induced protection manifest as a reduction in serum cardiac isoform of troponin I (cTnI). In the Jahania study, each patient's paired results were reported as a ratio from pre-CPB to post-CPB. The Gedik study reported the mean baseline (before cross-clamp) compared to the mean value at 10-minute reperfusion and may have missed individual pre-post changes. While the majority of observations to date suggest that cardiac autophagy is an active and adaptive response in humans, additional studies are needed to confirm these findings and determine whether enhancement of adaptive autophagy will open the door to new cardioprotective strategies.

## Pharmacological Methods of Inducing Protection

A number of pharmacological agents are known to limit I/R injury in animal models. Clinical trials involving many of these agents, however, have yielded mixed or negative results.<sup>191</sup> The failure to translate promising preclinical interventions and agents into effective clinical therapies prompted the National Heart Lung and Blood Institute to convene a panel of experts in 2011 to discuss the reasons for failure and to develop a series of recommendations designed to move the field of myocardial protection forward.<sup>192</sup> The working group concluded that future preclinical cardioprotection studies should concentrate on relevant animal models that reflect human comorbid conditions such as atherosclerosis, hypercholesterolemia, hypertension, diabetes, and advanced age. The panel also suggested that cardioprotective candidates for future clinical development should have demonstrated efficacy in multiple independent preclinical studies involving rodent and large-animal models. Early-stage clinical trials to evaluate safety of the most promising candidates should also show efficacy based on surrogate markers. In addition to cardiac enzymes, advances in MRI make it possible to assess infarct size,<sup>193</sup> ischemic and pharmacologic preconditioning, postconditioning, remote postconditioning, sodium-hydrogen exchange inhibitors, adenosine analogs, and cyclosporine A have shown promise in studies using healthy young animals but have not been adequately evaluated in animal models with comorbidities such as obesity or age. The purpose of this section is to review the status of several of these treatments that have been studied clinically.

### ADENOSINE

There is considerable preclinical evidence that activation of various adenosine receptor subtypes results in

cardioprotection similar to that induced by IPC. Preischemic administration of the nucleoside adenosine retards the rate of ischemia-induced ATP depletion, prolongs the time to onset of ischemic contracture, attenuates myocardial stunning, enhances postischemic myocardial energetics and reduces infarct size.<sup>194,195</sup> There are four distinct adenosine receptor sub-types: A<sub>1</sub>, A<sub>2a</sub>, A<sub>2b</sub>, and A<sub>3</sub>. While all of the receptors reportedly have cardioprotective properties, agonists of A<sub>1</sub> and A<sub>2a</sub> receptors have been the most widely investigated. The A<sub>2b</sub> receptor has also been shown to protect against I/R injury. These receptors are coupled to heterotrimeric guanine nucleotide-binding (G) proteins in which the subtype (G<sub>o</sub>, G<sub>iα2</sub>, G<sub>iα3</sub>, G<sub>q</sub>, and G<sub>s</sub>) varies according to the receptor and tissue. There is evidence that two and possibly three of the adenosine receptor subtypes are expressed in the adult human heart. Activation of the adenosine A<sub>1</sub> and A<sub>2a</sub> receptors confers protection in animal studies when administered prior to the onset of ischemia (preconditioning); the A<sub>2b</sub> receptor is protective when activated at the time of reperfusion.<sup>196-199</sup> Administration of adenosine is complicated by the fact that it causes systemic hypotension, limiting the use of prolonged administration or higher doses. Evidence that extracellular adenosine signaling can be protective has led to a number of clinical trials in the setting of PCI for acute MI and heart surgery. With respect to the former, two particularly intriguing ones are Acute Myocardial Infarction Study of Adenosine (AMISTAD-I) and AMISTAD-II.<sup>200-202</sup> In AMISTAD-I, 236 patients undergoing thrombolytic therapy for acute MI were randomized to receive adenosine or placebo within 6 hours of the onset of infarction. The primary endpoint was infarct size by technetium-<sup>99m</sup> sestamibi (single-photon emission computed tomography, SPECT); secondary endpoints included myocardial salvage index and a composite endpoint comprising death, reinfarction, shock, congestive heart failure (CHF), and stroke. In this study, there was a 67% relative reduction in infarct size in patients with anterior infarction; however, there was no reduction in patients with infarcts located elsewhere. It may be easier to detect an effect on infarct size if the area at risk is larger, which is often the case when the LAD coronary artery is involved. Although there was a trend toward achieving the composite secondary endpoint, there were no significant differences in clinical outcome between the two groups. This led to the AMISTAD-II trial. In this study, 2118 patients with evolving anterior infarcts and receiving thrombolysis or primary angioplasty were randomized to receive placebo or a low or high dose of adenosine. The primary composite endpoint consisted of new CHF, first rehospitalization for CHF, or death at 6 months. In a subset of patients (n = 243), infarct size was measured by SPECT. In this study, adenosine therapy had no effect on clinical outcomes; it did demonstrate however that, as in AMISTAD-I, adenosine treatment resulted in a dose-related reduction in infarct size. At the higher dose, a 57% relative reduction in infarct size was observed. A likely explanation for the divergence between reduced infarct size and yet no effect on outcomes is that the study was underpowered to show clinical improvement. The significance of these two studies however

is that for the first time there was evidence that a pharmacologic agent—specifically adenosine—could reduce infarct size when administered at reperfusion.

Other adenosine studies, however, failed to show efficacy. Desmet et al reported the effects of a high-dose intracoronary bolus of adenosine administered just prior to PCI. Patients were randomized to receive adenosine (4 mg) or placebo; infarct size was assessed using MRI. Four months later there was no evidence of infarct scar reduction or a decrease in microvascular obstruction by MRI.<sup>203</sup> Fokkema et al also evaluated the effect of high-dose adenosine given as intracoronary boluses on infarct size in patients with acute STEMI. Patients ( $n = 448$ ) were randomized to receive placebo ( $n = 222$ ) or two bolus injections of intracoronary adenosine ( $2 \times 120 \mu\text{g}$  in 20 mL saline) ( $n = 226$ ). The first bolus was administered after thrombus aspiration, and the second was given after stenting the infarct-related artery. In this study, adenosine treatment had no effect on infarct size as determined by CK and CK-MB or Thrombolysis In Myocardial Infarction (TIMI) flow.<sup>204</sup> A major limitation of both studies was the mode of administration. The half-life of adenosine in blood is measured in seconds; the retrospective inference is that a single or double bolus injection of adenosine is too short-lived to confer protection.<sup>191</sup>

With respect to adenosine and cardiac surgery, most of the studies have been relatively small as well. Fremes and colleagues reported the results of an open-label, nonrandomized CABG surgery study in which adenosine administration was combined with antegrade warm blood cardioplegia. The adenosine concentrations studied were 15, 20, and 25  $\mu\text{m}$ . These investigators reported that adenosine could be added safely as a supplement to cardioplegic solutions, but it had no effect on myocardial function at the doses studied.<sup>205</sup> Cohen and colleagues observed a similar lack of efficacy in a phase II double-blind, placebo-controlled trial performed in patients undergoing CABG surgery. Patients were treated with placebo (saline) or warm blood cardioplegia supplemented with 15, 50, or 100  $\mu\text{m}$  adenosine. These investigators found that adenosine did not alter survival, the incidence of MI or the incidence of low cardiac output syndrome. A limitation of this study was the use of low concentrations of adenosine in the setting of warm blood cardioplegia. In blood, the nucleoside is metabolized rapidly to inosine and hypoxanthine; its half-life is measured in seconds, thus limiting its potential effect.<sup>206</sup>

A beneficial effect was observed by Mentzer and colleagues, however, in an open-label, single-center study in which the safety, tolerance, and efficacy of high doses of adenosine were studied when added to cold blood cardioplegia in CABG surgery patients.<sup>207</sup> Sixty-one patients were randomized to receive standard cold blood cardioplegia or cold blood cardioplegia containing one of five adenosine doses ranging between 100  $\mu\text{m}$  and 2 mm. Invasive and noninvasive studies of myocardial function were obtained sequentially after bypass. Parameters included the recording of inotropic utilization rates for the postoperative treatment of low cardiac output. Blood samples were collected for the

measurement of nucleoside levels. High-dose adenosine treatment achieved a 249-fold increase in the plasma adenosine concentration and was associated with a reduction in postbypass inotropic drug utilization, improved regional wall motion and global function measured by transthoracic echocardiography.

Subsequently, Mentzer and colleagues examined the effects of high-dose adenosine treatment in 253 CABG surgery patients randomized to one of three treatment arms. This was a double-blind, placebo-controlled multicenter trial using cold blood cardioplegia. Adenosine was administered in three different doses and rates. Invasive and noninvasive measurements of ventricular performance were obtained before, during and after surgery. The study revealed a trend toward the decreased need for high-dose inotropic support and fewer perioperative MIs in the high-dose adenosine group, but it was underpowered to show an effect on any single endpoint. A post hoc composite outcome analysis revealed that patients who received high-dose adenosine were less likely to experience the composite endpoint of high-dose dopamine and epinephrine use, insertion of an intra-aortic balloon pump, MI, or death.<sup>208</sup>

In 2001, Wei et al<sup>208a</sup> initiated a prospective randomized, controlled study in 30 patients undergoing elective CABG surgery and CPB to investigate the effect of adenosine pretreatment on myocardial recovery and inflammatory response. Patients received a 7-minute infusion of adenosine prior to the initiation of CPB ( $n = 15$ ); outcomes were compared to a second group of patients ( $n = 15$ ) who did not receive the infusion. CPB was initiated 3 minutes after cessation of the adenosine infusion. Cold blood cardioplegic solution was infused antegrade retrograde during the period of aortic cross-clamping, and warm blood retrograde cardioplegia was administered at the end of cross-clamping. Postoperative CK-MB, perioperative leukocyte counts and various cytokines were measured. CK-MB levels were lower and the cardiac index was better in the adenosine-treated cohort. Leukocyte counts and cytokine levels were unaffected. The authors concluded that adenosine treatment was protective, but its mechanism of action was independent of effects on inflammation.

In contrast, Ahlsson et al did not detect a beneficial effect with adenosine added to cold blood cardioplegia administered continuously in patients undergoing isolated aortic valve replacement.<sup>209</sup> In this study, 80 patients were randomized into four groups: Group I—antegrade cardioplegia with adenosine ( $n = 19$ ); Group II—antegrade cardioplegia with placebo ( $n = 21$ ); Group III—retrograde cardioplegia with adenosine ( $n = 21$ ); and Group IV—retrograde cardioplegia with placebo ( $n = 19$ ). Adenine nucleotide content and lactate were determined from left ventricular biopsies obtained before aortic occlusion, after bolus cardioplegia, at 60 minutes of aortic occlusion and at 20 minutes after release of the aortic occlusion. CK-MB and troponin-T were measured at 1, 3, 6, 9, 12, and 24 hours after aortic occlusion. Hemodynamic profiles were obtained before surgery and 1, 8, and 24 hours after CPB. In this study, investigators observed

that retrograde blood cardioplegia was associated with a higher myocardial oxygen uptake and lactate accumulation than antegrade, but the addition of adenosine to cardioplegia showed no benefit.

In summary, it is still not clear whether adenosine is beneficial in the setting of heart surgery. It is possible that this conundrum will be solved with the development of receptor-selective adenosine analogs that confer protection without causing systemic hypotension.

### SODIUM-HYDROGEN EXCHANGER INHIBITORS

The sodium-hydrogen exchangers (NHEs) are a family of membrane proteins with nine isoforms that are involved in the transport of hydrogen ions in exchange for sodium ions. NHE-1 is the isoform that is expressed in the heart and most likely plays a minor role in the normal excitation-contraction coupling process. As discussed in the section, Intracellular Mechanisms of Ischemia/Reperfusion Injury, NHE-1 contributes to calcium overload and cell death. In the setting of I/R injury, NHE-1 contributes to arrhythmias, stunning, apoptosis, necrosis, postinfarction ventricular remodeling and heart failure.<sup>210,211</sup> In the context of heart surgery, there have been a number of small clinical trials to test whether inhibition of NHE-1 can prevent I/R injury. EXPEDITION was a phase III trial to address the safety and efficacy of NHE-1 inhibition by cariporide in the prevention of death or MI in patients undergoing CABG surgery. High-risk CABG patients ( $n = 5770$ ) were randomized to receive either intravenous cariporide or placebo. The composite endpoint was assessed at 5 days, and patients were followed for up to 6 months. The incidence of postoperative MI (which had very specific criteria involving EKG changes, CK-MB elevation, with or without chest pain) in this series of patients was 18%, much higher than previously thought. The results revealed an 18.3% relative risk reduction in the incidence of death or MI at 5 days ( $p = .0002$ ). The relative risk reduction for death or MI at day 30 and month 6 was 16.1% ( $p = .0009$ ) and 15.7% ( $p = .0006$ ), respectively. When MI risk was analyzed separately, the relative risk reduction was 23.8% at 5 days ( $p = .000005$ ) and 25.6% at month 6 ( $p = .000001$ ). This cardioprotective effect was extremely robust; however, the overall mortality rate increased at 5 days from 1.5% in the placebo group to 2.2% in the group with cariporide, which was attributed to an increase in the incidence of cerebrovascular events. Thus, while cariporide was effective in reducing the incidence of nonfatal MI, it increased the risk of death from cerebrovascular events resulting in an unacceptable safety profile. In this study the drug was administered continuously for 49 hours beginning preoperatively, although no preclinical studies had examined the necessity or possible adverse effects of prolonged administration; the preclinical studies utilized a single bolus. Nevertheless this study was significant because it was the first Phase III study in heart surgery patients to clearly demonstrate that it is possible to pharmacologically protect the heart and reduce the incidence of perioperative MI. The findings also suggest that NHE-1 inhibitors represent a new

class of drugs that hold promise for reduction of MI associated with I/R injury, provided it is possible to eliminate the risk of cerebrovascular events.<sup>1,212</sup> It is possible that some of the newer drugs in this class may be safer.

### ACADESINE

Acadesine (also known as 5-aminoimidazole-4-carboxamide-1- $\beta$ -D-ribofuranoside, AICA riboside) is a purine nucleoside analog which was thought to elevate tissue levels of adenosine selectively during ischemic conditions. Numerous preclinical studies demonstrated its cardioprotective efficacy, although it is not clear whether the protective effect is due to its effects on intracellular ATP synthesis, extracellular adenosine concentrations or its ability to activate AMP-activated protein kinase (AMPK) and thereby stimulate glucose uptake and autophagy.<sup>213,214</sup> Early preclinical studies indicated acadesine treatment improved left ventricular wall motion after intermittent ischemia, diminished the frequency of ventricular arrhythmias during reperfusion, attenuated myocardial stunning, and preserved myocardial function after cardiac arrest and cold cardioplegia. These observations led to several clinical trials in CABG surgery patients in the 1990s. The findings however were inconclusive due in part to the fact that they were underpowered. In 2006, Mangano performed a meta-analysis on the combined data from five trials comprising more than 4000 CABG patients to determine the effects of i.v. acadesine on the prespecified perioperative outcomes of MI, stroke, and cardiac death. In these five studies, acadesine was given intravenously prior to and during surgery along with a fixed concentration included in the cardioplegia solution. The meta-analysis concluded that acadesine was effective in reducing perioperative MI, cardiac death, and combined adverse cardiovascular outcomes.<sup>215</sup>

Mangano et al then examined the 2-year, all-cause mortality after perioperative MI in a follow-up of the Acadesine 1024 Trial. In this analysis, patients who received acadesine and had a postreperfusion MI had a significant four-fold reduction in mortality compared to the patients who had an MI but did not receive the drug (3/46 patients vs 15/54 patients, respectively).<sup>216</sup> This led to a large prospective randomized trial, Reduction in Cardiovascular Events by Acadesine in Patients Undergoing CABG (RED-CABG). High-risk CABG patients were randomized to receive either acadesine or placebo prior to the induction of anesthesia. The target enrolment was 7500 patients, and the primary composite endpoint was all-cause mortality, stroke and need for mechanical support for left ventricular failure. Midway into the study, a futility analysis indicated a low probability of detecting a statistically significant difference between treatment and placebo groups; the trial was terminated after 3080 patients had been enrolled.<sup>217</sup> In reviewing the outcome of RED-CABG the investigators acknowledged that planning a clinical trial based on a meta-analysis carries inherent risk. While the study was intended to enroll high-risk patients (a higher event rate would make it easier to discern a beneficial effect), it turned out that many of the patients were not high

risk resulting in a lower than expected event rate (the composite endpoint). Because MI was an exploratory outcome rather than a primary endpoint, enzyme levels were determined only during the first 24 hours. Despite these caveats however, the investigators concluded that acadesine treatment had no effect of all-cause mortality, nonfatal stroke or need for mechanical circulatory support. This disappointing outcome makes it unlikely that acadesine will be the subject of further clinical investigation.

### GLUCOSE-INSULIN-POTASSIUM

Numerous studies have shown that glucose-insulin-potassium (GIK) infusions are effective in reducing perioperative MIs, postischemic myocardial dysfunction and atrial fibrillation in patients undergoing heart surgery.<sup>218</sup> Increased glycolytic flux driven by glucose and insulin supplementation increases pyruvate generation and maintains the GSH/GSSG balance. Additionally glycolytic ATP protects membranes through stimulation of the Na<sup>+</sup>/K<sup>+</sup>-ATPase and supports uptake of Ca<sup>2+</sup> by the sarcoplasmic reticulum. Provision of K<sup>+</sup> improves sodium homeostasis of ischemic myocardium.

Despite a strong rationale for its application, the efficacy of GIK in the setting of heart surgery remains controversial. The use of GIK to treat patients with acute MI yielded mixed results in the 1990s. Fath-Ordoubadi and Beatt performed a meta-analysis on 1932 patients in nine small trials of GIK for acute MI and found it was beneficial. It should be noted that none of the patients underwent reperfusion therapy (thrombolysis or primary PCIs).<sup>219</sup> In 2003, van der Horst reported the results of a randomized open label study in which 940 patients with acute MI and eligible for angioplasty received either continuous infusion of GIK or no infusion.<sup>220</sup> GIK infusion had no effect on overall patient mortality, but a significant reduction in mortality was observed in the subgroup of patients without evidence of heart failure (1.2% vs 4.2%). The investigators concluded that the effect of GIK infusion in patients with heart failure was uncertain. To confirm these findings, a folstudy, GIPS-II, was initiated in 2003. The purpose was to confirm clinical benefit of GIK in STEMI patients without signs of heart failure. Patients were randomized to traditional care or additional GIK infusion. The study, however, was terminated early due to lack of efficacy. It was concluded that GIK in adjunct to reperfusion therapy in STEMI patients does not lower mortality.<sup>221</sup>

In follow up to the Fath-Ordoubadi and Beatt meta-analysis in 1997,<sup>219</sup> Mamas et al reported the results of a meta-analysis of GIK therapy for the treatment of acute MI in 2010.<sup>222</sup> Unlike the previous meta-analysis, this study included patients who underwent reperfusion therapy. A total of 16 randomized trials accounting for 28,373 patients were identified between 1966 and 2008. These investigators failed to find any life benefit for GIK therapy in STEMI patients. The findings were consistent with the combined subgroup analysis of GIK therapy for acute MI in the OASIS-6 and CREATE-ECLA trials which also showed that GIK infusion had no effect on key clinical endpoints.<sup>223</sup>

It was hypothesized that the efficacy of GIK infusions depends upon how soon it is administered after the onset of ischemia. Selker and colleagues tested this hypothesis in the IMMEDIATE Trial in 2012.<sup>224</sup> GIK was administered to presumed MI patients prior to hospitalization with the expectation that it would slow the progression of MI or STEMI. Secondary endpoints included the incidence of cardiac arrest, mortality and heart failure. A total of 911 patients were randomized; 59 were not enrolled because they did not give written consent on arrival at the hospital. The investigators found that MI progression did not differ between the GIK and the placebo groups, and GIK administration had no effect on 30-day survival; however, GIK was associated with a lower rate of the composite endpoint of cardiac arrest and in-hospital mortality. Moreover, infarct size was smaller in the subgroup of GIK-treated patients who underwent cardiac imaging at 30 days. The investigators concluded that early GIK therapy did not alter MI progression but had a beneficial effect on the secondary composite endpoint and called for additional studies. One-year follow-up revealed no significant differences in outcome with the exception of patients with STEMI in which the composites of cardiac arrest or 1-year mortality, and of cardiac arrest, death or rehospitalization for heart failure were significantly reduced.<sup>225</sup> These findings have fueled discussions over the timing of administration, target populations and overall efficacy of GIK as a cardioprotective intervention for patients with acute MI.

Bruemmer-Smith et al reported that GIK infusion during surgery had no effect on myocardial cellular damage as measured by cTnI levels 6 hours after CPB and was associated with increased hyperglycemia. Although this was a randomized, prospective, double-blind study in CABG surgery patients and the two groups were well matched for age and number of bypassed vessels, the study was most likely underpowered, given that only 42 patients were enrolled.<sup>226</sup> In another study, Lell et al reported on 46 patients undergoing elective off-pump CABG surgery; the patients received either normal saline or a GIK infusion for 12 hours. These investigators were also unable to demonstrate a beneficial effect on cardiac performance using the clinical measurements of cardiac index and inotropic requirements. They noted persistent hyperglycemia—a known risk factor for postoperative complications—despite the use of supplemental insulin.<sup>227</sup> Lazar et al<sup>228</sup> conducted a study in diabetic CABG patients to determine whether GIK solution with tight perioperative glycemic control was more effective than standard glycemic control and no GIK. The rationale was that GIK with tight glycemic control would optimize myocardial metabolism and improve perioperative outcomes. The preoperative patient profiles of the 141 randomized patients were similar with respect to age, sex, ejection fraction, urgency of surgery and the type of diabetes. Although the 30-day survival was comparable in both groups, the patients receiving GIK plus tight control had significantly higher cardiac indices and less need for inotropic support. There was also a lower incidence of atrial fibrillation. Follow-up data 5 years later were available in 60 of 70 GIK patients (83.3%) and in 60 of 69 placebo

patients (86.9%). Survival was significantly better in the patients who received GIK; the investigators attributed these long-lasting benefits to the perioperative GIK treatment, but it might also have been due to the careful glycemic control. In another study of patients with type-2 diabetes, Barcellos et al reported their findings in 24 patients who underwent CABG surgery. Patients were administered GIK or subcutaneous insulin from the onset of anesthesia until 12 hours postoperatively. The use of GIK neither improved the cardiac index nor reduced the use of inotropic agents.<sup>229</sup>

In another single-center study, Quinn et al conducted a prospective, randomized, double-blind, placebo-controlled trial in 280 nondiabetic CABG surgery patients.<sup>90</sup> They found that GIK treatment was associated with fewer episodes of low cardiac output, less inotropic support postoperatively and a reduction in serum cardiac troponin I levels. The authors concluded that GIK is an effective, inexpensive and safe cardioprotective adjunct.<sup>90</sup> Rabi et al conducted a meta-analysis of 20 clinical trials to determine the effect of GIK or glucose-insulin (GI) on in-hospital mortality and atrial fibrillation (AF).<sup>230</sup> They found that GIK/GI failed to significantly reduce mortality or AF in patients undergoing CABG surgery. The authors discouraged the routine use of GIK/GI in patients undergoing CABG surgery until future clinical trials provided sufficient evidence to warrant the practice. Fan et al, however, came to a different conclusion in their meta-analysis of 33 randomized clinical trials.<sup>231</sup> This analysis involved 2113 patients: 1150 were randomized to GIK and 963 served as a control group. Most of the studies were performed in CABG patients; six trials were based on valve or combined valve/CABG operations. Twenty studies used a placebo for control and 13 used standard of care as the control. Some studies included diabetic patients; glycemic control was used in 13 trials. The insulin dose and timing of infusions varied across studies. This meta-analysis showed that GIK therapy was associated with a significant reduction in perioperative MI and inotropic support, but had no effect on all-cause mortality, postoperative atrial fibrillation or length of hospital stay.

While most studies had focused on CABG patients, Howell et al sought to evaluate the effects of GIK in patients undergoing surgery for aortic stenosis.<sup>232</sup> Patients with critical aortic stenosis often have left ventricular hypertrophy (LVH), which is thought to compromise myocardial protection and put them at greater risk of a poor outcome. To test the benefits of GIK in this setting, the investigators initiated a single-center, double-blind placebo-controlled study with the primary endpoint a reduction in low cardiac output syndrome. Intermittent antegrade cardioplegia using St. Thomas solution buffered in cold blood was used for myocardial protection. Left ventricular biopsies were obtained to measure posttranslational modifications of specific proteins as an indication of GIK's effect on cardioprotective signaling. Over 4 years, 217 patients were randomized to GIK (n = 110) or placebo (n = 107). The investigators found that GIK treatment was associated with higher cardiac index from the beginning of treatment until 12 hours after the removal of the cross-clamp, a significant reduction in the incidence of low cardiac output

and frequency of inotrope use 6 to 12 hours postoperatively. This was accompanied by biochemical markers consistent with cardioprotective signaling. Although the investigators had expected that hypertrophic hearts would be at greater risk for myocardial necrosis and that GIK would therapy would be associated with lower troponin levels, they found that GIK had no effect on troponin levels. This was similar to the earlier study by Quinn et al from the same institution studying CABG patients.<sup>90</sup> The findings suggest that GIK ameliorates myocardial stunning but not necrosis.

GIK therapy has also been examined in the setting of patients undergoing urgent off-pump CABG surgery (OPCAB) for acute MI. Shim et al (2012) reported the results of a study in which 66 patients were randomized to receive GIK infusion or placebo.<sup>233</sup> The primary endpoints were the highest concentrations of CK-MB and troponin-T after reperfusion and the area under the curve (AUC) of serial troponin-T measurements obtained before the operation and at 12, 24, and 48 hours after reperfusion. The secondary endpoints were troponin-T levels greater than 0.8 ng/mL, MI defined by specific criteria and composite morbidity. The investigators found that GIK therapy was associated with a significant reduction in peak concentrations of CK-MB and troponin-T and the AUC of troponin-T. However, the incidence of postoperative MI was similar for both groups as were the other secondary clinical endpoints. In contrast to the Howell study, this clinical trial of urgent OPCAB for acute coronary syndrome found GIK attenuated myocardial necrosis (troponin-T and CK-MB) but did not alter incidence of MI or composite morbidity.

Taken altogether the evidence supporting the efficacy of GIK in the setting of heart surgery is still mixed. Meta-analyses of randomized clinical trials and numerous small studies indicate it may or may not be effective in preventing postischemic ventricular dysfunction, myocardial necrosis and atrial arrhythmias. This is due in part to the many small studies that are insufficiently powered to definitively conclude that GIK is ineffective; they can only conclude that they failed to see a benefit. Additional limitations include the heavy reliance on surrogate markers of injury, inherent limitations associated with meta-analyses, variability in managing hyperglycemia, variations in the specific composition and mode of administration of GIK and inclusion of low-risk patients (which lowers the event rate and limits the chance to detect a benefit). A large randomized, multi-center clinical trial specifically designed to address these issues will be required to resolve the controversies around the use of GIK for myocardial protection during heart surgery.

## CYCLOSPORINE

A major feature of reperfusion injury is the opening of the mitochondrial permeability transition pore (mPTP) which leads to necrotic cell death. For this reason preventing mPTP opening is considered a therapeutic target for I/R protection.<sup>234-237</sup> Cyclosporin A (CsA), Sanglifehrin A

and NIM 811 act directly on cyclophilin D, a key regulator of pore opening. As  $\text{Ca}^{2+}$  and ROS trigger pore opening, other preclinical interventions have targeted those upstream modulators. mPTP opening is also suppressed at acidic intracellular pH, which has been targeted by inhibiting NHE-1 to prevent proton extrusion.<sup>236,238</sup> CsA has been used extensively as an immunosuppressive agent in the management of transplant patients but is also a potent inhibitor of mPTP; its efficacy has been explored in small clinical trials involving patients undergoing heart surgery or PCI for acute MI.

In 2008, Ovize's group randomized 58 patients to receive CsA ( $n = 30$ ) or placebo ( $n = 28$ ) immediately prior to undergoing PCI for acute STEMI.<sup>239</sup> The primary endpoint was myocardial necrosis measured by CK and troponin-I; for a secondary endpoint in a subgroup of 27 patients, MRI was used to assess infarct size at 5 days as determined by the area of delayed hyper-enhancement. There were no differences between groups with respect to baseline characteristics, duration of ischemia, area at risk and ejection fraction. All patients underwent stenting of the culprit lesion. The CsA group demonstrated a 40% reduction in myocardial necrosis as assessed by serial CK, although, curiously there was no difference in troponin I release. They also compared CK levels to the area at risk estimated by circumferential extent of abnormally contracting segments and found that for any given size of the area at risk, smaller infarcts were observed in the CsA-treated patients. In the subgroup of patients who were studied by MRI, hyperenhancement was significantly reduced. Ejection fraction measured by echocardiography at 3 months did not differ between the two groups. While offering promise as a novel therapeutic approach, the strength of the study's conclusions are compromised by limitations subsequently pointed out in letters to the editor of the *New England Journal of Medicine* where the study had been published. There were outliers in the control group with respect to CK, TnI and infarct size assessed by MRI; it was suggested that these outliers skewed the control group mean and that eliminating them would remove the significant difference between the two groups. It was also noted that in the control group 13 patients had failed thrombolytic therapy before PCI versus only five in the CsA group, which might have biased outcome.

A similar small study was performed in 78 CABG surgery patients randomized to receive an intravenous bolus of CsA (2.5 mg/kg) ( $n = 40$ ) or placebo ( $n = 38$ ).<sup>240</sup> The drug was administered after induction of anesthesia and prior to sternotomy. Perioperative infarction was assessed by serial troponin-T (cTnT) and CK-MB levels. Cold blood cardioplegia or cross-clamp fibrillation was used for cardioprotection in both groups. The two groups were similar in patient characteristics and intraoperative vessels. While CsA treatment had no effect on postoperative CK-MB or cTnT levels, the investigators found in *post hoc* analysis that in patients with longer CPB times (120 vs 70 minutes), CsA treatment was associated with reduced cTnT release. They concluded that administration of

CsA prior to CABG surgery can reduce the incidence of perioperative myocardial injury in patients with longer CPB times, and the effect may be mediated by prevention mPTP opening. Concerns with this study however include the small sample size and the absence of any clinically relevant endpoints.

Subsequently, Ovize's group conducted a prospective, randomized, single-blinded, controlled study in which 61 valve surgery patients were assigned to receive an intravenous bolus of CsA ( $n = 30$ ) or saline ( $n = 31$ ) less than 10 minutes before aortic unclamping. The primary endpoint was the 72-hour area under the curve for cTnI release; secondary outcomes included extubation time and length of stay in the intensive care unit and hospital. After removal of the aortic cross-clamp, the need for defibrillation was the same; weaning from CPB was without incident for both groups. The CsA-treated group showed lower cTnI release (72 hours AUC) even after correcting for duration of cross-clamp time (global ischemia). There was no difference in the secondary outcomes. While this study was quite small in scope, it was exciting because the drug appeared to be effective when administered prior to reperfusion. For this reason, based on the reports that cyclosporine was effective in preventing reperfusion injury in patients undergoing PCI for AMI, coronary artery bypass surgery (CABG), and heart valve operations, the *Circus* trial was initiated.<sup>241</sup> This was a large randomized placebo, double-blind study involving patients with acute STEMI. Patients were randomized to receive intravenous cyclosporine ( $n = 396$ ) or placebo ( $n = 395$ ) prior to undergoing PCI revascularization for acute anterior S-T segment elevation myocardial infarction. The primary endpoint was a composite outcome comprised of death from any cause, worsening of heart failure during the initial hospitalization, re-hospitalization for heart failure, or adverse left ventricular remodeling at 1 year. In this study, cyclosporine had no effect on the incidence of the composite endpoint or any of the separate clinical components or other events, including recurrent infarction, unstable angina, and stroke. The findings in this multicenter trial highlight the importance of recognizing the limits of small single center myocardial protection studies, particularly those that rely on reductions of troponin levels as markers of myocardial injury as opposed to necrosis. At present the results of *Circus* trial call into question the clinical advantage of using mPTP inhibitors to protect the heart against I/R injury.

## MYOCARDIAL PROTECTION DURING BEATING HEART SURGERY

In an effort to minimize complications associated with cardiopulmonary bypass such as stroke and a systemic inflammatory response, a number of coronary artery bypass graft operations are performed without cardiopulmonary bypass (off-pump: OPCAB). The assumption is that avoidance of aortic cross-clamping will be associated with a lower incidence of cerebrovascular complications and perioperative MI, lower rates of renal and respiratory failure, less postoperative bleeding, less pain and shorter length of hospitalization. There is a concern, however, that OPCAB may be associated with incomplete

revascularization, a higher incidence of perioperative MI and a reduction in long-term graft patency.<sup>242-244</sup> While the relative benefits of OPCAB versus on-pump CABG surgery are still under investigation, as many as 20% of CABG patients undergo the procedure off-pump. Thus it is important to appreciate the principles and methods of myocardial protection as it relates to beating heart surgery.

The acceptance of OPCAB is due in part to the development and refinement of a myriad of surgical aids that allow for stabilization and local immobilization of the heart during grafting. Techniques include the temporary occlusion of the coronary artery or shunting of blood during sustained coronary artery occlusion. Since temporary occlusion of an already diseased artery may aggravate ongoing ischemia, pharmacologic agents and nonpharmacologic maneuvers are used to protect the heart during displacement required to access lateral and inferior wall vessels. Many of these interventions are designed to reduce myocardial oxygen demand at a time when supply is limited. Ischemia during temporary occlusion of a coronary artery during OPCAB may last from 6 to 25 minutes based on the surgeon's experience, quality and size of the vessel and adequacy of the exposure. Most patients with preexisting severe coronary heart disease have experienced self-limiting episodes of ischemia during daily life and may have acquired a certain degree of tolerance to the surgically induced ischemia. This tolerance has been documented using ECGs, transesophageal echocardiography and continuous mixed venous oxygen saturation (SVO<sub>2</sub>) monitoring. In order to better understand the differences in the ischemic stress between OPCAB and on-pump CABG surgery, Chowdhury et al studied 50 patients with respect to the release pattern of various cardiac biomarkers including cardiac troponin I, heart-type fatty acid-binding protein, CK-MB, high-sensitivity C-reactive protein and myoglobin.<sup>245</sup> Samples were obtained at baseline and then at hourly intervals up to 72 hours after completion of the last anastomosis in the noncardioplegic OPCAB group and after release of aortic cross-clamp in the cardioplegic group. The cardioplegic group exhibited greater release of cardiac troponin I, high-sensitivity C-reactive protein and heart-type fatty acid-binding protein consistent with the fact that OPCAB surgery puts less myocardium at ischemic risk. Ventricular function as measured by transthoracic echocardiography was similar in the two groups. Schroyer et al analyzed both short-term and long-term outcomes in 2203 patients randomized to undergo either on-pump or off-pump surgery.<sup>246</sup> The primary endpoints included mortality and complications such as reoperation, need for new mechanical support, cardiac arrest, coma, stroke or renal failure before discharge or within 30 days of surgery. The long-term outcome consisted of the composite endpoint of death from any cause, repeat revascularization procedure or a nonfatal MI within 1 year. Secondary endpoints included graft patency and neurologic outcomes. While there were no differences at 30 days, they observed that OPCAB patients had a higher incidence of death from cardiac causes within 1 year, tended to have lower graft patency and had fewer arteries bypassed. The incidence of stroke or resource utilization was similar for both on-pump and off-pump procedures. While

OPCAB puts less myocardium at risk, it is clear that there is still a need for ischemic protection.

One approach to minimizing the risk of injury is to reduce myocardial oxygen demand using pharmacologic beta-blockade. Ultra-short-acting beta blockers such as esmolol and labetalol are frequently used to reduce inotropy and achieve negative chronotropy. Another approach is to optimize systemic mean blood pressures while reducing afterload. Calcium channel blockers such as diltiazem are used to lower blood pressure with less compromise of myocardial contractility than beta blockers. Patients who become hypertensive during the operation may benefit from intravenous nitrates to enhance coronary vasodilation and increase blood flow via collaterals. Gentle core cooling, by allowing the body temperature to drift from 35 to 36°C, and deepening the level of anesthesia are other concurrent measures that can be employed to minimize cardiac work and concomitant oxygen requirements. IPC, RIPC and volatile anesthetics with conditioning-like effects have been used in beating heart surgery in an effort to mitigate I/R injury; however, none of these have been shown to improve clinical outcomes.<sup>247</sup> Thus while the OPCAB approach to myocardial revascularization reduces the amount of myocardium at risk, it does not obviate the need to develop new methods to attenuate I/R injury.

## Challenges of Myocardial Protection Trials

It has been difficult to translate promising cardioprotective agents identified in animal studies to the clinic. One reason may be that preclinical studies typically involve healthy young animals of a single sex. While a particular drug may show efficacy in this model, it may fail in humans when both sexes are enrolled and when the study includes patients with advanced age. Aging in itself affects numerous biological processes invoked during I/R. Furthermore, many patients may have comorbid conditions including hypertension, dyslipidemias, obesity and diabetes which may compromise the ability to mount a cardioprotective response. In support of this, preclinical studies have confirmed that obese animals show less infarct size reduction from ischemic preconditioning compared to lean animals, and it has also been reported that hypercholesterolemia interferes with ischemic preconditioning.<sup>235</sup> When a promising agent identified in preclinical studies advances to testing in humans, trial design is challenging. As an example of the difficulties in adapting experimental protocols to the clinical setting, agents that were shown to be protective when given prior to ischemia were much less effective when given at reperfusion which, in the case of PCI for acute MI, is the only clinically feasible approach. Clinical trials that are open-label or single-blind open the door for bias in postoperative management such as administration of inotropic support. Trials are often designed to test whether a particular agent or intervention has benefit. A far larger number of patients must be enrolled to prove the null hypothesis, that is, that the intervention has no benefit. This becomes a challenge if the endpoint, such as 30-day mortality, occurs with relatively low

frequency. Given the already low early mortality associated with current surgical approaches, the size of the trial needed to test the null hypothesis becomes daunting. The study by Lehrke et al showed a clear relationship between 48-hour postoperative cTnT levels  $\geq 0.46$   $\mu\text{g/L}$  and long-term (28 months) survival; it was also associated with perioperative MI, in-hospital heart failure and 30-day mortality suggesting that these short-term endpoints may be valid surrogate markers of long-term mortality.<sup>19</sup> A more recent meta-analysis confirmed an association between postoperative troponin release and short-term and mid-term (12-month) all-cause mortality.<sup>248</sup> Similar validation studies are needed for MRI assessment of infarct size and risk zone in order for this increasingly sophisticated imaging modality to become accepted as a reliable indicator of cardioprotection.<sup>249</sup> At present the U.S. Food and Drug Administration considers improvement in morbidity and mortality the only acceptable endpoints—rather than surrogate markers—for approval of a cardioprotective intervention. As a consequence the high cost of clinical trials has discouraged even large pharmaceutical companies from pursuing cardioprotection as a therapeutic target. In turn this has fostered the proliferation of small, single-center trials with short-term endpoints and surrogate markers that fall short of proving or disproving efficacy. Despite these considerations, cardiac surgery remains an ideal testing ground for study of cardioprotective treatments: in cardiac surgical patients it is possible to document the onset and duration of ischemia, establish the interval between onset of reperfusion and endpoint analysis and obtain MRIs before and after the ischemic stress to accurately document the volume of necrosis. This information should increase the predictive value of small clinical trials.

While considerable progress has been made in the field of myocardial protection over the past 50 years, the ideal cardioplegic solution, pharmacological intervention, technique or delivery method has yet to be determined. This is due in part to the increasing awareness of the complexity of I/R injury and the concern that surrogate markers or short-term mortality rates are only weakly predictive of durable beneficial outcomes. Myocardial stunning and necrosis remain significant challenges that impact short- and long-term outcomes; there is ongoing need to find new ways to protect the heart during cardiac surgery.

### Three Billion Heartbeats

Three billion heartbeats or maybe more  
 Before you reach life's other shore.  
 When things go wrong and blood flow's blocked  
 The loss of muscle by the minute is clocked.  
 Time is essence as muscle will die  
 Reflected in rising troponin I.  
 Protect the heart, try anything!  
 Drugs or cells or conditioning.  
 Studies hold hope yet still are unclear,  
 But an answer grows likelier every year.

Roberta A. Gottlieb
